Digestion is required to convert polymers into smaller units that can be absorbed across plasma membranes. Therefore, digestion requires enzymes that can hydrolyze the chemical bonds in carbohydrates, proteins, lipids, and nucleic acids. These enzymes are named after their substrates: polysaccharidases, proteases, lipases, and nucleases. Not all of the food that is

eaten, however, is digested; some substances such as vitamins do not require digestion and are absorbed intact.

Absorption of Food May Be Passive or Active

Once food is digested, the nutrients must be absorbed by the epithelial cells that line specialized portions of the alimentary canal. This occurs in different ways, either by passive or facilitated diffusion or by active transport. Small, hydrophobic molecules such as fatty acids diffuse down concentration gradients across the epithelium. Ions and other molecules are transported by facilitated diffusion or active transport. Minerals are ions and therefore do not readily cross plasma membranes. Instead, they are usually actively transported across the membranes of the epithelial cells of the canal by ATP-driven ion pumps. In other cases, small, hydrophilic organic nutrients are transported by secondary active transport, usually with Na^+.

After nutrients enter the epithelial cells of the alimentary canal, the cells use some of the nutrients for their own requirements. Most of the nutrients, however, are transported out of the epithelial cells and into nearby blood vessels, where they enter the blood and circulate to the other cells of the body. Thus, nutrients enter the alimentary canal in food, are digested within the canal into monomers that can be transported into epithelial cells, and from there are released into the blood, where they can reach all of the body's cells. In the special case of water, osmotic gradients established by the transport of ions and other nutrients out of the epithelial cells draw water by osmosis from the canal, across the epithelial cells, and from there into the blood.

The mechanisms that activate and control the digestive and absorptive functions of the alimentary canal have been extensively studied in vertebrates and have great importance for human health. In the rest of this chapter, we will explore the structure and function of the digestive systems of vertebrates.

45.4 Overview of Vertebrate Digestive Systems

The vertebrate **digestive system** consists of the alimentary canal—also known as the gastrointestinal, or GI, tract—plus several accessory structures (Figure 45.6). As illustrated in the example in Figure 45.6, the human GI tract consists of the oral cavity, pharynx, esophagus, stomach, small and large intestines, rectum, and anus. The accessory structures, not all of which are found in all vertebrates, are the tongue, teeth, salivary glands, liver, gallbladder, and pancreas. The differences between the digestive systems of various vertebrates reveal much about their respective feeding strategies. In this section, we will look at some of the most important differences as we discuss the form

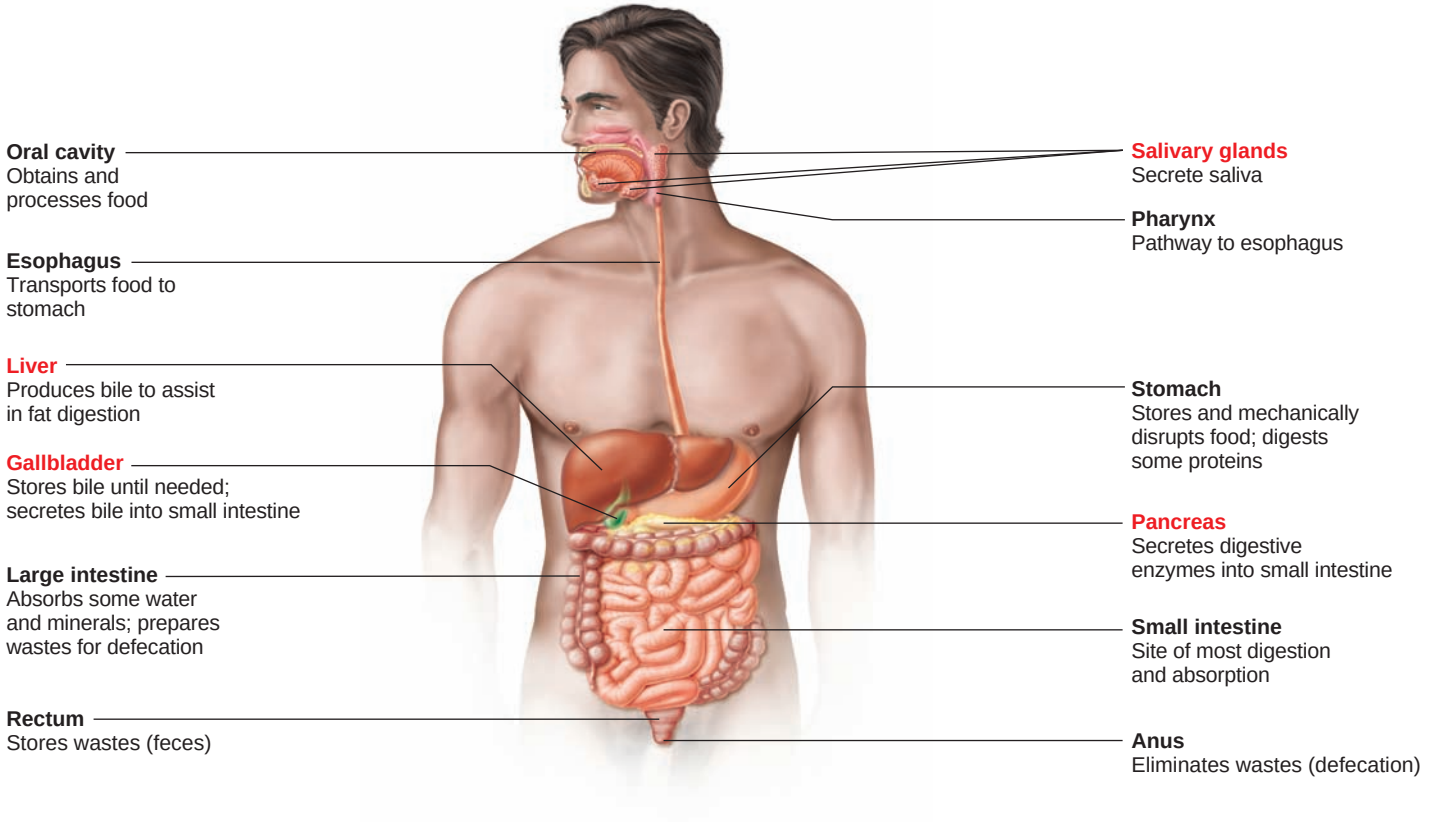

Figure 45.6 A vertebrate digestive system, as shown in the human. This figure shows the organs of the gastrointestinal tract (labeled in black) and the accessory structures (labeled in red). Not all vertebrates share identical features of the digestive system; for example, some fishes lack a stomach, and many birds lack a gallbladder.

and function of each part of the vertebrate digestive system. We begin with an overview of the form, or anatomy, of some typical vertebrate digestive systems.

Alimentary Canals Are Divided into Functional Regions

The alimentary canal is one continuous tube that changes in appearance and function along its length, with three general sections. The first section, at the anterior end, functions primarily in the ingestion of food. It contains the oral cavity, salivary glands, pharynx (throat), and esophagus. The middle portion, which functions in the storage and initial digestion of food, contains one or more food storage or digestive organs, including the crop, gizzard, and stomach(s), depending on species. This section also contains the upper part of the small intestine—where most of the digestion and absorption of food takes place—and accessory structures that connect with the intestine, including the pancreas, liver, and gallbladder. The third section, the posterior part of the canal, functions in final digestion and absorption and the elimination of nondigestible wastes. It consists of the remainder of the small intestine, and in most vertebrates other than fishes, a large intestine. Undigested material is excreted through an opening called an anus, or in many amphibians, reptiles, and birds, a cloaca (a common opening for the digestive and urogenital tracts).

From the mid-esophagus to the anus or cloaca, the gastrointestinal tract has the same general structure, with a hollow cavity called a lumen that is lined by a layer of epithelial cells. Included in the epithelial layer are secretory cells that release a protective coating of mucus into the lumen of the tract, and other cells that release hormones into the blood in response to the presence of food. Connected to the epithelium are secretory glands that release acid, enzymes, water, and ions into the lumen. From the stomach onward, the epithelial cells are linked along the edges of their luminal surfaces by tight junctions that prevent digestive enzymes and undigested food from moving between the cells and out of the canal. In some places, such as the small intestine, the luminal surface is highly convoluted, a feature that increases the surface area available for digestion and absorption.

The epithelial cell layer is surrounded by layers of tissue made up of smooth muscles, neurons, connective tissue, and blood vessels. The neurons are activated by nerves coming from the central nervous system that respond to the sight and smell of food. The gut neurons are also activated directly by the presence of food in the gut. Contraction of the muscles is controlled by these neurons and results in mechanical mixing of the contents within the stomach and intestine. This helps speed up digestion and also brings digested foods into contact with the epithelium to facilitate absorption.

Food Processing and Polysaccharide Digestion Begin in the Mouth

Once food enters the mouth, some animals, as stated earlier, chew it to reduce the size of each piece. Even in those animals that do not chew their food, however, the initial processing of food begins in the mouth because of the presence of saliva.

Saliva is a watery fluid containing proteins, mucus, and antibacterial agents. In terrestrial vertebrates, salivary glands in and around the mouth, cheeks, tongue, and throat produce a constant flow of saliva, which keeps the mouth moist and clean; fishes, which lack true salivary glands, secrete mucus from specialized cells in their mouth and pharynx. In response to food, chemical and pressure detectors in the walls of the mouth and tongue increase its secretion. Increased secretion of saliva can be produced in terrestrial vertebrates by a large increase in blood flow to the salivary glands, which occurs in response to signals sent from the nervous system. Saliva production in some animals can also be increased simply by the smell or sight of food, a feedforward response discussed in Chapter 40. In mammals, the volume of saliva secreted per gram of tissue is among the largest secretion of any of the glands in the animal.

Saliva has several functions, not all of which pertain to all vertebrates:

1. moisten and lubricate food to facilitate swallowing;
2. dissolve food particles to facilitate the ability of specialized chemical-sensing structures called taste buds to taste food;
3. kill ingested bacteria with a variety of antibacterial compounds, including antibodies; and
4. initiate digestion of polysaccharides through the action of a secreted enzyme called **amylase**.

Digestion is the least important of these functions in most vertebrates, few of which produce salivary amylase. In humans and other primates, salivary amylase is present and accounts for a few percent of total polysaccharide digestion. Depending on how much salivary amylase you produce, you may be able to detect the action of amylase in your own saliva with a simple test. If you chew on a starchy soda cracker and leave it in your mouth for a while, you may notice it begins to taste sweet. That is because some of the polymers in the cracker have been digested to sweet-tasting disaccharides.

The other functions of saliva, however, are very important. For example, imagine trying to swallow unchewed food with a perfectly dry mouth. Also, the antibiotic properties of saliva help cleanse the mouth. In people who have had cancerous salivary glands removed, the teeth and gums often become so diseased that tooth loss may occur.

Peristalsis Moves Swallowed Food Through the Esophagus to a Storage Organ

Once food has been sufficiently processed in the mouth, it is swallowed. The swallowed food moves into the next segments of the alimentary canal, the **pharynx** (throat) and **esophagus**. These structures do not contribute to digestion or absorption but serve as a pathway to storage organs such as the stomach.

Pharynx and Esophagus The muscles in the walls of the pharynx and esophagus contribute to swallowing. In the

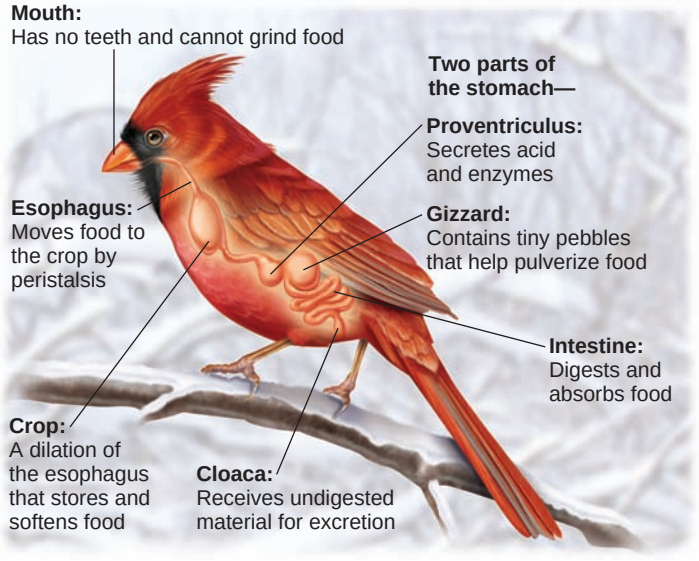

Figure 45.7 **The alimentary canal of birds.** The avian alimentary canal contains specialized regions for storing and softening food (the crop) and pulverizing food (the gizzard). The gizzard and proventriculus constitute the stomach. Undigested material is excreted through the cloaca.

Concept check: *Smooth, polished stones have been found in the stomach region of fossilized skeletons of ancient sauropod dinosaurs. What does this suggest about the alimentary canal of such animals?*

pharynx, swallowing begins as a voluntary action but continues in the esophagus by the process of **peristalsis**—rhythmic, spontaneous waves of muscle contraction that begin near the mouth and end at the stomach. When most vertebrates eat, the mouth and stomach are roughly horizontal with respect to each other. In fact, the head of a terrestrial grazing animal is usually lower than its stomach when eating. The wavelike action of peristalsis ensures that food will be pushed toward the stomach and not sit in the esophagus or even move backward into the mouth if the head is lowered.

The Crop In some animals, food moves directly from the esophagus to a storage organ called the **crop**, which is a dilation of the lower esophagus (Figure 45.7). Crops are found in most birds (and many invertebrates, including insects and some worms). Food is stored and softened by watery secretions in the crop, but little or no digestion occurs there. Because they process large amounts of tough food, birds that eat primarily grains and seeds have larger crops than birds that eat insects and worms. The material that birds regurgitate to their young comes from the crop. In some species, such as pigeons and doves, the cells that line the crop wall secrete a lipid-rich watery solution called crop or pigeon milk into the material to be regurgitated.

Food Processing Continues and Protein Digestion Begins in the Stomach

Once food passes through the esophagus and crop, if present, it reaches a storage organ such as a stomach. The **stomach** is a saclike organ that most likely evolved as a means of storing food. Stomach-like organs are found in all vertebrate classes, but a true stomach (one that produces hydrochloric acid) is absent in many species of herbivorous fishes. In addition to its storage function, the muscular nature of the stomach helps it to mechanically break up large chunks of food into smaller, more easily digestible fragments. Lastly, the stomach partially digests some of the macromolecules in food and regulates the rate at which the contents empty into the small intestine. Glands within the stomach wall secrete hydrochloric acid (HCl) and an inactive molecule called pepsinogen into the stomach lumen. One function of the acid is to convert pepsinogen into the active enzyme **pepsin**, which as a protease begins the digestion of protein. Why do stomach cells secrete pepsinogen instead of pepsin? The answer is that if the cells produced active pepsin, they would digest their own cellular proteins.

Within the stomach lumen, HCl kills many of the microbes that may have been ingested with food. The acid also helps dissolve the particulate matter in food. In addition, the acid environment in the stomach (or gastric) lumen alters the ionization of polar molecules, especially proteins. This disrupts the structural framework of the tissues in food and makes the proteins more accessible to pepsin. The proteins released by the dissolving action of HCl are partially digested in the stomach by pepsin. By contrast, no significant digestion of carbohydrates or lipids occurs in the stomach.

In birds, the stomach is divided into two parts: the proventriculus and the gizzard (Figure 45.7). The **proventriculus** is the glandular portion of the stomach, and it secretes acid and pepsinogen. Partially digested and acidified food then moves to the **gizzard**, a muscular structure with a rough inner lining that grinds food into smaller fragments.

The gizzard contains sand or tiny stones swallowed by the bird. The gritty sand and stones take the place of teeth and help mash and grind ingested food. Scientists think that this function of the gizzard may have evolved partly as an adaptation for flight, because large jaws and associated chewing muscles and teeth would result in a larger, heavier, and less aerodynamic head. Eventually, the pebbles in the gizzard become smaller as they are worn away, and they are excreted. Thus, birds must occasionally restock the gizzard with new grinding stones. Grain-eating birds, particularly chickens and other fowl, many passerines, and pigeons and doves, generally have more muscular gizzards than do insectivorous birds, because of the difficulty in breaking down plant cell walls. In other birds, such as owls, gizzards help compress the nondigestible parts of their meals (bones, teeth, fur, feathers) into a pellet that can be regurgitated. Gizzards, incidentally, are not unique to birds. Certain reptiles that are closely related to birds, such as crocodiles, also contain muscular gizzards. In addition, some species of herbivorous fishes (for example, members of the family Acanthuridae) ingest quantities of inorganic grit with their meals, which help to grind up food in a portion of the stomach that is modified into a strong, muscular grinding organ like a gizzard.

Digestive actions of the stomach reduce food particles to **chyme**, a solution that contains water, salts, molecular fragments of proteins, nucleic acids, polysaccharides, droplets of

fat, and various other small molecules. Virtually none of these molecules, except water, can cross the epithelium of the stomach wall; therefore, little or no absorption of organic nutrients occurs in the stomach.

Herbivores Use Microbes to Aid Digestion in the Stomach and Intestine

Herbivores face a special challenge because they must digest cellulose, but they lack the enzyme cellulase required for the job. Instead, herbivores rely on microbes living within their digestive tracts that have the capacity to digest cellulose. The microbes break down the cellulose into monosaccharides that can be absorbed along with other by-products of microbial digestion, such as fatty acids and some vitamins. In this way, bacteria and protists predigest the food for the animal.

Microbial cellulose digestion has been demonstrated in herbivores of all vertebrate classes but has been particularly well studied in mammals. In mammals with simple stomachs, such as horses, the microbes exist in the large intestine and the **cecum**, a blind outpocketing of the gut at the junction of the small and large intestines. Other herbivores, such as **ruminants** (for example, sheep, goats, llamas, and cows), have complex stomachs consisting of several chambers, beginning with three outpouchings of the lower esophagus collectively referred to as the forestomach (Figure 45.8). The forestomach is composed of the rumen, reticulum, and omasum, in sequence. The rumen and reticulum contain the microbes that digest cellulose, and the omasum absorbs some of the water and salts released from the chewed and partially digested food. The tough, partially digested food (the cud) is occasionally regurgitated, rechewed, and swallowed again. Eventually, the partially digested food, the microbes, and the by-products of microbial digestion reach the true stomach, the abomasum, which contains the acid and proteases typical of other vertebrate stomachs. From the abomasum, the material passes to the intestines, where digestion and absorption are completed. Some microbes remain in the rumen and quickly multiply to replenish their populations.

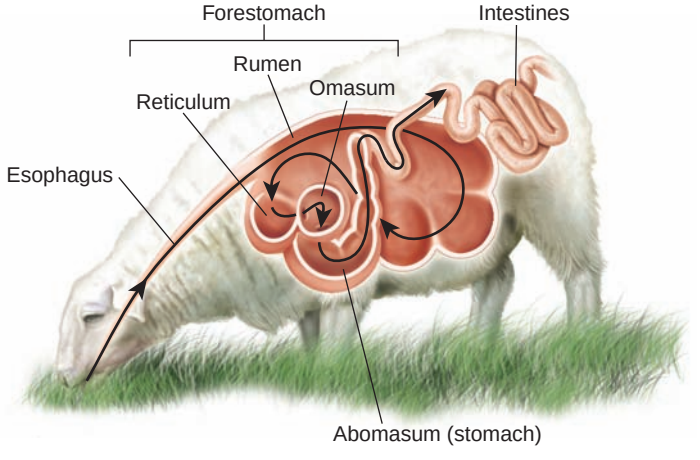

Figure 45.8 **Digestive tract of a ruminant.** Ruminants have a complex arrangement of three modified pouches, together called the forestomach, arising from the esophagus; these pouches are called the rumen, reticulum, and omasum. The rumen and reticulum act as storage and processing sites (in large ruminants, the rumen may store up to 95 liters of undigested food); the omasum absorbs some water and salts. The forestomach is connected to the true stomach, or abomasum. Digestion by acid and pepsin takes place in the abomasum, which then connects with the intestines.

Most Digestion and Absorption Occurs in the Small Intestine

Nearly all digestion of food and absorption of nutrients and water occur in the **small intestine**, the tube that leads from the stomach to the large intestine or, in some animals, directly to the anus or cloaca. Hydrolytic enzymes break down molecules of organic nutrients into monomers. Some of these hydrolytic enzymes are on the luminal surface of the intestinal epithelial cells, while others are secreted by the pancreas and enter the intestinal lumen. The products of digestion are absorbed across the epithelial cells and enter the blood. Vitamins and minerals, which do not require enzymatic digestion, are also absorbed in the small intestine. Water is absorbed by osmosis from the small intestine in response to the movement of nutrients across the intestinal epithelium. We will discuss the mechanisms of digestion and absorption in more detail later.

The ability of the small intestine to carry out the bulk of digestion and absorption is aided by mucosal infoldings and specializations along its length, as mentioned previously. Finger-like projections known as **villi** (singular villus) extend into the lumen of the vertebrate small intestine (Figure 45.9). The surface of each villus is covered with a layer of epithelial cells whose plasma membranes form small projections called **microvilli**, known collectively as the **brush border**. The combination of folded mucosa, villi, and microvilli increases the small intestine's surface area about 600-fold over that of a flat-surfaced tube having the same length and diameter. The small intestine is small in diameter compared to the large intestine, but it is very long—3 meters in an adult human (the small intestine is almost twice as long if removed from the abdomen, because the muscles relax). This brings the total surface area of the human small intestine to about 300 m^2—roughly the size of a tennis court! This enormous surface area means that the likelihood of an ingested food particle encountering a digestive enzyme and being absorbed across the epithelium is very high, so digestion and absorption proceed rapidly.

The center of each intestinal villus is occupied by a special type of vessel called a **lacteal**, which is part of the lymphatic system, and by capillaries, the smallest blood vessels in the body (Figure 45.9). Most of the fat absorbed in the small intestine exists as bulky protein-bound particles that are too large to enter capillaries. Consequently, absorbed fat enters the larger, wider lacteals. Material absorbed by the lacteals eventually empties into the circulatory system. Other nutrients are absorbed directly into the capillaries and from there into veins.

The length of the small intestine varies among species. Both terrestrial and aquatic herbivores generally have much longer small intestines than do carnivores, which allows added time for plant material to be digested and absorbed. Even within an

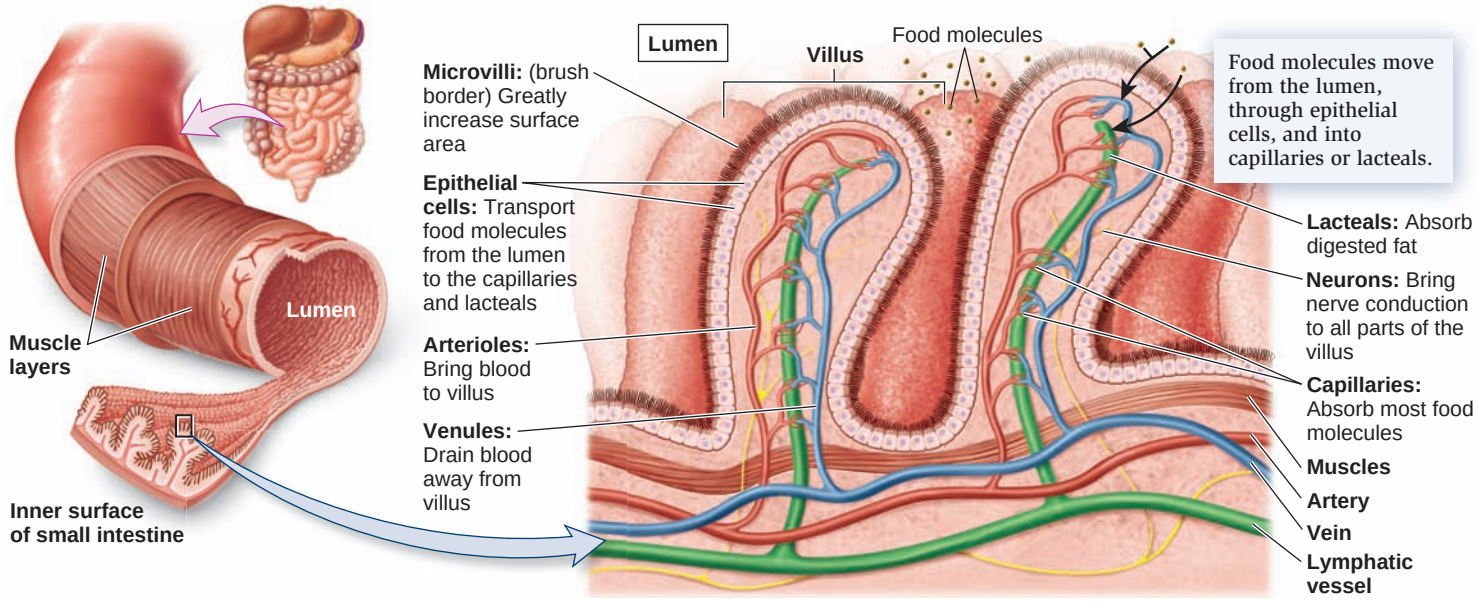

Figure 45.9 **The specialized arrangement of tissues in the small intestine.** The small intestine is folded into numerous villi, which increase the surface area for digestion and absorption. Within each villus are capillaries and lymphatic vessels (lacteals) into which absorbed nutrients are transported. The epithelial cells of the villi have extensions from their surface called microvilli. The microvilli constitute the brush border of the intestine and greatly add to the total surface area.

individual animal, the length of the small intestine can change. For example, in a bird that switches from eating insects and worms in summer to buds and other nutrient-poor vegetation in winter, the small intestine grows and elongates and increases its total absorptive surface area to meet the digestive challenges associated with an herbivorous diet.

The Pancreas and Liver Secrete Substances That Aid Digestion

During the process of chyme moving through the small intestine, two major organs—the pancreas and liver—secrete substances that flow via ducts into the first portion of the intestine called the duodenum (Figure 45.10). The **pancreas**, a complex organ located inferior to the stomach in humans (see Figure 45.6), has several functions, but in this chapter, we will focus on those that are directly involved in digestion. The gland secretes digestive enzymes and a fluid rich in bicarbonate ions (HCO_3^-). The bicarbonate neutralizes the acidity of chyme, which would otherwise inactivate the pancreatic enzymes in the small intestine and could also damage the intestinal epithelium.

The **liver** is the site of bile production. **Bile** contains bicarbonate ions, cholesterol, phospholipids, a number of organic wastes, and a group of substances collectively termed **bile salts**. The bicarbonate ions, like those from the pancreas, help neutralize acid from the stomach, while the bile salts break up dietary fat and increase its accessibility to digestive enzymes.

The liver secretes bile into small ducts that join to form the common hepatic duct (from the Greek *hepar*, meaning liver). Between meals, secreted bile is stored in the **gallbladder**, a small sac underneath the liver. During a meal, the smooth muscles in the gallbladder contract, injecting the bile solution into a connecting duct called the common bile duct (Figure

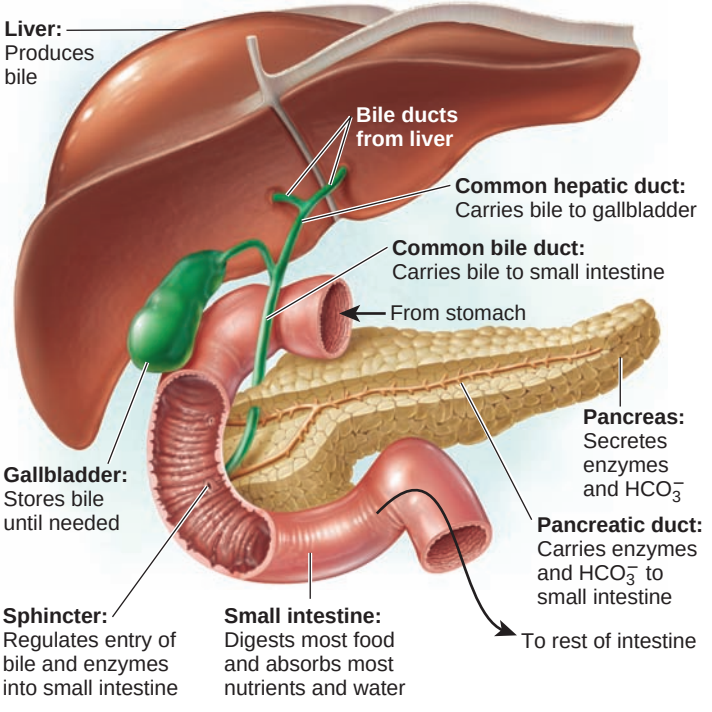

Figure 45.10 **The arrangement and functions of the vertebrate liver, gallbladder, pancreas, and small intestine.** Bile drains from the liver into the gallbladder through the common hepatic duct. During a meal, bile is secreted from the gallbladder and enters the duodenum of the small intestine through the common bile duct. Simultaneously, secretions from the pancreas travel through another duct that joins with that from the gallbladder and empties into the small intestine. A muscular sphincter controls the entrance to the small intestine.

Concept check: *What advantage does an animal gain by having a gallbladder?*

45.10). The opening of a sphincter allows the bile to flow into the lumen of the small intestine. The gallbladder, therefore, is a storage organ that allows the release of large amounts of bile to be precisely timed to the consumption of fats. However, many animals such as horses and doves that secrete bile do not have a gallbladder. In humans, the gallbladder can be surgically removed without impairing bile secretion by the liver or its flow into the intestinal tract. People without a gallbladder can still digest fat but may need to limit the amount of fat they eat at one time because bile secretion can no longer be timed to a meal.

The digested nutrients, along with water, are absorbed across the plasma membranes of the brush border cells. Peristalsis slowly propels the remaining contents through the later portions of the small intestine, called the jejunum and the ileum, where further absorption occurs. Finally, the remaining material enters the large intestine or the anus or cloaca.

The Large Intestine Concentrates Undigested Material, Which Is Then Eliminated via the Anus

The size of the large intestine varies greatly among different vertebrates, and the organ is vestigial or even absent in many animals, notably fishes. In humans, the large intestine is a tube about 6 cm in diameter and 1–1.5 meters long. Its first portion, the cecum, forms a small pouch from which extends the appendix, a finger-like projection having no known essential function but that may contribute to the body's immune defense mechanisms. The next part of the large intestine in humans and other mammals is called the **colon**, which consists of three segments—the ascending, transverse, and descending portions. The terminal portion of the descending colon in humans is S-shaped, forming the sigmoid colon, which empties into the rectum, a short segment of the large intestine that ends at the anus. The characteristic appearance of the mammalian colon is not widely found in other vertebrates, most of whom have a simple, straight large intestine.

Chyme from the small intestine enters the cecum through a sphincter. This sphincter is normally closed, but it periodically relaxes after a meal, allowing chyme to enter. Although the large intestine has a greater diameter than the small intestine, its epithelial surface area is far less—particularly in carnivores and omnivores—because it lacks the convolutions and villi of the small intestine.

The primary functions of the large intestine are to store and concentrate fecal material before defecation and to absorb some of the remaining salts and water that were not absorbed in the small intestine. Because most substances are absorbed in the small intestine, only a small volume of water and salts, along with undigested material, is passed on to the large intestine. The large intestine temporarily stores the undigested material and concentrates it by absorbing additional water and salts. **Defecation** occurs when contractions of the rectum and relaxation of associated sphincter muscles expel the feces through the final portion of the canal, the **anus** (see Figure 45.6). Some terrestrial herbivores—notably certain rabbits, hares, mice, and several families of birds—consume their own feces, a behavior called **coprophagy**. This is an adaptation to maximize the absorption of water, vitamins, and organic nutrients that were not fully absorbed as food passed through the small intestine and was eventually defecated. The resulting feces are not eaten a second time.

The large intestine also absorbs some of the products formed by bacteria inhabiting this region, including small amounts of vitamins. Although this source of vitamins generally provides only a small part of the normal daily requirement, it may make a significant contribution when dietary vitamin intake is low. Sometimes people develop a vitamin deficiency if treated with antibiotics that inhibit these species of bacteria. Other bacterial products include gas (flatus), which is a mixture of nitrogen and carbon dioxide, with small amounts of hydrogen, methane, and hydrogen sulfide. Bacterial processing of undigested polysaccharides produces these gases, except for nitrogen, which is derived from swallowed air. Certain foods (beans, for example) contain large amounts of carbohydrates that cannot be digested by intestinal enzymes but are readily metabolized by bacteria in the large intestine, producing flatus.

45.5 Mechanisms of Digestion and Absorption in Vertebrates

The preceding sections provided an overview of nutrition and the basic features of digestive systems. We turn now to a more detailed description of how carbohydrates, proteins, and lipids are processed in the vertebrate digestive system and how the end products of digestion are absorbed across intestinal cells.

Carbohydrates Are Digested and Absorbed in the Small Intestine

In a typical omnivore such as ourselves, most of the ingested carbohydrates are the polysaccharides starch and cellulose from plants and glycogen from animals. The remainder consists of simple carbohydrates, such as the monosaccharides fructose and glucose in fruit, and disaccharides, such as lactose in milk. Humans also add the disaccharide sucrose (table sugar) to their food. Other animals consume sucrose in its natural form from sources such as maple sap and sugarcane.

Starch digestion by salivary amylase begins in the mouth, but the acid in the stomach destroys the amylase and prevents further starch digestion there. Starch digestion resumes in the small intestine by amylase secreted into the intestine by the pancreas. The products of starch digestion via amylase are molecules of the disaccharide maltose (Figure 45.11). Maltose, along with ingested sucrose and lactose, is broken down into monosaccharides—fructose, glucose, and galactose—by enzymes located on the brush border of the small intestine epithelial cells. The monosaccharides are then absorbed into the epithelial cells. Fructose crosses the apical membrane of the epithelial cells by facilitated diffusion, whereas glucose and galactose undergo secondary active transport coupled to

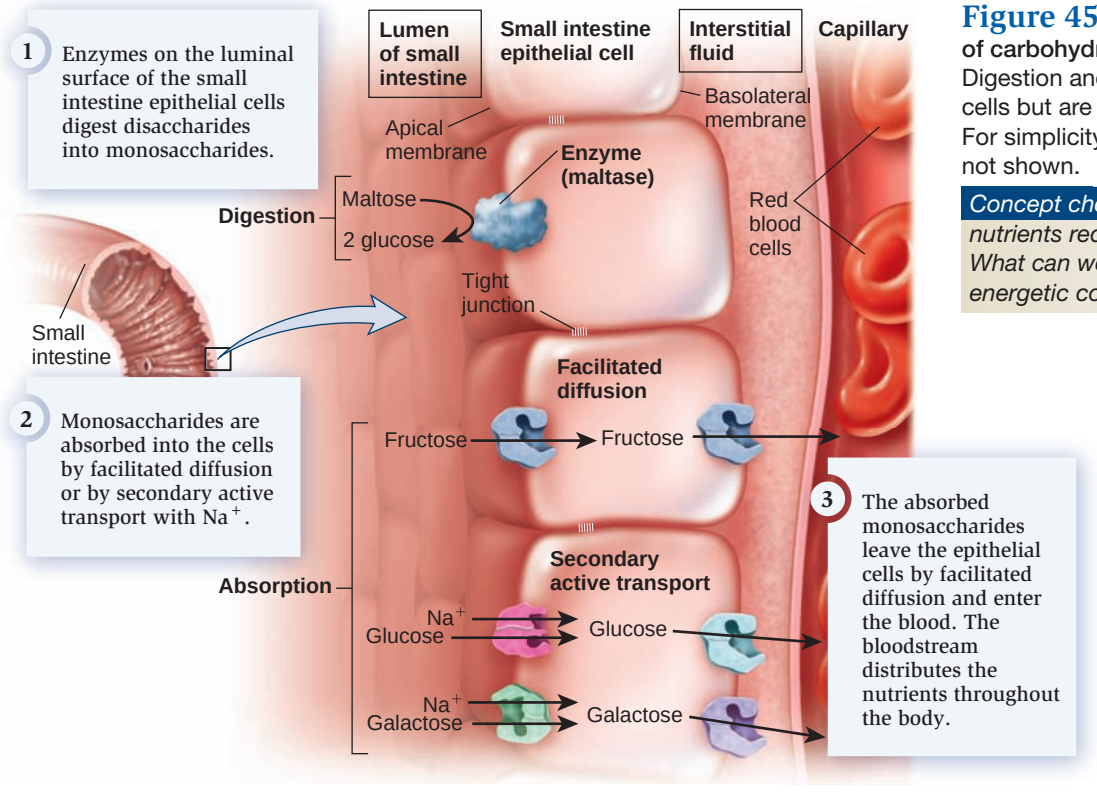

Figure 45.11 **Digestion and absorption of carbohydrates in the small intestine.** Digestion and absorption occur in the same cells but are shown separately here for clarity. For simplicity, the microvilli (brush border) are not shown.

Concept check: *The absorption of many nutrients requires secondary active transport. What can we conclude from that about the energetic cost of absorption?*

sodium ions. Monosaccharides then leave the epithelial cells by way of facilitated diffusion transporters located in the basolateral membranes of the epithelial cells and enter the blood. The transport of substances from the lumen to the blood is called **transepithelial transport** because it occurs across a layer of epithelial cells. The bloodstream distributes the monosaccharides and other absorbed nutrients to the cells of the body.

Do you feel ill after drinking milk or eating dairy products? If so, you are among the majority of people who cannot adequately digest lactose, the chief disaccharide in milk. A small percentage of humans, however, retain the ability to digest lactose throughout life. Next, we'll examine these phenomena along with their genetic causes.

Genomes & Proteomes Connection

Genetics Explains Lactose Intolerance

With rare exceptions, the milk of all mammals contains lactose. Lactose is digested by the intestinal enzyme lactase, which cleaves lactose into glucose and galactose. Humans with lactose intolerance cannot adequately digest lactose because their lactase is either inactive, absent, or present in small amounts.

Milk is the sole food of most mammals shortly after birth, and the primary food for various lengths of time thereafter until weaning, the transition from consuming mother's milk to eating a diet of solid foods. Once weaned, mammals never again drink milk, except, of course, for humans. The popular notion of adult cats lapping up milk from a bowl is a misconception. Some visits to the veterinarian are in fact related to gastrointestinal symptoms caused by well-meaning owners who fed milk to their adult pets.

Because the only dietary source for lactose is milk, it is not surprising that older mammals lose the ability to digest this disaccharide. This occurs because the gene that encodes lactase is shut off at the age of weaning or shortly thereafter. The developmental mechanisms that turn off lactase production and activity are not firmly established, but they are known to involve decreased transcription of the lactase gene.

If an adult mammal were to drink milk, the undigested lactose would remain in the gut. As a result, water that normally would be absorbed by osmosis with the digested monosaccharides formed from lactose would also remain in the gut. Farther down the alimentary canal, microbes in the large intestine digest some of the lactose for their own use and, in the process, release by-products such as hydrogen and other gases. The combination of water retention and bacterial action results in gastrointestinal symptoms such as diarrhea, gas, and cramps.

An estimated 90% of the world's human population cannot fully digest lactose after early childhood. In other words, lactose intolerance is not a disorder, it is a normal condition for humans just as it is for all other mammals.

Then why are some people able to consume dairy products without getting ill? Researchers have discovered that the ability of human adults to digest lactose is clearly linked to genetic background. Lactose intolerance is an example of a human polymorphism, a genetic trait that varies among people. Other than individuals who trace their ancestry to northern Europe and a few isolated regions in western Africa, nearly every population

of humans shows a considerable degree of lactose intolerance, reaching nearly 100% in most of south and east Asia. One hypothesis for this phenomenon appears to be a behavioral and cultural change that occurred in Neolithic times, when certain populations domesticated cattle and added cow's milk to their diet. Adults who were able to digest lactose—presumably due to some mutation affecting the expression of the lactase gene—enjoyed a selective advantage and tended to thrive and pass on their genes more frequently than those whose digestive systems could not handle milk. In other words, natural selection resulted in certain populations carrying mutations that caused the lactase gene to be expressed after weaning. Eventually, a substantial percentage of people in those regions of the world retained sufficient intestinal lactase to use milk as a staple food.

To understand how this trait was passed on, let's examine the gene that codes for lactase. Surprisingly, the coding regions of the lactase gene and the lactase core promoter are identical whether individuals are lactose tolerant or intolerant. Recently, however, Finnish investigators have uncovered two single nucleotide changes located in presumed regulatory sites that control the expression of the lactase gene. These changes are associated with prolonged lactase expression, allowing it to occur after weaning. People carrying these mutations are lactose tolerant and can consume milk products through adulthood. By comparison, adults who lack these mutations—and are therefore lactose intolerant—can consume dairy products only in small amounts or not at all. However, their ability to do so is greatly improved if the product has been commercially treated with purified lactase to predigest the lactose.

Proteins Are Digested in the Stomach and Small Intestine, and Absorbed in the Small Intestine

Proteins are broken down to peptide fragments in the stomach by pepsin, and in the small intestine by the proteases **trypsin** and **chymotrypsin**. The pancreas secretes the latter two enzymes as inactive precursors, which prevents the active enzymes from digesting the pancreas itself. Once the inactive form of trypsin enters the small intestine, it is cleaved into the active molecule by the enzyme enteropeptidase whose active site is located on the luminal membranes of the intestinal cells. Trypsin then activates the inactive forms of chymotrypsin and trypsin.

The peptide fragments produced by trypsin and chymotrypsin are further digested into individual amino acids by the actions of specific proteases in the small intestine. These proteases, which are called aminopeptidases and carboxypeptidases, are located on the lumen-facing membranes of the epithelial cells or secreted into the lumen by the pancreas. They cleave off one amino acid at a time from the N-terminus and C-terminus of peptides, respectively. Individual amino acids then enter the epithelial cells by secondary active transport coupled to sodium ions. Amino acids leave these cells and enter the blood by facilitated diffusion across the basolateral membrane. As with carbohydrates, protein digestion and absorption are largely completed in the upper portion of the small intestine.

Lipid Digestion and Absorption Occur in the Small Intestine

Most ingested lipid is in the form of triglycerides (fats). Fat digestion occurs almost entirely in the small intestine. The major digestive enzyme in this process is pancreatic **lipase**, secreted by cells of the pancreas into the small intestine. This lipase catalyzes the splitting of bonds in triglycerides, producing two free fatty acids and a monoglyceride.

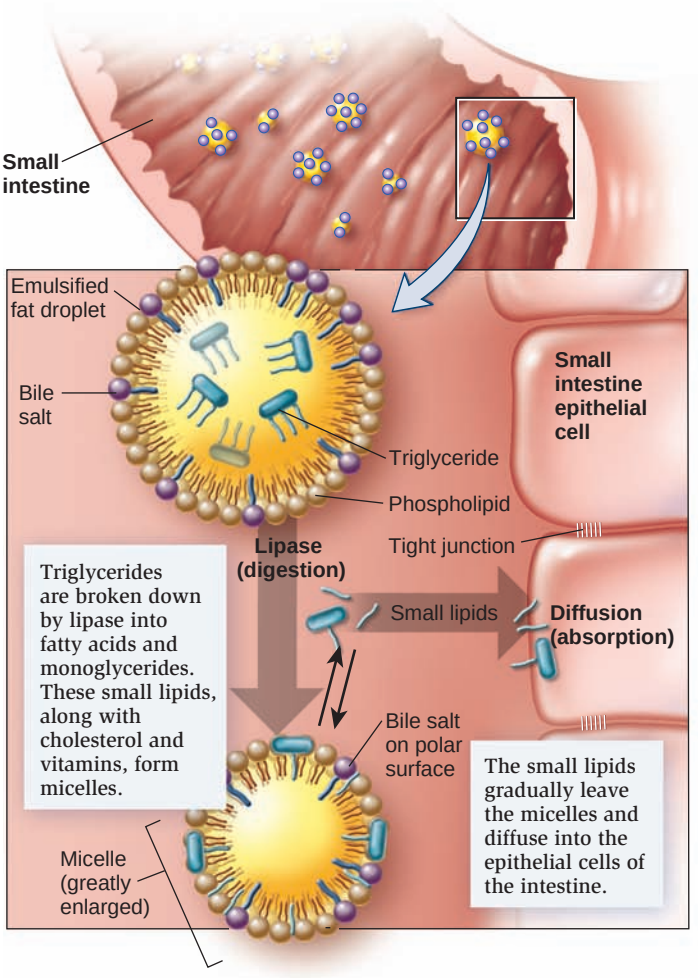
$$\text{Triglyceride} \rightarrow 2 \text{ fatty acids} + \text{Monoglyceride}$$

Fats are poorly soluble in water and aggregate into large lipid droplets, as you can see if you shake a salad dressing made of oil and vinegar. Because pancreatic lipase is a water-soluble enzyme, its digestive action in the small intestine can take place only at the surface layer of a lipid droplet. Therefore, if most of the ingested fat remained in large droplets, lipid digestion would be very slow. The rate of digestion is substantially increased by the process of **emulsification**, which disrupts the large lipid droplets into many tiny droplets, each about 1 mm in diameter, thereby increasing their total surface area and exposure to lipase action. The resulting suspension of small lipid droplets is called an emulsion.

Emulsification of fat requires mechanical disruption of the large fat droplets into smaller droplets and an emulsifying agent, which coats the outer surface of the small droplets and prevents them from recombining back into larger droplets. The muscular contractions of the stomach and small intestine provide mechanical disruption to mix the luminal contents. Bile salts and phospholipids, both secreted in the bile, serve as emulsifying agents.

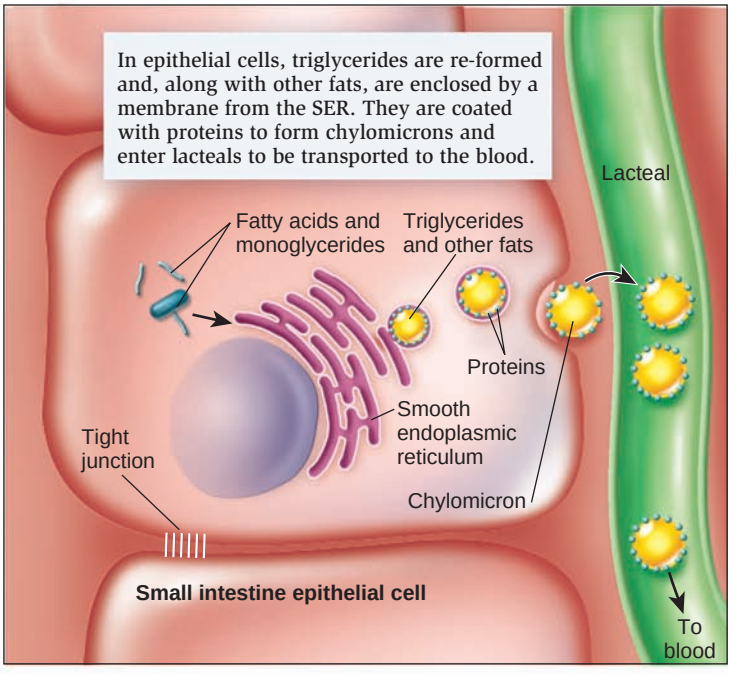
Although emulsification speeds up digestion of fats, absorption of the poorly soluble products of the lipase reaction is facilitated by a second action of the bile salts, the formation of **micelles**, which are similar in structure to emulsion droplets but much smaller at 4–7 nm in diameter (Figure 45.12a). Micelles consist of bile salts, phospholipids, fatty acids, and monoglycerides clustered together. Micelles continuously break down and re-form near the epithelium of the intestine. When a micelle breaks down, small lipid molecules are released into the solution and diffuse across the intestinal epithelium. As the lipids diffuse into epithelial cells, micelles release more lipids into the aqueous phase. Thus, the micelles keep most of the insoluble fat digestion products in small soluble aggregates while gradually releasing very small quantities of lipids to diffuse into the intestinal epithelium. Note that it is not the micelle that is absorbed but rather the individual lipid molecules that are released from the micelle.

During their passage through the epithelial cells, fatty acids and monoglycerides are resynthesized into triglycerides. This occurs in the smooth endoplasmic reticulum (SER), where the enzymes for triglyceride synthesis are located. This process lowers the concentration of cytosolic free fatty acids and monoglycerides in the epithelial cells, and so maintains a diffusion gradient for these molecules from the lumen into the cell. The resynthesized triglycerides aggregate into **chylomicrons**, large droplets coated with proteins that perform an emulsifying



(a) Digestion of emulsified fats into small lipids, and absorption into intestinal cells

Figure 45.12 Digestion and absorption of emulsified fat in the small intestine.



(b) Synthesis of triglycerides and the formation and release of chylomicrons

function similar to that of bile salts (Figure 45.12b). In addition to triglycerides, chylomicrons contain phospholipids, cholesterol, and fat-soluble vitamins that have been absorbed by the same process that led to fatty acid and monoglyceride movement into the epithelial cells of the small intestine.

Chylomicrons are released by exocytosis from the epithelial cells. Chylomicrons are too large to diffuse into blood capillaries. However, lacteals within the intestinal villi have large slit pores in their walls through which the chylomicrons can pass. The fluid from the lacteals eventually empties into a large vein and from there into the general blood circulation.

Vitamins, Minerals, and Water Are Not Digested but Must Be Absorbed

As stated earlier, vitamins, minerals, and water do not require digestion, and they are absorbed in their complete form. Most water-soluble vitamins are absorbed by diffusion or active transport in the small intestine. The fat-soluble vitamins—A, D, E, and K—follow the pathway for lipid absorption described in the previous section. Any interference with the secretion of bile or the action of bile salts in the intestine decreases the absorption of fat-soluble vitamins.

Water is the most abundant substance in chyme. Small amounts of ingested water are absorbed in the stomach, but the stomach has a small surface area available for diffusion and lacks the solute-absorbing mechanisms that create the osmotic gradients necessary for water absorption. The great majority of water absorption occurs in the small intestine. The epithelial membranes of the small intestine are very permeable to water, and water diffuses across the epithelium whenever an osmotic gradient is established by the active absorption of solutes, particularly Na^+, Cl^-, and HCO_3^-. Other minerals present in smaller concentrations, such as potassium, magnesium, and calcium, are also absorbed, as are trace elements such as zinc and iodide. The mechanisms of absorption of these molecules generally involve transport proteins and/or ion pumps.

45.6 Regulation of Digestion

The digestive systems of animals are under complex control regulated in part by other organ systems, especially the nervous and endocrine systems. Neurotransmitters from neurons and hormones from endocrine glands control the volume of saliva

produced, the amount of acid produced in the stomach, the timing and amount of secretions from the gallbladder and pancreas, and the rate and strength of muscle contractions along the walls of the alimentary canal. In this section, we examine the major mechanisms by which the nervous and endocrine systems control the activity of the vertebrate digestive system.

The Nervous System Controls Muscle and Secretory Activity

The nervous system can affect the activities of the digestive system in two major ways: (1) local control of muscle and glandular activity by the nerves within the alimentary canal and (2) long-distance regulation by the brain.

Within the walls along the length of the gastrointestinal tract is a highly branched, interconnected collection of neurons that function in local control of the digestive system. These neurons interact with nearby smooth muscles, glands, and epithelial cells located within the tract. Stimulation of neuronal activity at one point along the alimentary canal can lead to impulses that are transmitted up and down the canal. When food enters the small intestine, for example, the intestine is stretched. This directly activates the neurons in the intestinal wall. Impulses are sent from these neurons to the muscles of the stomach, where they decrease the contractions of the stomach. This slows the rate at which chyme moves from the stomach into the small intestine, giving the intestine sufficient time for digestion and absorption. In this way, the alimentary canal can regulate its own function independent of the brain.

However, in long-distance regulation, the brain can communicate with neurons in the walls of the stomach and intestines and thereby influence the movement and secretory activity of the gastrointestinal tract. For example, emotional stress, a brain-related event, can affect digestive processes. Likewise, the sight, smell, and taste of food activate digestive functions even before food reaches the stomach. These stimuli when processed by the nervous system act via nerves from the brain as a feedforward mechanism so that saliva production, stomach activity, and digestion can begin even as the food is first ingested.

Hormones Regulate the Rate of Digestion

Hormones are chemical messengers secreted by specialized cells into the blood, where they travel to all parts of the body and act on various target cells (see Chapter 50). Hormones that control the digestive system are secreted mainly by cells scattered throughout the epithelium of the stomach and small intestine. One surface of each hormone-producing cell is exposed to the lumen of the gastrointestinal tract. At this surface, chemical substances in chyme stimulate the cell to release its hormones into the blood, by which they travel to their target cells. In this process, the presence of food in the stomach induces cells in the stomach epithelium to secrete a hormone called gastrin, which reaches all the parts of the stomach through the bloodstream (Figure 45.13). The presence of gastrin stimulates smooth muscle contraction in the stomach, which helps move chyme into the small intestine. Gastrin also stimulates acid production by stomach epithelial cells. In the small intestine, the arrival of the acidic chyme stimulates release of the hormones cholecystokinin (CCK) and secretin from intestinal epithelial cells. These hormones travel through the bloodstream to reach their target cells. Cells of the pancreas respond to CCK and secretin by secreting digestive enzymes and acid-neutralizing bicarbonate ions into the small intestine. CCK also has a second function; it stimulates contraction of the gallbladder and therefore bile release.

Secretin holds a special place in the modern history of science. It is a polypeptide whose discovery provided the first clear understanding of how the gut and its accessory structures communicate, as well as initiating the field of endocrinology—the study of hormones.

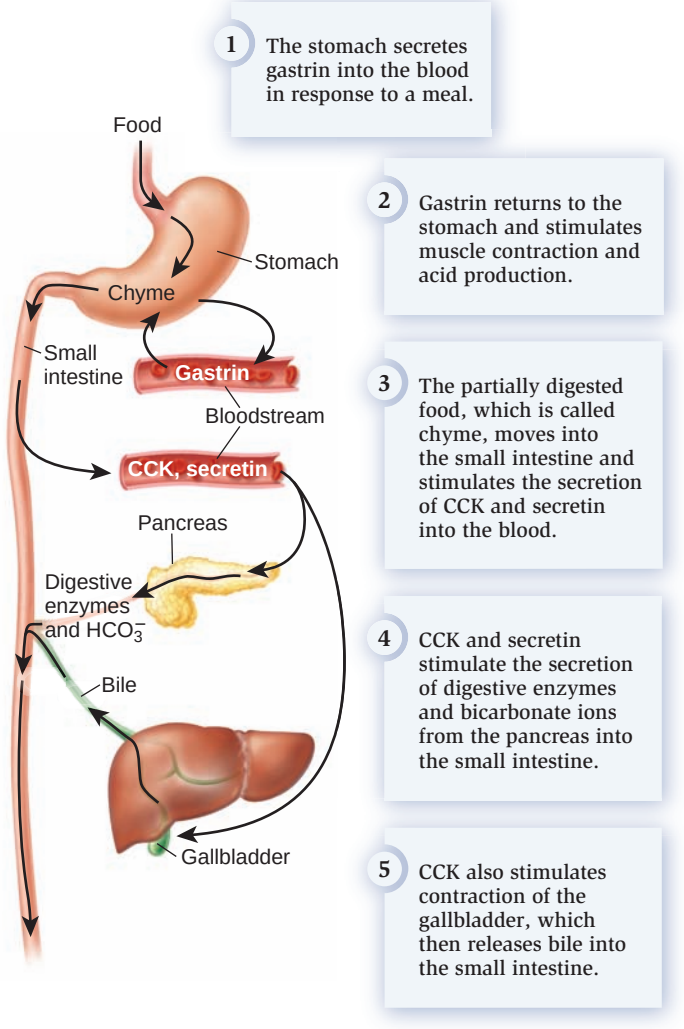


Figure 45.13 Hormonal regulation of digestion in the stomach and small intestine.

Concept check: Can you make a prediction about the possible effects, if any, of CCK on the stomach? Do you think CCK might stimulate or inhibit smooth muscle activity and acid production in the stomach? (Hint: Think about feedback principles you learned in Chapter 40.)

Feature Investigation

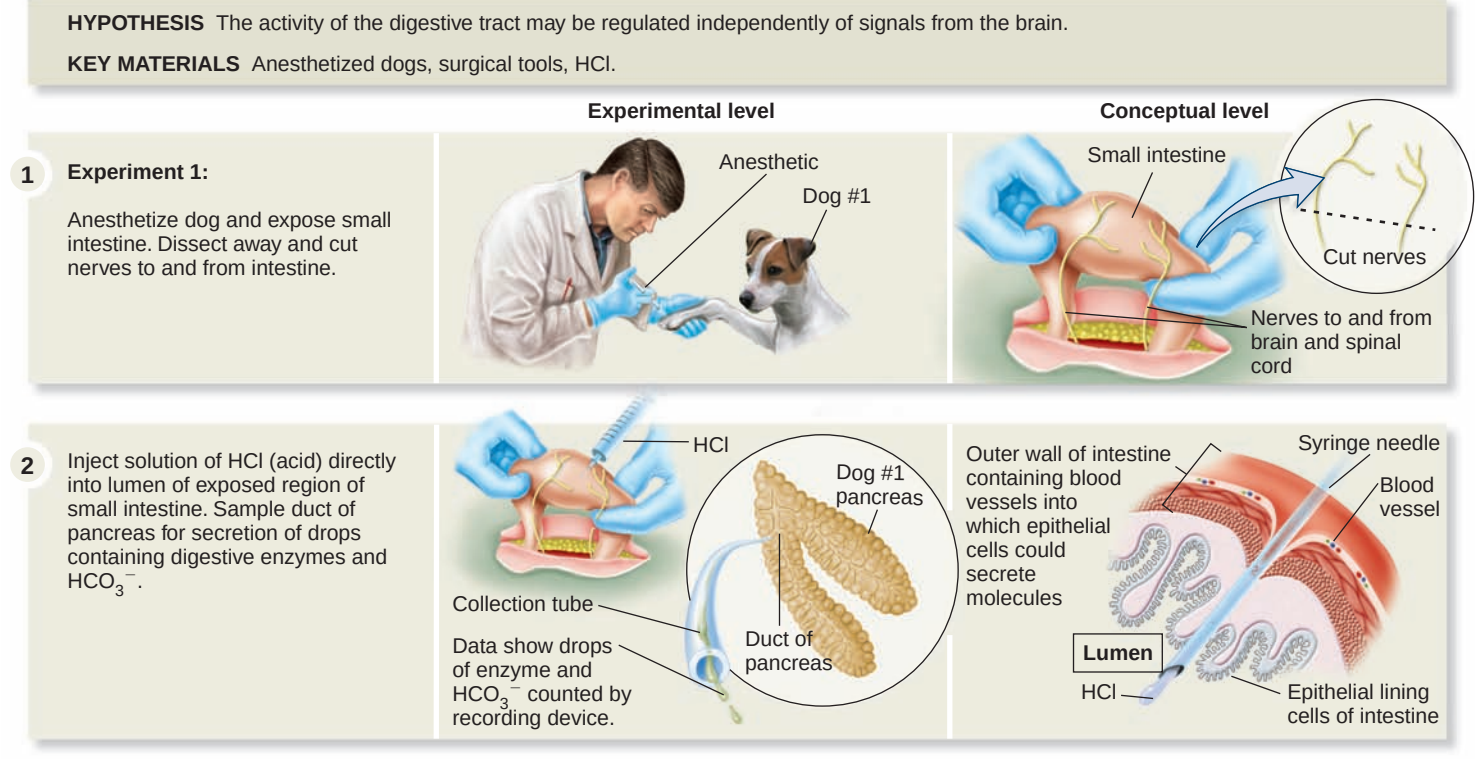
Bayliss and Starling Discovered a Mechanism by Which the Small Intestine Communicates with the Pancreas

The dependence of digestive function on the nervous system and the brain was established by the pioneering work of Ivan Pavlov. Pavlov's work in the early 1900s suggested that nerves conveyed signals between the gut and other structures, such as the brain and pancreas, and in this way, the gut could communicate with these structures. Such communication is essential for the synchronized release of pancreatic enzymes and bicarbonate ions with the arrival of food in the intestine. Shortly after Pavlov's work, two English scientists, William Bayliss and Ernest Starling, hypothesized that nerves were not the only structures controlling gut activity.

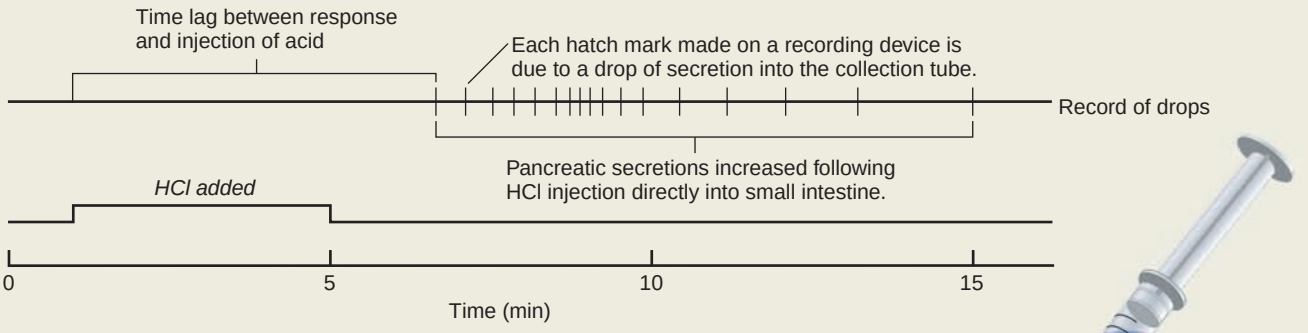
To test this hypothesis, Bayliss and Starling carefully dissected away and cut the nerves to the small intestine of an anesthetized dog, as shown in Figure 45.14. Next, they directly injected a small quantity of acid into the intestinal lumen, because it was known at the time that the acidic contents arriving from the stomach somehow triggered secretion of digestive enzymes and bicarbonate ions from the pancreas. They placed a tube into the duct that carries secretions from the pancreas to the small intestine, so they could collect the pancreatic secretions. Each drop of secretion was recorded as a hatch mark on a chart recorder. They discovered that even in the absence of intact nerves, simply adding acid into the intestinal lumen resulted in increased pancreatic secretions after a short lag period. Bayliss and Starling postulated that the lag was due to the time required for the intestinal cells to produce and secrete a factor that entered the blood and traveled to the pancreas.

To confirm their results and to counter the suggestion made by Pavlov and others that their first experiment merely failed to sever all the intestinal nerves, Bayliss and Starling performed a follow-up experiment. First, they removed a section of a dog's small intestine, added acid to it, and then ground it up in the acid. The mashed tissue was then filtered to produce an extract of any secretions that may have been produced by the intestine in response to the acid. Next, they injected the filtered extract into the bloodstream of another anesthetized dog whose pancreatic duct was opened as in the first experiment. What they discovered was remarkable: The extract derived from the acid-stimulated intestine of one dog caused the almost immediate secretion of pancreatic enzymes and bicarbonate ions from the second dog. This demonstrated that the small intestine secreted some chemical or chemicals in response to the presence of acid and that these secretions could reach the pancreas—presumably through the bloodstream—and stimulate the gland to release its contents. Bayliss and Starling called these chemicals hormones, from a Greek verb meaning to excite or arouse to action, and they named the hormone that activated the pancreas secretin. Thus was born not only the concept of a hormone but the recognition that these chemical messengers play a vital role in regulating the digestive system.

Figure 45.14 **Bayliss and Starling discovered the mechanism by which the small intestine and pancreas work together in digestion.**



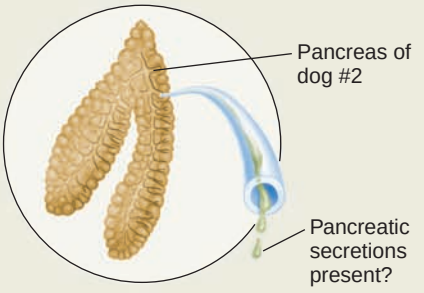
3 **THE DATA from Experiment 1:**



4 **Experiment 2:**

Cut out a piece of an untreated region of small intestine from dog #1. Expose the piece to acid, grind it up, and filter the ground tissue. Inject filtrate into bloodstream of another dog (dog #2).

5 Test for pancreatic secretions into small intestine of dog #2.

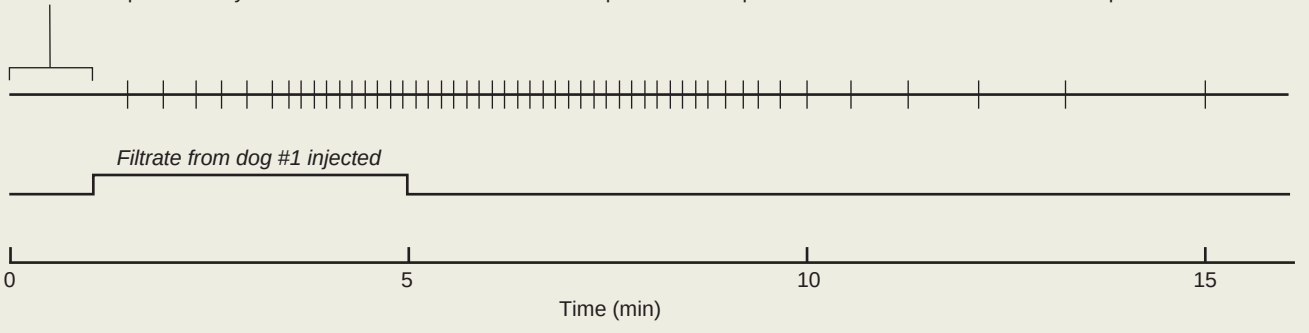


If the filtrate from dog #1 contained chemical signals released upon exposure to acid, those signals should stimulate the pancreas of dog #2 to secrete enzymes and HCO_3^-.

6 **THE DATA from Experiment 2:**

Prior to the injection of the filtrate into dog #2, the pancreas did not produce any secretion.

After the injection, pancreatic secretion increased rapidly. Each hatch mark corresponds to a drop of fluid collected from the duct of the pancreas.



7 **CONCLUSION** The small intestine contains molecules whose secretion into the blood is stimulated by acid. The molecules travel through the blood to the pancreas, causing secretion of pancreatic enzymes and HCO_3^-.

8 **SOURCE** Bayliss, W.M., and Starling, E.H. 1902. The mechanism of pancreatic secretion. *Journal of Physiology* 28:325–353.

In the rest of this chapter, we will examine the impact of digestive system disorders on human health.

Experimental Questions

1. Explain the first experiment conducted by Bayliss and Starling, which indicated that other factors besides signals from nerves may influence digestive gland secretion.
2. What criticism did Bayliss and Starling need to address to provide more conclusive evidence that the secretion was not due to neural regulation, and how did they address it?
3. What conclusions did the investigators draw from their second experiment?

45.7 Impact on Public Health

As we have seen, the functioning of the vertebrate digestive system is extraordinarily fine-tuned by the brain, nerves, and hormones. When people are well nourished, therefore, you might assume that digestive problems would be rare. However, each year in the U.S. alone, gastrointestinal complaints account for approximately 40 million visits to doctors and 10 million visits to hospitals and emergency rooms. Among the most common GI problems registered by hospitals and physicians are heartburn, ulcers, and diarrhea.

Excess Stomach Acid Production Can Lead to Heartburn

Approximately one in four people in the U.S. suffers at some time from heartburn. The term heartburn is a misnomer, because although the painful burning sensations of this disorder are felt in the vicinity of the heart, they are caused by stomach acid and arise within the esophagus, not the heart. Normally, the stomach contents do not move backward into the esophagus, largely because of the muscular sphincter at the esophageal/stomach juncture. However, under some conditions, the sphincter either does not close entirely or is forced open by the pressure of material in the stomach. When this happens, the acid in the stomach lumen enters the esophagus and irritates nerve endings there.

Many circumstances may contribute to heartburn. Overeating, for example, enlarges the volume of the stomach to the point of forcing its contents through the esophageal sphincter. Lying down after a big meal removes the effect of gravity on food in the stomach and may allow some acid to leak backward. Heartburn is also associated with smoking and consumption of alcohol, citrus fruits (which are acidic), chocolate (which contains caffeine, a known inducer of heartburn), and fatty foods (which take longer to digest than other foods and therefore remain in the stomach longer). One of the most common causes is pregnancy. Toward the middle of pregnancy, the growing fetus pushes up on the abdominal contents, which tends to force material from the stomach into the esophagus.

Common antacids contain carbonate ions, which buffer the acid in the stomach and esophagus. In severe cases, heartburn can damage the walls of the esophagus enough to cause a chronic cough and pain, or even perforate the esophagus. Antacids may not be sufficient to treat these patients, who are instead given drugs that inhibit the stomach's ability to produce acid. These drugs are among the most widely prescribed medications in the U.S.

Erosion of the Walls of the Alimentary Canal Causes an Ulcer

Although heartburn is usually treated before the acid begins eroding away the lining of the esophagus or stomach, occasionally this does occur. Erosion of any portion of the alimentary canal due to any cause is called an ulcer. Most ulcers occur in the stomach, lower esophagus, and the part of the small intestine that connects to the stomach, because these sites have the greatest acid concentrations. Ulcers are typically less than an inch wide; if untreated, luminal contents may leak into the surrounding body cavity where enzymes and acids from the stomach can do considerable damage. As many as 20 million Americans have an ulcer. Each year, 40,000 patients require surgery to repair tissue damaged by ulcers, and $\sim$6,000 die due to complications from the disease.

Acid is essential for ulcer formation, but we now know that it is not usually the primary cause. In fact, many patients with ulcers have perfectly normal rates of acid production. Contrary to popular belief, stress is probably not a major cause of ulcers either. So what is the main cause of ulcers?

In the 1980s, two Australian scientists, Barry Marshall and J. Robin Warren, proposed that most stomach ulcers arise from a bacterial infection. This idea did not gain quick acceptance because many scientists believed that bacteria could not survive the acidic conditions in the stomach. However, Marshall and Warren demonstrated the existence of *Helicobacter pylori* in the stomachs of a majority of patients with ulcers, and killing the bacteria with antibiotics proved to be an effective treatment. Once the bacteria are gone, the normal body repair mechanisms heal the wound created by their secretions. Marshall and Warren received the 2005 Nobel Prize in Medicine for their revolutionary discovery, which has improved the quality of life for millions of people. Currently, a combined treatment of antibiotics and the same drugs used to neutralize or inhibit stomach acid production in heartburn patients is effective in reducing or eliminating the symptoms of ulcers.

Diarrhea Is the Most Common Gastrointestinal Disorder Worldwide

Just in the U.S., there are over 1 billion cases of diarrhea—loose, watery stools occurring at least three times per day—every year. Nearly all episodes of diarrhea run their course in a

day or two. Typically they result from infection with a pathogen, such as a virus or bacterium. Other times, however, diarrhea may be caused by food sensitivities (such as lactose intolerance, discussed earlier), reactions to medications, stress-related disorders, or parasites that inhabit the rectum and large intestine.

Most cases of pathogen-related diarrhea in the U.S. result from exposure to one of several related types of bacteria, including those of the genus *Salmonella*, *Shigella*, and *Escherichia*. Often, these infections are handled by the body's immune system within a day or two, but sometimes medical attention is required. One cause of diarrhea stands apart as particularly dangerous, however. Cholera is a disease caused by the bacterium *Vibrio cholerae*, usually ingested by consuming contaminated food or water. According to the World Health Organization, at least 2,000 people die of cholera each year, with another 100,000 people contracting the disease but surviving. Nearly all cases of cholera occur in Africa, parts of Asia (notably China), and India, although scattered outbreaks have occurred nearly everywhere except the U.S., with the most recent worldwide pandemic lasting from 1961 to 1971. *V. cholerae* releases a toxin that alters the permeability of salts in the large intestine, resulting in a massive flow of these ions, followed by water, into the intestinal lumen. As in all cases of diarrhea, the chief concern with cholera is the loss of nutrients and water and the dehydration that ensues. In addition to killing the bacteria with antibiotics, therefore, the major treatment of cholera is the same as for any cause of diarrhea, which includes drinking solutions of salts and water to replace those that were lost in the feces.

Summary of Key Concepts

45.1 Animal Nutrition

- The four phases of food use in animals are ingestion, digestion, absorption, and elimination.
- Animals require organic nutrients—carbohydrates, proteins, lipids, and nucleic acids—and inorganic nutrients in the form of water and minerals. Differences in nutritional demands reflect an animal's physiology and environment.
- Essential nutrients (essential amino acids, essential fatty acids, vitamins, and minerals) must be obtained from the diet. There are eight essential amino acids that cannot be synthesized by humans and many other animals; they are required for building proteins. Vitamins are organic nutrients that serve as coenzymes for metabolic and biosynthetic reactions. Minerals are inorganic ions that serve many functions. (Tables 45.1, 45.2, 45.3)

45.2 Ingestion

- Herbivores eat only plants, carnivores consume animal flesh or fluids, and omnivores eat both plant and animal products.
- Animals display a variety of strategies for obtaining food. Three main strategies are suspension, bulk, and fluid-feeding.
- Suspension feeders sift water to filter out organic matter. Bulk feeders include carnivores, herbivores, and omnivores. Carnivores are generally predators or scavengers; they have teeth evolved for biting and tearing. The teeth and jaw muscles of herbivores are adapted for grinding plants. Fluid-feeders do not need teeth except to puncture an animal's skin. (Figures 45.2, 45.3, 45.4)

45.3 Principles of Digestion and Absorption of Food

- Intracellular digestion occurs in single-celled organisms and simple invertebrates.
- Most animals digest food via extracellular digestion. Flatworms and cnidarians have a gastrovascular cavity with one opening that serves as both entry and exit port. (Figure 45.5)
- All other animals have an alimentary canal, open at the mouth and anus or cloaca and segregated into specialized regions, through which food passes from one end to the other.
- Digestion of food requires hydrolytic enzymes.
- Once food has been digested, the nutrients must be absorbed via passive diffusion, facilitated diffusion, or primary or secondary active transport.

45.4 Overview of Vertebrate Digestive Systems

- The vertebrate digestive system consists of the alimentary canal plus associated structures, not all of which are found in all vertebrates. The anterior portion of the canal contains the oral cavity, salivary glands or mucus-secreting cells, pharynx (throat), and esophagus. The middle portion contains food storage or digestive organs (crop, gizzard, and/or stomach, depending on species), and the upper part of the small intestine. The posterior part of the alimentary canal contains the remainder of the small intestine, the large intestine (except in fishes), the rectum, and the anus or cloaca. (Figure 45.6)
- Saliva helps animals lubricate, chew, and swallow food. Peristalsis moves food through the pharynx and esophagus to the stomach. Some animals have a crop where food is stored and softened. (Figure 45.7)
- The stomach stores food, partially digests proteins, and regulates the rate at which chyme empties into the small intestine.
- Herbivores rely on microbes living within their digestive tracts to digest cellulose. (Figure 45.8)
- Nearly all digestion and absorption occur in the small intestine. The combination of villi and microvilli increases the small intestine's surface area and maximizes the efficiency of digestion and absorption. (Figure 45.9)
- The pancreas secretes digestive enzymes and a bicarbonate-rich fluid that neutralizes the acidic chyme. The liver secretes bile, which is stored in the gallbladder and aids in the digestion of fat. (Figure 45.10)
- The large intestine concentrates undigested material, which is then eliminated from the anus or cloaca.

45.5 Mechanisms of Digestion and Absorption in Vertebrates

- Carbohydrate digestion occurs in the small intestine of most vertebrates. Starch is digested by amylases into molecules of the disaccharide maltose. Maltose and other disaccharides are digested into monomers by enzymes located at the brush border and transported across epithelial cells into the blood. (Figure 45.11)
- Humans with lactose intolerance cannot digest lactose because the intestinal enzyme lactase is not expressed after weaning, a trait that is linked to genetic background.

- Proteins are broken down to peptide fragments in the stomach by pepsin; these fragments are further broken down into amino acids in the small intestine by trypsin and chymotrypsin.
- Lipid digestion occurs entirely in the small intestine by the action of pancreatic lipase. (Figure 45.12)
- Most water-soluble vitamins are absorbed by diffusion or active transport. Fat-soluble vitamins follow the pathway for fat absorption.
- The large intestine absorbs some of the remaining salts and water that were not absorbed in the small intestine.

45.6 Regulation of Digestion

- The digestive systems of animals are regulated in part by other organ systems, especially the nervous and endocrine systems. The nervous system can affect the digestive system in two major ways: (1) local control of muscular and glandular activity by the nerves in the alimentary canal and (2) long-distance regulation by the brain.
- Several hormones work together to regulate the rate of digestion. Bayliss and Starling demonstrated that a hormone from the small intestine triggers secretions from the pancreas into the small intestine. (Figures 45.13, 45.14)

45.7 Impact on Public Health

- Common GI complaints registered by hospitals and physicians include heartburn, ulcers, and diarrhea.

Assess and Discuss

Test Yourself

1. The process of enzymatically breaking down large molecules into smaller molecules that can be used by cells is
   a. absorption.
   b. secretion.
   c. ingestion.
   d. digestion.
2. The term "essential nutrients" refers to
   a. all the carbohydrates, proteins, and lipids ingested by an organism.
   b. nutrients that an animal cannot manufacture.
   c. nutrients that must be obtained from the diet in their complete form.
   d. all of the above.
   e. b and c only.
3. An animal that has a strong preference for a particular food but can adjust its diet if necessary is said to be
   a. herbivorous.
   b. omnivorous.
   c. carnivorous.
   d. opportunistic.
   e. both b and d.
4. Which of the following statements is not correct?
   a. Fluid-feeders include animals that consume animal or plant fluids.
   b. Suspension feeding occurs only in invertebrates.
   c. Predators are animals that kill and consume live prey.
   d. Herbivory occurs in both aquatic and terrestrial species.
   e. Blood-sucking animals may contain anticoagulants in their saliva.
5. The pancreas connects to which part of the alimentary canal?
   a. esophagus
   b. stomach
   c. small intestine
   d. cecum
   e. large intestine
6. Which of the following statements regarding the vertebrate stomach is not correct?
   a. Its cells secrete the active protease enzyme pepsin.
   b. It is a saclike organ that evolved to store food.
   c. Its cells secrete hydrochloric acid.
   d. It is the initial site of protein digestion.
   e. Little or no absorption of nutrients occurs there.
7. Absorption in the small intestine is increased by
   a. the many villi that are present on the inner surface of the small intestine.
   b. the brush border formed by microvilli on the cells of the villi.
   c. the presence of numerous transporter molecules on the epithelial cells.
   d. all of the above.
   e. a and b only.
8. In birds, the secretion of acid and pepsinogen occurs in
   a. the crop.
   b. the gizzard.
   c. the proventriculus.
   d. the cloaca.
   e. the gallbladder.
9. Bile is produced by
   a. the liver.
   b. the gallbladder.
   c. the pancreas.
   d. the small intestine.
   e. the cecum.
10. Which of the following is a function of the large intestine?
    a. It participates in cellulose digestion by microbes that exist in the cecum of herbivores.
    b. It stores and concentrates fecal material.
    c. Its cells absorb salts and water that remain in chyme after it leaves the small intestine.
    d. Its cells absorb certain vitamins produced by bacteria.
    e. All of the above are functions of the large intestine.

Conceptual Questions

1. Distinguish between digestion and absorption.
2. Explain some of the differences between the teeth of herbivores and carnivores and how these differences are adaptive for the animal's diet.
3. Explain the functions of the crop and gizzard in birds. Why don't humans have a crop or gizzard?

Collaborative Questions

1. Describe several strategies that animals use to obtain food.
2. Define "nutrient." On the basis of that definition, do you consider water a nutrient? Briefly discuss the essential nutrients, vitamins, and minerals that animals must obtain through their diet.

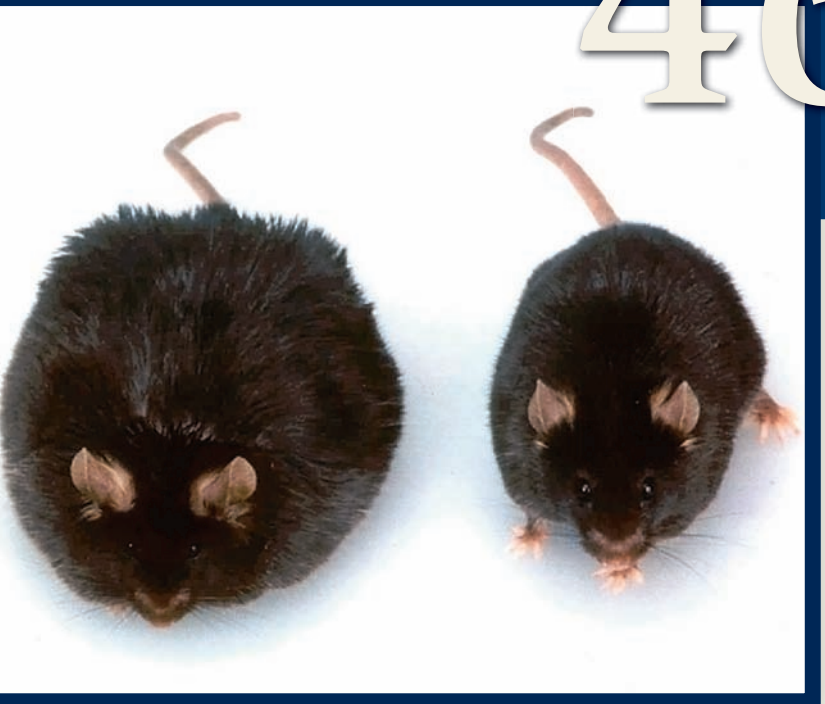
Control of Energy Balance, Metabolic Rate, and Body Temperature

46

Chapter Outline



A genetically obese, leptin-deficient mouse and a normal mouse.

In 1997, two young cousins being treated for extreme obesity were brought to the attention of researchers studying a newly discovered hormone called leptin. Leptin had been demonstrated in laboratory rodents to inhibit appetite. The researchers hypothesized that the children—who weighed approximately 30 kg by age 2, and in one case, 86 kg by age 9—were not producing leptin. This hypothesis was confirmed by molecular analyses that identified a mutation in the children's leptin gene. Subsequently, several other individuals with mutations in leptin were identified, leading in each case to extreme childhood obesity. Treatment of these individuals with leptin has proven beneficial in restoring normal body weight. Although leptin deficiency is rare and is only one of many possible causes of obesity in humans, animal models of leptin deficiency, such as the mice shown in the chapter-opening photo, represent a remarkable breakthrough in our understanding of the genetic bases of the control of appetite and metabolism. How nutrients that supply energy are processed, stored, and used by animals' bodies in times of food abundance or fasting is a subject of this chapter.

In Chapter 45, we saw that all animals require nutrients to assemble the macromolecules that make up body tissues. Some of the ingested nutrients, such as carbohydrates, lipids, and proteins, also represent a form of fuel, or energy, that can be used to generate ATP within cells. Most animals, however, do not have a constant supply of nutrients. Insects, cephalopods, and all vertebrates, for instance, sleep or have periods of greatly reduced activity for part of the day, during which time they do not eat. In addition, environmental changes may reduce the food supply, leading to long fasts. As a consequence of the irregular and sometimes unpredictable flow of nutrients into the body, animals have evolved an array of mechanisms to adequately maintain levels of important fuel molecules even during a fast. In the first two sections of this chapter, we will explore how ingested nutrients are stored in the body for such times of need and the mechanisms by which these stores are tapped.

Metabolism refers to all the bodily activities and chemical reactions in an organism that maintain life. **Metabolic rate** describes the rate at which an organism uses energy to power these reactions. Animals may have widely different metabolic rates, which determine the amount of nutrients they need. The greater an animal's metabolic rate, the more heat it generates as a by-product of breaking down nutrients and using the energy of their chemical bonds to synthesize ATP. Some of this heat escapes to the environment, and some is used to warm an animal's body. Metabolism and body temperature are therefore closely related, and we will examine this relationship in the next two sections of the chapter. We will also discuss energy balance, the balance between energy expenditure and consumption. We conclude with the public health impact of human disorders associated with metabolism, including obesity.

46.1 Nutrient Use and Storage

Once nutrients have been ingested, they are used or stored by the body. The use of nutrients can be divided into two alternating phases. The **absorptive state** occurs when ingested nutrients enter the blood from the gastrointestinal tract. The **postabsorptive state** occurs when the gastrointestinal tract is empty of nutrients and the body's own stores must supply energy. During the absorptive period, some ingested nutrients supply the

immediate energy requirements of the body. The rest are added to the body's energy stores to be called upon during the next postabsorptive period. An average meal in a human requires about 4 hours for complete absorption. Therefore, our usual three-meal-a-day pattern places us in the postabsorptive state during the late morning and afternoon and part of the night. Total-body energy stores are adequate for the average human to withstand a fast of several weeks. By contrast, some animals can barely survive a single skipped meal—particularly if they have low energy reserves—because their metabolic needs are much higher than our own. In this section, we will focus on nutrient absorption, use, and storage in vertebrates, with a closer look at mammals.

In the Absorptive State, Nutrients Are Absorbed and Used for Energy or Stored

The categories of nutrients that are absorbed during the absorptive state include or are formed from carbohydrates, lipids, proteins, nucleic acids, vitamins, minerals, and water. We will look in depth at the first three of these; Figure 46.1 gives an overview of what happens to these nutrients. Digested carbohydrates are absorbed as monosaccharides, particularly glucose. Digested lipids (fats) are absorbed after first being resynthesized into triglycerides in intestinal epithelial cells. Proteins are broken down into amino acids and then absorbed.

Absorbed Carbohydrates: Energy or Storage The chief carbohydrate monomers absorbed from the gastrointestinal tract of vertebrates are glucose, galactose, and fructose. In mammals, the latter two sugars are either converted to glucose by the liver or enter the same metabolic pathways as glucose does.

Glucose is one of the body's two major energy sources during the absorptive state (triglycerides being the other). Much of the absorbed glucose enters cells and is enzymatically broken down, resulting in the formation of hydrogen ions, carbon dioxide, and water and, in the process, releasing the energy required to form ATP (Figure 46.1a). Because skeletal muscle makes up a large fraction of body mass in most vertebrates, it is a major consumer of glucose, particularly when an animal is active. In all vertebrates, skeletal muscle also incorporates some of the glucose into the polymer glycogen (see Chapter 3), which is stored in the muscles to be used later. If more glucose is absorbed than is needed for immediate energy, a portion of the excess is incorporated into glycogen in the liver, and the remainder into triglycerides in fat cells. The structures of glycogen and triglycerides are described in Chapter 3.

Absorbed Triglycerides: Storage Triglycerides are too large to diffuse across the plasma membranes of the intestinal epithelial cells. As described in Chapter 45, they are digested into fatty acids and monoglycerides in the lumen of the small intestine and then resynthesized into triglycerides once they diffuse into the intestinal epithelial cells. The triglycerides and other ingested lipids (for example, cholesterol) are packaged into chylomicrons, which enter lymph and from there the blood circulation. As blood moves through adipose tissue, a blood vessel enzyme called lipoprotein lipase releases the fatty acids from the triglycerides in the chylomicrons. The released fatty acids then enter adipose cells and combine with glycerol to re-form triglycerides (Figure 46.1b). These triglycerides are stored in fat cells until the body requires additional fuel.

As with glucose, some of the ingested fat is not stored but is used by most organs other than the brain during the absorptive state to provide energy. The relative amounts of carbohydrate and fat used for energy during the absorptive period depend largely on the composition of a meal.

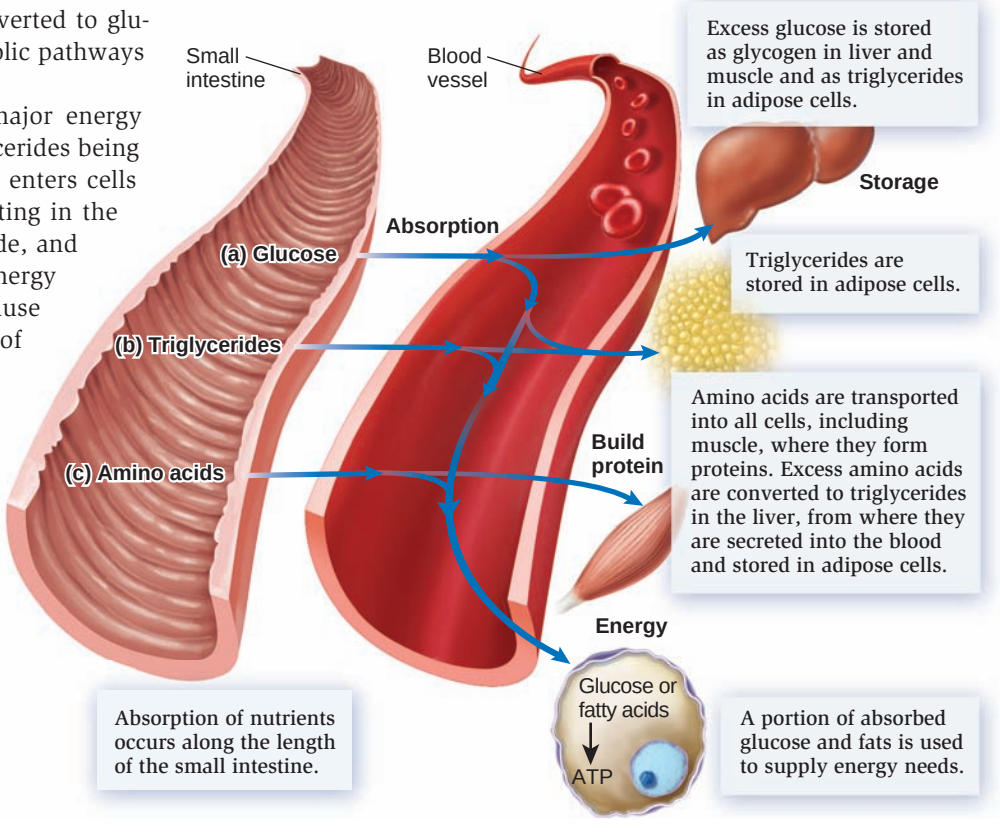


Figure 46.1 Events of the absorptive state. The products of digestion are absorbed into the blood along the length of the small intestine. (Note that for simplicity, triglycerides are shown being absorbed directly into blood, not into lacteals; see Chapter 45 for details.) These nutrients are used for immediate energy needs, or they are deposited in cells as energy stores or as macromolecules important in cell function, such as for building proteins.

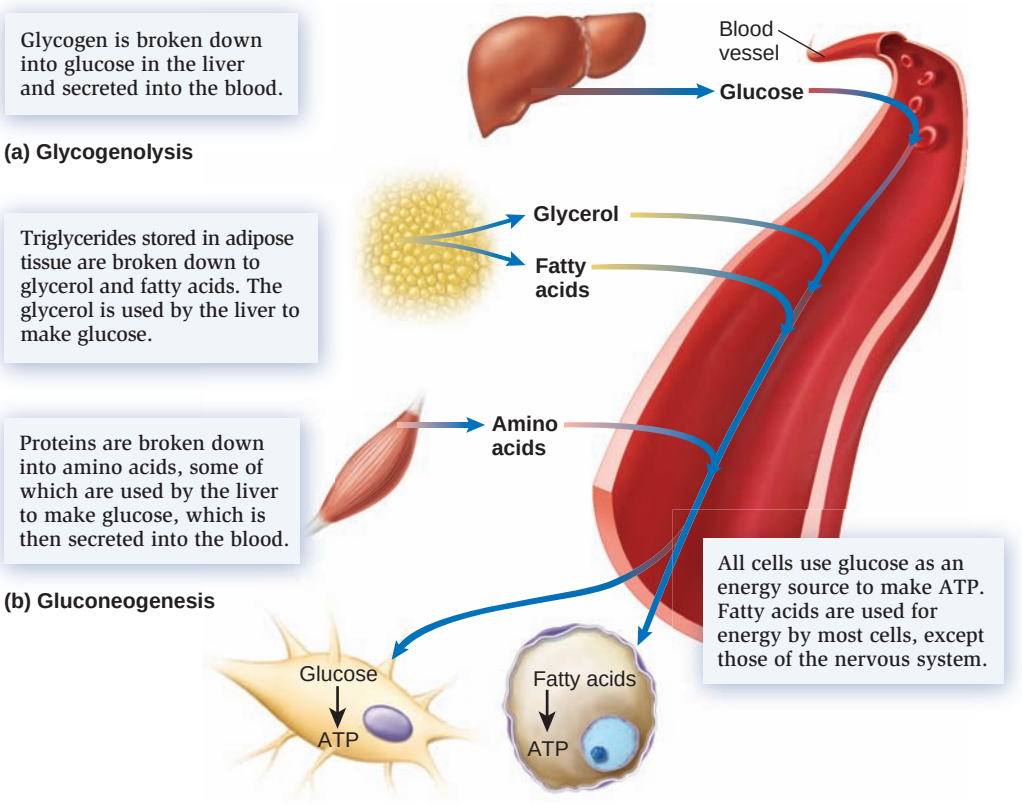

Figure 46.2 Events of the postabsorptive state. In this state, macromolecules formed during the absorptive state are broken down to supply monomers that can be used for energy. **(a)** This begins with glycogenolysis—the breakdown of glycogen into glucose. **(b)** In gluconeogenesis, the breakdown products of triglycerides and proteins, namely, fatty acids, glycerol, and amino acids, can be used for energy either directly or indirectly by their conversion in the liver to glucose.

Absorbed Amino Acids: Protein Building Amino acids are taken up by all body cells, where they are used to synthesize proteins (Figure 46.1c). All cells require a constant supply of amino acids, because proteins are constantly being synthesized and degraded. However, unlike excess glucose and fatty acids which are stored as glycogen and triglycerides, excess amino acids that are ingested are not stored as protein. Instead, amino acids are enzymatically converted by liver cells into fatty acids and from there into triglycerides, which then get released into the blood and are taken up and stored in adipose cells. Therefore, eating large amounts of protein does not normally increase stores of body protein. An exception would be a young, rapidly growing animal with its continuous increase in body protein.

In the Postabsorptive State, Stored Nutrients Are Released and Used

As the postabsorptive state begins, synthesis of glycogen and lipids slows, and the breakdown of these substances begins. During this state, macromolecules formed during the absorptive state are broken down to supply monomers that can be used for energy. No glucose is absorbed from the intestines during this time, yet the blood glucose concentration must be maintained because the cells of the central nervous system (CNS) normally use only glucose for energy. A large decrease in blood glucose levels can disrupt CNS functions, ranging from subtle impairment of mental function to seizures, coma, or even death.

The events that maintain blood glucose concentration fall into two categories: (1) reactions that provide glucose to the blood and (2) cellular use of fat for energy, thus sparing glucose for the CNS. Let's look at each of these.

Glucose from Glycogen and Noncarbohydrate Precursors Vertebrates can increase their blood glucose levels during the postabsorptive period in two major ways: by breaking down glycogen and by making new glucose. First, the glycogen that was formed during the absorptive period can be broken back down into molecules of glucose by hydrolysis, a process known as **glycogenolysis** (Figure 46.2a). This occurs primarily in the liver, following which the glucose is released into the blood, where it can travel to all cells. Muscle glycogen is also broken down into glucose by glycogenolysis, but this glucose is used exclusively by muscle cells and not secreted into the blood.

The amount of liver glycogen available to provide glucose during the postabsorptive period varies among animals, but it is generally sufficient to maintain blood glucose levels for only a brief time, such as an overnight fast in a human. Therefore, a second mechanism for maintaining blood glucose levels is required when the postabsorptive period continues longer. In the process of **gluconeogenesis** (literally, creation of new glucose), enzymes in the liver convert noncarbohydrates into glucose, which is then secreted into the blood (Figure 46.2b). This process occurs in all vertebrates but appears to be especially important in mammals.

A major precursor for gluconeogenesis is glycerol, which is released from triglycerides in adipose tissue by the breakdown process called lipolysis. In lipolysis, enzymes within fat cells hydrolyze triglycerides into fatty acids and glycerol, both of which enter the bloodstream. The fatty acids diffuse into cells, where they are used as an alternate energy source to glucose (except for the CNS, which continues to require glucose). The glycerol is taken up by the liver, where enzymes convert it into glucose, which is then released back into the bloodstream.

Table 46.1 Relative Changes in the Use and Generation of Energy Sources During the Absorptive and Postabsorptive Periods

	Glucose absorption from gut	Glucose use by cells	Synthesis of triglycerides	Use of fatty acids for energy by cells	Breakdown of glycogen in muscle and liver	Blood levels of glucose
Absorptive period	High	High	High	Low/moderate	Low	Normal
Postabsorptive period	Absent	Moderate (some glucose is spared for CNS use)	Low	High	High	Normal

When the postabsorptive period continues for an extended period of time—as when an animal fails to find food—protein becomes an important source of blood glucose. Large quantities of protein in muscle and other tissues can be broken down to amino acids without serious tissue damage or loss of function. The amino acids enter the blood and are taken up by the liver. In the liver, the amino group is removed from each amino acid, and the remaining molecule is converted into glucose. This process, however, has limits. Continued protein loss can result in the death of cells throughout the body because they depend on proteins for such vital processes as plasma membrane function, enzymatic activity, and formation of organelles.

Lipid Metabolism by Other Tissues: Glucose Sparing

Another way that glucose is made available to the organs and tissues that need it the most—such as the brain—in the postabsorptive state is by having other organs and tissues reduce their dependence on glucose. They do this by increasing their use of fat as an energy supply during this period. This metabolic adjustment, called **glucose sparing**, reserves (or spares) the glucose produced by the liver by glycogenolysis and gluconeogenesis for use by the nervous system.

The essential step in glucose sparing is lipolysis, the breakdown of adipose tissue triglycerides, which, as stated earlier, liberates fatty acids and glycerol into the blood. In vertebrates, the circulating fatty acids are taken up and used to provide energy by almost all tissues, excluding the nervous system, whose cells do not express the enzymes required to break down fatty acids for energy.

Of the vertebrate body's tissues and organs, the liver is unique in that most of the fatty acids entering it during the postabsorptive state are not used by that organ for energy. Instead they are processed into three small compounds collectively called **ketones**, or ketone bodies. Ketones are released into the blood during prolonged fasting. They provide an important energy source for the many tissues, including the brain, capable of oxidizing ketones through the citric acid cycle.

The use of fatty acids and ketones during fasting provides energy for the body, sparing the available glucose for the brain. Moreover, as just mentioned, the brain can use ketones as energy, and it does so increasingly as ketones build up in the blood during the first few days of a fast. The survival value of this phenomenon is significant. When the brain reduces its glucose requirement by using ketones, much less protein breakdown is required to supply amino acids for gluconeogenesis. Protein stores last longer, enabling the animal to survive a long fast without serious tissue damage.

The combined effects of glycogenolysis, gluconeogenesis, and glucose sparing are so efficient that, after several days of complete fasting, human blood levels of glucose fall by only a small percentage. Table 46.1 summarizes the relative changes in these and other variables during the absorptive and postabsorptive periods.

46.2 Regulation of the Absorptive and Postabsorptive States

Tight control mechanisms are required to maintain homeostatic levels of energy-providing molecules in the blood. These controls come in two forms: endocrine and nervous. Cells of the endocrine system produce blood-borne signaling molecules called hormones. Several hormones as well as signals arising from cells of the nervous system work together in this coordination. In this section, we will learn that one common function of the endocrine and nervous systems is to regulate the processes of glycogenolysis and gluconeogenesis so that glucose is made available to cells at all times.

Insulin Is a Key Regulator of Metabolism

The blood concentration of insulin, a hormone made by the pancreas, increases during the absorptive state and decreases during the postabsorptive state. **Insulin** regulates metabolism in several ways, primarily by regulating the blood glucose concentration. It does this by promoting the transport of glucose from extracellular fluid into cells, where it can be used for metabolism. Glucose is a relatively large, polar molecule that cannot cross plasma membranes without the aid of a transporter protein. Insulin increases glucose uptake by binding to a cell-surface receptor and stimulating an intracellular signaling pathway. This pathway increases the availability of transport proteins called glucose transporters (GLUTs) in the plasma membrane (Figure 46.3). These GLUTs are located within preformed vesicles that are stored in the cytosol of cells. When these vesicles are stimulated, they fuse with the plasma membrane, making more GLUTs available to transport glucose into the cell. Consequently, insulin lowers the blood glucose level. Insulin also regulates metabolism by inhibiting glycogenolysis and gluconeogenesis in the liver, because these processes are not required during the absorptive state.

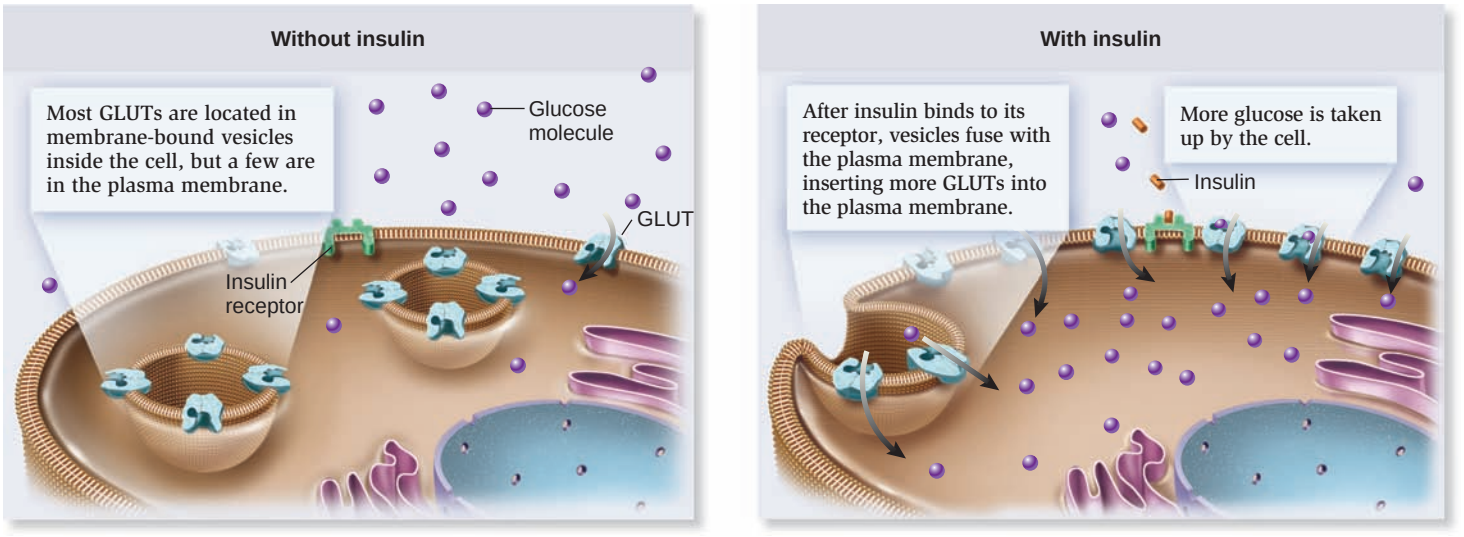

Figure 46.3 **The effect of insulin on the location of glucose transport (GLUT) proteins.** The presence of insulin results in the fusion of intracellular vesicles containing GLUT proteins with the plasma membrane, where they facilitate glucose uptake into the cell.

Concept check: *What benefit is there to having GLUT proteins premanufactured and stored in intracellular vesicles?*

Insulin exerts its effects mainly on muscle cells and adipose tissue cells, because these cells have insulin receptors in their plasma membranes. However, not all GLUTs are identical, and not all require insulin for their activity, as described next.

Genomes & Proteomes Connection

GLUT Proteins Transport Glucose in Animal Cells

All animal cells require transporters to move glucose across their plasma membranes. GLUTs in mammals make up a family of at least 14 related proteins that share similar structures but are expressed in different tissues. GLUTs typically have 12 membrane-spanning helical domains that anchor the protein in plasma membranes. The structures of GLUTs are very similar across phyla. For example, the coding sequence of one *Drosophila* GLUT gene is nearly 70% identical to that of one of the human GLUTs. In more closely related taxa, such as birds and mammals, GLUTs are even more similar, with up to 95% of their amino acid sequences being the same. These and other considerations indicate that the GLUTs arose by accumulated mutations of a common ancestral gene.

The different GLUTs vary in their ability to bind glucose. For example, some GLUTs have high affinity for glucose, and others have low affinity. High affinity means the protein binds glucose even at very low concentrations of glucose. Let's look at the properties of three mammalian GLUTs, named GLUT1, GLUT3, and GLUT4. Muscle and fat cells express the protein GLUT4, which has a low affinity for glucose, but one that is sufficient for the concentration of glucose normally found in blood. This is also the only GLUT protein whose movement to the plasma membrane requires the cell to be stimulated by insulin. Consequently, as the glucose level rises in the blood after a meal, insulin recruits more GLUT4 molecules from the cell cytosol to the plasma membrane of muscle and fat cells.

By comparison, GLUT1 and GLUT3 are found predominantly in the brain, where they act in concert to mediate the transport of glucose from blood vessels to the interstitial fluid of the brain, and from there into brain cells. GLUT1 and GLUT3 have much higher affinity for glucose than do other GLUT proteins. This means that neurons of the brain can transport glucose into their cytosol even when the concentration of glucose in the extracellular fluid is very low. In addition, insulin is not required for GLUT1 and GLUT3 to be present in the plasma membrane, unlike the situation for GLUT4. As a result of these properties of GLUT1 and GLUT3, neurons of the brain would still receive adequate energy for survival even if an animal's blood glucose level plummeted, perhaps due to disease or starvation.

Expressing multiple types of the same functional class of protein means that different parts of an animal's body can meet their own particular metabolic demands. Moreover, these needs may change during development. For example, high-affinity GLUTs such as GLUT1 and GLUT3 are present in high numbers in embryonic cells when there is a greater need for glucose but smaller numbers during other stages of life.

Because insulin, through its actions on GLUT4, is the key regulatory molecule that controls blood glucose levels, it is important to understand the regulation of insulin production and release. This is described next.

The Blood Glucose Concentration Is Maintained Within a Normal Range

Like all important variables in an animal's body, blood glucose concentrations are controlled by a system of checks and balances. In the absorptive state, after a meal has been eaten,

the blood glucose level increases; in the postabsorptive state, depending on how long it lasts, the level may go too low. What homeostatic mechanisms keep the blood glucose level within a normal range?

Increased Glucose in the Absorptive State The primary factor controlling the secretion of insulin from the pancreas is the blood glucose level (Figure 46.4a). An increase in an animal's blood glucose level directly stimulates the cells of the pancreas to secrete insulin in proportion to the amount of glucose in the blood. Later, after insulin helps the cells of the body take up glucose, the resulting decrease in the blood glucose level removes the signal for insulin secretion. This is an example of negative feedback, as described in Chapter 40.

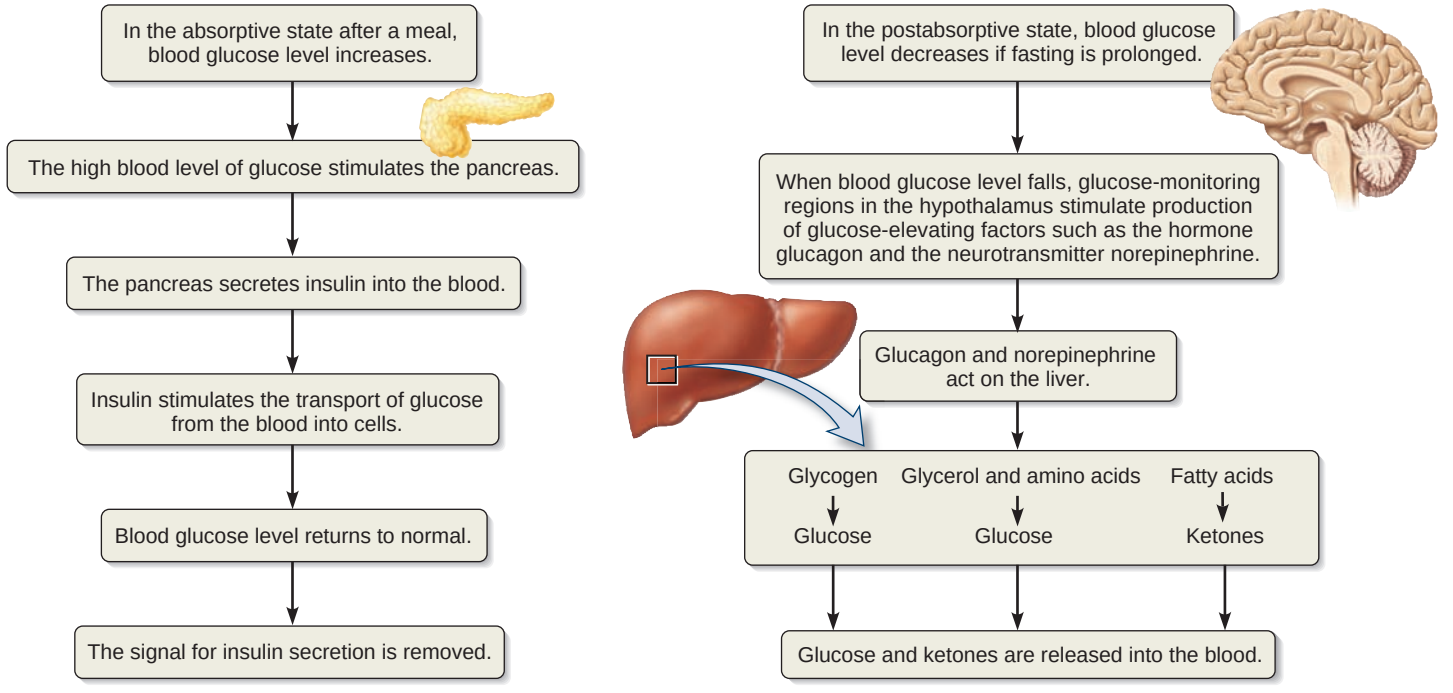
In addition to blood glucose level, inputs from the nervous system to the pancreas also play a role in the regulation of insulin secretion. During a meal, signals from the parasympathetic nervous system (see "rest-or-digest" response in Chapter 42) stimulate the secretion of insulin into the blood, ultimately reducing circulating glucose levels back to normal.

Decreased Glucose in the Postabsorptive State Several factors act in concert to prevent blood glucose from decreasing below the normal homeostatic range, even during a short fast. Otherwise, glucose could fall so low—a condition called hypoglycemia—that despite the high-affinity GLUT1 and GLUT3 proteins in brain cells, there would not be enough glucose to keep brain cells alive.

If for any reason—such as a prolonged fast—the blood glucose level decreases below the normal homeostatic range for an animal, neurons that respond to changes in the extracellular concentration of glucose are activated within the hypothalamus (Figure 46.4b). Signals from the hypothalamus then stimulate the production of glucose-elevating factors. These include numerous hormones, notably another one produced by the pancreas called glucagon. **Glucagon** is a protein hormone that stimulates the processes of glycogenolysis, gluconeogenesis, and the synthesis of ketones in the liver. In addition, certain other hormones from various endocrine glands, as well as the neurotransmitter norepinephrine released from neurons of the sympathetic nervous system, stimulate adipose tissue to release fatty acids into the blood. The fatty acids diffuse across plasma membranes and provide another source of energy for the synthesis of ATP. The overall effect is to increase the blood concentrations of glucose, fatty acids, and ketones during the postabsorptive period or during a prolonged fast.

More Energy Is Required During Exercise or Stress

We think of exercise as something humans do for fun or fitness, but in its broadest sense, **exercise** can be defined as any physical activity that increases an animal's metabolic rate. Generally, an animal becomes active to seek something, such as food, shelter, or a mate, or to elude something, such as a predator or a storm. What we consider exercise can also be a response to a stressful situation. The type of exercise animals engage in,



(a) When blood glucose level is high **(b) When blood glucose level is low**

Figure 46.4 Maintenance of normal blood glucose levels.

Concept check: *What are the sources of the glycerol, fatty acids, and amino acids used to make glucose?*

therefore, can be quite varied. When a cheetah sprints after a small antelope, for example, the activity of both predator and prey is brief and intense, perhaps lasting only a few seconds. By contrast, a tuna may never stop swimming, and a migrating bird may fly a hundred miles a day or more over a span of weeks.

For any type of exercise, including that which results from an animal's behavioral responses to stress, nutrients must be available to provide the energy required for such things as skeletal muscle contraction, increased heart and lung activity, and increased activity of the nervous system. These energy-providing nutrients include glucose and fatty acids as well as the muscle's own glycogen.

The liver supplies the blood with the glucose used during exercise by breaking down its glycogen stores and by gluconeogenesis. This occurs even in the absorptive state, and thus the blood glucose level increases above normal when an animal exercises at such times. In addition, an increase in adipose tissue lipolysis releases fatty acids into the blood, which provides an additional source of energy for the exercising muscle.

These events are mediated by the same hormones and nerves responsible for the regulation of the postabsorptive state. For example, inputs from the sympathetic nervous system to the pancreas inhibit insulin secretion during exercise or acutely stressful situations. Consequently, glucose transport into muscle and fat cells is decreased, which tends to raise blood glucose levels (this is part of the fight-or-flight response described in Chapter 42). Because the brain does not depend on insulin for glucose transport across neuronal membranes, as just described, more of the body's supply of glucose is available to the brain at such times, while other cells can use fatty acids for energy. Therefore, the body uses all available forms of energy in response to fasting, exercise, and stress.

46.3 Energy Balance

Animals have a wide range of metabolic needs that depend on numerous factors. Active animals, such as migrating birds, burn fuel more rapidly than inactive animals, such as hibernating mammals. Juveniles typically burn fuel more quickly than mature animals. An animal's **energy expenditure** is the same as its metabolic rate, which was already defined as the amount of energy it uses in a given period of time to power all of its metabolic requirements.

A fundamental characteristic of energy is that it can be neither created nor destroyed, but it can be converted from one form to another (see Chapter 6). The breakdown of organic molecules liberates energy locked in their chemical bonds and transfers it to the bonds in ATP. This is the energy that cells use to perform various biological activities such as muscle contraction, active transport, and molecular synthesis. We refer to these functions as work. Not all of the energy is used to do work, however. Some of it appears as heat, which contributes to an animal's body temperature or is dissipated to the environment. In this section, we examine how metabolic rate is measured in animals and how a balance is achieved between energy consumption and expenditure.

Metabolic Rate Can Be Measured by Calorimetry and Compared Among Different Animals

The standard unit of energy is the joule, but biologists have historically quantified the energy of metabolism in calories. A **calorie** (equivalent to 4.187 joules) is the amount of heat required to raise the temperature of 1 gram of water 1 degree Celsius. Most biological activities, however, require much greater amounts of energy than a calorie, and consequently, the more common unit of measurement is the kilocalorie (1,000 calories, or **kcal**). (In food labeling, a Calorie with a capital C is also the same as kcal.) As noted above, the metabolic rate is the total energy expenditure of an animal per unit of time. Biologists often measure and compare the metabolic rates of different animals to learn, for example, how some animals are capable of hibernating, how an animal's body temperature influences its metabolic rate, and how hormones and other factors alter an animal's metabolism.

The most common measure used to compare the metabolic rates of different species is the **basal metabolic rate** (**BMR**). The BMR is called the metabolic cost of living, and most of it can be attributed to the routine functions of the heart, liver, kidneys, and brain. In the basal condition, the animal is at rest in the postabsorptive state and at a standard temperature. For **endotherms**, animals that generate their own internal heat and maintain a relatively narrow range of body temperatures, the standard temperature is within the range that causes the animal to neither gain heat (for example, by shivering) nor lose heat (for example, by perspiration). This temperature range is called an animal's thermoneutral zone. The BMR of **ectotherms**, animals whose body temperature changes with the environmental temperature, must be measured at a standard temperature for each species—one that approximates the average temperature that a species normally encounters. In this case, the term **standard metabolic rate** (**SMR**) is used instead of BMR, because the basal condition in ectotherms is harder to define than for endotherms. Because BMR and SMR apply only to resting, postabsorptive animals at a standard temperature, any animal that has recently eaten or been active has a higher metabolic rate than its basal metabolic rate.

Two methods used to obtain a good estimate of BMR are direct and indirect calorimetry. **Direct calorimetry** was invented by French chemist and biologist Antoine Lavoisier in 1780 (Figure 46.5). In Lavoisier's procedure, an animal was placed in an enclosed, insulated chamber surrounded by ice. As the animal metabolized fuel, it generated heat, which dissipated into the chamber and melted the ice. The amount of water collected from an opening at the bottom of the chamber could be used to estimate the amount of heat generated by the animal. Today, direct calorimetry is measured using more sophisticated instrumentation, but the principle remains the same. It provides an accurate measure of metabolism, because energy expenditure and heat production are directly related. However, the method is not very practical, particularly with large animals.

The second and more practical method of measuring BMR, **indirect calorimetry**, is based on the principle that animals require oxygen to metabolize fuel. The more fuel being

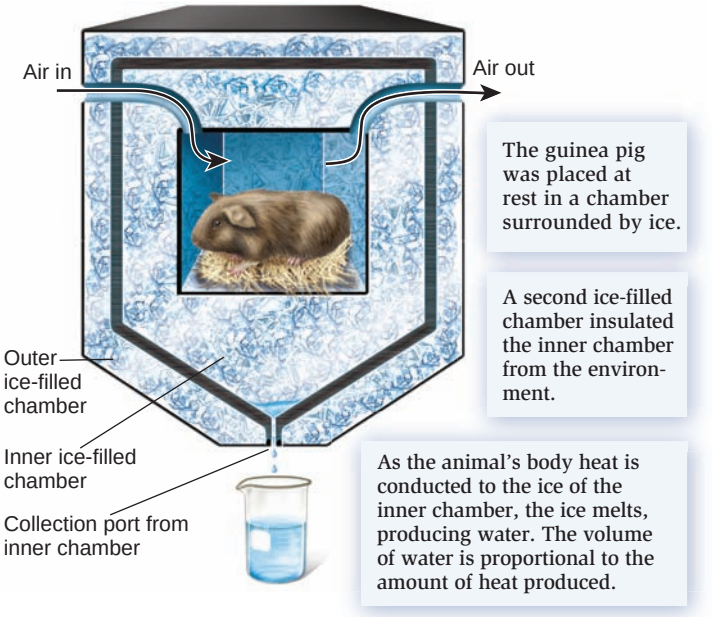


Figure 46.5 **Lavoisier's pioneering method of measuring BMR: direct calorimetry.** Direct calorimetry determines an animal's basal metabolic rate, such as that of this guinea pig, by determining how much the heat given off by its body raises the temperature of a surrounding ice-filled chamber.

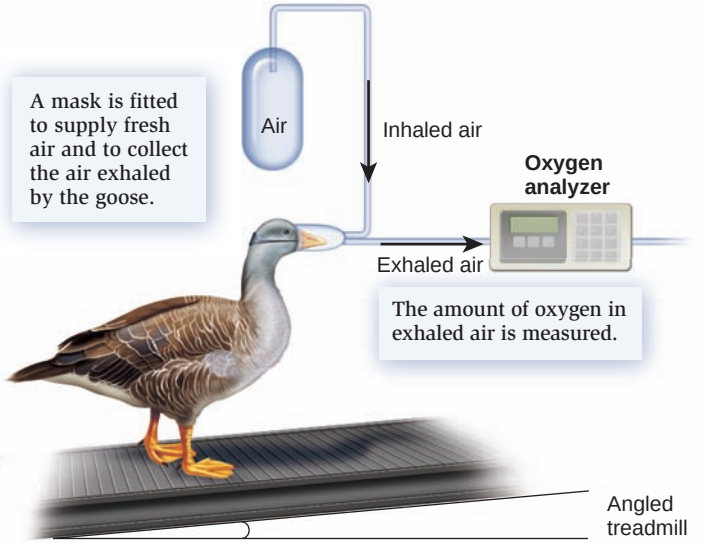

Figure 46.6 **Measuring BMR via oxygen consumption with indirect calorimetry.** Many animals, such as this goose, can be trained to walk on a treadmill, which allows scientists to compare metabolism during rest and exercise. Oxygen consumption can be determined by sampling the air exhaled into a tightly fitting mask. One-way valves prevent inhaled and exhaled air from mixing.

Concept check: *If the air had been sampled from the mask just before starting the treadmill while the goose was not yet exercising, would this have been a good estimate of BMR?*

metabolized—that is, the greater the BMR—the more oxygen must be consumed by the animal. By measuring the rate at which an animal uses oxygen, therefore, we can obtain a good estimate of BMR. Indirect calorimetry can also be used to compare the metabolic rates of an animal during rest and activity, when oxygen consumption increases (Figure 46.6). One limitation to this method is that a small percentage of fuel is metabolized without oxygen consumption, and thus indirect calorimetry underestimates actual metabolic rate.

Activity, Digestion, and Size Influence Metabolic Rate

BMR and SMR are indicators of total body resting metabolic rates. However, metabolic rate is not always basal. Not all tissues in the body use oxygen and produce heat at the same rate. Some structures, such as skin, consume relatively little oxygen under resting conditions, whereas others, such as the brain, heart, and liver, have high rates of metabolism even when an animal is sleeping. Moreover, the metabolic rates of different tissues can vary independently of each other. For example, the metabolism of the gut increases when food is being digested, and that of skeletal muscle increases during exercise (Figure 46.7).You can see from this that many factors have an impact on metabolism, including skeletal muscle activity, whether an animal has recently eaten, the size of an animal, and whether an animal is frightened, sleeping, or hibernating.

The primary factor that increases metabolic rate is altered skeletal muscle activity. Even minimal increases in muscle contraction significantly increase metabolic rate; strenuous activity increases it even more. For example, the total daily expenditure of kilocalories may vary for a healthy adult human from approximately 1,350 kcal for a small person at rest to more than 7,000 kcal for a cyclist competing in the Tour de France. Changes in muscle activity also affect metabolic rate during sleep due to decreased muscle activity, and during exposure to cold temperatures due to increased muscle activity from shivering.

Eating and digesting food also increase the metabolic rate. Particularly in mammals that eat meat, this may raise metabolic rate (and associated heat production) by 10–50% for a few hours after eating. You may have noticed this **food-induced thermogenesis** after consuming a large meal, such as Thanksgiving dinner. Ingested protein—for example, turkey—produces the greatest effect, whereas carbohydrate and fat produce less. The increased heat is believed to result partly from the processing of the absorbed nutrients by the liver and from the energy expended by the gastrointestinal tract in digestion and absorption. Food-induced thermogenesis is observed in nearly all vertebrates, but it is most notable in certain reptiles that eat large and infrequent meals. Because of food-induced thermogenesis, BMR tests must be performed in the postabsorptive state.

Another factor affecting metabolic rate is body size. In general, a large animal uses greater amounts of energy than does a small animal because the large animal has more mass and more cells, all of which consume fuel and generate heat. The total energy expenditure and heat generation of an elephant is clearly greater than that of a mouse, for instance. However, when the energy expenditures of an elephant and a mouse are scaled to their respective body masses, we find that

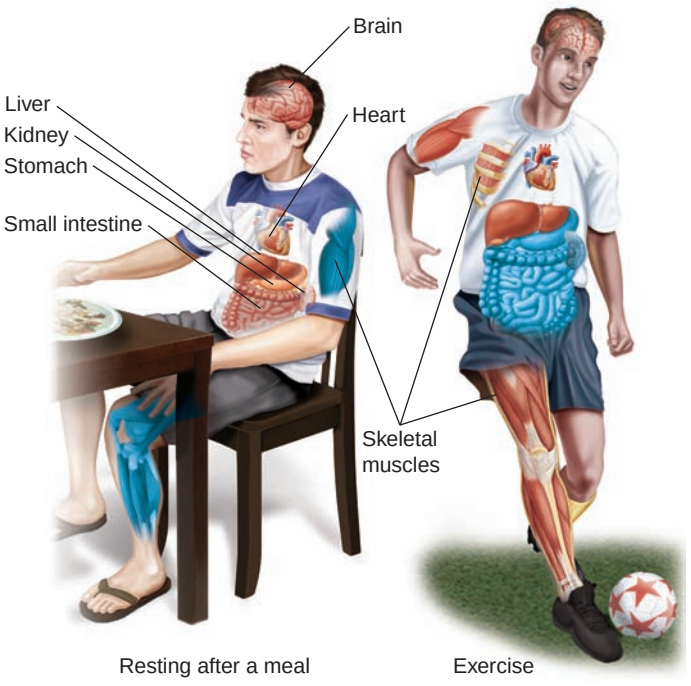

Figure 46.7 **Changes in metabolic rate of selected structures in a mammal's body during different activities.** Red areas are regions of high metabolism; blue areas are regions of low metabolism. Note that during exercise, skeletal muscle becomes more active, and areas associated with food digestion and absorption become less active. At all times, however, the heart, liver, and brain are highly active.

Concept check: *Why does metabolism decrease in the gut during exercise?*

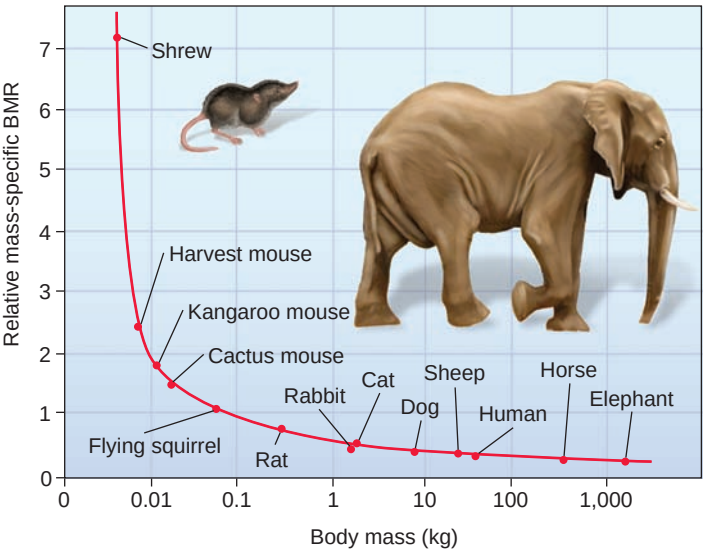

Figure 46.8 **Metabolic rates of animals that differ in size.** Metabolism can be scaled to body mass by measuring oxygen consumption and normalizing it to the animal's body mass (mass-specific BMR). Note that when expressed in this way, the mass-specific BMR of a shrew is higher than that of an elephant, even though the total oxygen consumption and heat output of the elephant would be much greater. The values on the y-axis are relative units of metabolism. Sizes of the animals shown are not to scale.

Concept check: *Can the relationship between body size and metabolic rate be used to propose hypotheses about metabolic rates of extinct animals?*

the energy expenditure per gram of body mass in a mouse is much higher than the comparable calculation in an elephant. **Mass-specific BMR** is the amount of energy expended per gram of body mass. Mass-specific BMR is a relative term that allows scientists to compare the metabolic rates among animals of different sizes. Research has shown that the relationship between mass-specific BMR and body mass follows an exponential curve (Figure 46.8). One possible explanation for this phenomenon is that because the ratio of an animal's surface area to its body mass is greater in smaller animals than in larger animals, smaller animals lose heat more rapidly than larger ones. According to this hypothesis, smaller animals must generate more heat per gram of body mass than larger animals to replace their heat loss. However, while this hypothesis appears to provide an explanation for the relationship between metabolism and body size in endotherms, it does not explain the observation that the same relationship exists in almost all animals, including ectotherms.

The smallest endotherms—hummingbirds, shrews, mice and other rodents, and some bats—face the special challenge of fueling their very high mass-specific metabolic rates. This becomes difficult and even impossible during cold months or any time when food is unavailable. Many animals have evolved a strategy of lowering their internal body temperature to just a few degrees above that of the environment, a process called **torpor**. Torpor may occur on a nightly basis, while the animal continues to be active during the daylight hours, or it can extend for months, in which case it is called **hibernation**. Torpor-like conditions are not unique to small vertebrates, however, as even some large animals such as bears enter extended periods of rest or torpor during months when food is not available.

A reduction in body temperature reduces the metabolic demands of all body cells. BMR in a small hibernating rodent, for example, may drop to less than 1% of what it would be at the normal body temperature of around 38°C. This allows the animal to conserve energy for remarkably long times. Ground squirrels of the genus *Spermophilus*, for example, may hibernate for up to 8 months.

Total Body Energy Stores Are Balanced Between Consumption and Expenditure

When the daily amount of energy an animal consumes is equal to the amount of energy it expends, the animal's body weight remains stable. Tipping the balance in either direction causes weight gain or loss, that is, the total body mass increases or decreases. Normally, energy is stored in the form of fat in adipose tissue.

Body weight in an adult animal is usually regulated around a predetermined set point that differs among species. Body weight is maintained by adjusting caloric intake and energy

expenditure in response to changes in body weight. This mechanism usually works very precisely in those animals in which it has been studied. For example, a mammal that eats less one day will eat enough the next day to compensate for the previous day's deficit. Similarly, if an animal is overfed one day, it may eat less the next day. Scientists currently think that appetite and metabolism change when food intake is more or less than the amount required to maintain the body's set point. This phenomenon explains why some dieters initially lose weight easily and then become stuck at a plateau, because appetite increases and metabolic rate decreases to compensate for the weight loss. Conversely, it also helps explain why some very thin people have difficulty gaining weight.

Hormones and the Nervous System Control Food Intake

Short-term control of feeding generally involves a feeling of **satiety**, that is, satisfaction or fullness. As an animal's stomach and small intestine stretch to accommodate food, nerves send signals from these structures to the hypothalamus. At the same time, the stomach and small intestine release hormones into the blood that reach the hypothalamus and suppress appetite. These **satiety signals** remove the sensation of hunger and set the time period before hunger returns again.

Over the long term, such as weeks, months, or years, an animal's total energy consumption tends to remain fairly stable. The animal may go through a period of fasting and then make up for it when food becomes available. In other words, meals may vary from day to day or during different seasons of the year, but the average amount of food consumed over the long term does not change much. Long-term control of food intake is mediated by many different brain molecules, by hormones, and by emotional state, particularly in humans.

One hormone that has received considerable attention in recent years for its ability to control appetite and metabolic rate is **leptin** (from the Greek *leptos*, meaning thin). Leptin has been identified in all classes of vertebrates but has been most extensively studied in mammals. In these animals, leptin is produced by adipose cells in proportion to fat mass: As more fat is stored in the body, more leptin is secreted into the blood. Leptin acts on the hypothalamus to reduce appetite and increase metabolic rate (Figure 46.9a). In this way, the brain is made aware of how much fat is stored in the body at all times, and it can adjust appetite and energy expenditure appropriately if fat stores decline or increase.

If an animal fasts for a period of time, its adipose cells shrink as they release their stored fat into the blood. The decrease in leptin secretion resulting from the decreased fat mass results in a decrease in BMR and an increase in appetite. This may be the true evolutionary significance of leptin, namely that its disappearance from the blood lowers the BMR, consequently prolonging life during periods of starvation (Figure 46.9b). Leptin was not discovered until 1994, but its existence was postulated decades before that by the pioneering work of Douglas Coleman, who investigated the nature of mutations in mice that result in obesity.

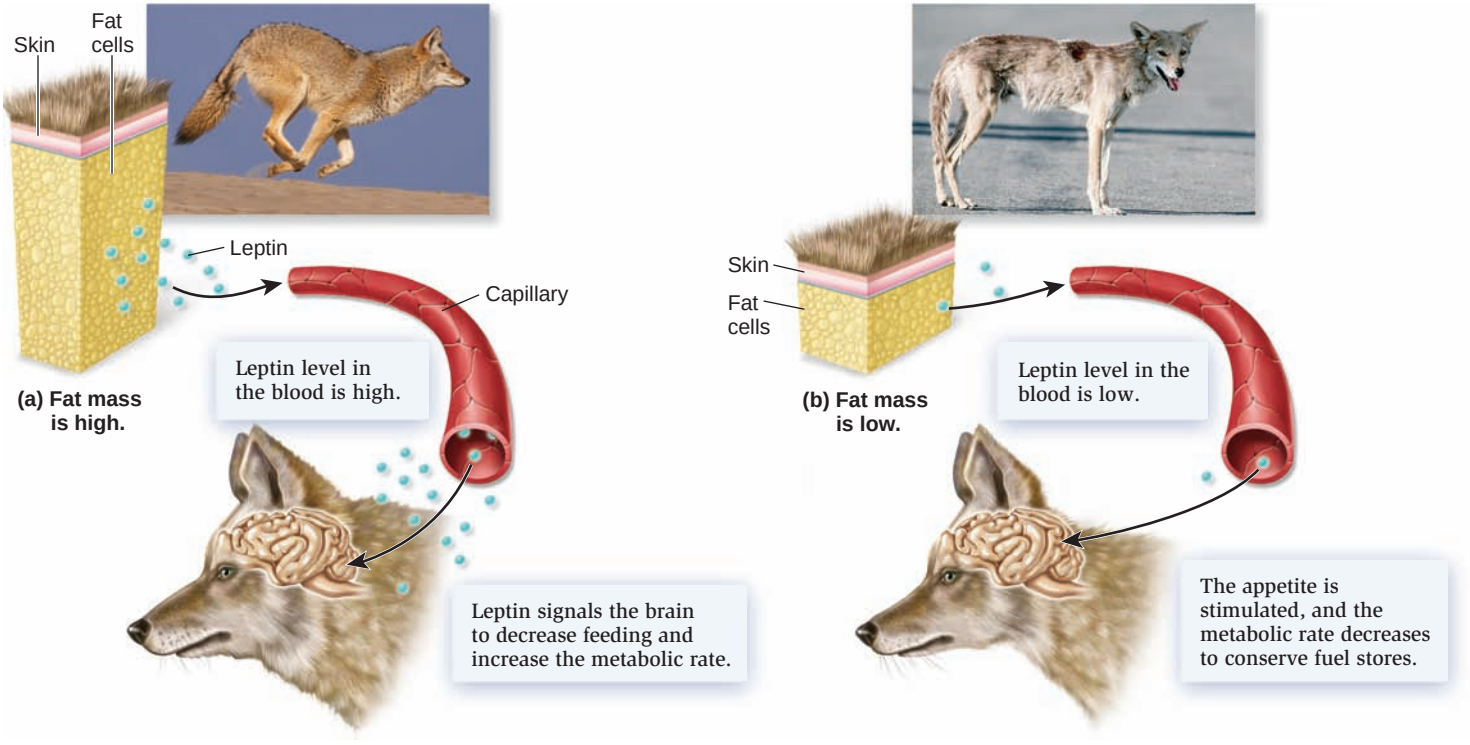

Figure 46.9 **The role of leptin in regulating appetite and metabolic rate.** In animals such as this coyote, changes in the blood leptin level result directly from changes in fat mass. Animals with more fat make more leptin.

Feature Investigation

Coleman Revealed a Satiety Factor in Mammals

For many years, scientists wondered how most animals appeared to regulate their body mass around a predetermined set point, despite fluctuations in the food supply. They postulated that other parts of the body somehow communicated with the brain to signal when energy stores were above or below normal. In the 1970s, Canadian-American researcher Douglas Coleman tested this hypothesis in an experiment involving parabiosis, the surgical connection of the abdominal walls of two animals, such that the blood supply from one animal intermixes with that of the other.

Coleman used two strains of mice called ob and db mice, carrying different mutations that resulted in inherited forms of obesity (an example of an ob mouse is shown in the chapter-opening photo). Coleman first connected a wild-type mouse, one that lacked these mutations, with either an ob mouse or a db mouse, as shown in Figure 46.10. He discovered that when the circulatory system of the ob mouse was in contact with that of the wild-type mouse, the ob mouse ate less and gained less weight than usual. This suggested that the blood of the wild-type mouse contained a circulating factor that signals the brain when an animal has sufficient fat stored in its body and adjusts appetite accordingly. The ob animal apparently lacked this factor, but when exposed to it through the wild-type mouse's circulation, it responded in the appropriate way. The wild-type mouse of the parabiosis pair apparently retained a sufficient amount of the factor in its blood, because it maintained its body weight at a normal level.

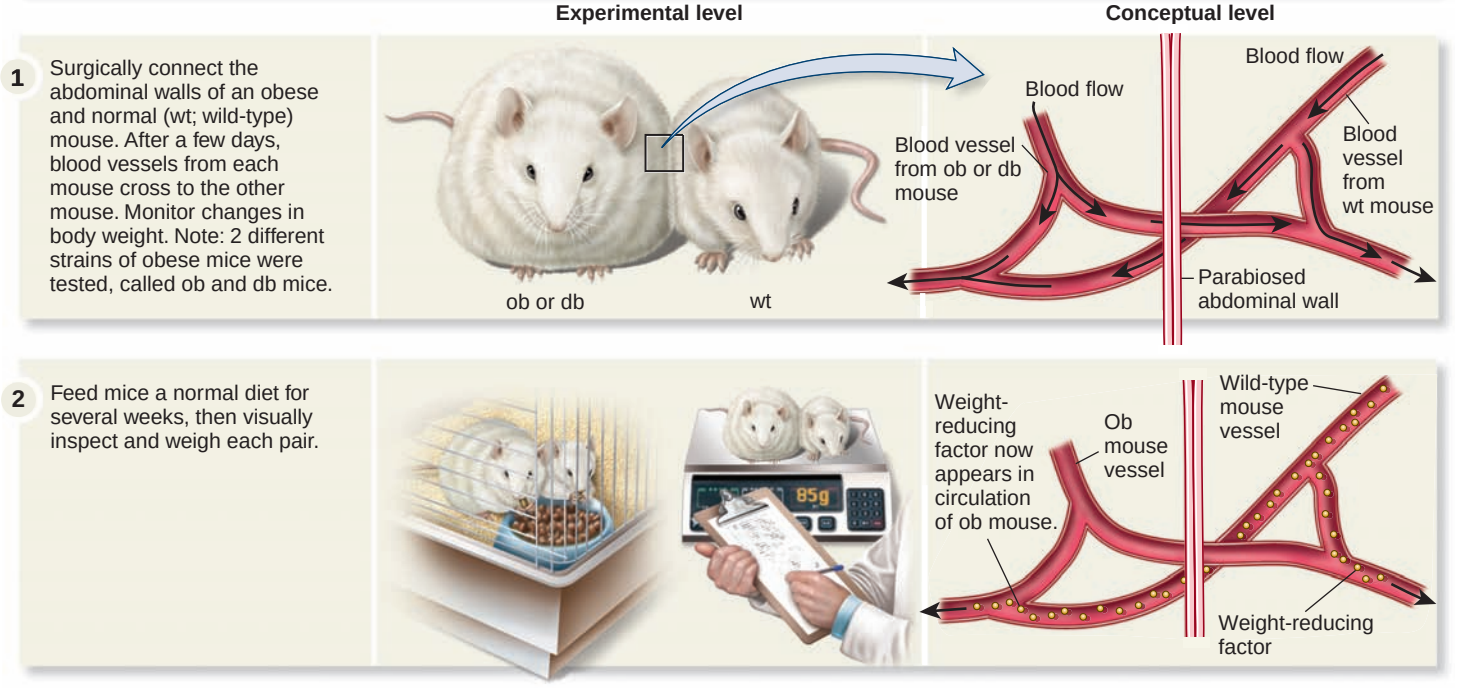
Coleman noticed, however, that a db mouse continued to gain weight at an abnormally high rate even when parabiosed with a wild-type mouse. In this case, the wild-type animal actually lost weight while the db animal remained obese. Coleman concluded that the db mouse must produce the same factor as the wild-type mouse, but for some reason, it was unable to respond to it. The wild-type mouse that was parabiosed to the db mouse lost weight because it received the factor from the db mouse, in addition to having its own supply of the factor. Thus, whether the factor was absent as in the ob mouse, or present but unable to function as in the db mouse, the resulting phenotype was the same—obesity.

In 1994, Jeffrey Friedman and coworkers at Rockefeller University identified this circulating factor as the hormone leptin. The ob mice were found to be homozygous for a mutation in the leptin gene, which produced an inactive leptin molecule, whereas db mice produced leptin but did not respond to it. In fact, the db mice were found to produce even greater amounts of leptin than wild-type mice, which explained why the wild-type mouse in Coleman's experiments lost weight when parabiosed with a db mouse. Friedman and others later showed that

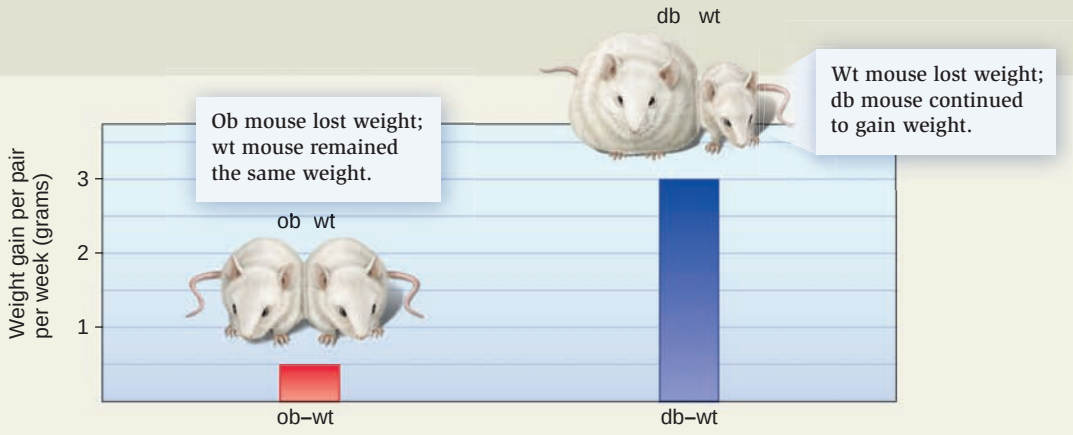
Figure 46.10 **Coleman's parabiosis experiments revealed a satiety factor in wild-type mice that was absent in genetically obese mice.**

HYPOTHESIS Body weight is controlled by a factor that circulates in the blood. This factor is absent in strains of mice that have an inherited form of obesity.

KEY MATERIALS Two different strains of genetically obese mice, normal (wild-type) mice.



3 THE DATA



4 CONCLUSION Wild-type mice secrete a blood-borne factor that reduces body weight. The factor is absent from ob mice but present in db mice. Ob mice retain the ability to respond to the factor, unlike db mice, which cannot respond to it.

5 SOURCE Coleman, D.L. 1973. Effects of parabiosis of obese with diabetes and normal mice. *Diabetologia* 9:294–298.

adipose cells produce leptin in direct proportion to the total fat mass of an animal, as stated earlier. Biologists now know that all classes of vertebrates produce leptin.

At first, the work of Coleman and Friedman generated considerable excitement that leptin might be useful to treat obesity in humans, but this has thus far proven difficult. Why? Recent research has revealed that most obese humans are more like the db mice than the ob mice. That is, they produce leptin but fail to respond adequately to it, and therefore, simply increasing blood levels of leptin may not have a significant effect on body weight. However, other studies have shown that leptin normally acts in nonobese humans in a manner much like it does in wild-type rodents. As noted in the chapter introduction, researchers have identified rare individuals in whom leptin is not produced due to a mutation in the leptin gene. These individuals are extremely obese and respond well to injections of leptin, losing considerable weight. The body weight disorders of such individuals, therefore, are reminiscent of ob mice.

Experimental Questions

1. What observation led to the experiments conducted by Coleman?
2. What was the hypothesis tested by Coleman, and how did he test it?
3. How did the experimental linking of the bloodstreams of the wild-type mice and the mutant mice affect the body weight of both strains?

46.4 Regulation of Body Temperature

As we have seen, metabolic rate is linked to body temperature. Next, we discuss why body temperature is important for the health and survival of all animals, and consider mechanisms by which animals gain or lose heat.

Temperature Affects Chemical Reactions, Protein Function, and Plasma Membrane Structure

Most animals can survive only in a relatively narrow range of temperatures. Temperature has an effect on animals' bodies in three main areas: chemical reactions (and the enzymes that catalyze them), other protein function, and membrane structure. First, chemical reactions depend on temperature. Heat accelerates the motion of molecules, so as an animal's temperature rises, the rates at which the molecules in its body move and contact each other also increase. Consequently, the rate of most chemical reactions in animals doubles or even triples for every 10°C increase in body temperature. In addition, enzymes, which catalyze many reactions in the body, including those involved in metabolism, have an optimal temperature range for their maximal catalytic function. Low temperatures slow down chemical reactions, making it harder for an animal to remain active and carry out internal functions such as digestion, reproduction, and immunity. The latter is particularly important, as many vertebrates become susceptible to disease when their body temperatures are reduced for long periods.

A second effect of unusually high temperature is that it causes many proteins to become denatured; that is, they lose the three-dimensional structure that is crucial to their ability to function properly. This occurs because the bonds that form tertiary and quaternary protein structures result from weak interactions, such as hydrogen bonds, and can be disrupted by

heat. Denaturation of enzymes is especially serious because of the major role they play in metabolism. Most animals have an upper limit of body temperature at which they can survive. To start with, most mammals have a resting body temperature of 35–38°C (95–100°F). In humans, a body temperature of 41°C (106°F) causes loss of protein function and breakdown of the nervous system, and a body temperature of 42–43°C (107–109°F) is fatal. Birds, which have slightly higher resting body temperatures than mammals (approximately 40–41°C [104–106°F]), cannot survive at body temperatures above 46–47°C (115–117°F). At environmental temperatures greater than 50°C (122°F), nearly all animals die.

A third effect of temperature is that heat alters the structures of plasma and intracellular membranes. At low temperatures, membranes become less fluid and more rigid. Rigid membranes are less able to perform biological functions, such as transporting ions and fuels and binding extracellular molecules to receptors on the membrane surface. Alternatively, if the temperature becomes too high, membranes can become leaky.

Compared to extreme heat, animals can better tolerate extreme cold. For example, some animals can survive after freezing and thawing. This is normally dangerous because ice crystals form inside cells and rupture membranes. Also, the ice forms from water in the cells' cytosol, which dehydrates the cells. However, many ectotherms, including certain insects such as the woolly caterpillar, a few species of amphibia such as several types of frogs, and a very small number of reptiles such as the painted turtle, can prevent crystal formation in their cells. They do this by responding to ice on their skin surfaces with an enormous outpouring of glucose from the liver. The glucose enters the blood and cells, acting like antifreeze and lowering the freezing point so that the cells do not completely freeze solid. Other regions of the body that are less critical, such as the lumens of the stomach and bladder, do freeze. These animals can have 65% or more of their bodies completely frozen for long periods, only to thaw during warm periods without harmful effects. The glucose is reabsorbed by the liver at that time. An alternative strategy to cope with extremely cold temperatures is seen in certain fishes inhabiting Arctic or Antarctic waters. As described in Chapter 23, such fishes do not freeze like the terrestrial vertebrates just described, but instead contain large amounts of highly specialized antifreeze proteins in their blood that stop ice crystal formation.

Ectotherms and Endotherms May Have Fluctuating or Stable Body Temperatures

In the past, animals were classified as either cold blooded or warm blooded. Cold-blooded animals were thought to require an external heat source such as sunlight to warm themselves. By contrast, warm-blooded animals were thought to use internal heat to maintain their body temperature. These terms are misleading and incorrect, however, because many cold-blooded animals generate considerable heat by exercising their skeletal muscles. Indeed, many have a body temperature during daylight hours that is at least as warm as that of warm-blooded animals like birds and mammals. Moreover, many so-called warm-blooded animals spend portions of their lives with greatly reduced body temperatures that are close to that of their environment.

Biologists now classify animals according to both their source of heat and their ability to maintain body temperature. Recall that ectotherms depend on external heat sources to warm their bodies, whereas endotherms use their own metabolically generated heat to warm themselves. **Homeotherms** maintain their body temperature within a narrow range, whereas **heterotherms** have body temperatures that vary with the environment (Figure 46.11). Most animals fall into two categories. Generally, birds and mammals are endothermic and homeothermic. Other vertebrates and most invertebrates are ectothermic and heterothermic.

Not all animals, however, can be neatly classified into two categories at all times. Hibernating mammals, for example, are endotherms. They are usually homeothermic, but during the winter, their body temperature drops dramatically as their metabolism slows to conserve energy for the winter. Hibernators behave like heterotherms during the transition from fall to winter and again from winter to spring. During the winter, however, they are again homeothermic except for brief periods of arousal, but at a lower body temperature than at other times of year. Similarly, a fish swimming in deep ocean waters is an ectotherm but also homeothermic because the temperature of the water—and therefore of its body—is essentially constant. Fishes that live in waters with fluctuating temperatures, by contrast, are ectothermic and heterothermic.

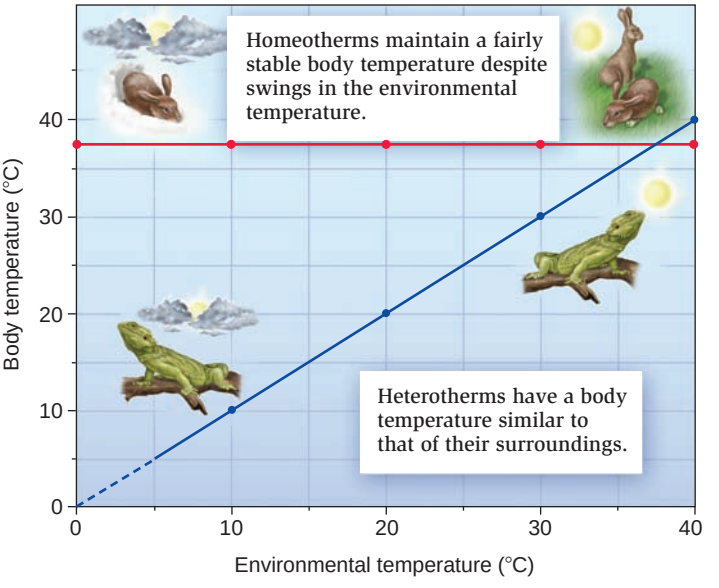


Figure 46.11 **Body temperature and environmental temperature in homeotherms and heterotherms.** Homeotherms maintain stable body temperatures across a wide range of environmental temperatures. Heterotherms, by contrast, have body temperatures that depend in part on the temperature of their surroundings.

Concept check: *What thermoregulatory categories do humans fit into?*

Even endothermic homeotherms do not have truly constant body temperatures. They have a narrow range of body temperatures that increases or decreases slightly in extreme climates, during exercise, or during sleep. The important feature is that birds and mammals can quickly adjust the body's mechanisms for retaining or releasing heat such that body temperature remains within the required narrow range. This provides the advantage that the body's chemical reactions are at optimal levels even when the environment imposes extreme challenges. The metabolic rate of a resting mammal, for example, is roughly six times greater than that of a comparably sized reptile. A suddenly awakened mammal is instantly capable of intense activity even on a winter day, but an icy-cold reptile could be at the mercy of a predator because of the time required to warm itself in order to flee.

Endothermy does have three major disadvantages, however. First, to produce sufficient heat by metabolic processes, endotherms must consume larger amounts of food to provide the nutrients used by cells in the formation of ATP, during which heat is generated. Small endotherms with high BMRs, such as shrews, must eat almost continuously and may die if deprived of food for as little as a day. By contrast, many ectotherms, such as snakes, can go for weeks without eating. Second, endotherms have a greater risk of hyperthermia, or overheating, during periods of intense activity, even in cold weather. Third, because lowering body temperature requires the evaporation of bodily fluids (as described next), endotherms are often restricted to environments where water is plentiful.

Animals Exchange Heat with the Environment in Four Ways

The surface of an animal's body can lose or gain heat from the external environment via four mechanisms. These are radiation, evaporation, convection, and conduction (Figure 46.12).

Radiation is the emission of electromagnetic waves by the surfaces of objects. The rate of emission is determined by the temperature of the radiating surface. Thus, if the body surface is warmer than the environment, the body loses heat at a rate that depends on the temperature difference. If the outside temperature is warmer than body temperature, the body gains heat, for instance from sunlight. We can observe radiated heat from an animal's body with imaging devices that detect infrared light (Figure 46.13).

Animals can lose body heat through **evaporation** of water from the skin and membranes lining the respiratory tract, including the surface of the tongue. A large amount of energy in the form of heat is required to transform water from the liquid to the gaseous state. Whenever water vaporizes from the body's surface, the heat required to drive the process is conducted from the surface, thereby cooling the animal.

Convection is the transfer of heat by the movement of air or water next to the body. For example, the air close to an endotherm's body is heated by conduction. Because warm air is less dense than cold air, the warm air near the body rises and carries away heat by convection. Convection is aided by creating currents of air around an animal's body. Humans do this by sitting near fans, but other animals can create cooling air currents by other means such as when an elephant waves its ears or a bat flaps its wings.

In **conduction**, the body surface loses or gains heat through direct contact with cooler or warmer substances. The greater

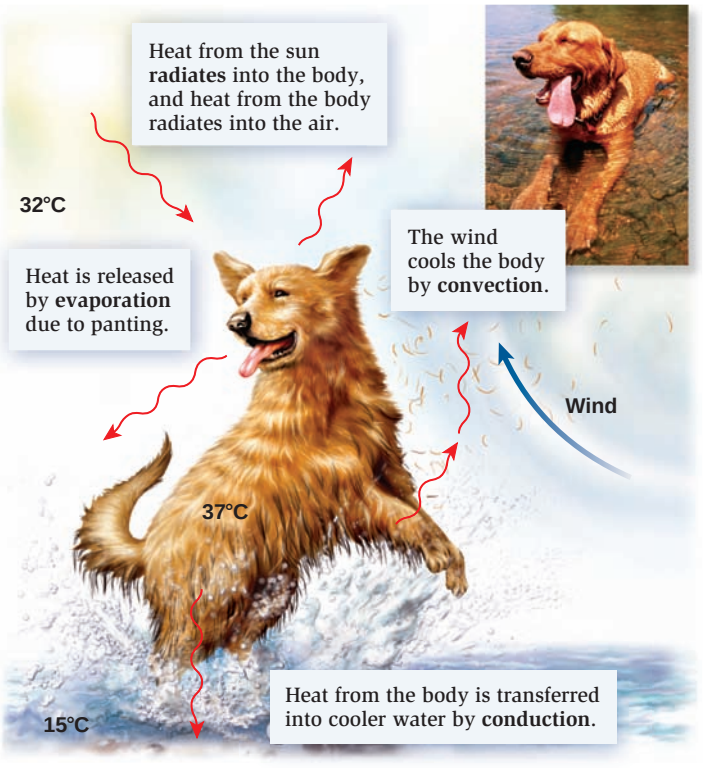

Figure 46.12 **Types of heat exchange.** The four ways in which animals exchange heat with the environment are radiation, evaporation, convection, and conduction.

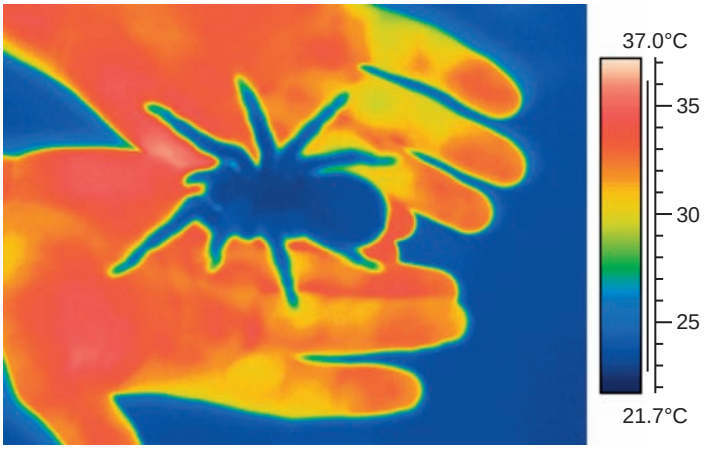

Figure 46.13 **Visualization of heat exchange in an ectotherm and an endotherm.** Thermal-imaging cameras can detect heat radiated from an animal's body. Note the warm skin of the endotherm (the human) and the cold skin of the ectotherm (the tarantula), even though both animals are at the same environmental temperature.

the temperature difference, the greater is the rate of heat transfer. Different materials have different abilities to absorb heat, however. As we saw in Chapter 2, water has a higher heat capacity than air, meaning that at any temperature, water will retain greater amounts of heat than will air. Consequently, aquatic animals in water that is 10°C lose considerably more heat in a short time than terrestrial animals lose in air that is 10°C. Indeed, on a hot day, terrestrial animals can lose heat efficiently by immersing themselves in cooler water. An animal's body surface area plays an important role in the rate of heat conduction across its body surface. In some animals, certain body regions are particularly good heat conductors, such as the ears of an elephant or the wings of a bat.

The four processes of heat transfer just described can be regulated in animals, such that heat is retained within the body at some times and lost at other times, as we see next.

Several Mechanisms Can Alter Rates of Heat Gain or Loss in Endotherms

For purposes of temperature control, think of an endotherm's body as a central core surrounded by a shell consisting of skin and subcutaneous (just below the skin) tissue. The temperature of the central core of endotherms is regulated at approximately 37–40°C (97–104°F), but the temperature of the outer surface of the skin varies considerably. If the skin were a perfect insulator, the body would never lose or gain heat by conduction. The skin does not insulate completely, however, so the temperature of its outer surface generally is somewhere between that of the external environment and the core. Only in animals that store large amounts of subcutaneous fat (blubber) does the body surface provide considerable insulation. In endotherms without blubber, the main form of insulation is a covering of hair, fur, or feathers, which traps heat from the body in a layer of warm air near the skin, reducing heat loss. Given these structures, then, let's take a look at mechanisms that different endotherms use to regulate how much heat is gained or lost from their surface. We will cover four such mechanisms here: changes in skin blood flow, countercurrent heat exchange, evaporative heat loss, and behavioral adaptations.

Changes in Skin Blood Flow Rather than acting as an insulator as in most animals, in some animals the skin functions as a heat exchanger that can be adjusted to increase or decrease heat loss from the body. Skin surface blood vessels dilate (widen to increase blood flow) on hot days to dissipate heat to the environment, and they constrict (get narrower to reduce blood flow) on cold days to retain body heat (Figure 46.14). Signals from the nervous system regulate the relaxation or contraction of the smooth muscles that control the opening and closing of these blood vessels. Diving birds and diving mammals are good examples of animals that use this mechanism. Ducks, seals, and walruses dramatically reduce the amount of blood flowing to the skin when they dive in cold waters. This allows them to retain body heat that would otherwise be conducted into the water. In many terrestrial endotherms, certain

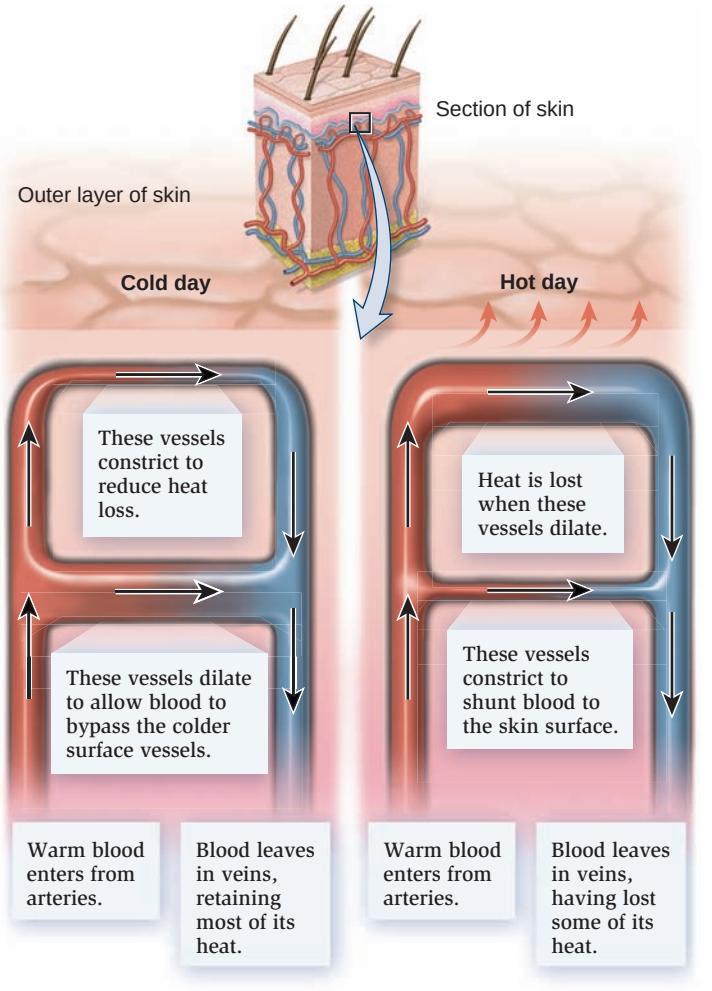

Figure 46.14 **Regulation of heat exchange in the skin.** As shown in this schematic illustration, the skin functions as a variable heat exchanger. The arrows in the blood vessels indicate direction of blood flow.

areas of skin play a more prominent role in heat exchange than others—recall the elephant ears and bat wings mentioned earlier—so skin temperature varies with its location in the body.

Countercurrent Heat Exchange Both endotherms and ectotherms regulate heat loss to the environment through **countercurrent heat exchange**, which retains heat by returning it to the body's core and keeping the core much warmer than the extremities. In endotherms, countercurrent heat exchange occurs primarily in the extremities—the flippers of dolphins, for example, or the legs of birds and certain other terrestrial animals (Figure 46.15a). As warm blood travels from the core through arteries down a bird's leg, heat moves by conduction from the artery to adjacent veins carrying cooler blood in the other direction (Figure 46.15b). By the time the arterial blood reaches the tip of the leg, its temperature has dropped considerably, reducing the amount of heat lost to the environment, and returning the heat to the body's core.

Ectotherms such as many fishes use countercurrent heat exchange to warm their muscles. As the swimming muscles become active, they generate heat from metabolism that warms the blood in the veins leaving the muscles. The veins are in

Figure 46.15 Countercurrent heat exchange.
(a) Countercurrent exchange retains heat in the leg of an endotherm such as this bird. Black arrows in vessels indicate direction of blood flow. **(b)** An SEM of the arrangement of veins surrounding an artery in a bird's leg. The artery is almost completely covered by overlying veins, allowing efficient heat exchange between the vessels.

close contact with nearby arteries bringing fresh, oxygen-rich blood from the gills. In tuna, as in other ectotherms, arterial blood is cold. Blood entering the gills comes in contact with cold seawater, and its temperature rapidly adjusts to that of the seawater. As the cold blood reaches the muscles, however, heat from the warm veins leaving the muscles is conducted from the veins into the nearby arteries entering the muscle. In this way, the heat generated by the muscles is returned to the muscles rather than being lost from the gills. As warm temperatures stimulate the rate of chemical reactions, the muscles are able to operate more efficiently.

Evaporative Heat Loss Recall that some animals can lose body heat through evaporation of water from the skin and membranes lining the respiratory tract. Heat exchange in some mammals can be regulated by changing the rate of water evaporation through perspiration. Nerves to the sweat glands stimulate the production of sweat, a dilute solution containing sodium chloride. The most important factor determining evaporation rate—and therefore heat loss—is the water vapor concentration, or humidity, of the air. The discomfort you feel on a humid day is due to the failure of evaporation. Your sweat glands continue to secrete, but the sweat simply remains on your skin with body temperature remaining elevated, especially during exercise.

In endotherms that lack sweat glands, such as birds, or have very few glands, such as dogs and cats, panting (short, rapid breaths with the mouth open) promotes evaporation of water from the tongue surface. Panting has advantages over sweating, because no salt is lost, and panting provides the air current that promotes heat exchange by convection. However, the surface area of the mouth and tongue is relatively small, which limits the rate at which heat can be eliminated. Interestingly, many reptiles, while not endotherms, also pant on hot days, suggesting that panting evolved prior to endothermy.

Animals that neither sweat nor pant can still benefit from evaporative heat loss. The evaporation of fluids deposited on the body surface by licking the skin or splashing the skin with water also draws heat from the body.

Behavioral Adaptations Behavioral mechanisms can also alter heat loss by radiation and conduction. Two such behaviors involve changing exposed surface area and changing surroundings. On hot days, birds may ruffle their feathers and raise their wings, while many mammals will reduce their activity and spread their limbs; these postural changes increase the surface area available for heat transfer. Terrestrial ectotherms and many endotherms seek shade, partially immerse themselves in water, or burrow into the ground when the sun is high. Pigs, which lack sweat glands, roll in the mud to cool down. Fishes may migrate from hot waters to cooler regions.

Similarly, animals respond to cold temperatures with numerous behavioral adaptations. Huddling in groups, curling up into a ball, hunching the shoulders, burying the head and feet in feathers, and similar maneuvers reduce the surface area exposed to a cold environment and decrease heat loss by radiation and conduction. Changing environments is also a common strategy for coping with cold. Migration from cold to warmer regions occurs in numerous species of fishes, birds, and mammals. Burrowing is not only useful to escape the heat of the sun, as mentioned previously, but is also a useful way to avoid the cold without migrating to a completely new environment. For example, many temperate zone frogs, toads, salamanders, turtles, and snakes burrow as much as a meter beneath the frost line during winter, where they hibernate.

Muscle Activity and Brown Adipose Tissue Metabolism Increase Heat Production

We have discussed how heat is gained or lost to the environment and how heat can be retained by reducing blood flow to the skin on a cold day. Body temperature, however, is a balance between these factors and heat production. Changes in muscle activity constitute the major control of heat production for temperature regulation in endotherms.

When an endotherm is in its thermoneutral zone, no significant adjustments are necessary to maintain core body temperature. When exposed to conditions below the thermoneutral

zone, however, core body temperature begins to fall. The primary response to falling temperatures is to reduce the flow of blood to regions that permit conduction of heat. If this does not adequately reduce heat loss, skeletal muscle contraction is increased. This may lead to shivering, which consists of rapid muscle contractions without any locomotion. Virtually all of the energy liberated by the contracting muscles appears as internal heat, a process known as **shivering thermogenesis**. Many birds that remain in cold climates during the winter shiver almost continuously.

In many mammals, chronic cold exposure also induces **nonshivering thermogenesis**, an increase in the metabolic rate and therefore heat production that is not due to increased muscle activity. Nonshivering thermogenesis occurs primarily in **brown adipose tissue** (also called brown fat), a specialized tissue in small mammals such as hibernating bats, small rodents living in cold environments, and many newborn mammals, including humans. Brown adipose tissue is responsive to hormones and signals from the nervous system, which are activated when body temperature falls. The mitochondria in the brown adipose tissue contain uncoupling proteins, a class of proteins that uncouple oxidative phosphorylation, described in Chapter 6. The H^+ gradient becomes uncoupled from ATP synthesis and instead is used to generate heat, which helps maintain body temperature. Recently, researchers have discovered brown adipose tissue in adult humans. Because brown adipose tissue metabolizes fat rather than storing it, researchers are currently investigating ways in which adipose tissue stem cells may be induced to differentiate into brown fat in adult humans. The goal of such research is to increase a person's ability to burn rather than store ingested fat and thereby prevent or reverse obesity.

Endotherms Can Adapt to Chronic Changes in the Temperature of Their Environments

Although many animals—notably deep-sea-dwelling fishes and invertebrates—spend their lives in relatively unchanging environmental temperatures, most others do not. Such animals, therefore, must adapt to environmental changes using the mechanisms we have discussed in this section. In some cases, however, long-term exposure to a challenging environment, either very hot or very cold, results in a fine-tuning of the adaptive mechanisms that persist for as long as the animal lives in that environment. This process of **acclimatization** occurs particularly well in humans, who have more sweat glands than any known mammal. Increases in the amount and rate of sweat production and a decrease in the temperature threshold for initiating sweating, for example, can acclimatize an animal such as ourselves to chronic high temperatures. A person newly arrived in a hot climate initially has trouble coping. Body temperature rises, and too much activity can lead to a breakdown in the body's temperature-regulating systems. After several days to weeks, however, acclimatization occurs. Body temperature stabilizes, and the person finds it much easier to function at a normal activity level. Body temperature does not rise as much as it did initially upon moving to the hot climate because sweating begins sooner and the volume of sweat produced is greater. Long-term exposure to hot conditions also increases the dilation of skin blood vessels and blood flow to the skin, helping to dissipate heat by conduction.

Cold acclimatization has been less studied than heat acclimatization, but seasonal changes occur in many endotherms that live in variable climates. Birds grow an extra layer of insulating feathers, and mammals may grow additional fur in the winter. The additional insulation reduces heat loss up to 50% in some animals. Such feathers and fur are shed in the summer. Ectotherms, too, can acclimatize to changes in temperature. For example, marine animals that migrate from warm to very cold waters undergo a change in the lipid composition of their cellular membranes. The membranes contain more unsaturated fats and therefore remain fluid even at extremely cold temperatures. In addition, many cold-acclimated ectotherms have cellular enzymes with a wider range of temperature tolerance than those that are found in animals living in mild climates.

46.5 Impact on Public Health

As we have seen, most animals, when provided adequate nutrients, maintain their body mass around a set point that is normal for their species. We rarely observe healthy animals in nature that are overweight. Generally, only domesticated animals become sufficiently sedentary that they gain weight (think of an overweight housecat). Humans, too, are prone to weight gain, particularly when living sedentary lives. Many people maintain a healthy body weight, but, as discussed in this section, an increasing number are unable to meet this goal.

Obesity Is a Global Health Issue

Excess body fat in humans (and in other mammals) increases the risk of many diseases, including high blood pressure, cancer, heart disease, and diabetes. In diabetes, there is either insufficient insulin available from the pancreas to control blood glucose levels, or the insulin that is present is no longer effective. In the U.S. alone, about 8% of the population—nearly 24,000,000 people—have diabetes mellitus. Of all diabetics in the U.S., more than 90% have the form called Type 2 diabetes mellitus that results from insulin being ineffective. Compelling evidence has directly linked the incidence of this type of diabetes with being overweight. At what point does fat accumulation in humans start to pose a health risk? Historically, this question has been evaluated by research studies that investigate possible correlations between disease rates and some measure of body fat.

One of the currently preferred methods for assessing body fat and health risks is the **body mass index** (**BMI**), a ratio of weight compared to height. A person's BMI is calculated by dividing their weight in kilograms by the square of their height in meters. For example, a 70-kg human with a height of 180 cm would have a BMI of 21.6 kg/m^2 ($70/1.8^2$).

Current National Institutes of Health guidelines categorize BMIs of 25 or more as **overweight**, that is, as having increased health risk because of excess adipose tissue. BMIs of 30 or greater are considered **obese**, with a highly increased health risk. Data compiled by The Centers for Disease Control and Prevention in Atlanta, Georgia, and other U.S. federal agencies indicate that approximately 2/3 of U.S. adults age 20–74 are now overweight or obese. One of the more troubling statistics is that the percentage of adults who are overweight but not obese has remained relatively unchanged since 1960, at roughly 30–35%. However, the percentage of obese adults has risen during that time from about 13% to the current level of 33–34%. Since as recently as the early 1990s, the CDC estimates that the average body weight of Americans has risen by 10 pounds. Even more troubling, the rate of childhood obesity has also risen. In the U.S., the incidence of obesity in children age 6–11 has increased from 2–3% in 1960 to the current estimate of more than 15%.

The recent increase in overweight and obesity categories is a worldwide trend. According to the World Health Organization, more than 1 billion adults globally are overweight and 300 million are obese. One ray of hope is that the incidence of obesity in the U.S. population has leveled off since 2003, suggesting that efforts at educating the public about the health consequences of obesity may be starting to have a positive result.

The increased health risk associated with obesity may be at least partly due to a lack of physical activity, not body fat *per se*. Humans today are more sedentary than were past generations, with many participating in forms of recreation that do not require physical activity, such as television, computer games, and the Internet, and most having careers with reduced physical exertion when compared to past generations. Lack of exercise is associated with fat accumulation because it reduces total daily energy expenditure.

Growing evidence suggests that the location of body fat has important health consequences, too. For reasons that are not yet completely clear, people with mostly abdominal fat are at greater risk for developing diabetes and cardiovascular disease than are people whose fat is mainly in the lower body, on the buttocks, hips, and thighs.

Some studies indicate that genetic factors play an important role in obesity. Identical twins separated soon after birth and raised in different households have strikingly similar body weights as adults. Researchers hypothesize that natural selection favored the evolution of so-called **thrifty genes**, which boosted our ancestors' ability to store fat from each feast in order to sustain them through the next famine. Given today's abundance of high-fat foods in many countries, what was once a survival mechanism may now be a liability.

The methods and goals of treating obesity are undergoing extensive rethinking. An increase in body fat must be due to an excess of energy intake over energy expenditure, and overweight people have traditionally been advised to follow a low-calorie diet. However, such diets alone have limited effectiveness, because over 90% of obese people regain most or all of their lost weight within 5 years. This disturbing phenomenon may be related to the observation that metabolic rate decreases as leptin levels decrease, sometimes falling low enough to prevent further weight loss on as little as 1,000 calories per day.

Research indicates that crash diets are not an effective long-term method for controlling weight. Instead, caloric intake should be set at a realistic level that can be maintained for the rest of one's life. This should lead to a slow, steady weight loss of no more than 1 pound per week until body weight stabilizes at a new, lower level. Most important, any program of weight loss should include increased physical activity. The exercise itself burns calories, but more importantly, it partially offsets the tendency for the metabolic rate to decrease. As a bonus, the combination of exercise and caloric restriction causes the person to lose more fat and less protein than with caloric restriction alone.

The impact of obesity on public health is enormous, accounting for many illnesses requiring hospitalization and chronic drug therapy and well over 100,000 premature deaths per year. Its impact is far-reaching on the economy as well. The economic toll of obesity-related illnesses is felt in the loss of worker-hours in the workplace, in the cost of hospital stays, physician office visits, nursing home care, and medication costs. In fact, current estimates are that nearly 10% of all U.S. healthcare expenditures are directly or indirectly related to obesity!

Obesity can impact society in unexpected ways. As an example, the increasing weight load of passengers forces airplanes to burn 350 million additional gallons of fuel each year, compared to just 12 years ago! This translates into nearly 4 million tons of additional pollution released into the atmosphere every year.

Anorexia Nervosa and Bulimia Nervosa Can Have Serious Health Consequences

Being obese can be dangerous, but so can being extremely underweight. Here we will look at two eating disorders that can leave people underweight: anorexia nervosa and bulimia nervosa.

Anorexia nervosa is characterized by weight loss and is found primarily in adolescent girls and young women. People with anorexia nervosa become pathologically obsessed with weight and body image, and they reduce their food intake to the point of starving. Anorexia nervosa may have both biological and psychological causes. Many other abnormalities are associated with the disorder, such as loss of menstrual periods, low blood pressure, low body temperature, and altered secretion of many hormones. These may be simply signs of starvation, although they may also result from malfunction of the parts of the brain that normally control appetite.

Bulimia nervosa (often simply called bulimia) involves recurrent episodes of fasting and overeating. Weight loss may occur because of regular self-induced vomiting and the use of laxatives to stimulate bowel movements or diuretics to stimulate urination, as well as strict dieting, fasting, or vigorous exercise. As with individuals with anorexia nervosa, people with bulimia are obsessed with body weight, although they are usually within 10% of their ideal weight. Successful treatments for anorexia and bulimia rely primarily on counseling, nutritional education, and medications.

Summary of Key Concepts

46.1 Nutrient Use and Storage

- From an energetic point of view, an animal's life can be divided into two phases: the absorptive state, during which ingested nutrients are entering the blood from the gastrointestinal tract, and the postabsorptive state, during which the GI tract is empty of nutrients and the body's own stores must supply energy.
- Glucose and fats are the two major energy sources during the absorptive state. Much of the absorbed glucose immediately enters cells and is enzymatically broken down, providing energy required to synthesize ATP. Most absorbed triglycerides are stored in fat cells until the body requires additional energy. Amino acids are taken up by all body cells and used to synthesize proteins. (Figure 46.1)
- The events that maintain blood glucose concentration in the postabsorptive state fall into two categories: (1) the reactions glycogenolysis and gluconeogenesis, which provide glucose to the blood and (2) cellular use of fat for energy, which spares glucose for use by the nervous system. (Figure 46.2, Table 46.1)

46.2 Regulation of the Absorptive and Postabsorptive States

- Tight control mechanisms, in the form of several hormones and the nervous system, maintain homeostatic levels of fuel in the blood. The hormone insulin acts on cells to facilitate the diffusion of glucose from blood into the cell cytosol via glucose transporters (GLUTs). All animal cells use GLUTs to transport glucose across their plasma membranes. (Figure 46.3)
- In vertebrates, an increase in blood glucose level in the absorptive state stimulates the cells of the pancreas to secrete insulin; a decrease in glucose level removes the signal for secretion. In the postabsorptive state, when the blood glucose level falls, glucose-monitoring regions in the hypothalamus stimulate production of glucose-elevating factors such as glucagon and norepinephrine. (Figure 46.4)
- Exercise is any type of physical activity that increases an animal's metabolic rate. Exercise increases an animal's requirement for nutrients to provide energy. The source of these nutrients includes glucose and fatty acids.

46.3 Energy Balance

- An animal's energy expenditure, or metabolic rate, refers to the amount of energy it uses in a given period of time to power all of its metabolic requirements.
- The most common measure for comparing metabolic rates of different species is to compare the basal metabolic rate (BMR). Most of the basal metabolism is due to the routine functions of the heart, liver, kidneys, and brain. (Figures 46.5, 46.6)
- Many factors have an impact on metabolism, including skeletal muscle activity, whether an animal has recently eaten, and body size. (Figures 46.7, 46.8)
- Torpor and hibernation allow animals to conserve energy during changing environmental conditions, such as reduced environmental temperature and lack of available food.
- When the daily amount of energy consumed equals the amount of energy expended, body weight remains stable. Tipping the balance in either direction causes weight gain or loss by increasing or decreasing total body energy content.
- Short-term control of feeding generally involves satiety signals that remove the sensation of hunger and set the time period before hunger returns again. Experiments by Coleman and Friedman investigated the hormone leptin as a satiety factor in mammals. Leptin has since been found in all classes of vertebrates. (Figures 46.9, 46.10)

46.4 Regulation of Body Temperature

- Most animals can survive only in a relatively narrow temperature range that allows molecules in the body to move and react with one another, maintains the structures of membranes, and avoids denaturing proteins. A few animals, however, have the ability to survive being partially frozen.
- Animals can be classified according to their source of heat and their ability to maintain body temperature. Ectotherms depend on external heat sources to warm their bodies, whereas endotherms use their own metabolically generated heat to warm themselves. Homeotherms maintain their body temperature within a narrow range, whereas heterotherms have body temperatures that vary with environmental conditions. All animals fall into two of these categories. (Figure 46.11)
- The surface of an animal's body can lose or gain heat from the external environment via four mechanisms: radiation, evaporation, convection, and conduction. (Figures 46.12, 46.13)
- The skin can function as a variable heat exchanger; blood vessels near the skin surface dilate to dissipate heat or constrict to retain it. Both endotherms and ectotherms regulate heat loss through countercurrent heat exchange, which retains heat by returning it to the body's core and keeping it warmer than the extremities. Heat exchange can also be regulated by changing the rate of water evaporation via perspiration. Behavioral mechanisms can alter heat loss by radiation, conduction, and convection. (Figures 46.14, 46.15)
- Muscle activity (shivering thermogenesis) and brown adipose tissue metabolism (nonshivering thermogenesis) increase the production of heat.
- Acclimatization can fine-tune an animal's adaptive mechanisms to a changing environment.

46.5 Impact on Public Health

- Excess body fat increases the risk of many diseases. A body mass index (BMI) of 25 kg/m^2 or more is considered overweight; $\geq$ 30 kg/m^2 is considered obese.
- Being underweight is also unhealthy. People with anorexia nervosa become pathologically obsessed with weight and body image and reduce their food intake to the point of starving. Bulimia nervosa involves recurrent episodes of fasting and overeating, plus self-induced vomiting of ingested food. Both eating disorders can be treated with counseling, nutritional education, and medications.

Assess and Discuss

Test Yourself

1. During the absorptive phase, an animal is
   a. fasting.
   b. relying entirely on stored molecules for energy.
   c. absorbing nutrients from a recently ingested meal.
   d. metabolizing lipids stored in adipose tissue to supply ATP to its cells.
   e. both a and b
2. Gluconeogenesis
   a. occurs when the liver synthesizes glucose from noncarbohydrate precursors.
   b. is the process by which glycogen is broken down to glucose.
   c. occurs primarily when an animal is in the absorptive phase.
   d. occurs when triglycerides are being formed and stored in adipose cells.
   e. none of the above
3. In the process of _____, most tissues of the vertebrate body metabolize fat instead of glucose to ensure that _____ tissue has an adequate supply of glucose.
   a. gluconeogenesis, muscle
   b. glucose sparing, epithelial
   c. glycogenolysis, nervous
   d. glucose sparing, nervous
   e. gluconeogenesis, epithelial
4. Ketones are compounds derived from
   a. glucose. c. fatty acids. e. proteins.
   b. glycogen. d. amino acids.
5. Insulin primarily regulates blood glucose levels by
   a. stimulating the recruitment of glucose transporter proteins from the cytosol to the plasma membrane for transport of glucose from extracellular to intracellular fluid.
   b. stimulating gluconeogenesis.
   c. suppressing glucose uptake by muscle tissue.
   d. stimulating the release of glucose from glycogen reserves in the liver.
   e. inhibiting the synthesis of new GLUT proteins.
6. The rate at which an animal uses energy is called
   a. body mass index.
   b. an animal's energy consumption.
   c. metabolic rate.
   d. an animal's energy expenditure.
   e. both c and d.
7. Which factor may increase metabolic rate?
   a. hibernation d. fasting
   b. reduced muscle activity e. consumption of a meal
   c. sleeping
8. Which molecule acts on brain centers to reduce appetite in mammals and other vertebrates?
   a. GLUT4 c. leptin e. ketones
   b. glycogen d. glucagon
9. Animals that have body temperatures that are maintained within a narrow range are
   a. endotherms. c. homeotherms. e. both b and d.
   b. ectotherms. d. heterotherms.
10. The rate of heat loss in a mammal is regulated by
    a. the degree of blood flow at the surface of the skin.
    b. the amount of perspiration.
    c. behavioral adaptations.
    d. air currents near the animal's body.
    e. all of the above.

Conceptual Questions

1. Explain the functions of insulin. Why do you think a hormone such as insulin is required to carry out these functions?
2. Explain how appetite is controlled by the brain. What is the benefit of having a hormone released from adipose cells in proportion to total fat mass?
3. Explain countercurrent heat exchange.

Collaborative Questions

1. Discuss the differences between being ectothermic and endothermic and between being heterothermic and homeothermic.
2. Discuss four ways animals exchange heat with their environment.

Circulatory Systems

47

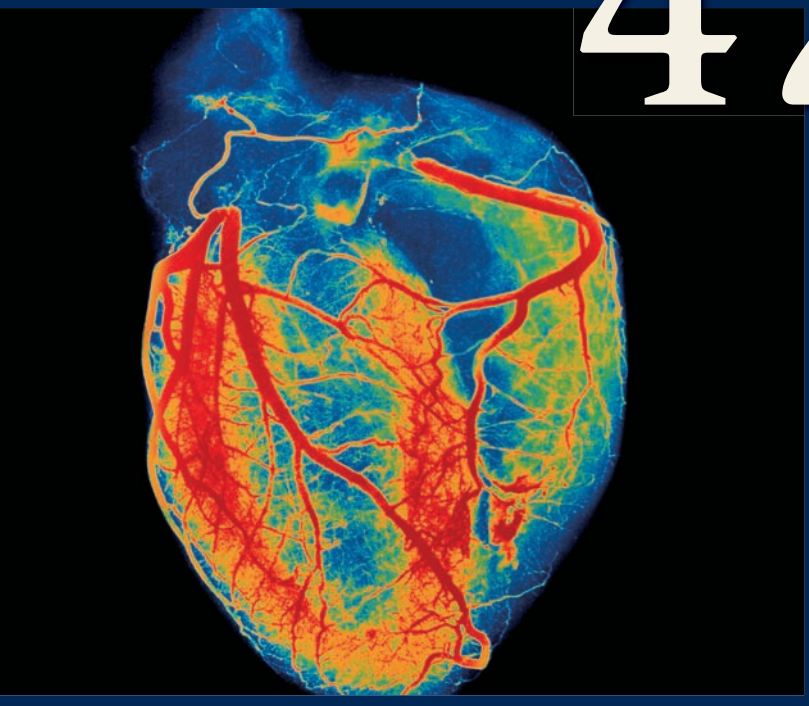

Image from cardiac angiography (dye contrast injection to visualize coronary blood vessels).

Chapter Outline

In the time it takes you to read this chapter introduction, three people in the United States will have suffered a heart attack, and one of those individuals will likely have died as a result. Diseases of the heart and blood vessels are the number one cause of death in the U.S. and in much of the rest of the world. In the U.S. alone, an estimated 80,000,000 people have one or more diseases that affect the heart and blood vessels. About 1,200,000 of those individuals will have a heart attack in the next year, and nearly 500,000 of those attacks will be fatal.

The heart is a muscular pump that works ceaselessly. Because of this constant activity, heart muscle requires a steady and large amount of blood, bringing with it the nutrients and oxygen required to sustain that muscular effort. The chapter-opening photo shows the extensive network of blood vessels coursing through the human heart. Should any of those vessels become diseased, the regions of the heart supplied by those vessels can die. That is what happens during a heart attack. If a heart attack occurs, the damaged heart may not be able to pump blood forcefully enough to generate the blood pressure required to reach all the cells of the body.

The heart, blood, and blood pressure are all features of the circulatory system. The primary function of **circulatory systems** is to transport necessary materials to all the cells of an animal's body, and to transport waste products away from the cells where they can be released into the environment. In this chapter, we will examine how this occurs. Single-celled organisms are small enough that dissolved substances are able to diffuse into and out of the cell. In larger animals, however, dissolved substances must move greater distances between cells, as well as between the internal and external environments. The time required for osmosis of water and diffusion of solutes throughout the body and between environments would be too great to sustain life in such animals. In the circulatory systems of larger animals, the heart pumps blood through blood vessels throughout the body. The blood carries nutrients and oxygen to all the body's cells, and takes away waste products and carbon dioxide. Most circulatory systems are capable of adjusting their activities to an animal's changing metabolic demands. For instance, we will see how exercise increases the ability of the vertebrate heart to pump blood and directs blood to the skeletal muscles where it is most needed. Understanding the relationships between the heart, blood, and blood pressure is a major concept addressed in this chapter. Finally, we consider some of the causes, symptoms, and treatments of the major types of cardiovascular disease in humans.

47.1 Types of Circulatory Systems

The three basic types of circulatory systems are gastrovascular cavities, open systems, and closed systems. We begin with the simplest form of circulation, that provided by the water in which certain invertebrates live.

Gastrovascular Cavities

In cnidarians (jellyfish, hydras, sea anemones, and corals) and some flatworms, the surrounding water not only contains the nutrients and oxygen needed to sustain life but also functions as a circulatory system. These animals rely on water currents to bring a steady supply of water into contact with their body surfaces. Water enters the **gastrovascular cavity**, a body cavity with a single opening to the outside. As described in Chapter 45, food is digested within the cavity and absorbed by body

cells, and wastes are excreted into the cavity. Nutrients obtained from digested food reach all the cells because water circulates throughout the entire cavity. Because the animals are only a few cells thick, all cells in their bodies are located close to the gastrovascular cavity or in slender extensions that branch from it.

In some cnidarians, cilia that line the opening of the gastrovascular cavity propel water through these extensions, increasing the circulation of water. In addition, muscular efforts of the body wall—as a *Hydra* stretches and relaxes, for instance, or a jellyfish propels itself by contracting its bell—help circulate water throughout the cavity (Figure 47.1). The harder the muscles work, the more effectively they propel water, thus providing a rudimentary but effective circulation.

Open Circulatory Systems

Arthropods and some mollusks have a circulatory system with three basic components:

1. **hemolymph**, a body fluid containing dissolved solutes;
2. **vessels**, a system of hollow tubes within the body through which hemolymph travels;
3. one or more **hearts**, muscular structures that pump hemolymph through the vessels.

A circulatory system containing these three components is also known as a **cardiovascular system** (from the Greek *kardia*, meaning heart, and Latin *vas*, meaning vessel). In an **open circulatory system**, the vessels open into the animal's body cavity. Therefore, the fluid in the vessels and the interstitial fluid that surrounds cells mingle in one large, mixed compartment, rather than being located in separate body compartments. The mixed fluid is hemolymph. The heart or hearts pump hemolymph through the vessels, where it exits into the animal's body cavity

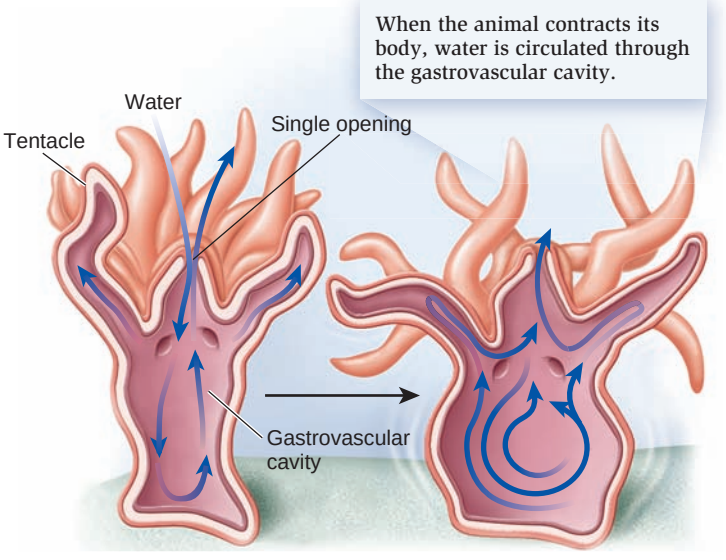

Figure 47.1 **Circulation of water through the gastrovascular cavity of *Hydra*.** The animal's movements assist the flow of water throughout the cavity, which extends into the tentacles.

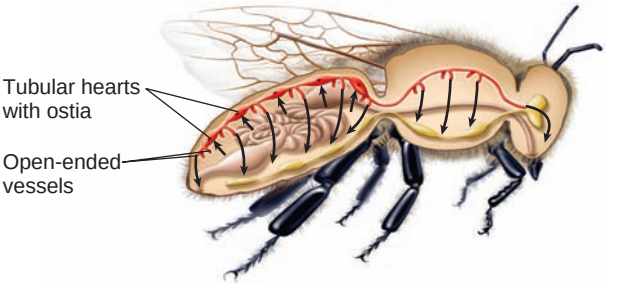

Figure 47.2 **An open circulatory system.** In open systems, one or more muscular, tubelike hearts pump hemolymph through open-ended vessels, where it percolates through the body. In arthropods such as this honeybee, hemolymph reenters the heart through ostia. The arrows show the movement of hemolymph.

Concept check: *Why is it incorrect to think of open circulatory systems as "primitive" compared to closed systems?*

(Figure 47.2). Nutrients and wastes are exchanged by diffusion between the hemolymph and body cells, and the hemolymph is recirculated back to the heart. In mollusks with open circulatory systems, hemolymph reenters the heart through vessels, whereas in arthropods, it returns to the heart through small openings called ostia.

In insects, hemolymph primarily transports nutrients and wastes; in mollusks, it also brings oxygen to body cells. Insects have a unique oxygen-delivery system that does not involve the circulatory system (see Chapter 48).

Open circulatory systems are metabolically inexpensive because they do not require much energy to circulate hemolymph. In addition, open systems can adapt to changes in an animal's metabolic demands. As an insect takes flight, for example, its flight muscles contract more forcefully and rapidly, which acts to expand and compress the animal's thorax. This helps propel hemolymph more rapidly throughout the body cavity and into and out of the hearts. In other words, as the animal's activity increases, its circulation becomes more efficient, recharging metabolically active cells with nutrients. As noted earlier, the ability to adjust circulation to meet an animal's requirements is one of the most important features of any circulatory system. Open systems, therefore, are highly effective, particularly for smaller animals.

Despite the phenomenal success of species with open systems, certain limitations are associated with this type of circulation. For instance, because the hemolymph empties in bulk into the general body cavity, it cannot be selectively delivered to body cells whose metabolic activity may have increased compared to other cells. By contrast, during exercise in vertebrates, larger amounts of blood are delivered to leg muscles and away from less metabolically active structures, an adaptation that results in greater endurance. This is possible because these animals have closed circulatory systems, as we see next.

Closed Circulatory Systems

Open circulatory systems are not ideal for larger, more active animals in which higher pressure is required to pump blood to all body cells at a rate sufficient to meet energetic demands. In these groups of animals, a closed circulatory system has evolved.

In a **closed circulatory system**, blood and interstitial fluid are physically separated, and they differ in their components and chemical composition. Closed circulatory systems are found in earthworms, cephalopods (squids and octopuses), and all vertebrates (Figure 47.3). Despite differences in structure, closed circulatory systems share certain key features.

- **Blood**—a watery solution containing solutes to be transported throughout the body—is pumped under pressure by one or more contractile, muscular hearts.
- Blood remains within tubelike vessels that distribute it throughout the body.
- The solutes in blood can be exchanged with the environment and the body's cells.
- In most cases, blood contains disease-fighting cells and molecules.
- The activity of the closed circulatory system can be adjusted to match an animal's metabolic demands.
- Closed systems generally can heal themselves when wounded, by forming clots at the site of injury.
- These systems grow in size as an animal grows.

A closed circulatory system offers several advantages. First, animals can grow to a larger size, because blood can be directed to every cell of an animal's body, no matter how large. Nearly all body cells are within one or two cell-widths of a blood vessel. Second, blood flow can be selectively increased or decreased to supply different parts of the body with the precise amount of blood needed at any given moment. After a meal, for example, more blood can be directed to the gut to absorb nutrients, and on a hot day, additional blood can be routed to the skin to dissipate heat. Animals with open systems cannot make these adjustments.

The closed circulatory systems of vertebrates can be divided into two major groups: single and double circulations. In a single circulation, blood is pumped under low pressure from the heart to the respiratory surface (for example, gills), where it picks up oxygen and drops off carbon dioxide. From there, blood circulates to the tissues of the body, where it releases oxygen and picks up carbon dioxide. The blood then circulates back to the heart. In a double circulation, blood is pumped under low pressure from the heart to the lungs, and then back to the heart, to be pumped under high pressure to the tissues and finally returned again to the heart. Single circulations are seen in fishes, and double circulations are seen in crocodiles, birds, and mammals. Amphibians and most reptiles have a type of circulation that combines features of both.

Single Circulation: Fishes In the single circulation of fishes, the heart has a single filling chamber—an **atrium**—to collect blood from the tissues, and an exit chamber—a **ventricle**—to pump blood out of the heart (Figure 47.4a). Blood vessels called **arteries** carry blood away from the heart to the gills, which pick up oxygen from the water in which the fish swims and unload carbon dioxide into the water. The freshly oxygenated blood then circulates via other arteries to the rest of the body. There, oxygen and nutrients are delivered to cells, and carbon dioxide diffuses from cells into the blood. Finally, the deoxygenated blood is returned to the heart via blood vessels called **veins**, where it is pumped back to the gills for another load of oxygen.

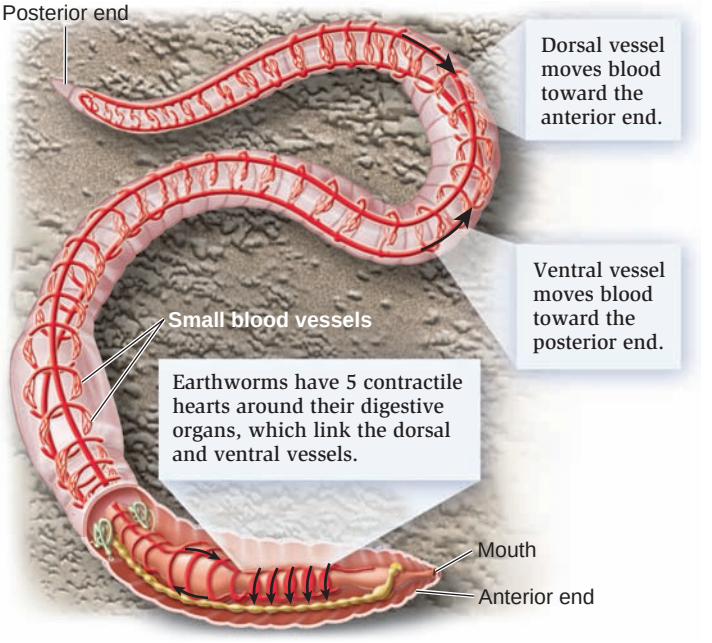

Figure 47.3 **A closed circulatory system.** In closed systems, such as that of the earthworm, blood remains in vessels and hearts and recirculates without emptying into the body cavity. Arrows indicate direction of blood flow.

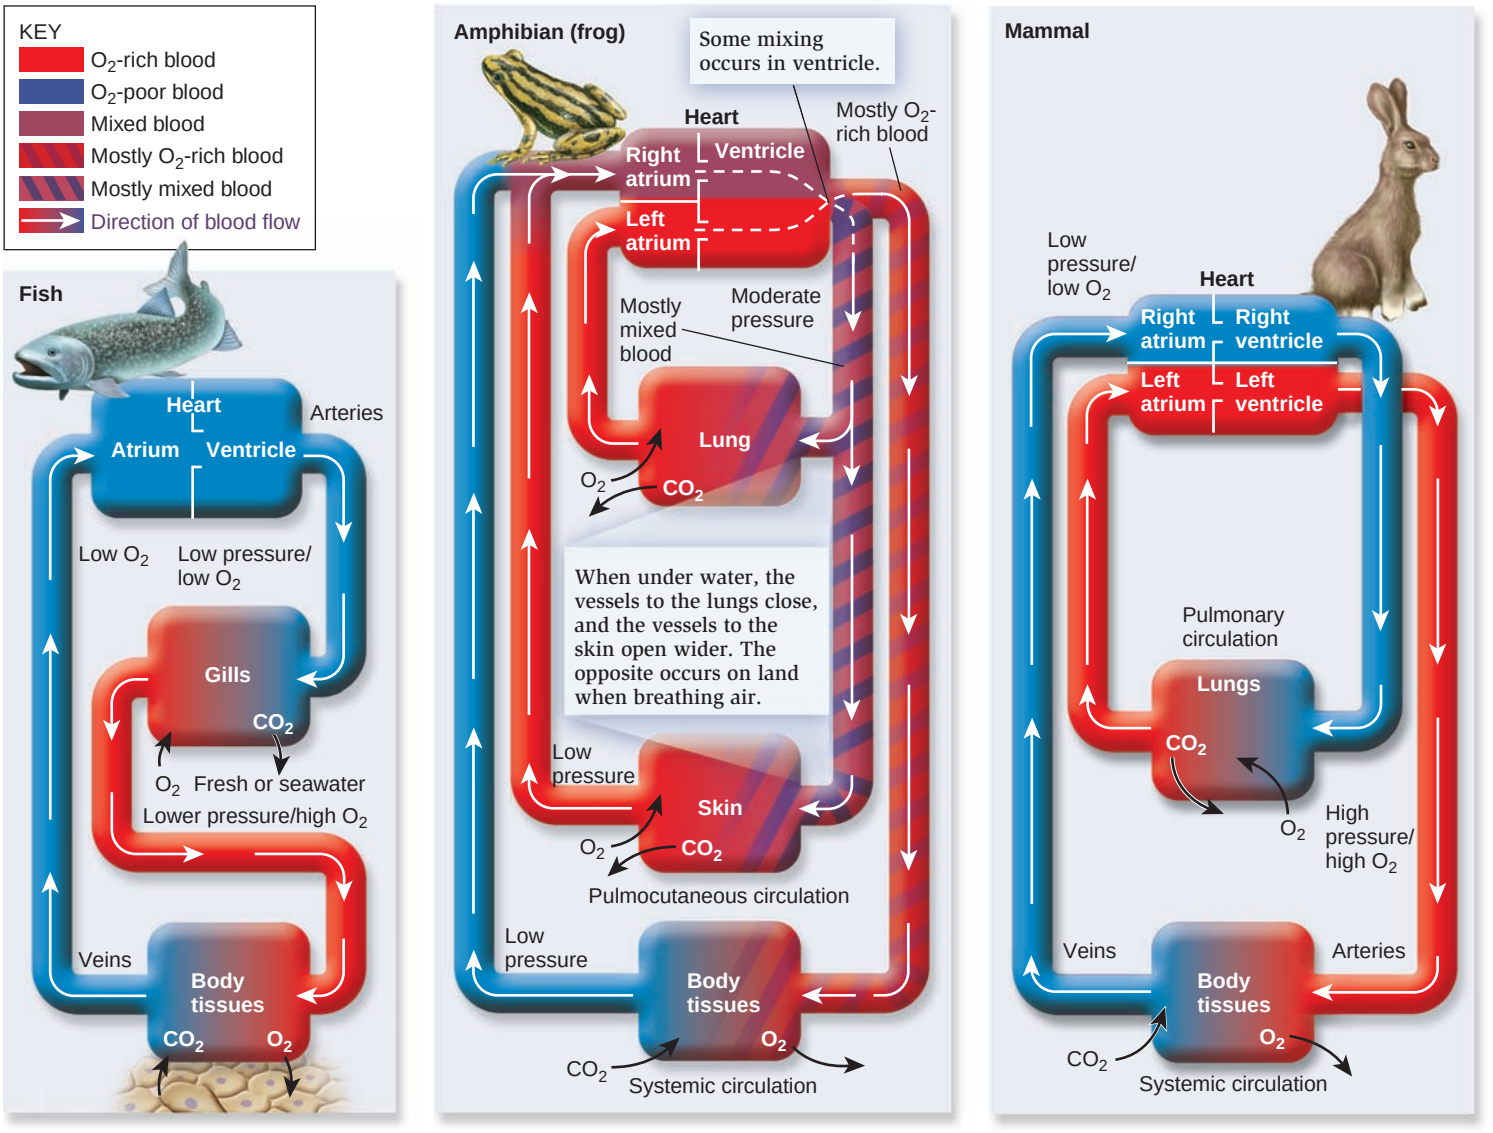
An important feature of all respiratory surfaces is that they function best when the blood flowing through them is maintained at a low pressure. The fish heart does not generate high pressure when it pumps blood to the gills. This means that blood leaving the gills will also be under low pressure, therefore limiting the rate at which oxygenated blood can be delivered to the body's cells.

Intermediate Circulatory Features: Amphibians and Most Reptiles Unlike fishes, most adult amphibians rely on lungs and their permeable skin to obtain oxygen and rid themselves of carbon dioxide. While amphibians are on land, their deoxygenated blood is pumped from the heart to the lungs and, to a lesser extent, the skin. Oxygen diffuses from the air into the blood vessels within the lungs and beneath the skin, and carbon dioxide diffuses in the opposite direction. While amphibians are under water, deoxygenated blood from the heart bypasses the lungs and is directed almost entirely to the skin so that oxygen in the water can diffuse across the skin and into the circulation. Oxygenated blood from the lungs and skin does not travel directly to the rest of the body but instead returns to the heart, where it is pumped out to the tissues of the body.

The amphibian heart, therefore, pumps oxygenated and deoxygenated blood to two separate locations. Blood is routed from the heart through different vessels to either the respiratory surfaces (the **pulmocutaneous circulation**) or the body tissues (the **systemic circulation**). This would not be possible if an amphibian's heart and circulation were the same as that of a



(a) Single circulation in fishes

(b) Features of both single and double circulation in most amphibians

(c) Double circulation in birds and mammals

Figure 47.4 Representative vertebrate circulatory systems. **(a)** Fishes have a single circulation in which blood is pumped from the heart to the gills, from where it circulates to the rest of the body tissues, and finally returns to the heart. **(b)** Amphibians, such as frogs, have a heart with a single ventricle that nevertheless has an internal structure that separates most of the oxygenated and deoxygenated blood entering it from the two atria. Some mixing does occur, however, as represented in this figure by the dashed lines. A significant advantage of this type of circulation is the ability to redirect blood to the skin instead of the lungs when under water. Because the skin is somewhat permeable to oxygen, this partly compensates for the lack of air-breathing. Note that blood returning from the skin has picked up oxygen, but is returned to the right atrium, not the left atrium as is the case with the lungs. **(c)** Birds and mammals have a double circulation, in which oxygenated blood is pumped under high pressure to the body's tissues, and deoxygenated blood is pumped under low pressure to the lungs. No mixing of the two types of blood occurs.

Concept check: *What is the advantage of completely separating oxygenated and deoxygenated blood in a double circulation?*

fish, where blood travels through a single circulation. Instead, the amphibian heart has two separate atria for collecting blood (Figure 47.4b). The right atrium receives blood that has passed through all of the body except the lungs and is therefore depleted of some of its oxygen. However, some oxygen-rich blood returning from the skin also enters the right atrium and mixes with the blood returning from the systemic circulation. This is an important adaptation for amphibians when they are under water, because as stated, the circulation through the lungs is decreased at such times and, therefore, diffusion across the skin becomes the sole means of obtaining oxygen.

When an amphibian breathes air, oxygen-rich blood from the lungs is delivered to the left atrium. Each atrium of the amphibian heart empties its blood into a single large ventricle. The internal structure of the single ventricle consists of flaps and folds of tissue that keeps the oxygenated and deoxygenated blood from the two atria mostly separate. Some mixing of the two streams of blood, however, does occur in the ventricle.

This would not occur if each atrium emptied into a separate ventricle. Because there is only a single ventricle, however, the slightly mixed blood traveling to the tissues is not fully oxygenated. The more oxygen that is dissolved in an animal's blood, the faster the oxygen is able to diffuse from the blood, through the interstitial fluid, and into cells where it is required. The mixed blood of amphibians, therefore, imposes limits on their metabolic activity.

Like amphibians, all of the reptiles except for crocodiles have hearts with two atria and a single ventricle, although the ventricle is further subdivided into two partially but incompletely separated chambers. These chambers allow more efficient separation of deoxygenated and oxygenated blood entering the ventricle from the two atria; this, in turn, contributes in part to the higher activity levels of reptiles compared to amphibians. Because these reptiles and amphibians have only a single ventricle that must pump blood to both the tissues and respiratory surfaces, blood must be pumped under low or moderate pressure in these animals to minimize the pressure of blood flowing through the delicate lung tissue.

Double Circulation: Crocodiles, Birds, and Mammals In crocodiles, birds, and mammals, oxygenated and deoxygenated blood are completely separated into two distinct circuits, the systemic circulation and the **pulmonary circulation** (Figure 47.4c). This is made possible by a heart that has two complete ventricles. The crocodilian circulatory system has evolved to be somewhat different from that of birds and mammals. It allows crocodiles to spend part of their lives under water and it reflects that they are considerably less active than birds and mammals. When resting or underwater, crocodiles can divert blood between the two circuits in ways that birds and mammals cannot. Nonetheless, all animals with double circulations have a left and right atrium and a left and right ventricle.

In a double circulatory system, the pulmonary circulation delivers oxygenated blood from the lungs to the left atrium, which then passes it on to the left ventricle. The left ventricle pumps blood to all the body's tissues via the systemic circulation. The systemic circulation delivers deoxygenated blood from the tissues to the right atrium, which then sends it to the right ventricle. The right ventricle pumps this blood to the lungs via the pulmonary circulation, and the cycle starts again.

An advantage of a double circulation is that the two ventricles can function as if they were, in effect, two hearts, each with its own ability to pump blood under different pressures. This means that blood from the right ventricle can be pumped under low pressure to the lungs. Once the blood picks up oxygen from the lungs, it can be returned to the left side of the heart. The left ventricle is more muscular than the right ventricle and therefore generates higher pressures when pumping blood. Thus, the oxygenated blood leaving the left side of the heart has sufficiently high pressure to reach all the cells of the animal's body and deliver oxygen and nutrients at a high rate, even to regions above the heart that must contend with gravity. This is no small feat considering the distance blood must travel in some large mammals. The left ventricle of a giraffe, for example, is particularly muscular compared to that of other animals.

47.2 Blood and Blood Components

Blood is the transport medium of many animals' bodies. It moves necessary materials, including nutrients and gases such as oxygen, to all cells and takes away waste products, including carbon dioxide and other breakdown products of metabolism. What components of blood allow it to perform its functions?

Blood Is Composed of Cells and Water with Dissolved Solutes

Blood is a fluid connective tissue consisting of cells and, in mammals, cell fragments suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules. If we collect a blood sample and spin it in a centrifuge, the blood separates into three layers (Figure 47.5). These layers correspond to three of blood's four components: plasma, leukocytes, and erythrocytes. (A fourth component is the much less abundant platelets or thrombocytes, and is not readily visible.) Let's take a look at each of these.

Plasma The top layer of the centrifuged blood sample is **plasma**, a yellowish solution of water and solutes (Figure 47.5). Plasma typically makes up about 35–60% of the total volume of blood in vertebrates. It contains water and the dissolved organic and inorganic nutrients that were absorbed from the digestive tract or secreted from cells. Plasma also contains dissolved oxygen; waste products of metabolism, such as carbon dioxide; and other molecules released by cells, such as hormones. Plasma also transports cells of the immune system and cells involved in oxygen transport, as well as proteins that serve several important functions, such as forming blood clots, which seal off wounds to blood vessels.

In addition to transporting molecules throughout the body, plasma has other functions. For example, plasma contains buffers that help keep the body's pH within its normal range. It is also important in maintaining the fluid balance of cells. Changes in plasma salt and protein concentrations can affect the movement of water between intracellular and extracellular fluid compartments.

Leukocytes Beneath the plasma in our sample is a narrow white layer of **leukocytes**, also known as **white blood cells** (Figure 47.5). Leukocytes develop from a specialized connective tissue (the marrow) of certain bones in vertebrates. Although there are several types—which we describe further in Chapter 53—all leukocytes perform vital functions that defend the body against infection and disease.

Erythrocytes The bottom visible layer of our blood sample consists of **erythrocytes**, also called **red blood cells** because of their color (Figure 47.5). **Hematocrit** refers to the volume of blood that is composed of red blood cells, usually between 40 and 65% among vertebrates. Red blood cells serve the critical function of transporting oxygen throughout the body. There are approximately a thousand times more red blood cells than white blood cells in the circulation. Like leukocytes, red blood cells are

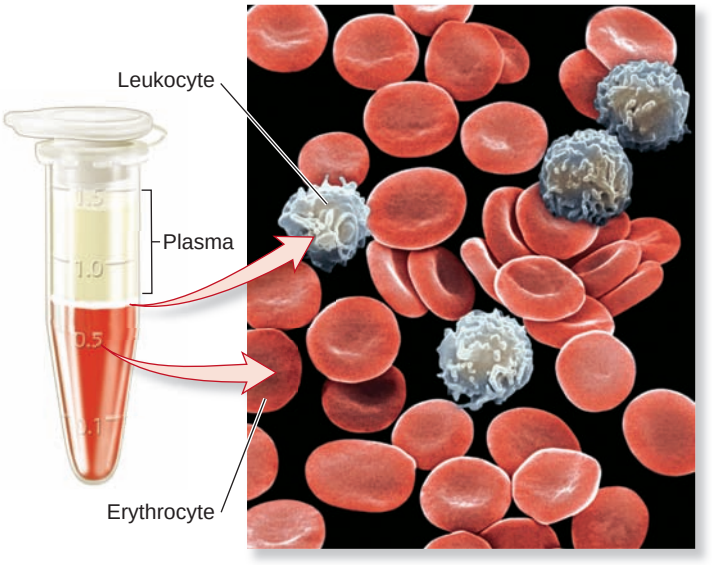


Figure 47.5 **Components of blood.** When a blood sample that has been prevented from clotting is centrifuged, it forms three visible layers. Leukocytes, shown in the scanning electron micrograph, are the white blood cells that make up part of the immune system. Erythrocytes are red blood cells and function to carry oxygen. An additional component of blood is not visible under these conditions because of small numbers and size. These are the platelets in mammals (or thrombocytes in other vertebrates) that participate in blood clotting reactions. Note: The leukocyte layer is enlarged and not to scale, for illustrative purposes.

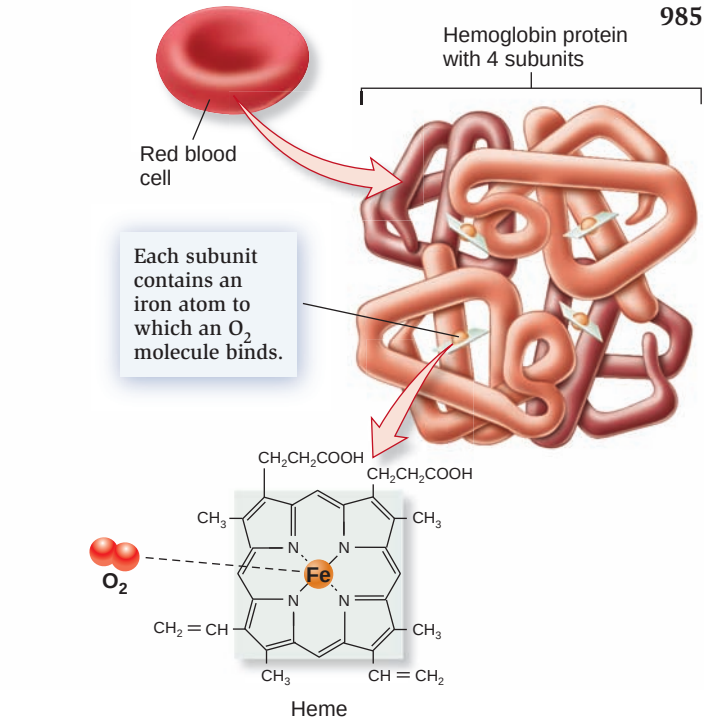

Figure 47.6 **Hemoglobin.** Erythrocytes contain large amounts of the protein hemoglobin. Oxygen binds reversibly to iron atoms in the heme portion of each subunit of hemoglobin.

Concept check: How many atoms of oxygen can be bound to a single molecule of hemoglobin?

derived from cells in the bone marrow. In most vertebrates, mature red blood cells retain their nuclei and other cellular organelles, but in all mammals (and a few species of fishes and amphibia), the nuclei are lost upon maturation. The lack of a nucleus and many other organelles in the mammalian red blood cell increases the cell's oxygen-carrying capacity and contributes to its characteristic biconcave shape (Figure 47.5). The biconcave shape of the mammalian red blood cell increases its surface area compared to the flattened disc or oval shape seen in most other vertebrates. This is believed to make gas exchange between the red blood cell and the surrounding body fluids more efficient.

Oxygen is poorly soluble in plasma. Consequently, the amount of oxygen that dissolves in plasma usually cannot support a vertebrate's basal metabolic rate, let alone more strenuous activity. The components of red blood cells solve this problem. Within the cytosol of red blood cells are large amounts of the protein **hemoglobin**. Each molecule of hemoglobin contains four protein subunits, each with an atom of iron in a heme group at its core; each iron reversibly binds to a molecule of oxygen (Figure 47.6). Thus, each hemoglobin molecule has four iron atoms and can reversibly bind four oxygen molecules. The oxygen attached to hemoglobin greatly increases the reservoir of oxygen in the blood and enables animals to be more active. Chapter 48 describes the mechanisms by which hemoglobin binds and releases oxygen.

Anemia refers to lower than normal levels of hemoglobin, which reduces the amount of oxygen that can be stored in the blood. Among possible causes are loss of blood, decreased production of hemoglobin, impaired production of erythrocytes, or increased breakdown of erythrocytes, each of which reduces hematocrit.

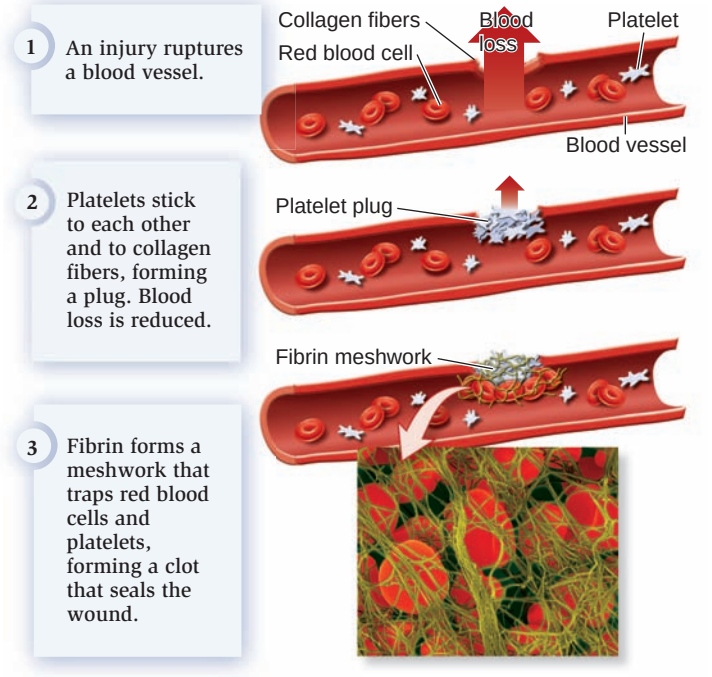
Platelets Vertebrate blood has a fourth component—called platelets in mammals and thrombocytes in other vertebrates—that would not be visible in our centrifuge sample because of their low numbers. **Platelets** are cell fragments that lack a nucleus, whereas **thrombocytes** are intact cells; they play a crucial role in the formation of blood clots, which limit blood loss after injury. Like leukocytes and erythrocytes, platelets and thrombocytes are formed in the bone marrow.

Although clot formation in mammals is a multistep process, two essential steps involve platelets (Figure 47.7a). First, platelets secrete substances that cause platelets to clump together and bind to collagen fibers in the surrounding connective tissue at the wound site; this forms a plug that prevents continued blood loss. Second, other platelet secretions interact with plasma proteins to cause the precipitation from solution of the fibrous protein **fibrin**. Fibrin forms a meshwork of threadlike fibers that wrap around and between platelets and red blood cells, enlarging and thickening the plug to form a clot. Blood clotting begins within seconds and helps prevent injured animals from bleeding to death. Eventually, the body absorbs the clot as the injured vessel heals. The importance of clotting is most evident when it fails to occur normally, as we see next.

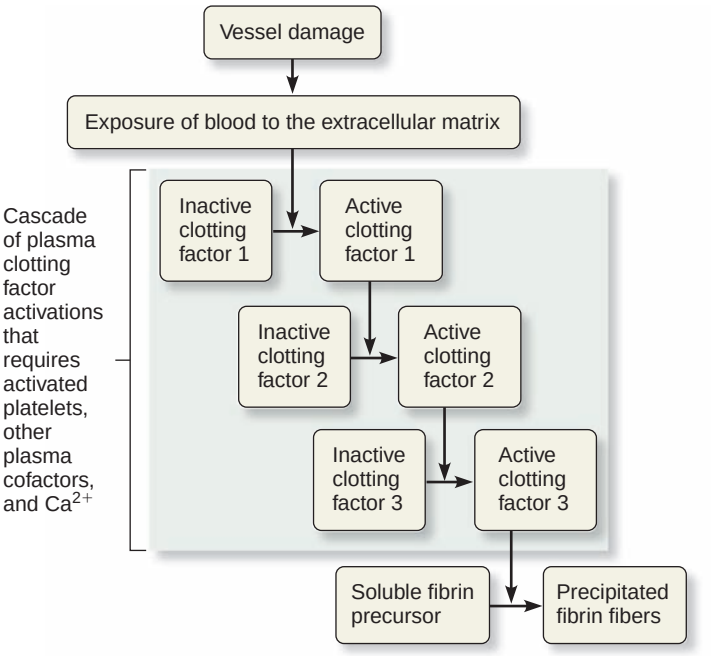
Genomes & Proteomes Connection

Hemophilia Is Caused by a Genetic Defect in Clotting Factors

The process of blood clotting is not a simple one—at least a dozen different substances must be present in the right amounts



(a) Formation of a blood clot



(b) Role of clotting factors in clot formation

Figure 47.7 **Platelets and the process of blood clot formation.** **(a)** A blood clot forms in two major steps: A platelet plug reduces initial blood loss, and a fibrin clot then seals the wound. An example of a fibrin clot is shown in the scanning electron micrograph. **(b)** Formation of the clot requires several clotting factors working together. These include enzymes, which catalyze a cascade of reactions that leads to the production of fibrin fibers. Several steps in the process are omitted here for simplicity.

for a clot to form. These substances are known as clotting factors and include proteins and ions such as Ca^{2+}. Platelets secrete some of these substances; others circulate in the plasma in an inactive form until activated by platelet and cellular secretions.

The clotting process is a chain reaction that begins when an injury to a blood vessel exposes blood to the surrounding extracellular matrix (Figure 47.7b). When one particular clotting factor in blood interacts with proteins in the matrix, the factor is activated. This initiates a cascade in which clotting factors sequentially activate each other, finally producing fibrin.

In the disease **hemophilia**, an inherited deficiency of a specific clotting factor inhibits the clotting process. The absence of the clotting factor interrupts the process leading to fibrin formation. Consequently, injured blood vessels take longer to heal and blood loss is excessive. Minor cuts are not necessarily serious, but uncontrolled bleeding in internal tissues and joints can be life-threatening.

Hemophilia in humans occurs in three forms, called the A, B, and C forms. In the most common form of hemophilia, the A form, an X-linked recessive mutation results in the inability to make an enzyme that is one of the clotting factors. Because the mutation is X-linked and recessive, it is much more common in males than females. Females who are heterozygous for the mutation are carriers and have a 50% chance of passing the disease genes to their sons.

Treating hemophilia requires transfusions of clotting factors purified from great amounts of human blood or from genetically engineered organisms. These procedures are extremely expensive, and transfusions run the risk of introducing infection or disease from the donor blood. Currently, researchers are attempting to treat hemophilia with gene therapy by using a viral vector (see Chapter 20) to introduce the normal gene into liver cells, which then secrete the missing factor into the blood. Even if the introduced gene is not extremely efficient at forming new clotting factor, it could still improve patients' symptoms. This is because the missing clotting factor is an enzyme. Like all enzymes, it can act over and over again without being destroyed or chemically altered by the reaction it catalyzes. In addition, this enzyme is known to remain in the circulation for long periods without being degraded or excreted. Recent estimates suggest that restoring the clotting factor to only 2–5% of normal levels should prevent most symptoms of hemophilia. Gene therapy has proven to be effective in curing laboratory rodents and dogs of hemophilia, and testing has recently begun in humans. The results thus far are mixed but hopeful. One problem that needs to be overcome is that human immune systems appear to be more likely than those of experimental animals to destroy cells that incorporate the viral vector.

47.3 The Vertebrate Heart and Its Function

Now let's move on to the heart. As described earlier, all vertebrate hearts have at least one upper or anterior chamber called an atrium and at least one lower or posterior chamber called a ventricle (Figure 47.8). In hearts with more than one atrium or ventricle, such as the mammalian heart, which has two of each chamber, the chambers are physically separated by a thick strip

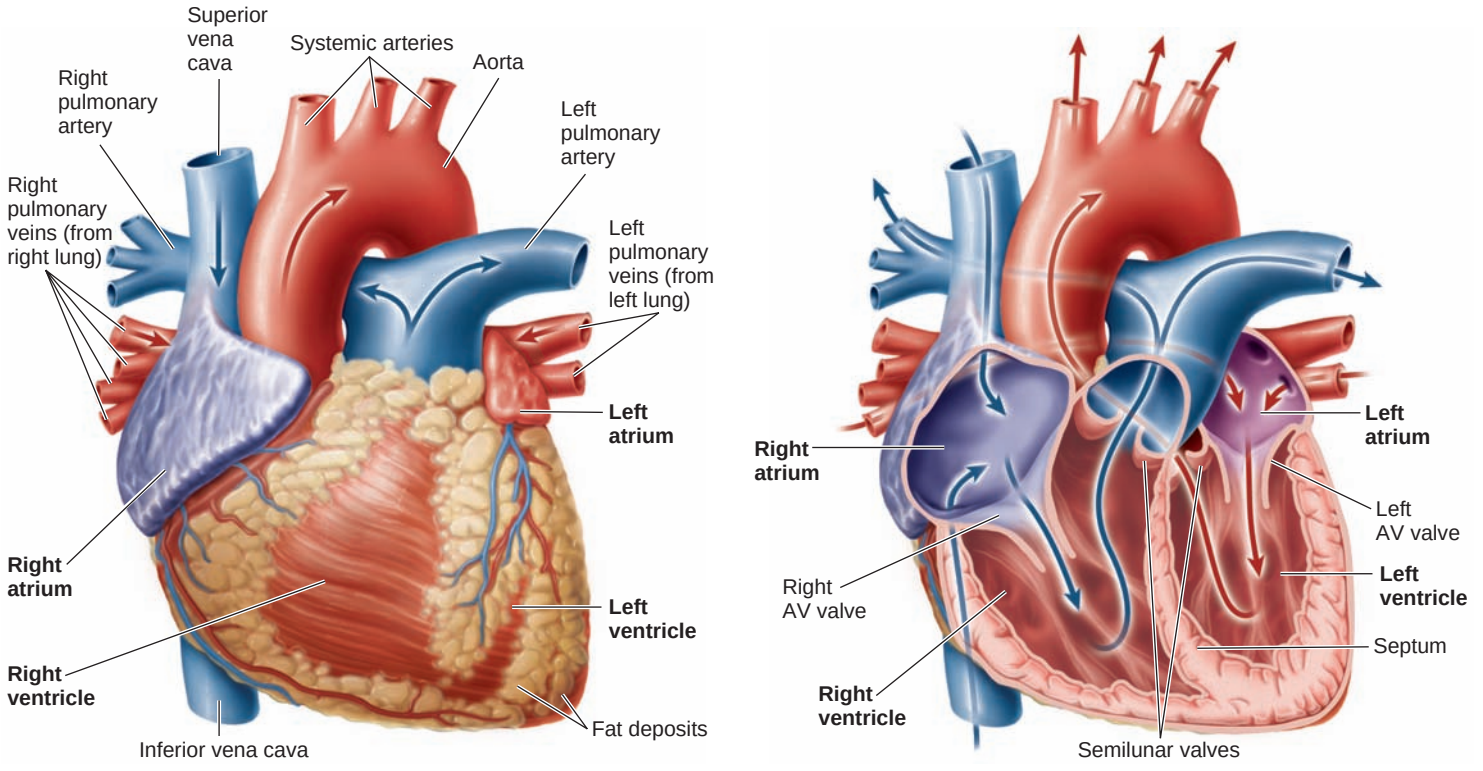


Figure 47.8 **The mammalian heart and the route blood takes through it.** The figure shows the major blood vessels entering and leaving the heart, the locations of the valves, and the direction of blood flow through the chambers of the heart. Oxygenated blood is shown in red, deoxygenated in blue. Note that the pulmonary veins carry oxygenated blood because they return blood from the lungs, while veins from the systemic circulation carry deoxygenated blood.

of connective tissue called a septum. Between each atrium and ventricle there are valves called **atrioventricular** (**AV**) **valves** that control the movement of blood between them. Similarly, between each ventricle and the blood vessels it empties into, there are valves called **semilunar valves**. Each atrium is fed by systemic or pulmonary veins; the systemic veins return blood from the body, and the pulmonary veins return blood from the lungs. Each ventricle empties into systemic or pulmonary arteries. The **aorta** leads to the systemic circulation, and the pulmonary arteries lead to the right and left lung.

The heart beats with a steady rhythm; each beat propels blood through the various chambers of the heart. Figure 47.8 also depicts the route blood takes through the mammalian heart. Recall from Figure 47.4c that each ventricle in the mammalian heart functions as a separate pump. The right ventricle pumps deoxygenated blood returning from the body to the lungs, while the left ventricle pumps oxygenated blood coming from the lungs to the body. Blood enters the atria from systemic or pulmonary veins, moves down a pressure gradient through the AV valves into the ventricles, and is pumped out through the semilunar valves into the systemic and pulmonary arteries. Note that the blood can flow only one way through the valves.

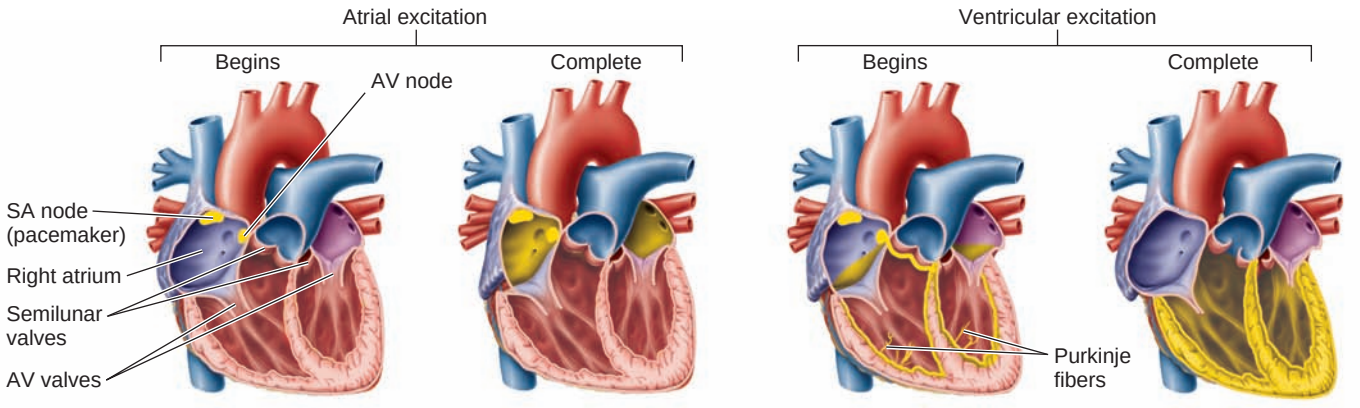
Vertebrates Have Myogenic Hearts Capable of Beating on Their Own

What causes the heart to beat so steadily? Animals cannot consciously initiate heart contractions. The beating of the heart is initiated either by nerves or by intrinsic activity of the heart muscle cells themselves. Many arthropods and decapod crustaceans have a **neurogenic heart** that will not beat unless it receives regular electrical impulses from the nervous system. All vertebrates, however, have a **myogenic heart**; that is, the signaling mechanism that initiates contraction resides within the cardiac muscle itself.

Myogenic hearts are electrically excitable and generate their own action potentials. Electrical signals produced by cells of these hearts initiate the cellular events that trigger muscle contraction (see Chapter 44). The rate and forcefulness of the beating of myogenic hearts can, however, be regulated by the nervous system. Nonetheless, myogenic hearts will continue to beat on their own if dissected out of an animal and placed in a nutrient bath, even with no nerves present.

Excitation of the Vertebrate Heart Begins in the SA Node in the Atria and Spreads to the Ventricles via the AV Node

The electrical excitation of the myogenic vertebrate heart has two phases: atrial and ventricular. In atrial excitation, electrical signals are generated at the junction of the veins and single atrium in fishes, and within the wall of the right atrium in other vertebrates, at what is called the **sinoatrial** (**SA**) **node**, or **pacemaker** (Figure 47.9). The SA node is a collection of modified cardiac cells that have an inherently unstable resting membrane potential. Ion channels in the membranes of these cells are opened spontaneously and allow the influx of positively charged ions into the cytosol, thereby depolarizing the cell.



AV valves	OPEN	OPEN	Beginning to close	CLOSED
Semilunar valves	CLOSED	CLOSED	CLOSED	OPEN
Phase of cardiac cycle	Diastole	Diastole	Systole beginning	Systole
Atria	Relaxed	Contracted	Beginning to relax	Relaxed
Ventricles	Relaxed	Relaxed	Beginning to contract	Contracted
Site of highest pressure	Atria	Atria	Ventricles	Ventricles

Figure 47.9 **Coupling of electrical and mechanical activity in the mammalian heart.** Electrical activity, which is depicted as yellow color, begins in the SA node and quickly spreads through the atria to the AV node. Branches from the AV node transmit electrical activity throughout the ventricles along the Purkinje fibers. The atria and ventricles do not contract until they have become electrically excited. Changes in fluid pressure gradients between the atria and ventricles, and between the ventricles and the aorta and pulmonary arteries, are the forces that open or close the four heart valves. Note: The aortic valve is not visible in this section.

These depolarizations produce action potentials in the SA node cells with a frequency that is characteristic for a given species; this frequency is an animal's heart rate. Once the SA node cells generate action potentials, the potentials quickly spread across one or both atria. This occurs because cardiac muscle forms a structure called a syncytium—a group of cells, all of which are electrically coupled by gap junctions (see Chapter 10). The action potentials trigger an influx of Ca^{2+} into the muscle cell cytosol, which activates contraction. Because the gap junctions between cardiac muscle cells allow electric charge to flow freely from one cell to the next, the impulses spread very rapidly across the atria, so both atria contract almost as if they were one large muscle cell. Atrial contraction pumps blood through the AV valves into the ventricles.

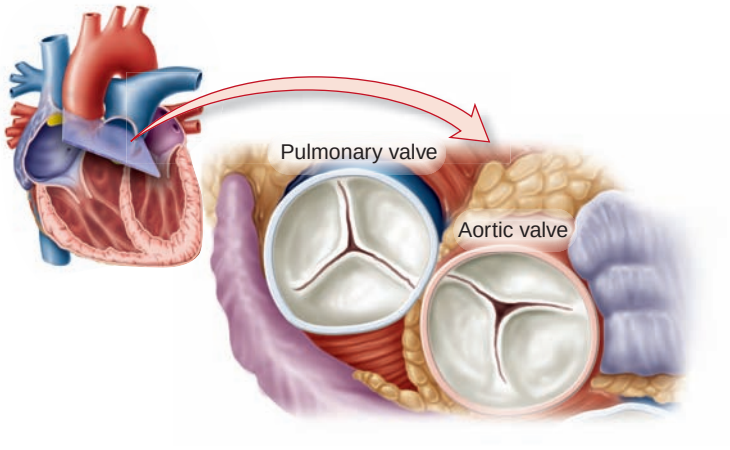
To begin ventricular excitation, action potentials initiated in the SA node first reach another node of specialized cardiac cells, the **atrioventricular (AV) node**. The AV node is located near the junction of the atria and ventricles and conducts the electrical signals from the atria to the ventricles. This is important, because there are no gap junctions connecting atrial and ventricular cells. Like the SA node, the AV node is electrically excitable, but its cells require a longer time to become excited than do the cells of the atria. This allows time for the atria to contract before the ventricles do. Fibers branching from the AV node spread electrical impulses along a conducting system of cardiac muscle cells called Purkinje fibers, which are specialized to rapidly conduct electricity. These fibers branch throughout the muscular walls of the ventricles, ensuring that all of the ventricular muscle gets depolarized quickly and nearly simultaneously (Figure 47.9). In this way, the entire mass of both ventricles contracts in unison in response to depolarization.

The Cardiac Cycle Has Two Phases: Diastole and Systole

Each beat of the vertebrate heart requires the coordinated activities of the atria and ventricles. The events that produce a single heartbeat are known as the **cardiac cycle**, which can be divided into two phases (Figure 47.9). In the first phase, **diastole**, the ventricles fill with blood coming from the atria through the open AV valves. In the second phase, **systole**, the ventricles contract and eject the blood through the open semilunar valves.

The valves open and close as a result of pressure gradients established between the atria and ventricles, and the ventricles and arteries. During diastole, pressure in the ventricles is lower than in the atria and the arteries; therefore, the AV valves are open, but the semilunar valves are closed (Figure 47.10a). Once the ventricles are electrically excited, they begin contracting, and the pressure within the ventricles rapidly increases. This marks the beginning of systole. When the pressure in the ventricles exceeds that in the atria, the AV valves are forced closed. Closure of the AV valves makes the "lub" sound of the familiar "lub-dup" heard through a stethoscope. Ventricular pressure continues to rise; when it exceeds the pressure in the arteries, the semilunar valves open (Figure 47.10b). Blood is ejected through the open semilunar valves into the arteries.

Because the ventricular walls are thicker and stronger than the atrial walls, ventricular contractions generate much greater pressure. The pressure exerted by the ventricles on the blood within their cavities causes the AV valves to shut, preventing blood from flowing backward into the atria. This is why the electrical delay that is built into the AV node is important. If the atria and ventricles were excited and contracted at the same



(a) Semilunar valves in nearly closed position

(b) Semilunar valves in opened position

Figure 47.10 **Appearance and function of the semilunar valves.** The four heart valves are sheathlike structures with flaps that open and close, as in this illustration of semilunar valves.

time, the AV valves would close too soon, and the ventricles would not receive their normal volume of blood.

The pressure in the arteries increases during systole. As this is happening, the ventricles begin to return to their resting, unexcited state, and the pressure in the ventricles falls below that in the arteries. The higher pressure in the arteries closes the semilunar valves, which prevents blood from flowing back into the heart. Closure of the semilunar valves creates the second heart sound, "dup," heard through a stethoscope. Throughout systole, meanwhile, the atria continue to fill with blood, which raises the pressure in the atria. Soon the pressure in the atria exceeds that in the relaxed ventricles, and the AV valves open again, bringing a new volume of blood into the ventricles and starting a new diastole.

Blood pressure, which is defined as the force exerted by blood on the walls of blood vessels, is highest in the arteries during systole and lowest during diastole. For this reason, blood pressure is measured with two numbers, the systolic and diastolic pressures. For historical reasons, the units are usually given as mmHg (millimeters of mercury). Blood pressures are highest in mammals and birds and lowest in fishes and invertebrates. For example, a typical blood pressure in humans is around 120/80 mmHg (systolic/diastolic).

An ECG Tracks Electrical Events During the Cardiac Cycle

An **electrocardiogram** (**ECG** or **EKG**) is a medical test used to investigate the function of the heart. An ECG is a record of the electrical potentials between various points on the body. These potentials arise from the electrical signals generated during the cardiac cycle. Sensitive electrodes are placed on the surface of the body to monitor the wave of electricity initiated by the SA node, which travels through the atria, AV node, and ventricles. This procedure works because the body fluids that surround the heart conduct electricity, even the very weak impulses generated by a beating heart.

The trace on an ECG reveals several waves of electrical excitation (Figure 47.11). The first is the P wave, which begins when the SA node fires, and ends when the two atria completely depolarize. The next wave of excitation is a cluster of three waves, called the QRS complex. It begins when the branches from the AV node excite the ventricles, and ends when both ventricles depolarize completely. The final wave is the T wave, which results from the repolarization of the ventricles back to their resting state. The T wave is upward on the ECG tracing because the wave of ventricular repolarization proceeds in the opposite direction of depolarization. No wave is visible

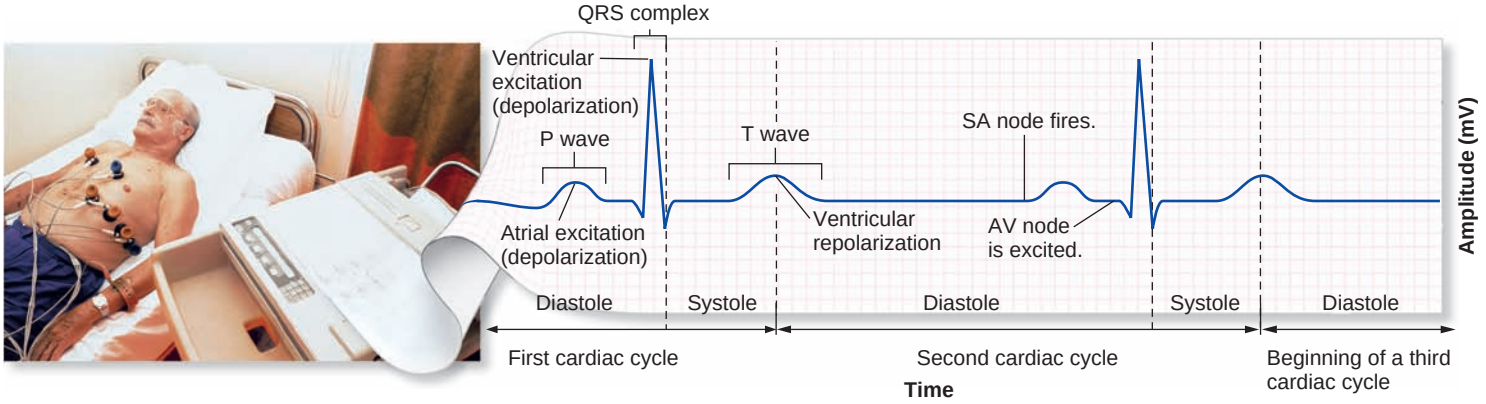


Figure 47.11 **An electrocardiogram (ECG).** Electrodes placed on the skin detect electrical impulses occurring in the heart, and an electrocardiogram visualizes them. The resultant waveform is a useful indicator of cardiac health. Note that the ventricular wave (QRS complex) is taller than the atrial wave (P wave). This is because the ventricles are larger than the atria and generate more electrical activity.

Concept check: *Why is it possible to detect electrical changes in the heart using electrodes placed on the surface of the skin? (Hint: Think about body fluids and their ability to conduct electricity.)*

for atrial repolarization because it occurs simultaneously with the large QRS complex.

The ECG monitor displays both the amplitude (strength) of the electrical signal and the direction that the signal is moving in the chest. From this information, physicians can determine whether a person's heart is generating signals with a normal frequency, strength, duration, and direction.

47.4 Blood Vessels

Now that we have discussed the vertebrate heart, let's examine the vessels that transport blood to and from the heart and throughout the body. Figure 47.12 illustrates the route that blood follows in a closed circulatory system. Blood is pumped by the heart to large arteries and then flows to smaller arteries and eventually to the smallest arteries, called **arterioles**. Arterioles lead the blood to flow through the smallest vessels, which are called **capillaries**. Gas and nutrient exchange occurs between the blood in the capillaries and the cells surrounding the capillaries. The blood then flows back to the heart, leaving the capillaries through the smallest veins, called **venules**, to small veins and, finally, to large veins.

Arteries Distribute Blood to Organs and Tissues

Arteries are thick-walled vessels that consist of layers of smooth muscle and connective tissue wrapped around a single-celled inner layer, the **endothelium**, which forms a smooth lining in contact with the blood (Figure 47.13). Because of the thick layers of tissue surrounding the endothelium, most dissolved substances cannot diffuse across arteries. Instead, arteries act as conducting tubes that distribute blood leaving the heart to all the organs and tissues of an animal's body.

In vertebrates, the walls of the largest arteries, such as the aorta, also contain one or more layers of proteins that have elastic properties (Figure 47.13). As the aorta stretches to accommodate blood arriving from the heart, the elastic proteins also stretch. The thick layers of tissue in the aorta and other large arteries prevent them from stretching more than a small amount. When the heart relaxes as it readies for another beat, the elastic proteins in the aorta and largest arteries recoil to their original state, something like releasing a stretched rubber band. The recoiling vessels generate a force on the blood within them; this helps prevent blood pressure from decreasing too much while the heart is relaxing during diastole.

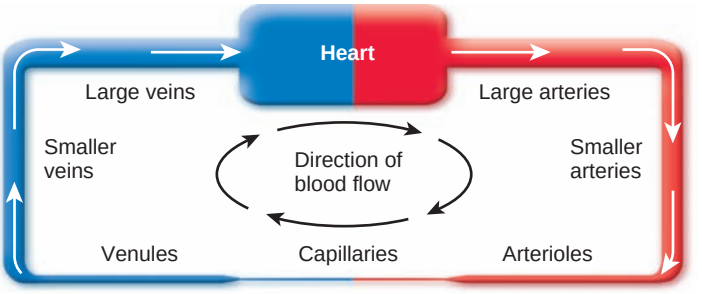

Figure 47.12 Overview of blood flow through vessels in a closed circulatory system. Regions of gas exchange with the environment have been omitted for clarity.

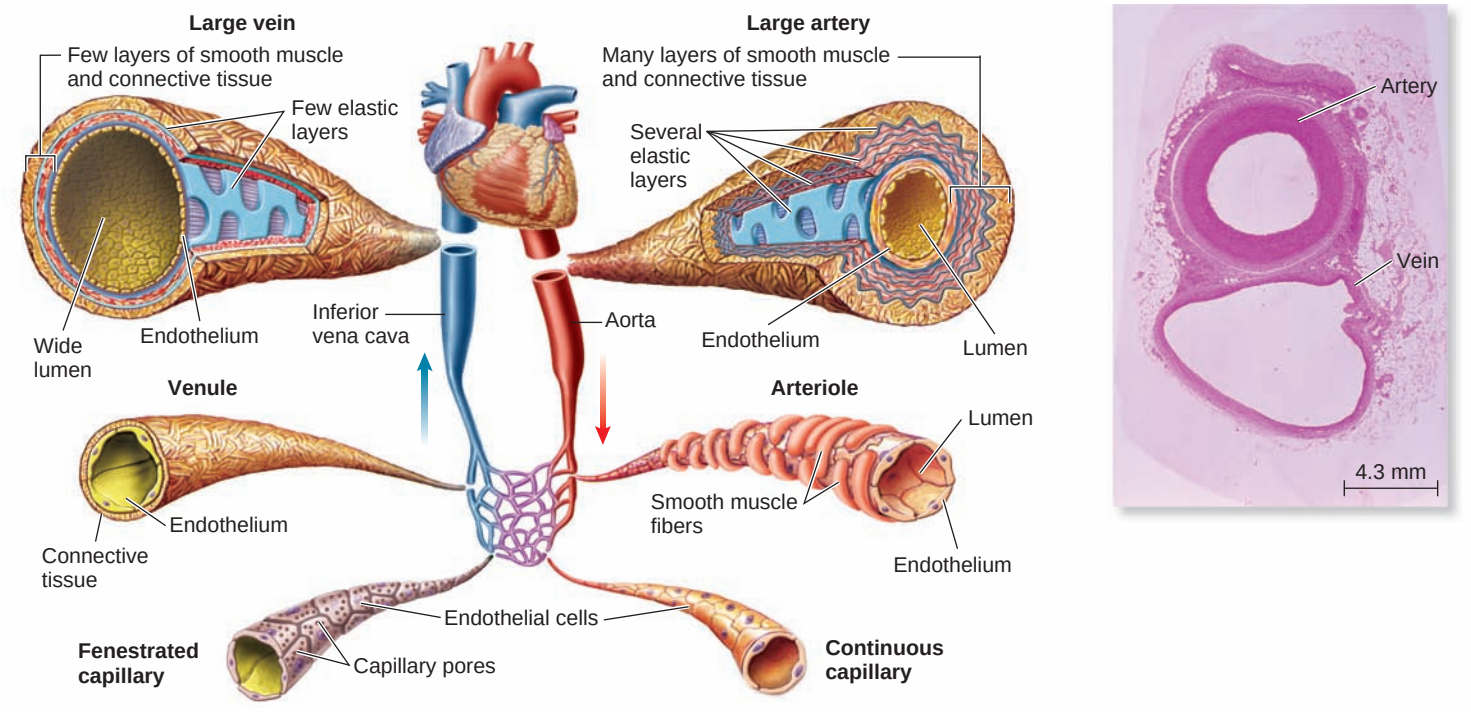

Figure 47.13 Comparative features of blood vessels. Sizes are not drawn to scale. Both types of capillaries are illustrated, but they do not actually appear together in this way. Fenestrated capillaries are typically found in secretory glands, such as the pancreas, or organs where blood is filtered, such as the kidney. Inset: Light micrograph (enlarged four times) of a medium-sized artery near a vein. Note the difference between the two vessels in wall thickness and lumen diameter.

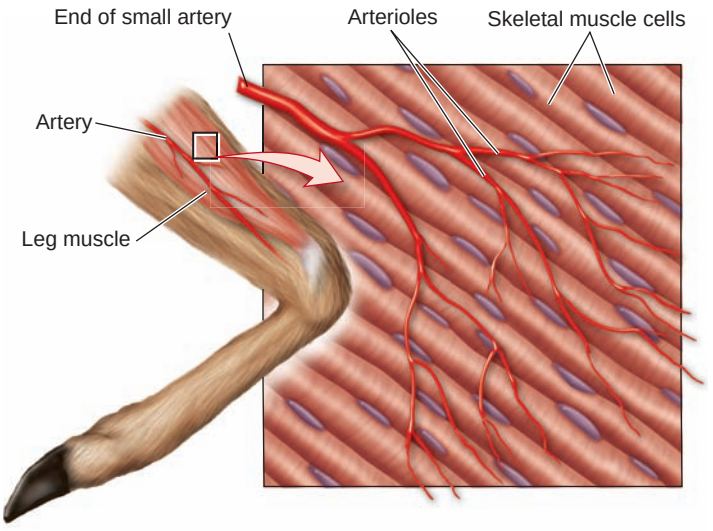

Figure 47.14 **Arteries and arterioles.** Arteries branch into smaller arteries, and into even smaller arterioles, in order to penetrate to all the cells of tissues and organs.

Concept check: *What would happen to the diameter of the arterioles of the animal's leg muscle when the animal is active?*

Arterioles Distribute Blood to Capillaries

As arteries carry blood away from the heart, they branch repeatedly and become narrower to penetrate to the smallest reaches of an organ or tissue (Figure 47.14). Eventually, the vessels are little more than a single-celled layer of endothelium surrounded by one or two layers of smooth muscle and connective tissue (see Figure 47.13). These arterioles deliver blood to the capillaries and distribute blood to regions of the body in proportion to metabolic demands. This is accomplished by changing the diameter of arterioles, such that they widen, or dilate, in areas of high metabolic activity and narrow, or constrict, in inactive regions. Arterioles dilate when the smooth muscle cells around them relax, and they constrict when these cells contract.

Capillaries Are the Site of Gas and Nutrient Exchange

Arterioles branch into the tiny thin-walled capillaries. At the capillaries, materials in the blood are delivered to the other cells of the body, and waste products and secretions from cells are delivered to the blood. Capillaries are tubes composed of a single-celled layer of endothelium resting on an extracellular matrix called a basement membrane.

There are two types of capillaries: continuous and fenestrated. Continuous capillaries have smooth walls and are the most common; fenestrated capillaries contain tiny openings called fenestrations (see Figure 47.13). Because of their fenestrations, such capillaries are much leakier than continuous capillaries. Fenestrated capillaries are found in places such as the vertebrate kidney, where large amounts of plasma are filtered to remove wastes, and in glands such as the pancreas that secrete watery fluids. Capillaries are the narrowest blood vessels in the body; essentially every cell in an animal's body is near one. The diameter of a capillary is about the same as the width of a red blood cell, so erythrocytes move through them in single file (Figure 47.15).

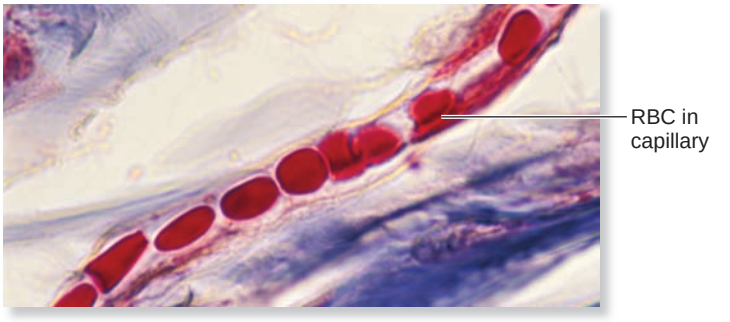

Figure 47.15 **Erythrocytes (red blood cells; RBCs) moving through a capillary in single file, as seen through a light microscope.**

Blood enters capillaries under pressure that is created by the beating of the heart as blood is pumped into the arteries. This pressure forces some of the water in blood out through the fenestrations and other tiny openings in capillary walls into the interstitial fluid (Figure 47.16). These openings are wide enough to permit water and small solutes, including O_2, but not red blood cells and most proteins, to leave the capillary. Once in interstitial fluid, the solutes may diffuse into body cells. Conversely, body cells release secretions and metabolic waste

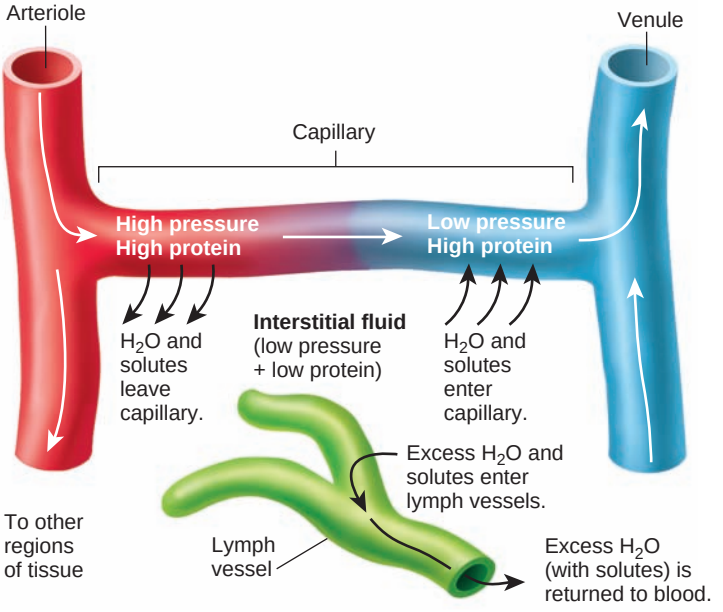

Figure 47.16 **Water movement between capillaries and interstitial fluid.** Water and dissolved solutes (other than proteins) exit capillaries near the arteriolar end because the capillary pressure is much greater than that of the interstitial fluid. As the volume of the water in the capillary decreases, however, the pressure within the capillary also decreases (but remains greater than interstitial fluid). Proteins remaining in the capillary contribute an osmotic force that tends to draw water back into the capillary. The combination of decreased pressure within the capillary and the osmotic force due to the proteins leads to the recapture of much of the water that left the capillary. Lymph vessels drain any excess fluid from the interstitial fluid. For clarity, the system shown here contains a single capillary connecting an arteriole and venule, instead of the typical situation where capillaries divide into numerous branching vessels.

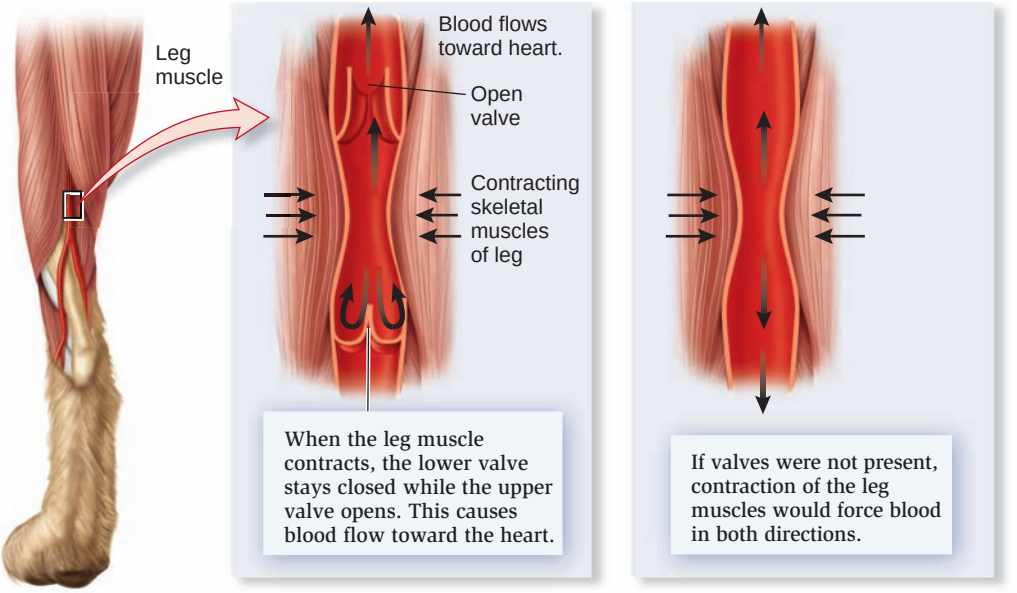

Figure 47.17 One-way valves in veins. Valves are typically present in the limbs, as shown in this dog's leg. **(a)** In some veins, one-way valves assist the return of blood to the heart against the force of gravity. **(b)** Blood moving in a vein without valves would flow in both directions.

Concept check: Unlike most mammals, giraffes have one-way valves in the veins of their long necks. Which way do you think the valves open, toward the heart or toward the head, and why? (Hint: Picture the way a giraffe drinks from a body of water.)

products including CO_2 gas into interstitial fluid, where they diffuse into capillaries to be carried away.

If the water that leaves a capillary were to remain in the interstitial fluid, the volume of plasma in the blood would decrease, and the interstitial fluid would swell. Most of the water that leaves at the beginning of a capillary, however, is recaptured at the capillary's end, for two reasons (Figure 47.16). First, near the arteriole, the blood pressure inside the capillary is higher than the fluid pressure of the surrounding interstitial fluid, which creates a force that moves water out of the capillary. However, by the time blood reaches the end of a capillary, its pressure has decreased considerably, partly as a result of the loss of water. Second, proteins are trapped within the capillary because they are too large to diffuse through the capillary walls or to leak out of the tiny openings. This creates an osmotic force that draws water back into the capillary from the interstitial fluid. Near the end of a capillary, the osmotic force drawing water into the capillary is greater than the pressure forcing water out; therefore, water and dissolved solutes reenter the capillary.

Despite the ability of capillaries to recapture their own fluid, the process is not 100% effective. Another set of vessels, those of the **lymphatic system**, collects excess fluid and returns it to the blood. The lymphatic system is part of the defense mechanisms of the animal body (see Chapter 53).

Venules and Veins Return Blood to the Heart

Once blood travels through capillaries, picking up any substances secreted from the cells of the body, it enters the venules, small, thin-walled extensions of capillaries. The venules empty into the larger veins that return blood to the heart. The largest of these veins are the vena cavae. In humans, the superior vena cava drains body tissues above the heart, while the inferior vena cava drains those below the heart. The walls of veins are much thinner, less muscular, and more easily distended or stretched than those of arteries (see Figure 47.13).

By the time blood has traveled through the capillaries and reached the veins, the pressure of the blood is very low. Consequently, veins can fill with considerable volumes of blood, particularly veins in the lower parts of an animal's body, such as the legs, where gravity tends to cause blood to pool. Several factors assist the blood on its way toward the heart when flowing against gravity. One factor is stimulation of the contraction of smooth muscle in leg veins by the sympathetic nervous system, which compresses the veins and helps force blood back to the heart. Another factor is the activity of skeletal muscles in the limbs that assists the return of venous blood to the heart. For example, each time the leg skeletal muscles contract, they squeeze the veins passing through them (Figure 47.17). This alone would not move blood upward toward the heart, though, because each time a vein is squeezed, blood could be forced both up and down. This does not happen because one-way valves inside veins ensure that blood returning from below the heart moves in only one direction, toward the heart. By contrast, veins located above the heart, like those in the necks of bipeds and some quadrupeds, lack valves because gravity pulls blood toward the heart.

Many people can easily observe the effects of gravity on venous blood flow. When the arms are held down by their side, the veins are visible on the backs of their hands. When the arms are raised above the head, the bulging veins quickly lose blood and become less visible. When blood from the veins returns to the heart, it must travel against gravity when your arms are at your side and with gravity when your arms are elevated. Blood drains from veins much more efficiently when gravity works in its favor.

47.5 Relationships Between Blood Pressure, Blood Flow, and Resistance

Blood pressure is responsible for blood flow, or moving blood through the vessels. It is not the same in all regions of an animal's body, however, because of resistance. **Resistance** (**R**) refers to the tendency of blood vessels to slow down the flow of blood through their lumens. As we saw earlier, the blood pressure in arteries is much higher than in veins. For this reason, we

generally speak only of arterial pressure when discussing blood pressure. The relationships between blood pressure, blood flow, and resistance can be considered on two levels, local and systemic, as we see next.

Resistance Determines Local Blood Pressure and Flow

The physical characteristics of a blood vessel determine the amount of blood that flows through it and how fast that blood flows. This affects how much blood reaches particular areas of the body at any given time. For example, the diameter of different blood vessels can be increased or decreased to change the amount of blood flowing through them. As stated earlier, the ability to distribute blood to different parts of the body in amounts proportional to that body part's metabolic requirements is a key adaptation of closed circulatory systems.

Resistance Resistance is a function of three variables: vessel radius, length, and blood viscosity. Wide, short tubes provide less resistance to flow than narrow, long tubes. Resistance is increased by the blood's viscosity, which is a measure of the blood's hematocrit. A high hematocrit increases the blood's viscosity—it makes the blood more sludgelike—and hinders its smooth flow through vessels.

The relationship between blood pressure, flow, and resistance is stated by Poiseuille's law, which was derived in the 1840s by Jean Marie Louis Poiseuille, a French physician and physiologist. His law is simplified here:

$$\text{Flow (F)} = \Delta \text{ Pressure (P)}/\text{Resistance (R)}$$

Stated mathematically, blood flow through a blood vessel is directly proportional to the difference (Δ) in pressure of the blood at the beginning and end of the vessel, and inversely proportional to the resistance created by that vessel. Changes in any of these three variables determine how much blood flows through different body regions at any moment. The equation can be rearranged as $\Delta P = F \times R$, which demonstrates that blood pressure depends on both blood flow and resistance. Poiseuille's law applies to blood flow through a single vessel, an organ, or the entire body.

Vasodilation and Vasocontriction Changes in arteriolar resistance are the major mechanism for increasing or decreasing blood flow to a region. In the short term, the length of an arteriole and the viscosity of blood do not normally change. Therefore, the radii of arterioles become the most important factor in determining minute-to-minute resistance.

The relationship between arteriolar radius and resistance is not linear. Resistance is inversely proportional to the radius of the vessel raised to the fourth power: $R \propto 1/r^4$, where $\propto$ means "proportional to," and r is the radius of the arteriolar lumen. Let's consider an arteriole with a radius that increases by a factor of two. This would occur if the smooth muscles around the arteriolar wall relax sufficiently to allow the vessel to dilate and double its original radius. Because resistance is inversely proportional to the fourth power of vessel radius, an increase in radius by a factor of two will result in a decrease in resistance of 2^4 ($2 \times 2 \times 2 \times 2$), or 16-fold.

Vasodilation refers to an increase in blood vessel radius, and **vasoconstriction** refers to a decrease in blood vessel radius. The signals that control arteriolar radius come from three sources, including locally produced substances, hormones, and nervous system inputs. Locally, metabolic by-products such as carbon dioxide and lactic acid, as well as potassium ions and other substances secreted by metabolically active tissues, cause nearby arterioles to vasodilate immediately. According to Poiseuille's law, this permits more blood flow to the active region, facilitating oxygen and nutrient delivery and waste removal. Hormones secreted by glands throughout the body can also regulate arteriolar radius. For example, some hormones cause arterioles that deliver blood to the small intestine to vasoconstrict during fight-or-flight responses, routing blood away from the intestine and to areas of more immediate need such as the heart and skeletal muscles. Finally, smooth muscle cells that make up the outer wall of arterioles receive inputs from nerves that can stimulate the muscles to contract or relax. One of the most important regulators of blood vessel diameters, however, is a gas, as we see next.

Feature Investigation

Furchgott Discovered a Vasodilatory Factor Produced by Endothelial Cells

As we have seen, the cells surrounding blood vessels can produce ions, acids, and gases that diffuse to arteriolar smooth muscle cells and cause these cells to relax and vasodilate. Beginning in the 1970s, American biochemist Robert Furchgott provided evidence that an unidentified substance released from within an artery—that is, from the endothelial lining of the vessel—also played a key role in regulating blood vessel radius.

For many years, Furchgott had used flattened strips of rabbit aorta in a culture bath to test whether various compounds stimulated or inhibited contraction of the smooth muscle in the artery. Although large arteries such as the aorta do not show the dramatic vasodilation and vasoconstriction that arterioles do, they were more useful in experiments because of their larger size.

One of the compounds he tested was the neurotransmitter acetylcholine (ACh). Scientists knew at the time that when ACh is injected into an animal, it causes vasodilation by relaxing smooth muscle in arterioles. However, in Furchgott's in vitro preparations, ACh caused the flattened strips of artery to contract. To determine if this apparent paradox could be the result of the method in which the tissues were prepared for in vitro tests, Furchgott compared the effects of ACh in different types of preparations. He discovered that ACh produced muscle relaxation when applied to circular rings of aorta, as described in step 1 in Figure 47.18.

How did Furchgott explain that the muscle contracted when ACh was applied to the flattened strips of aorta? After examining

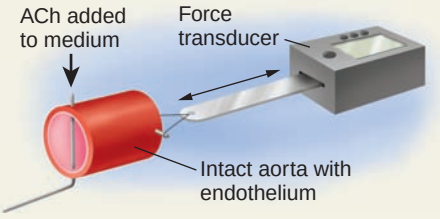
Figure 47.18 Furchgott's discovery that endothelial cells produce a vasodilating substance.

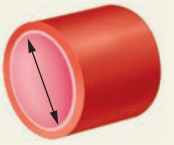
HYPOTHESIS The endothelium of arteries produces a vasodilatory substance.

KEY MATERIALS Strips or rings of rabbit aorta, force transducers, acetylcholine.

Experimental level | **Conceptual level**

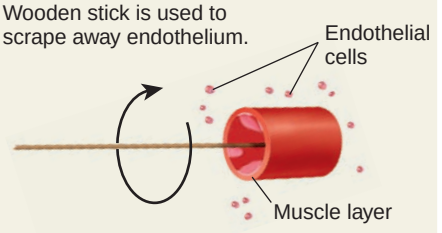
1 Attach a ring of aorta to a pressure gauge. Add acetylcholine (ACh) to bath medium. Record change in force (increased force = increased muscle contraction; decreased force = decreased muscle contraction).



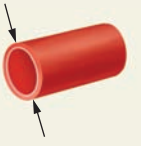


In the presence of endothelium, ACh relaxes the muscles of the aorta, causing the vessel to widen.

2 Denude ring of its endothelium. The muscle layer is left behind. Retest effect of ACh.

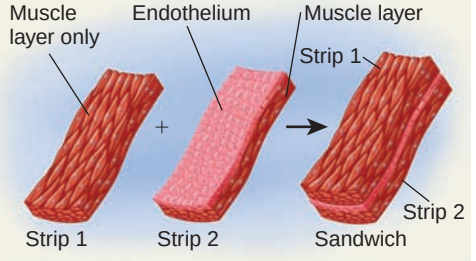


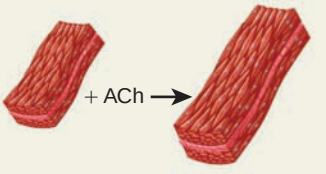
The denuded ring is then placed in recording apparatus as before.



In the absence of endothelium, ACh stimulates the muscles to contract, which narrows the vessel.

3 Perform "sandwich" experiment by combining denuded strip of aorta with an intact strip. Record effect of ACh on strip 1 alone, strip 2 alone, and strip 1 while part of a sandwich with strip 2.

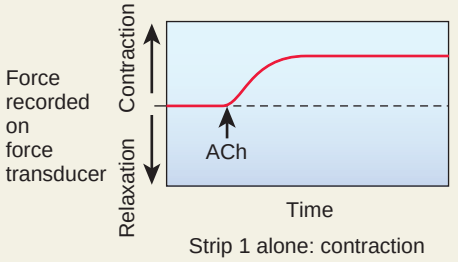




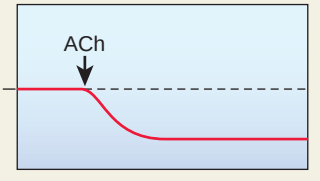
Endothelium produces a vasodilating substance following ACh treatment that diffuses from strip 2 to strip 1, and causes strip 1 to relax.

4 THE DATA

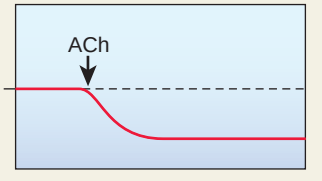
Results of sandwich experiment



Strip 1 alone: contraction



Strip 2 alone: relaxation



Strip 1 recorded while attached to strip 2: relaxation

5 CONCLUSION Endothelial cells release a factor that diffuses to the surrounding smooth muscle, causing it to relax. Relaxation of the vascular smooth muscle causes dilation of the blood vessel.

6 SOURCE Furchgott, R.F., and Zawadzki, J.V. 1980. The obligatory role of the endothelium in the relaxation of arterial smooth muscle by acetylcholine. *Nature* 288:373–376.

the two preparations of tissue, Furchgott realized that the lining of endothelial cells along the inner wall of the vessel had been scraped away during preparation of the strips, but the endothelial lining was still present in the rings. He hypothesized that the endothelial cells must produce a factor whose secretion was stimulated by ACh, and that not only prevented contraction, but even caused smooth muscles surrounding the blood vessel to relax. If so, this would explain the observation that when ACh was injected into rabbits, it resulted in vasodilation, because the intact vessels of the animals contained their endothelial lining and thus resembled Furchgott's aortic rings.

To test his hypothesis, Furchgott performed two experiments. As shown in step 2 of Figure 47.18, he used a wooden rod to scrape away the endothelium from circular rings of aorta and discovered that the relaxation effect of ACh was lost, as predicted. In step 3, he used a sandwich technique, in which he tested the effects of ACh on muscle contraction in a "denuded" strip of artery with the endothelium removed, and then again on the same strip, which was attached ("sandwiched") to another strip in which the endothelium remained intact. When ACh was added to the water bath before the sandwich was formed, the denuded strip contracted, as expected. When the denuded strip was attached to the intact strip in such a way that its muscle layer was exposed to the intact strip's endothelial surface, the denuded strip relaxed after ACh was added. This was consistent with the hypothesis that the endothelium released a vasodilatory factor that diffused to the denuded strip and relaxed its muscles.

Two other scientists, Americans Louis Ignarro and Ferid Murad, later determined that this factor was the gas nitric oxide (NO). The discovery of this function of NO revealed a new category of signaling molecules. Ignarro and Murad also revealed that nitroglycerin, which had for many years been used to treat patients with cardiovascular disease, acted by generating NO in the blood to produce vasodilation and lower blood pressure. Today NO is considered one of the most potent and important naturally occurring vasodilators in animals. Knowledge of the NO signaling pathway has led to new therapies for treating a wide variety of health disorders associated with blood vessels, including high blood pressure, glaucoma (an eye disease), and erectile dysfunction (see Chapter 51). For their efforts, Furchgott, Ignarro, and Murad shared the 1998 Nobel Prize.

Experimental Questions

1. What observation did Furchgott make when testing the effects of acetylcholine on different treatments of rabbit aorta? How did he explain the results?
2. Based on his observations of the effects of acetylcholine on different preparations of rabbit aorta, what hypothesis did Furchgott propose to explain the relationship of acetylcholine and vasodilation? How did he test this hypothesis?
3. What did Furchgott conclude based on his results?

Cardiac Output and Resistance Determine Systemic Blood Pressure and Flow

Because blood vessels provide resistance to blood flow, the heart must beat forcefully enough to overcome that resistance throughout the whole body. **Cardiac output** (**CO**) is the amount of blood the heart pumps per unit time, usually expressed in units of L/min. Poiseuille's law can be adapted to the whole body. In this case, pressure refers to arterial blood pressure (BP) recorded using a blood pressure cuff, flow refers to CO, and resistance refers to the sum of all the resistances in all the arterioles (**total peripheral resistance**, or **TPR**). Thus, we have BP = CO × TPR. The CO and TPR determine the pressure the blood exerts in the arteries of a closed circulatory system. Let's examine these variables in more detail.

Cardiac Output The cardiac output depends on the size of an animal's heart, how often it beats each minute, and how much blood it ejects with each beat. Each beat, or stroke, of the heart ejects an amount of blood known as the **stroke volume** (**SV**) that is roughly proportional to the size of the heart (Table 47.1). Thus, if we know the stroke volume of a heart and can measure the heart rate (HR: the number of beats per minute), we can determine the CO. Simply put, CO = SV × HR.

Naturally, the CO of an elephant is far greater than that of a mouse, a sparrow, or a salmon. Typically, heart size varies in proportion to body mass within a given class of vertebrates, with birds and mammals having larger hearts than do similarly sized fishes, amphibians, or reptiles. Note in Table 47.1 that heart rate decreases as mammals get larger, but heart mass and stroke volume increase roughly in proportion with body mass. Similar relationships are observed in other vertebrates, notably birds. Smaller animals have smaller hearts and, therefore, smaller stroke volumes. The heart of a typical shrew, for example, is the size of a small pea, whereas the heart of a blue whale is as large as a cow. Their stroke volumes are similarly proportioned. However, small animals have faster heart rates than do large animals. A hummingbird's or shrew's resting heart rate may be more than 800

Table 47.1 Comparative Features of Representative Mammalian Hearts

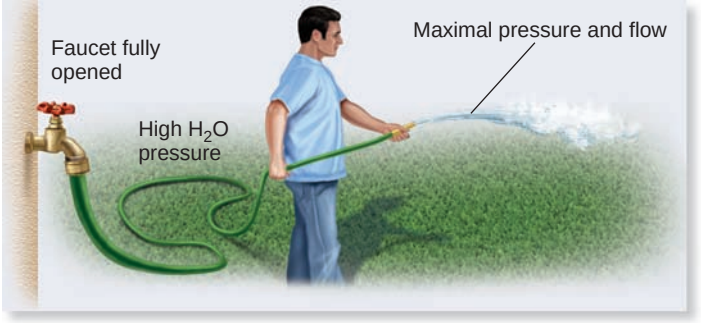
Animal	Body mass* (kg)	Heart mass* (kg)	Stroke volume* (L)	Heart rate* (bpm)†
Shrew‡	0.0024 (2.4 g)	0.000035 (35 mg)	0.000008 (8 µl)	835
Rat	0.20	0.001	0.0018	360
Dog	23	0.12	0.025	95
Human	75	0.38	0.075	70
Elephant	4,000	25	4.0	25
Blue whale	100,000	600	100	10

*Values are based on average body masses and resting conditions. In some cases, stroke volumes are estimates based on heart size. †bpm = beats per minute. ‡The shrew reported here is the Etruscan shrew, one of the smallest known mammals. Its heart is somewhat larger than would be predicted for its body mass. Note its heart rate; at 835 bpm, the heart beats 14 times per second!

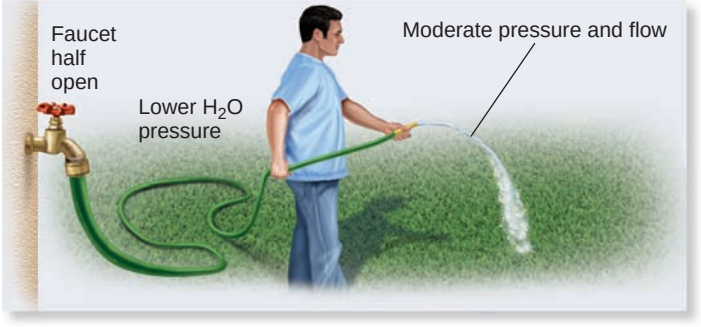
beats per minute, whereas a blue whale's heart may beat only 10 times per minute (although the amount of blood ejected with each of those beats is enormous!). Recall from Chapter 46 that metabolic rate is relatively greater in smaller animals. The higher heart rates of small animals give them a greater cardiac output than would be predicted for the size of their hearts, which helps them meet the extraordinary oxygen and nutrient demands of such highly metabolic organisms.

Systemic Blood Pressure The greater the cardiac output and the higher the resistance to blood flow, the higher will be the blood pressure. Imagine that the circulatory system is like a faucet (the heart) connected to a garden hose (the arteries) (Figure 47.19). If the faucet is fully open, analogous to maximal cardiac output, and the hose is not blocked, analogous to low arteriolar resistance, the amount of water rushing into the hose will be high and so will the water pressure, representing blood pressure. If the faucet is only partially open, the water pressure will be lower. However, now imagine that the faucet is partially open but the end of the hose is constricted, representing a region of high arteriolar resistance. In that case, the pressure of the water in the hose will increase between the faucet and the point where the hose is squeezed, and will decrease beyond the constriction, as will the flow of water (representing blood).

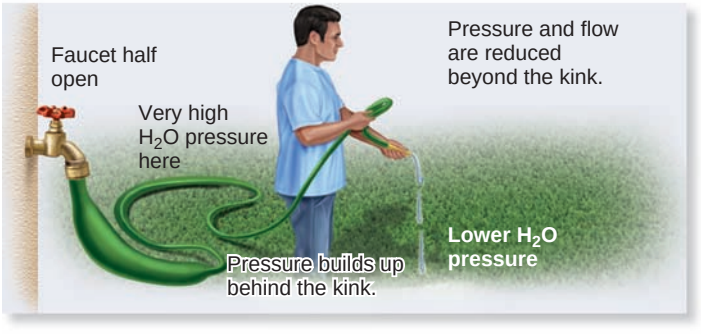
Arterial blood pressure, therefore, is a function of how hard the heart is working and how constricted or dilated the various arterioles are. Blood pressure must be high enough for blood to reach all body tissues even at the farthest extremities but not high enough to damage blood vessels or force excess plasma out of capillaries. Blood pressure is roughly similar among mammals. Although species differences exist, they are not as diverse as, for example, species differences in heart rates. Blood pressure is relatively low in nonmammalian vertebrates and in invertebrates.



(a) Maximal cardiac output with low resistance



(b) Moderate cardiac output with low resistance



(c) Moderate cardiac output with high resistance

Figure 47.19 An analogy for how cardiac output, resistance, and blood pressure are related. A hose analogy shows the way in which cardiac output (the faucet) and resistance (constriction of the hose) impact blood pressure.

47.6 Adaptive Functions of Closed Circulatory Systems

A circulatory system must not only pump blood and return it to the heart, it must also adapt to changes, including sleep, activity, and emergencies such as blood loss or dehydration. In this section, we examine how changes in the circulatory system help maintain cardiovascular activity during exercise and when an animal experiences a change in blood pressure.

Circulatory Function Adapts to Exercise

Nearly all animals have periods of rest and activity. Therefore, the activity of the heart must adjust to fluctuating metabolic demands. For this reason, blood must be sent to different areas in proportion to their requirements for oxygen and nutrients. Exercise provides a dramatic illustration of rapid changes in circulatory function.

We often think of exercise as voluntary. In nature, exercise means an increase in locomotion for any reason. Typically, an animal exercises when it needs something, such as food or shelter, or when it is escaping something, such as a predator. The increased activity may be momentary and moderate, as when a fish briefly swims faster to avoid the tentacles of an anemone, or it may last longer and be more intense, as when a cheetah sprints after a gazelle. Exercise may last for very long periods of time, as when a salmon migrates from the sea to its freshwater spawning grounds or a migratory goose flies thousands of miles over several weeks. The circulatory systems of animals must quickly adapt to these increased metabolic demands and adjust to the intensity, duration, and type of exercise.

We have already noted some adjustments, such as vasodilation and vasoconstriction. These are the result of changes in the radius of arterioles. During exercise, these vessels vasodilate in regions that require more energy and oxygen—for example, skeletal muscles and the heart—and vasoconstrict in areas that require less energy and oxygen, such as the gut.

In addition, cardiac output increases during exercise to supply more blood to the tissues that require it. This happens by increasing stroke volume or heart rate, or both. Fishes typically increase stroke volume more than heart rate, whereas birds and mammals do the opposite. In humans, for example, stroke volume increases from approximately 75 mL (milliliters) at rest to 110 mL during exercise, a change of 1.5-fold, and heart rate can almost triple from about 70 bpm to nearly 200 bpm. Thus, the combined effects of increasing stroke volume and heart rate raise the cardiac output by about 4.5-fold.

Whichever way cardiac output increases, one of the major mechanisms involved is an increase in blood levels of epinephrine, also known as adrenaline. **Epinephrine** is a hormone secreted by the adrenal glands, which are activated by the sympathetic nervous system during exercise. Epinephrine binds to receptors on heart ventricular muscle cells, making them contract more vigorously, thereby increasing stroke volume. In addition, epinephrine binds to receptors in the atrial SA node cells, stimulating them to initiate electrical signals at a faster rate, thereby increasing heart rate. The latter effect of epinephrine is enhanced by the release of the neurotransmitter **norepinephrine** (or noradrenaline) directly from sympathetic nerve endings onto the SA node cells.

At rest, the heart does not pump out its entire content of blood. A reservoir of blood remains in each ventricle at the end of a beat. During exercise, some of this reservoir is tapped when epinephrine stimulates the heart muscles. In addition, the mechanical process of exercise itself enhances the return of blood to the heart, as skeletal muscles squeeze the veins within them and open their one-way valves. The combination of more blood getting returned to the heart and the enhanced emptying of the built-in reservoir of blood from the ventricles provides increased stroke volume during exercise.

Because BP equals CO $\times$ TPR, you might imagine that increased cardiac output would raise blood pressure to possibly harmful levels during exercise. Although blood pressure does increase somewhat, it does not rise as much as you might predict. This is because the blood vessels of skeletal muscles dilate (that is, resistance is decreased) to allow more blood to enter; similarly, the vessels in the skin of terrestrial animals dilate as a means of dissipating heat. Therefore, even though CO increases in exercise, the total peripheral resistance in the body decreases, negating some of the effect on blood pressure.

Regular, long-term exercise induces additional adaptive responses in the circulatory system. For example, the thickness of the muscle of the ventricles of the human heart is greater in athletes than in sedentary individuals, which makes the athletic heart a more efficient pump.

Baroreceptors Maintain Blood Pressure

How do vertebrate circulatory systems adapt to changes in blood pressure? Within the walls of certain arteries, notably the aorta and the carotid arteries, are pressure-sensitive regions that contain the endings of neurons. These neurons, known as **baroreceptors** (from the Greek *baros*, weight or pressure), are in constant communication with the brain (Figure 47.20).

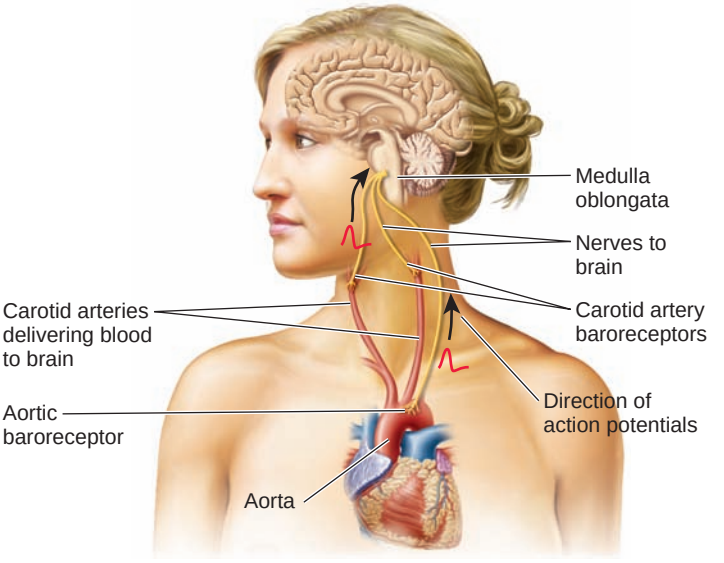


Figure 47.20 **Location of the major baroreceptors.** Increased blood pressure stretches arteries. This activates baroreceptors in the arteries, which send action potentials to the medulla oblongata in the brain. Nerve signals from the brain then initiate changes in heart function and total peripheral resistance that help restore blood pressure to normal.

Concept check: *In Chapters 41–43, we discussed the different types of ion channels found in neurons and the ways in which such channels open and close. What type of channels would you expect to be activated when baroreceptors are stimulated?*

If blood pressure increases above the normal range, these large arteries stretch more than normal as a result; this makes the endings of the baroreceptors stretch, too. The stretching of the baroreceptors opens ion channels in the cell membrane, resulting in the generation of action potentials. Nerves carry the signals to the brain, which interprets this as a signal that blood pressure is above normal. The response is a decrease in the amount of norepinephrine released from neurons of the autonomic nervous system onto the cardiac SA node, and a decrease in the secretion of epinephrine from the adrenal glands. The result is a decreased heart rate and stroke volume, resulting in lower cardiac output. In addition, nerves throughout the body release less vasoconstricting neurotransmitters from their neurons onto the smooth muscle cells of arterioles, thereby promoting vasodilation and reducing total peripheral resistance. The combination of decreased cardiac output and decreased resistance lowers blood pressure toward normal. Elevations in blood pressure are not common in animals, but when it occurs in humans, it can have serious medical consequences (see Section 47.7 of this chapter).

By contrast, if blood pressure falls below normal, the walls of these arteries would be less stretched than they normally are, and the baroreceptors would send fewer impulses to the brain. This results in a sequence of events that are opposite to those just described. More norepinephrine and epinephrine are secreted, thereby increasing cardiac output and vasoconstriction and consequently increasing blood pressure toward normal. One situation in which blood pressure might decrease is

dehydration, which is a reduction in the amount of water in the body. Because blood is mostly water, dehydration reduces blood volume, and arteries—including those that contain baroreceptors—are filled with less blood than normal. Blood pressure could also drop due to **hemorrhage**, loss of blood from a ruptured blood vessel. Dehydration is primarily a problem for terrestrial animals, but hemorrhage may occur in any animal that has been injured. In a hemorrhage, both plasma and blood cells are lost; therefore, hemorrhage may be more serious than dehydration. Like dehydration, though, hemorrhage results in reduced blood volume and therefore less baroreceptor activity.

Without baroreceptors, the circulatory system would have no means of relaying information about its status to the brain, and the brain would be unable to initiate compensatory actions to maintain normal pressure. Baroreceptors even mediate nearly instantaneous adjustments to blood pressure, such as when you jump up quickly from a reclining position. Upon standing suddenly, gravity causes more blood to pool in the lower legs, temporarily reducing the volume and pressure of blood reaching the brain. This is why you may sometimes feel woozy when you stand up quickly. Baroreceptors immediately detect the change in pressure in your neck arteries, however, and cardiac output is rapidly increased to bring pressure back to normal until the system stabilizes.

47.7 Impact on Public Health

Cardiovascular disease—conditions affecting the heart and blood vessels—accounts for more deaths each year in the U.S. than any other cause, making it one of the most intensely researched areas of human health. Why is cardiovascular disease so devastating? One reason is that damage to these structures often occurs slowly, over many years, and without symptoms until the disease has reached late stages. In this section, we will consider several common cardiovascular disorders and their causes and treatments.

Systemic Hypertension and Atherosclerosis May Cause Heart and Blood Vessel Disease

Systemic hypertension, often called hypertension or high blood pressure, refers to an arterial blood pressure that is chronically above normal. The normal range in humans varies from systolic/diastolic pressures of about 90/60 to 120/80 mmHg. A resting blood pressure above 140/90 mmHg defines hypertension, and values between 140/90 and 120/80 mmHg are considered borderline (sometimes called "prehypertension"). Hypertension can have many causes, including obesity, smoking, aging, kidney disease, excess male hormones, and genetic factors, although in many cases, the cause is unknown. It can often be treated with diet and exercise and with drugs that cause vasodilation, thereby reducing arterial resistance.

Systemic hypertension rarely has any noticeable symptoms. For this reason, it is important to have your blood pressure checked regularly. Systemic hypertension is dangerous because it

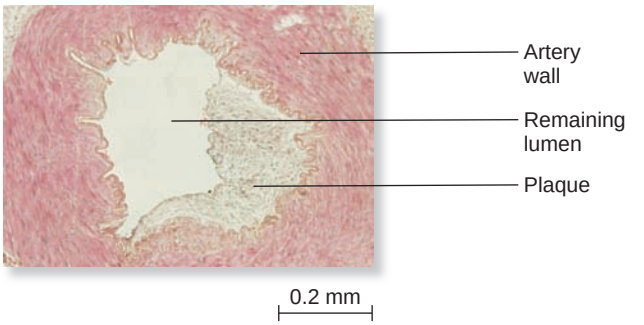

Figure 47.21 An atherosclerotic plaque in an artery. Compare this with the normal artery shown in the micrograph in Figure 47.13.

can damage arteries, contributing to the formation of **plaques**—deposits of lipids, fibrous tissue, and smooth muscle cells—inside arterial walls and leading to a condition known as **atherosclerosis** ("hardening of the arteries") (Figure 47.21). Large plaques may occlude (block) the lumen of the artery entirely. In addition to hypertension, plaques are known to arise from a variety of factors, including calcium and fat deposits, and are correlated with obesity, high blood cholesterol levels, and smoking.

If plaques form in any artery, the regions of the body supplied with blood by that artery receive less oxygen and nutrients. Although atherosclerosis is dangerous anywhere, it is especially significant if it affects the **coronary arteries**, which carry oxygen and nutrients to the thick heart muscle. **Coronary artery disease** occurs when plaques form in the coronary vessels, and it can be life-threatening. One warning sign of coronary artery disease is **angina pectoris**, chest pain during exertion due to the heart being deprived of oxygen.

Myocardial Infarction Results in Death of Cardiac Muscle Cells

If a region of the heart is deprived of blood for an extended time, the result may be a **myocardial infarction** (**MI**), or **heart attack**. This is usually caused by a blockage of one of the coronary arteries. Some heart attacks are relatively minor; in fact, the discomfort of a small heart attack may not even alarm someone enough to seek medical attention. However, more serious heart attacks can lead to significant damage or death of part of the heart muscle. Dead cardiac muscle tissue does not regenerate, diminishing the heart's ability to pump. As noted earlier, reduced pumping activity of the heart—notably the left ventricle—can result in congestive heart failure. As noted in the chapter introduction, each year in the U.S., more than 1 million people suffer a heart attack, and about 40% of them are fatal.

Preventing a heart attack in the first place is the best way to increase survival rates. Procedures are available that allow physicians to monitor the status of the coronary vessels in people suspected of having heart disease. The coronary vessels can be visualized by injecting a dye into a person's veins and then taking an X-ray image of the chest, allowing a physician to determine if the vessels are narrowed by disease. This procedure is called cardiac angiography.

If problems with the coronary arteries are found, several common treatments can restore blood flow through a blood

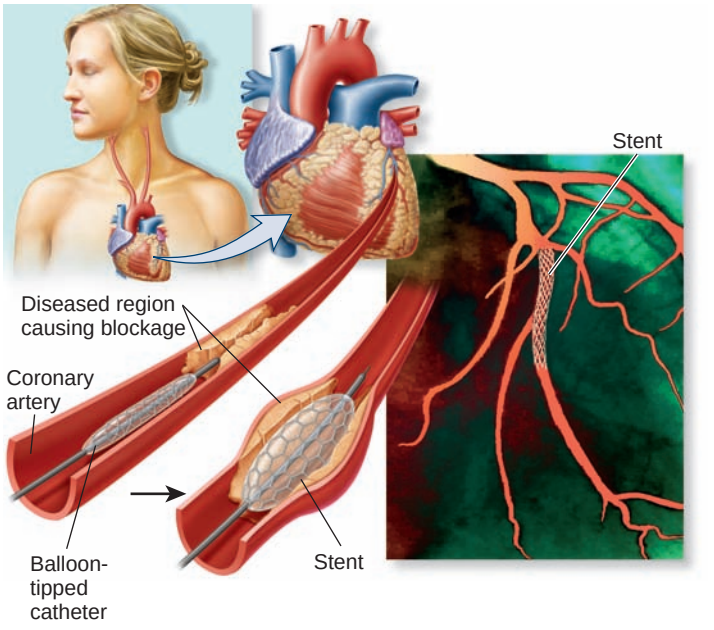

Figure 47.22 **A treatment for blocked blood vessels.** Balloon angioplasty can widen diseased arteries, followed by insertion of a stent. The inset shows a stent placed in a coronary artery of a human patient.

vessel. One is **balloon angioplasty**, in which a thin tube with a tiny, inflatable balloon at its tip is threaded through the artery to the diseased area. Inflating the balloon compresses the plaque against the arterial wall, widening the lumen. In most cases, a wire-mesh device called a stent is inserted into the diseased artery after angioplasty has expanded it, providing a sort of lattice to hold the artery open (Figure 47.22). A treatment for more serious coronary artery disease is a **coronary artery bypass**, in which a small piece of healthy blood vessel is removed from one part of the body and surgically grafted onto the coronary circulation in such a way that blood bypasses the diseased artery.

Summary of Key Concepts

47.1 Types of Circulatory Systems

- Circulatory systems transport necessary materials to all cells of an animal's body and transport waste products away from cells. The three basic types of circulatory systems are gastrovascular cavities, open systems, and closed systems.
- Cnidarians and some flatworms have a gastrovascular cavity that serves two functions: digestion of food and circulation of water containing the digested food. (Figure 47.1)
- An open circulatory system contains three components: hemolymph, vessels, and one or more hearts. The vessels open into the animal's body cavity. (Figure 47.2)
- In a closed circulatory system—found in earthworms, cephalopods, and all vertebrates—blood and interstitial fluid are physically separated by blood vessel walls and differ in their components and chemical composition. (Figure 47.3)
- The closed circulatory systems of vertebrates can be divided into single or double circulations. In the double circulation of crocodiles, birds, and mammals, oxygenated and deoxygenated blood are completely separated into the systemic circulation and pulmonary circulation. (Figure 47.4)

47.2 Blood and Blood Components

- Blood is a fluid connective tissue consisting of cells and (in mammals) cell fragments suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules. Blood has four components: plasma, leukocytes, erythrocytes, and platelets or thrombocytes. (Figures 47.5, 47.6, 47.7)

47.3 The Vertebrate Heart and Its Function

- All vertebrate hearts have at least one atrium and one ventricle. In hearts with more than one atrium or ventricle, connective tissue separates the atria and ventricles. Blood enters the atria from systemic or pulmonary veins, moves down a pressure gradient through the AV valves into the ventricles, and is pumped out through the semilunar valves into the systemic and pulmonary arteries. (Figure 47.8)
- Many arthropods and decapod crustaceans have a neurogenic heart that cannot beat on its own; all vertebrates have a myogenic heart, which beats on its own without electrical stimulation, but which can be regulated by the nervous system.
- The electrical signals of myogenic hearts are generated either at the junction of the veins and the single atrium (in fishes) or at the sinoatrial (SA) node (in other vertebrates). The electrical impulses spread through the atria and ventricles and stimulate the heart muscle to contract. The cardiac cycle has two phases, diastole and systole. (Figures 47.9, 47.10, 47.11)

47.4 Blood Vessels

- Arteries are thick-walled vessels that carry blood away from the heart. Arterioles distribute blood to capillaries, and capillaries are the site of gas and nutrient exchange. (Figures 47.12, 47.13, 47.14, 47.15, 47.16)
- Blood leaving the capillaries empties into venules and then into veins, which return it to the heart. One-way venous valves help to return blood to the heart. (Figure 47.17)

47.5 Relationships Between Blood Pressure, Blood Flow, and Resistance

- Blood pressure is the force exerted by blood on the walls of blood vessels, and it is responsible for moving blood through the vessels. Resistance refers to the tendency of blood vessels to slow down the flow of blood through their lumens.
- Local blood flow through a vessel is directly proportional to the pressure of the blood entering the vessel and inversely proportional to the resistance created by that vessel. Arteriole radius is the major factor that regulates resistance. The endothelium of arteries produces a vasodilatory substance. (Figure 47.18)
- Cardiac output overcomes resistance to generate systemic blood pressure. Cardiac output depends on the size of an animal's heart, how often it beats each minute, and how strongly it contracts with each beat. (Table 47.1)
- Cardiac output and total peripheral resistance determine blood pressure: $BP = CO \times TPR$. Blood pressure must be high

enough for blood to adequately reach all body tissues and cells, but not so high as to damage blood vessels. (Figure 47.19)

47.6 Adaptive Functions of Closed Circulatory Systems

- The circulatory system adjusts to fluctuating metabolic requirements through changes in cardiac output, vasodilation, and vasoconstriction. Baroreceptors maintain blood pressure by relaying information about circulatory system status to the brain, which initiates compensatory mechanisms. (Figure 47.20)

47.7 Impact on Public Health

- Cardiovascular disease accounts for more deaths each year in the U.S. than any other cause. Cardiovascular conditions include systemic hypertension, atherosclerosis, coronary artery disease, angina pectoris, and myocardial infarction (MI, or heart attack). (Figure 47.21)
- Cardiovascular diagnostic techniques and treatments include cardiac angiography, balloon angioplasty, and coronary artery bypass. (Figure 47.22)

Assess and Discuss

Test Yourself

1. Hemolymph differs from blood in that it
   a. does not contain blood cells.
   b. is a mixture of fluid in blood vessels and interstitium.
   c. circulates through closed circulatory systems only.
   d. functions only in defense of the body and not transport.
   e. does not pass through a heart.
2. The heart chamber that receives oxygenated blood from the lungs of animals with a double circulation is
   a. the left atrium.
   b. the right ventricle.
   c. the left ventricle.
   d. the right atrium.
3. Amphibians are adapted for life in and out of water because
   a. they are the only vertebrates with an open circulatory system.
   b. oxygen diffuses out of their blood into the environment through their skin.
   c. oxygen diffuses into the blood from the lungs or through the skin.
   d. they have a four-chambered heart.
   e. they can direct blood away from the skin when they are submerged under water.
4. A major advantage of a double circulation is that
   a. blood can be pumped to the upper portions of the body by one circuit and to the lower portions of the body by the other circuit.
   b. each circuit can pump blood with differing pressures to optimize the function of each.
   c. the oxygenated blood can mix with the deoxygenated blood before being pumped to the tissues of the body.
   d. less energy is required to provide nutrients and oxygen to the tissues of the body.
   e. all of the above
5. The function of erythrocytes is to
   a. transport oxygen throughout the body.
   b. defend the body against infection and disease.
   c. transport chemical signals throughout the body.
   d. secrete the proteins that form blood clots.
   e. a and d are both correct.
6. The mammalian heart is an example of a myogenic heart, meaning
   a. it is composed of four chambers.
   b. it acts as two pumps for two different circulations.
   c. contraction is regulated solely by the nervous system.
   d. electrical activity is initiated by specialized cells of the heart.
   e. the nervous system plays no role in its function.
7. During systole of the cardiac cycle
   a. the ventricles of the heart are both relaxed.
   b. the ventricles of the heart are both filling.
   c. the ventricles of the heart are both contracting.
   d. the right ventricle is contracting while the left ventricle is at rest.
   e. the left ventricle is contracting while the right ventricle is at rest.
8. Considering blood flow through a closed circulation, which is the correct sequence of vessels beginning at the heart?
   a. arteriole, artery, capillary, vein, venule
   b. artery, capillary, arteriole, venule, vein
   c. vein, venule, capillary, arteriole, artery
   d. artery, arteriole, capillary, venule, vein
   e. artery, arteriole, capillary, vein, venule
9. Gas and nutrient exchange between the circulation and the tissues occurs primarily at
   a. the arteries.
   b. the arterioles.
   c. the capillaries.
   d. the venules.
   e. the veins.
10. Which of the following factors determines arterial blood pressure?
    a. cardiac output
    b. resistance
    c. arteriole diameter
    d. a, b, and c
    e. a and b only

Conceptual Questions

1. What are the three basic components of a true circulatory system?
2. Discuss the difference between closed and open circulatory systems. What advantages does a closed system provide?
3. Explain the cardiac cycle. Why must heart valves open in only one direction?

Collaborative Questions

1. List and briefly explain the components of blood.
2. Discuss the types of closed circulatory systems found in vertebrates.

Chapter Outline

Respiratory Systems

48

Llama (*Lama glama*) in the Andes Mountains.

Except during illnesses such as the flu and during periods of intense exercise, we take our respiratory system for granted. The biology of respiration, however, is filled with many intriguing questions. For example, have you ever wondered why it is easy for an animal like the llama in the chapter-opening photo to live at great altitudes, whereas most humans become ill when they ascend to such heights? What is it about the atmosphere in mountainous regions that makes it hard for us to function normally, and how do some people and animals adapt to those conditions if given sufficient time? As another example, think how limited we are in our ability to control our respiratory system. How long can you hold your breath, for example? Why do you continue breathing while asleep? Why do you not need to consciously adjust your breathing rate to match your level of activity? If our respiratory system did not operate automatically, think how challenging, indeed impossible, life would be.

In Chapter 47, we saw how circulatory systems function to transport blood or hemolymph throughout an animal's body. These fluids also carry the oxygen that animals require. The oxygen enters the body via a respiratory (breathing) structure. It then dissolves into bodily fluids and is distributed to cells throughout the body. As described in Chapter 7, O_2 is used by mitochondria in the formation of ATP. One of the waste products of that reaction is carbon dioxide—CO_2—which diffuses out of cells. CO_2 is returned by the circulatory system to the respiratory organ and is then released into the environment, either the air or water. The process of moving oxygen and carbon dioxide in opposite directions between the environment, bodily fluids, and cells is called **gas exchange** (Figure 48.1). A **respiratory system** includes all the structures of an animal that contribute to gas exchange. This chapter deals with the mechanisms by which animals obtain and transport oxygen, rid themselves of carbon dioxide, and cope with the challenges imposed by their environments and their changing metabolic needs. We begin with an overview of the properties of gases in air and water.

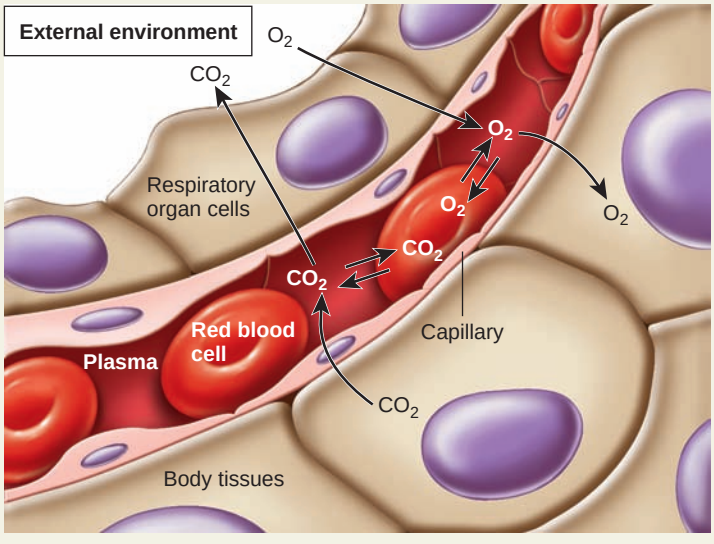

Figure 48.1 Overview of gas exchange between the environment, blood, and cells. In vertebrates, oxygen diffuses from the environment across the cells of a respiratory organ into the blood (plasma and red blood cells). From there, oxygen diffuses into tissue cells, where it is used during the formation of ATP. Cells generate carbon dioxide as a waste product, which diffuses out of cells and into blood, and then across the respiratory organ into the environment. Note: Interstitial fluid is omitted for simplicity.

48.1 Physical Properties of Gases

Oxygen and carbon dioxide exchange between the environment and the fluids of an animal's body depend on the physical properties of these gases. These properties include such things as the solubility of the gas in water and the rate and mechanism of diffusion of the gas. At one time, it was unknown that air was actually a mixture of gases. In 1774, however, the British physiologist Joseph Priestley demonstrated that heating mercuric oxide produced a pure gas that was "five or six times as good as common air." He based this conclusion on the ability of the pure gas to sustain a burning candle or prevent a mouse from suffocating in an enclosed bell jar. Today, we know that the life-sustaining component of Priestley's experiment was oxygen and that air is composed of about 21% oxygen, 78% nitrogen, and less than 1% carbon dioxide and other gases. From a respiratory standpoint, nitrogen gas can usually be ignored because it plays no role in energy production nor is it created as a waste product of metabolism. In this section, we begin by examining some of the basic properties of the two major gases that are important in respiration.

Gases Exert Pressure Which Depends on Altitude

The gases in air exert pressure on the body surfaces of animals, although the pressure is not perceptible (unless it changes suddenly, like when your ears "pop" in a descending airplane). This pressure is called **atmospheric** (or **barometric**) **pressure**. It can be measured by noting how high a column of mercury is forced upward by the air pressure in a device called a mercury manometer. The traditional unit of gas pressure, therefore, is the same as for blood pressure—mmHg—although there are several other ways of expressing pressure. For example, U.S. weather stations report atmospheric pressure in inches of Hg instead of mmHg, and most researchers today record gas pressures in units called kilopascals (kPa; 1 kPa = 7.5 mmHg).

At sea level, atmospheric pressure is 760 mmHg. It decreases as we ascend to higher elevations because the gravitational effect of the Earth decreases and there are fewer gas molecules in a given volume of air (Figure 48.2). To visualize why gas pressure decreases at higher altitudes, think about how hydrostatic pressure decreases from the ocean floor to the ocean surface. Now, imagine that you are standing at the bottom of an "ocean" of air. The closer you get to the "ocean" surface (the top of the atmosphere), the lower the pressure exerted on your body. At an elevation of 1,700 m, as in Denver, the pressure is only about 640 mmHg, while at the highest elevations continuously inhabited by humans—in the Andes Mountains at 5,500 m—the pressure falls to 375 mmHg.

Atmospheric pressure is the sum of the pressures exerted by each gas in air, in exact proportion to their amounts. The individual pressure of each gas is its **partial pressure**, symbolized by a capital P and a subscript depending on the gas. Thus, the partial pressure of oxygen (P_{O_2}) in the air we breathe is 21% of the atmospheric pressure at sea level, or 160 mmHg (0.21 × 760 mmHg). The percentage of oxygen and other gases in air remains the same regardless of altitude, but the lower the atmospheric pressure, the lower the partial pressure of oxygen in air.

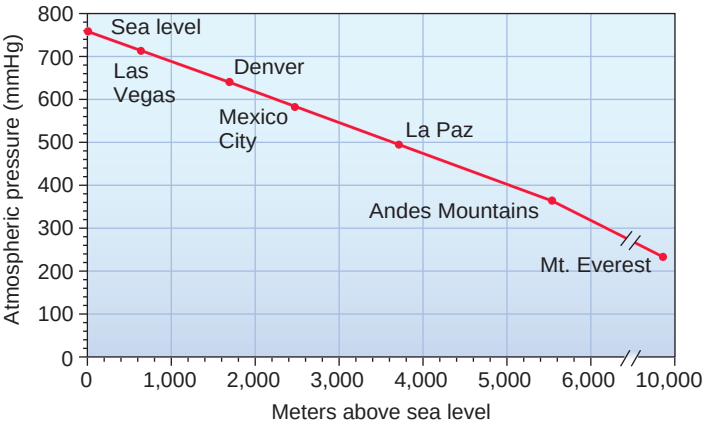

Figure 48.2 The relationship between atmospheric pressure and altitude. Atmospheric pressure decreases as altitude increases.

Concept check: Is there less percent oxygen in the air over Mt. Everest than there is at sea level?

The partial pressure of oxygen in the environment provides the driving force for its diffusion from air or water across the respiratory surface and into the blood. All gases diffuse along pressure gradients, from regions of high pressure to regions of lower pressure. This is analogous to the diffusion of dissolved solids from regions of high to low concentration, or the way heat moves from hotter to cooler regions. Consequently, the rate of oxygen diffusion into the bloodstream of a terrestrial animal decreases when the animal moves from sea level to a higher altitude, where the partial pressure of oxygen is lower.

Pressure, Temperature, and Other Solutes Influence the Solubility of Gases

Gases dissolve in solution, including fresh water, seawater, and all body fluids. Gases such as oxygen exert their biological effects while in solution. However, most gases dissolve rather poorly in water. There is less oxygen in a given volume of water than in air, for example, which limits how active many aquatic organisms can be. Among the factors that influence the solubility of a gas in water, three are particularly important: the pressure of the gas, the temperature of the water, and the presence of other solutes.

The higher the pressure of a gas that comes into contact with water, the more of that gas that will dissolve, up to a limit that is specific for each gas at a given temperature. Not all gases dissolve equally. Oxygen is less soluble in water than carbon dioxide, but more soluble than nitrogen. The partial pressure of gas in water is given in the same units as atmospheric pressure—mmHg. For example, if a solution of water is in contact

with air that contains a P_{O_2} of 160 mmHg, the P_{O_2} of the water is also 160 mmHg.

Solubility also depends on the water's temperature, with more O_2 and CO_2 dissolved in 1 L of cold water than in 1 L of warm water. You can observe this effect of temperature with the following experiment. Open two bottles of a carbonated beverage (that is, one in which carbon dioxide gas has been added) and keep one on ice and the other at room temperature. Note that the "fizz" of the room-temperature beverage disappears sooner, as CO_2 escapes due to its lower solubility at that temperature. Why does this happen? At higher temperatures, gases in solution have more thermal energy and are therefore more likely to escape the liquid. In terms of biological systems, this effect of water temperature means that animals inhabiting very warm waters have less oxygen available to them than do animals living, for example, in the waters off Antarctica. Animals that live in shallow water such as ponds or tide pools, where water temperature can fluctuate widely over a single day, must be able to adapt to large swings in oxygen.

Finally, the presence of other solutes, namely salts, reduces the amount of gas that dissolves in water. Thus, warm salty blood dissolves less oxygen than does cold water. Likewise, less oxygen dissolves in seawater than fresh water at any given temperature and pressure. Animals living in cold freshwater lakes, therefore, typically have more oxygen available to them than do animals living in warm salty seas (although other factors can also influence the amount of dissolved oxygen, such as water depth and the amount of aquatic plant life).

48.2 Types of Respiratory Systems

Despite the wide array of animal shapes, sizes, and habitats, animals obtain oxygen from their surroundings with one of four major types of respiratory structures: the body surface, gills, tracheae, or lungs. In these organs, gas exchange occurs by diffusion of oxygen across the body surface or across specialized respiratory surfaces. **Ventilation** is the process of bringing oxygenated water or air into contact with a gas-exchange surface. In this section, we will examine the mechanisms of ventilation used by animals with different respiratory systems.

The Structures of Respiratory Organs Are Adapted for Gas Exchange

Whether an animal uses specialized respiratory organs or its body surface to obtain oxygen and expel carbon dioxide, all gas exchange structures share certain common features. All of them have moist surfaces in which the gases can dissolve and diffuse. Further, all have adaptations that increase the amount of surface area available for gas exchange. As an example, the total exchange surface of the human lung is roughly equal to that of a tennis court!

The extensive surface area of respiratory organs is coupled with equally extensive blood flow, except in the special case of insects, described later in this chapter. The density of capillaries in gills and lungs, for example, is among the highest found anywhere in an animal's body. The greater the amount of blood flowing to a respiratory surface, the more efficient will be the delivery and removal of gases.

Thick barriers greatly slow the diffusion of a gas. As a result, respiratory organs tend to be thin, delicate structures, which also means they are easily damaged. For instance, the inner structures of fish gills are so thin that they cannot support their own weight out of water, and they collapse when exposed to air.

Water-Breathing and Air-Breathing Animals Face Different Challenges

Exchanging gases in water or in air requires respiratory organs that can deal with the challenges of those different environments. As noted earlier, water-breathing animals generally have less oxygen available to them than do air-breathing animals, which means that an active water-breathing animal requires a very efficient means of extracting oxygen from water. In addition, unlike air-breathing animals, water-breathing animals must adapt to fluctuating oxygen availability when the temperature changes. By contrast, air-breathing animals must cope with the dryness of air. Passing dry air over the lung surfaces runs the risk of drying out the lungs, which would damage them, dehydrate the animal, and reduce the ability of gases to dissolve.

Water-breathing animals bring water, not air, over their respiratory surfaces and therefore do not usually risk dehydration in the way that air-breathing animals do. However, moving water over a gas-exchange surface creates its own challenges. First, because water is denser than air, more energy (muscular work) is required to move water. Second, fresh water or cold seawater moving over the richly vascular gills removes considerable heat from an animal's body, due to the high heat capacity of water. Third, moving fresh or salt water over a gas-exchange surface can create osmotic movement of water across the surface, potentially resulting in water imbalances in an animal's body.

Some Animals Use Their Body Surface to Exchange Gases with the Environment; Some Can Switch Between Water- and Air-Breathing

In those invertebrates that are only one or a few cell layers thick, oxygen and carbon dioxide can diffuse directly across the body surface. In this way, oxygen reaches all the interior cells, in some cases without any specialized transport mechanism or circulatory system.

Even in some large, complex animals, the body surface may be permeable to gases (Figure 48.3). Amphibians, and a few species of fishes including eels, have unusually permeable skin. On land, amphibians rely on their lungs and their moist skin to obtain oxygen and release carbon dioxide. Under water, however, the lungs are no longer useful because they are not

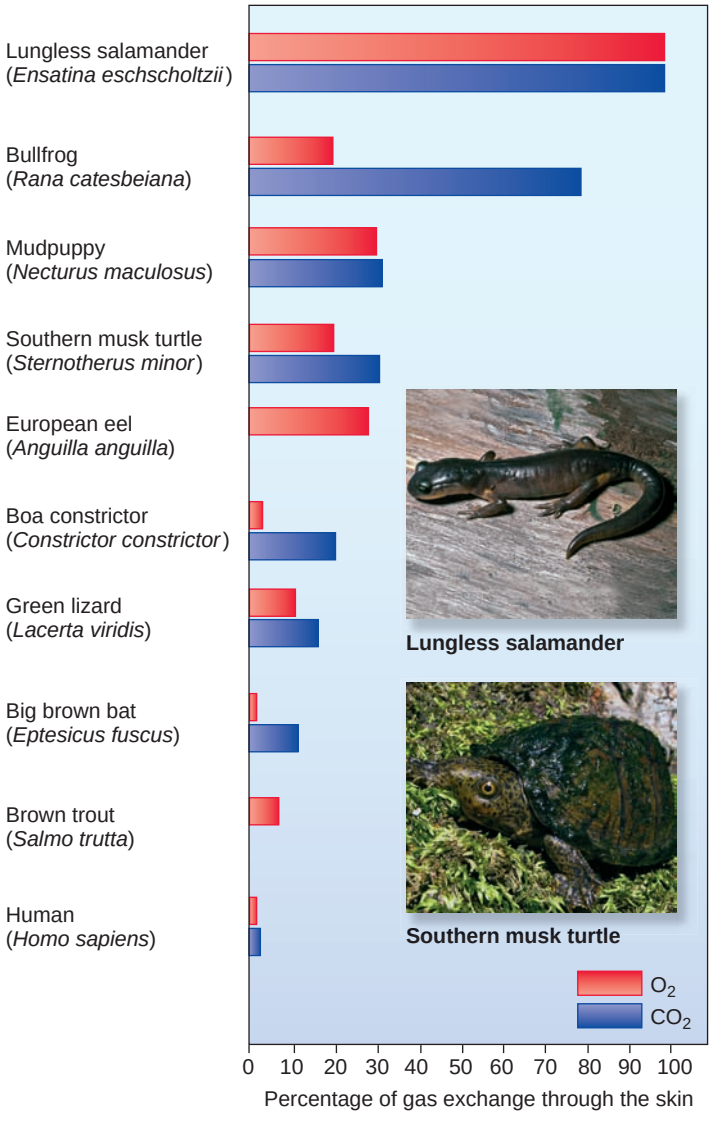

Figure 48.3 **Gas exchange across body surfaces.** This type of gas exchange occurs readily in amphibians and, to a lesser extent, in marine reptiles and some fishes. Among mammals, it occurs to a negligable extent and primarily in species with body features that have high surface area, such as bat wings. Note: CO_2 determinations were not made in all species.

Concept check: What would happen to gas exchange in lungless salamanders if the animals were allowed to dry out?

suited for extracting oxygen from water. Although oxygen diffusion across the skin is less efficient than in the lungs, this secondary ability to exchange gas permits amphibians to spend prolonged times underwater.

Many vertebrates such as seals are amphibious, in that they spend part of their lives on land and part in water, but only amphibians have skin that is highly permeable to gases and can obtain significant amounts of oxygen across their skin. With some exceptions, very little gas diffuses across the body surfaces of fishes, reptiles, birds, and mammals. Some reptiles, however, such as marine iguanas, can obtain oxygen from the water across the highly permeable mucous membranes of the nose, mouth, and anus. Although this provides less oxygen than does air-breathing, it nonetheless allows them to remain underwater for extended periods, as when foraging for food. Some animals have highly specialized body regions with considerable surface area—like the wings of a bat—that permit a small amount of gas exchange (Figure 48.3). Except for amphibians, however, no vertebrates can rely for long periods of time exclusively on their skin to obtain oxygen and remain active.

Water-Breathing Animals Use Gills for Gas Exchange

Most water-breathing animals use specialized respiratory structures called **gills**. Gills can be either external or internal. External gills are uncovered extensions from the body surface, as occur in many invertebrates and the larval forms of some amphibians. Internal gills, which occur in fishes, are enclosed in a protective cavity.

External Gills External gills vary widely in appearance, but all have a large surface area, often in the form of extensive projections (Figure 48.4). External gills may exist in one region of the body or be scattered over a large area. In many cases, they are ventilated by waving back and forth through the water. The ability to move external gills is particularly important for sessile invertebrates, which must otherwise rely on sporadic local water currents or muscular efforts of their bodies to create local currents for ventilation.

Despite the success of marine invertebrates, external gills have several limitations. First, they are unprotected and therefore are susceptible to damage from the environment. Second, because water is much more dense than air, considerable energy is required to continually wave the gills back and forth through the water (think of the difference between waving your hands through air or water). Finally, their appearance and motion may draw the attention of predators.

Internal Gills By contrast, fishes have internal gills, which are covered by a bony plate called an operculum (Figure 48.5a). Fish gills have a more uniform appearance than external gills and are confined within the opercular cavity, which protects the gills and helps streamline the fish body.

The internal gills of fishes contain numerous rows of **lamellae**, platelike structures that branch from structures called filaments. The filaments, in turn, arise from the main support structure of the gills, the gill arches (Figure 48.5b). Blood vessels run the length of the filaments, with oxygen-poor blood traveling through the afferent vessel along one side of the filament, and oxygen-rich blood returning through the efferent vessel along the other side. Within the lamellae are numerous capillaries, all oriented with blood flowing in the same direction, from the oxygen-poor vessel to the oxygen-rich one.

Water enters a fish's mouth and flows between the lamellae in the opposite direction to blood flowing through the lamellar capillaries. This arrangement of water and blood flow is another example of a **countercurrent exchange mechanism**

(c) SEM of gill filaments

Figure 48.5 **Structure of fish gills.** **(a)** The gills are protected beneath the operculum, which has been lifted open in this photo to reveal the gills underneath. **(b)** The gills are composed of gill arches, from which numerous pairs of filaments arise. Thin, platelike lamellae with large surface areas are arrayed along the filaments. Blood vessels from the filaments form capillaries in the lamellae. Blood flows through the capillaries in the opposite direction of water flowing between lamellae, a process called countercurrent exchange. **(c)** Several filaments with their lamellae as revealed in a scanning electron micrograph.

Concept check: *Why do fishes die when out of water? (Hint: Consider the thin, delicate appearance of the water-covered lamellae.)*

(see Chapters 40 and 46). As oxygenated water encounters the lamellae, it comes into contact with blood in the gill capillaries. Recall that oxygen diffuses along pressure gradients from a region of high oxygen pressure to low oxygen pressure. Thus, oxygen diffuses from the water into the capillaries of the lamellae. As water continues to flow across the lamellar surface, it encounters regions of capillaries that have not yet picked up oxygen—in other words, even as oxygen begins to diffuse from the water into the gill capillaries, a sufficient pressure gradient remains along the lamellae to permit diffusion of more of the remaining oxygen from the water. This is an extremely efficient way to remove as much oxygen from the water as possible before the water passes out of the operculum.

Fishes use one of two mechanisms to ventilate their gills, buccal pumping or ram ventilation. The first method, **buccal pumping** (the buccal cavity refers to the mouth), makes use of the muscles of the mouth and operculum to create a hydrostatic pressure gradient for water to flow in one direction (Figure 48.6a). First, the jaw is lowered, which enlarges the buccal cavity and lowers the pressure in the mouth, something like a suction pump. This draws water into the mouth, raising the water pressure again. At roughly the same time, the operculum begins to swing out from the body, enlarging the opercular cavity and lowering the water pressure there. This second suction pump is stronger than the buccal pump, so water flows down its hydrostatic pressure gradient from the outside to the mouth and into the opercular cavity. Next, the mouth closes, and the buccal cavity is compressed. This creates positive pressure that forces water across the gills and out through the operculum, which is now open. A flap of tissue at the back of the mouth helps prevent accidental flow of water down the esophagus. Consequently, fishes do not swallow the water they inhale but instead send it on a one-way journey across their gills. In buccal pumping, a fish can remain stationary and still ventilate even in stagnant water by drawing water into its mouth.

The second way in which some fishes ventilate their gills, **ram ventilation**, consists of swimming with their mouths open, in essence using their large swimming muscles to bring water into their buccal cavity and from there across their gills (Figure 48.6b). This method of ventilation is more energy efficient than buccal pumping. Ram ventilation still requires energy expenditure, but in this case, the energy is used for swimming or for using muscles to remain stationary while facing upstream in moving water. Many fishes employ both methods of ventilation, using buccal pumping when swimming slowly or in stagnant water and switching to ram ventilation when swimming quickly or facing upstream. Some fishes—such as tuna—can only ram ventilate and therefore rarely stop moving.

Both buccal pumping and ram ventilation are **flow-through systems**—water moves unidirectionally in such a way that the gills are constantly in contact with fresh, oxygenated water. As we will see, many air-breathing animals use a less efficient method of ventilating their lungs, called tidal ventilation, in which fresh air is breathed in and stale air is breathed out through the same route. Later in this chapter, we will discuss an example of an air-breathing animal that also uses a

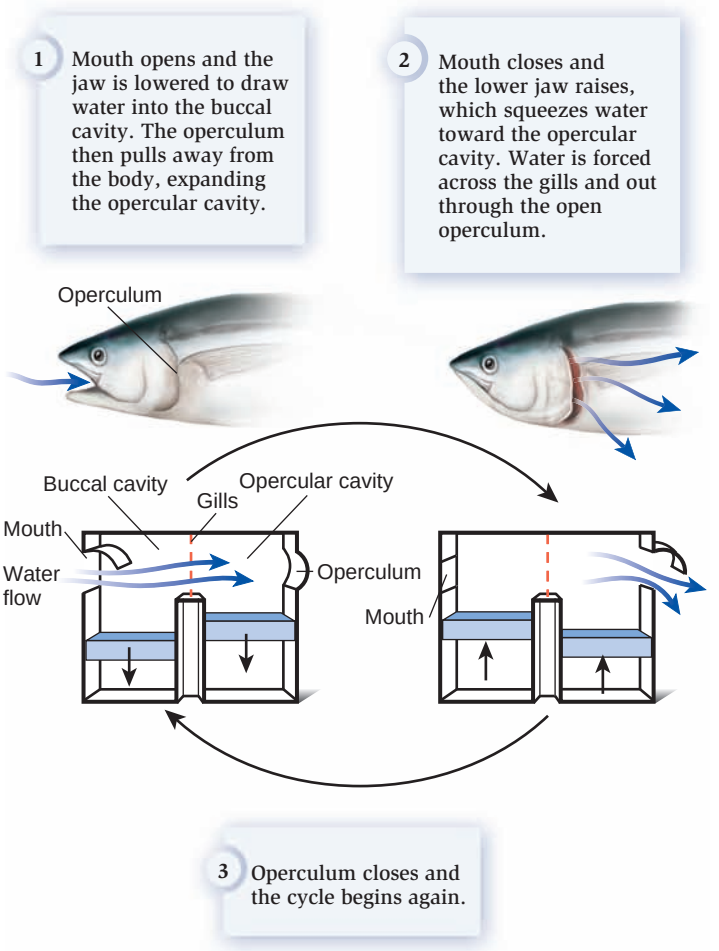

Figure 48.6 **Mechanisms of gill ventilation.** Some species use both buccal pumping and ram ventilation, while some can only use one. **(a)** Buccal pumping. The expansion of the buccal and opercular cavities acts like a suction pump, and closing these cavities acts like a pressure pump. **(b)** Ram ventilation. Many fishes can ventilate their gills by swimming forward, such as this tuna, or by facing upstream in moving water with their mouths open. This causes the water to move through the mouth and operculum. During both types of ventilation, flaps of tissue in the mouth, throat, and operculum help prevent water from moving in the reverse direction or down the esophagus.

flow-through system. Despite the efficiency of flow-through systems in water for maximizing oxygen extraction, they are energetically costly because of the work required to overcome the density of water. Fishes may devote up to 10–20% of their resting metabolic rate simply to ventilating their gills, whereas a typical air-breather may allocate only 1–2% of its total energy usage to ventilating the lungs at rest.

Insects Use Tracheal Systems to Exchange Gases with the Air

Except for terrestrial isopods such as the pill bug (*Armadillidium vulgare*), which breathe air through very small, moist gills, the delicate nature of gill lamellae makes them unsuitable for gas exchange in air. Air-breathing probably evolved as an adaptation in aquatic animals inhabiting regions that were subject to periodic drought. One of the major mechanisms that animals evolved to breathe air is the tracheal system found in insects.

Running along the surface of both sides of an insect's body are tiny openings to the outside, called spiracles. Arising from the spiracles are **tracheae** (singular, trachea), sturdy tubes that are reinforced with the polysaccharide chitin to keep them open (Figure 48.7). Tracheae branch extensively into ever-smaller tubes called tracheoles, which eventually become small enough that their tips contact virtually every cell in the body. At their tips, tracheoles are filled with a small amount of fluid. Air flowing down the tracheoles comes into contact with this fluid. Oxygen from the air dissolves in the fluid, and from there it diffuses across the tracheole wall and into nearby cells. Carbon dioxide diffuses in the opposite direction, from cells into the tracheoles, and from there to the environment.

When an insect's oxygen demands increase, muscular movements of its abdomen and thorax draw air into and out of the tracheae like a bellows, a phenomenon first demonstrated in the early 20th century by Danish physiologist and Nobel Laureate August Krogh, who studied the mechanics of ventilation in locusts. Krogh showed that an insect's muscles and tracheal system match ventilation with the animal's exercise intensity and oxygen requirements. This is particularly important in flying insects, whose metabolic demands are high. The faster an insect flies, the more oxygen it uses. Likewise, the more intensely and rapidly the body wall muscles move, the more air is moved in and out of the tracheae.

As discussed in Chapter 47, the open circulatory system of insects does not participate in gas exchange. Oxygen diffuses directly from air to trachea to tracheoles and finally to body cells. This mechanism of ventilation and oxygen delivery is very efficient. The metabolic rate of insect flight muscles is among the highest known of any tissue in any animal, and the tracheal system supplies enough oxygen to meet those enormous demands.

Air-Breathing Vertebrates Use Lungs to Exchange Gases

Except for some amphibians such as lungless salamanders (family Plethodontidae), all air-breathing terrestrial vertebrates use

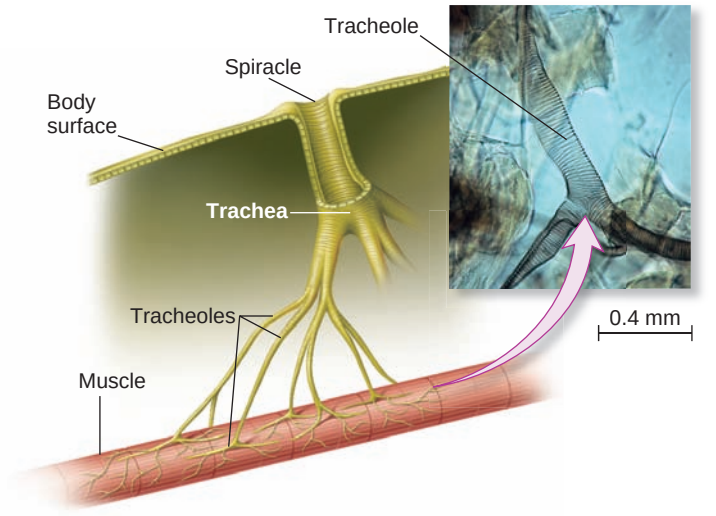

Figure 48.7 **The tracheal system of insects.** Air enters holes on the body surface called spiracles. Oxygen diffuses directly from the fluid-filled tracheole tips to cells that come into contact with the tips. The circulatory system plays no role in gas exchange. The micrograph illustrates a few branching tracheoles.

Concept check: *How might the structure of the respiratory system of insects be related to why insects tend to be smaller than vertebrates?*

lungs to bring oxygen into the circulatory system and remove carbon dioxide from it. Lungs are internal paired structures that arise from the pharynx (throat). All lungs receive deoxygenated blood from the heart and return oxygenated blood back to the heart. Depending on the class of vertebrate, lungs may be filled using positive or negative pressure, and they may be ventilated by a tidal system or a flow-through system.

Most amphibians have lungs that are simple sacs with relatively little surface area, making them less-effective surfaces for oxygen diffusion than are the lungs of other vertebrates. A 30-g mouse's lung, for example, has nearly 50 times more gas-exchange surface per cubic centimeter of lung tissue than a 30-g frog's lung.

The method by which amphibians ventilate their lungs is similar in some ways to the buccal pumping of fishes. A frog, for example, lowers its jaw, which decreases the air pressure inside the mouth cavity. According to Boyle's law, gas pressure and volume are inversely related (Figure 48.8). For example, when the volume in which a gas is contained increases, the pressure of the gas in that container decreases. By expanding its mouth cavity, therefore, a frog creates a pressure gradient for air to move from the atmosphere (higher pressure) into its mouth (lower pressure). The mouth and nostrils then close, and the mouth cavity is compressed by raising the bottom jaw. This raises the air pressure in the mouth, forcing air through a series of valves into the lungs. Thus, **positive pressure filling** means that frogs and most other amphibians gulp air and force it under pressure into the lungs, as if inflating a balloon. They may do this many times in a row before exhaling.

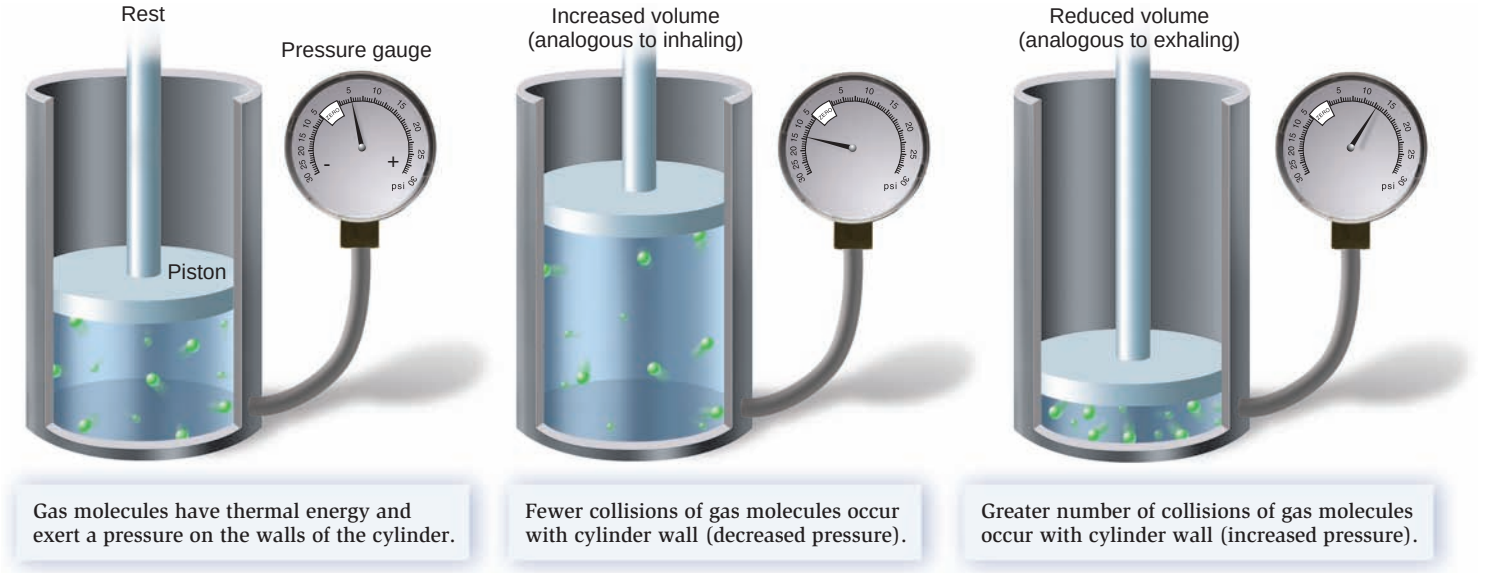

Figure 48.8 **Boyle's law.** At a constant temperature, the volume and pressure of a gas are inversely related. This relationship creates the gas pressure gradients needed to ventilate the vertebrate lungs.

Except for a few species of reptiles—such as members of the genus *Varanus*—that can in some circumstances also employ positive pressure filling, all other terrestrial vertebrates use a different method of ventilation, called negative pressure filling. To understand how negative pressure filling works, we will first examine the anatomy of the respiratory tract in vertebrates, using the mammalian and avian systems as models.

48.3 Structure and Function of the Mammalian and Avian Respiratory Systems

In vertebrates, the respiratory system includes all components of the body that contribute to the exchange of gas between the external environment and the blood. In this section, we begin by examining the structures of the mammalian respiratory system and the mechanisms by which mammals ventilate their lungs. We then compare and contrast this with the highly specialized and unique way in which birds ventilate their lungs. Although both mammals and birds fill their lungs using negative pressure, mammals breathe by tidal ventilation, and birds use a flow-through system.

During Ventilation, Air Follows a Series of Branching Tubes in the Mammalian Respiratory System

In mammals, the respiratory system includes the nose, mouth, airways, lungs, and muscles and connective tissues that encase these structures within the thoracic (chest) cavity (Figure 48.9a). When humans and other mammals breathe, air first enters the nose and mouth, where it is warmed and humidified. These processes protect the lungs from drying out. While in the nose, the air is cleansed as it flows over a coating of sticky mucus in the nasal cavity. The mucus and hairs in the nasal cavity trap some of the larger dust and other particles that are inhaled with air. These are then removed by the body's defense cells or swallowed.

The inhaled air from the mouth and nose converges at the back of the throat, or **pharynx**, a common passageway for air and food. From there, air passes through the **larynx**. Within the larynx are the vocal cords, folds of tissue through which air passes to create sound. Air flows from the larynx down the **trachea**, a tube that leads to the lungs. At the opening to the larynx, a flap of tissue called the epiglottis prevents food from entering the trachea by closing when food is swallowed.

The trachea is ringed by C-shaped cartilage supports that provide rigidity and ensure that the trachea always remains open. The inner wall of the trachea is lined with cilia and cells called goblet cells (Figure 48.9b). These cells secrete mucus into the lumen of the trachea, coating the cilia. This mucous layer captures potentially harmful or irritating particles that escaped the nasal cleaning mechanism. The cilia constantly beat toward the mouth and move the mucus and its trapped particles into the mouth, where it can be expelled or swallowed. Without these active cilia, repeated coughing would be needed to force the mucus out of the trachea. This is why people who smoke tobacco develop a chronic "smoker's cough"—the smoke and its components reduce the number of cilia, causing mucus to pool in the trachea.

Inhaled air moves down the trachea as it branches into two smaller tubes, called **bronchi** (singular, bronchus), which lead to each lung. The bronchi branch repeatedly into smaller and

Figure 48.9 **The mammalian respiratory system.** **(a)** In this overview, the ribs have been removed in front, and the major airways have been drawn in the lungs. The thoracic cavity is bounded by the ribs and intercostal muscles and the muscular diaphragm. For simplicity, external and internal intercostal muscles are not indicated separately. **(b)** Ciliated epithelial cells and mucus-producing goblet cells line the trachea. The mucus traps inhaled particles, and the cilia help move the mucus toward the mouth, where it can be swallowed. **(c)** The bronchioles deliver air to clusters of alveoli. Note the smooth muscle cells around the bronchioles, which can cause the bronchioles to constrict or dilate. Capillaries surround the alveoli. Red represents oxygenated blood; blue represents partly deoxygenated blood. **(d)** Cross section through a cluster of alveoli. Note the single cell layer of alveoli cells and their close proximity to adjacent capillaries.

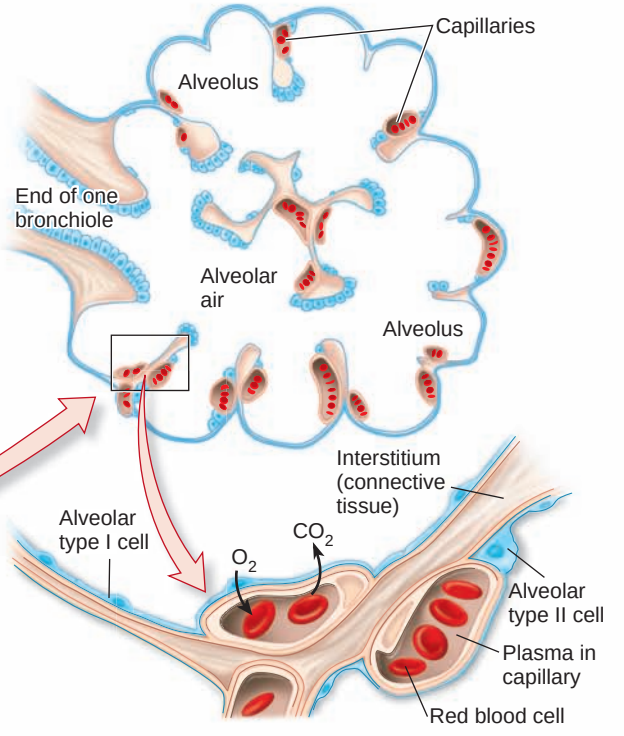
(c) Structure of a bronchiole and alveoli



(d) Cross section of an alveolar cluster, with enlarged region

smaller tubes, eventually becoming thin-walled **bronchioles** surrounded by circular rings of smooth muscle (Figure 48.9c). Bronchioles can dilate or constrict in a manner analogous to that of arterioles (see Chapter 47). They may partially constrict when a damaging particle—such as a small bit of inhaled pollutant or dust—gets past the mucous layers of the upper airways. Constriction of a bronchiole prevents foreign particles from reaching delicate lung tissue. Once the body's defense cells have removed the particles, the bronchiole reopens to its normal diameter.

The bronchioles empty into the final, saclike regions of the lungs where gas exchange occurs—the **alveoli** (singular, alveolus; Figure 48.9c). Until now, air has flowed through the air tubes without any gas exchange taking place. The alveoli are highly adapted for gas exchange and consist of two major types of cells. Type I cells are those across which gases diffuse, whereas Type II cells are secretory cells (described later). The alveoli are only one cell thick and resemble extremely thin sacs, appearing like bunches of grapes on a stem. Many capillaries containing deoxygenated blood pumped from the right ventricle of the heart surround the alveoli. Oxygen diffuses from the lumen of each alveolus across the alveolar cells, through the interstitial space outside the cells, and into the capillaries (Figure 48.9d). Carbon dioxide diffuses in the opposite direction. The oxygenated blood from the lungs then flows to the left atrium of the heart and from there enters the left ventricle, where it is pumped out through the aorta to the rest of the body.

The Pleural Sac Protects the Lungs

The lungs are soft, delicate tissues that could easily be damaged by the surrounding bone, muscle, and connective tissue of the thoracic cavity if not protected. Each lung is encased in a **pleural sac**, a double layer of thin, moist tissue. Between the two layers of tissue is a microscopically thin layer of water that acts as a lubricant and makes the two tissue layers adhere to each other.

In addition to protecting the lungs, the inner pleural sac adheres to its lung, and the outer pleural sac adheres to the chest wall. In this way, movements of the chest wall result in similar movements of the lungs. This is important because the lungs are not muscular and so cannot inflate themselves. Instead, as we will see, the lungs are inflated by the expansion of the thoracic cavity, which results from the contraction of muscles in the thorax.

Negative Pressure Is Used to Fill Both Mammalian and Avian Lungs

The way in which you inflate a balloon, by forcing air from your mouth into the balloon, is called positive pressure filling. It is reminiscent of how amphibians ventilate their lungs. **Negative pressure filling**, by contrast, is the mechanism by which reptiles, birds, and mammals ventilate their lungs. In this process, the volume of the lungs expands, creating a negative pressure that draws air into the lungs. The process differs in some ways among classes of vertebrates, but in mammals, the work is provided by the **external intercostal muscles**, which surround and connect the ribs in the chest, and a large muscle called the **diaphragm** (Figure 48.9a), which divides the thoracic cavity from the abdomen.

Let's follow the process when a mammal ventilates its lungs (Figure 48.10). At the start of a breath, the diaphragm contracts, pulling downward and enlarging the thoracic cavity. Simultaneously, the external intercostal muscles contract, moving the chest upward and outward, which also helps to enlarge the thoracic cavity. Recall that the pleural sacs adhere the lungs to the chest wall, so as the chest expands, the lungs expand with it. According to Boyle's law, as the volume of the lungs increases, the pressures of the gases within them must decrease. In other words, the pressure in the lungs becomes negative with respect to the outside air. Air, therefore, flows down its pressure gradient from outside the mouth and nose, into the lungs.

Once the lungs are inflated with air, the chest muscles and diaphragm relax and recoil back to their original positions as an animal exhales. This compresses the lungs and forces air out of the airways. Whereas inhaling requires the expenditure of significant amounts of energy, exhaling is mostly passive and does not require much energy. During exercise, however, exhalation is assisted by contraction of another set of rib muscles, called the internal intercostal muscles. The contraction of these muscles depresses the rib cage and provides a more forceful exhalation; this increases the rate at which ventilation occurs and helps empty the larger volume of air from the lungs.

Mammals Breathe by Tidal Ventilation

When mammals exhale, air leaves via the same route that it entered during inhalation, and no new oxygen is delivered to the airways at that time. As mentioned, this type of breathing is called **tidal ventilation** (think of air flowing in and out of the lungs like the tides of an ocean). Tidal ventilation is less efficient than the unidirectional, flow-through system of fishes in which gills are always exposed to oxygenated water during all phases of the respiratory cycle.

As you know from experience, the lungs are neither fully inflated nor deflated at rest. For example, you could easily take a larger breath than normal if you wished, or exhale more than the usual amount of air. The volume of air that is normally breathed in and out at rest is the **tidal volume**, about 0.5 L in an average-sized human. Tidal volume is proportional to body size both among humans and between species. A 6-foot-tall adult, for example, has a larger tidal volume than a 4-foot-tall child because the adult has larger lungs. Similarly, horses have larger tidal volumes than humans, and humans have larger tidal volumes than dogs (Table 48.1). During exertion, the lungs can be inflated further than the resting tidal volume to provide additional oxygen. Likewise, the lungs can be deflated beyond their normal limits at rest, by exerting a strong effort during exhalation. The lungs never fully deflate, however, partly because they are held open by their adherence to the chest wall. This is important for a simple reason. Think again of our analogy of a

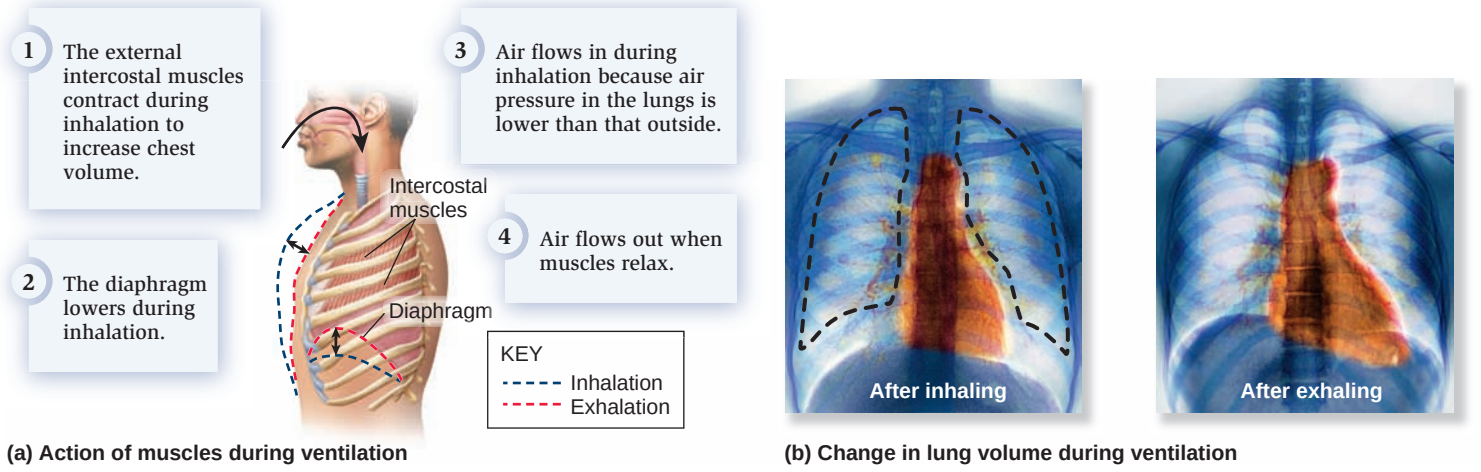


Figure 48.10 **Ventilation of the mammalian lung by negative pressure filling.** **(a)** The external intercostal muscles contract, which expands the chest cavity by moving the ribs up and out. The diaphragm also contracts, causing it to pull downwards, further expanding the cavity. The muscular efforts require energy, whereas the return to the resting state by exhaling is primarily by recoil. **(b)** X-ray images of the chest of an adult man after inhaling and exhaling. The volume of the lungs after exhaling is superimposed on the left, using dashed lines to illustrate the relative change in lung volume after inhaling.

Table 48.1 Respiratory Characteristics of Different Mammals

Animal	Body mass	Breaths/min	Tidal volume
Shrew	0.0024 kg	700	30 µL
Dog	25 kg	20	0.27 L
Human	75 kg	12	0.50 L
Horse	465 kg	9	6.50 L

Note: All values are averages from resting animals. Tidal volume is the volume of air breathed in with each breath. Note that tidal volume increases as an animal's mass and lung size increase. By contrast, breathing rate is higher in smaller animals. Similar relationships occur in other vertebrates, notably birds.

balloon. It is much easier to fill a balloon that is already partly inflated than it is to inflate a completely empty balloon. The same is true of the lungs. The most difficult breath is the very first one that a newborn mammal takes—the only time its lungs are ever completely empty of air.

Surfactant Facilitates Lung Inflation by Reducing Surface Tension

Like all cells, those that make up the lining of the alveoli are surrounded by extracellular fluid. This fluid layer is where gases dissolve. Unlike other internal body cells, however, alveolar cells come into contact with air, creating an air/liquid interface along the inner surface of the alveoli. This results in surface tension (see Chapter 2) within the alveoli. Surface tension results from the attractive forces between water molecules at the air/liquid interface and partly explains why droplets of water form beads. It also produces a force that makes alveoli tend to collapse as water molecules lining its surfaces are attracted to each other. If many or all of the alveoli collapsed, however, the amount of surface area available for gas exchange in the lungs would be greatly reduced. What prevents them from collapsing? The Type II cells of the alveoli produce **surfactant**, a mixture of proteins and amphipathic lipids (that is, lipids with both polar and nonpolar regions), and secrete it into the alveolar lumen. There, it forms a barrier between the air and the fluid layer inside the alveoli. This barrier reduces surface tension in the alveolar walls, allowing them to remain open.

Surface tension is particularly important in the transition from fetal to postnatal life in mammals. Most mammalian fetuses are encased in fluid within the uterus. Consequently, their lungs do not have an air/liquid interface, and they do not start producing surfactant until the final stages of pregnancy. In humans, surfactant production begins around week 26 of gestation but does not increase to final levels until after week 33 (normal pregnancy length is about 40 weeks). If a human baby is born prematurely (defined as prior to week 37 of gestation), sufficient surfactant may not be available, and consequently, many alveoli may collapse after birth. This condition, known as **respiratory distress syndrome of the newborn**, can be partially alleviated by inserting a tube in the trachea and injecting synthetic surfactant. Each year in the U.S., approximately 450,000 babies are born prematurely; of those, roughly 40,000 will be born sufficiently premature as to be diagnosed with respiratory distress syndrome of the newborn.

The Avian Respiratory System Is a Flow-Through System

The avian respiratory system provides a stark contrast to that of mammals, despite the similarity that negative pressure is used

to fill the lungs in both cases. Unlike mammals, ventilation in birds is a flow-through system. The avian respiratory system is unique among vertebrates in that it is supplemented with numerous **air sacs** (Figure 48.11a), which for simplicity we can group together as those at the anterior or posterior regions of the body. The air sacs—not the lungs—expand when a bird inhales and shrink when it exhales. They expand by movements of the chest muscles, not by a diaphragm.

The air sacs, however, do not participate in gas exchange, as first demonstrated in an experiment by French physiologist J. Soum in 1896. Soum surgically plugged the openings of one of a pigeon's air sacs and then injected poisonous carbon monoxide (CO) gas into the sac. Birds are very sensitive to the toxic effects of CO, but in this experiment, the pigeon showed no signs of being poisoned. Soum concluded that gases do not diffuse from the air sacs into the blood.

When a bird inhales, air enters its trachea and from there moves into two bronchi. Instead of branching into bronchioles and then alveoli, however, avian bronchi branch into a series of parallel air tubes called **parabronchi** that make up the lungs (Figure 48.11b). The parabronchi are the regions of gas exchange. They have enormous surface area and an extensive network of blood capillaries. Blood flows through the lungs in a crosscurrent direction with respect to movement of air. This is less efficient in extracting oxygen than the countercurrent flow arrangement in fish gills, because air and blood do not move in exactly opposite directions along the length of the capillaries; it is more efficient than the tidal ventilation system of mammalian lungs, however (Figure 48.12). Precisely how air moves through avian lungs and the function of the air sacs remained a mystery to physiologists for many years, however, until the ingenious work of American physiologist Knut Schmidt-Nielsen, as described next.

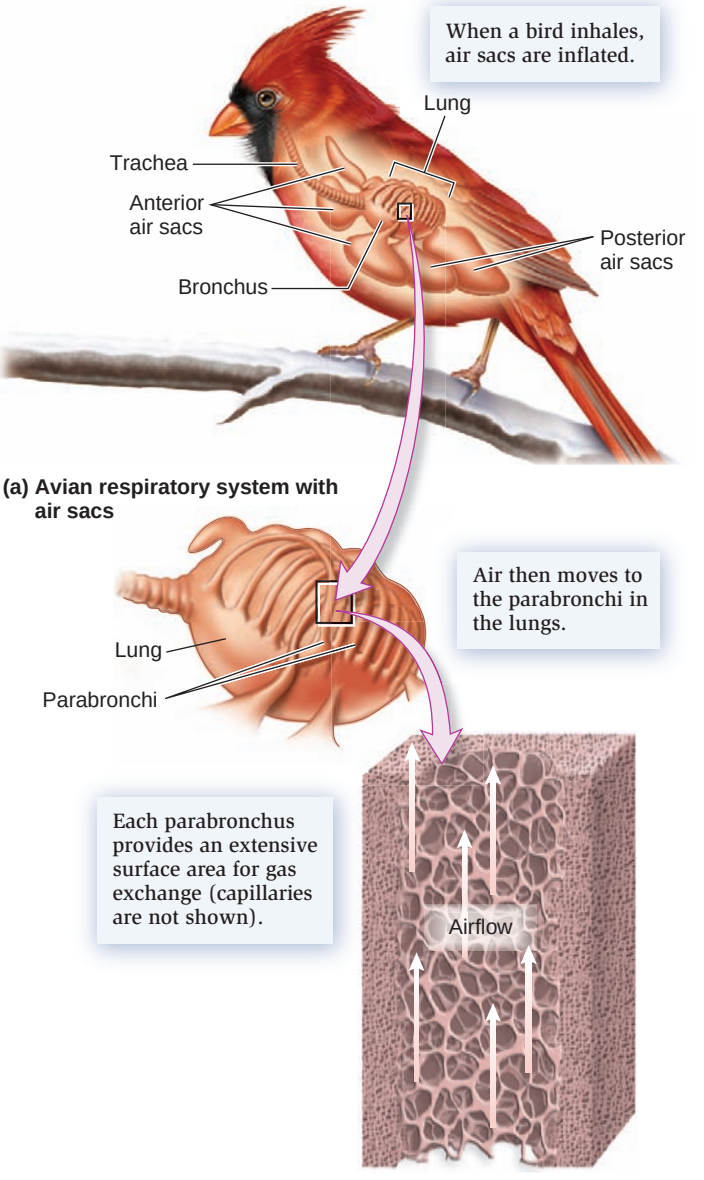

Figure 48.11 Respiratory system of a bird.

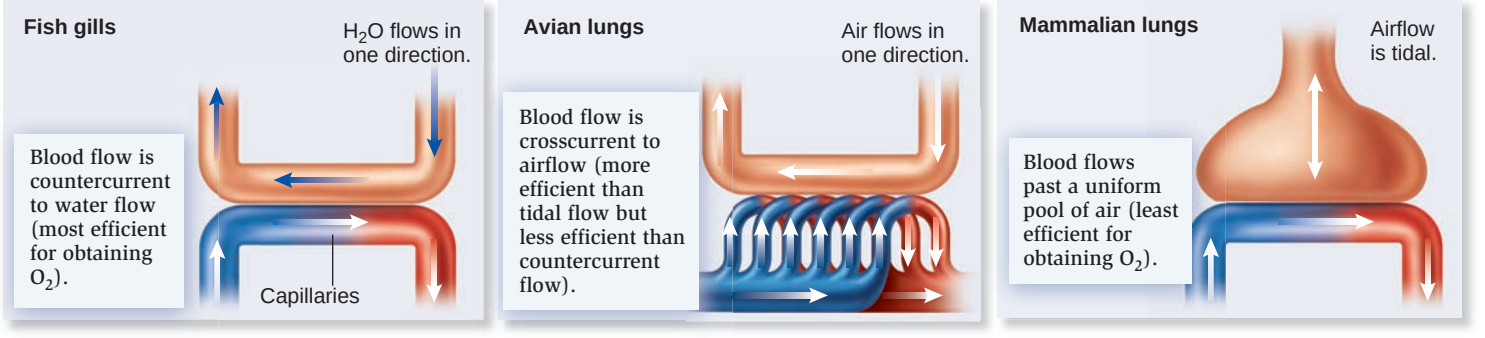

Figure 48.12 Relationships between direction of flow of blood and water or air in different vertebrates.

Concept check: What might you conclude about the relative amounts of oxygen available in water and air based on the differences described in this figure?

Feature Investigation

Schmidt-Nielsen Mapped Airflow in the Avian Respiratory System

In 1967, American researcher Knut Schmidt-Nielsen and coworkers conducted a series of experiments designed to determine the mechanisms of ventilation and gas exchange in avian lungs, using ostriches because of their large lung volumes. The researchers used O_2- and CO_2-sensitive probes to determine the concentrations of these gases in the birds' air sacs. In their first experiment, described in Figure 48.13, the investigators allowed the birds to breathe ordinary room air, which contained 21% oxygen. They used special syringes to extract a gas sample from the large air sacs of the birds and analyzed the gas composition with the probes. They discovered that the O_2 content was high (21%) and the CO_2 content low in the posterior air sacs, with the reverse pattern in the anterior sacs. They concluded that fresh air must move through the trachea and into the posterior air sacs, while "stale" air, which had previously given up much of its oxygen and picked up CO_2 in the lungs, must have entered the anterior sacs.

To test this hypothesis, they developed a method to track the movement of oxygen through the ostrich's respiratory system, as shown in the second experiment of Figure 48.13. In this experiment, the scientists fitted ostriches with face masks, through which the birds inhaled a single breath of pure (100%) oxygen. O_2-sensitive probes were surgically inserted into the posterior and anterior air sacs to monitor when the pure oxygen gas appeared in each sac. The researchers discovered that during the first inhalation, high levels of oxygen appeared in the posterior air sac but not the anterior sac. As the ostrich exhaled, some oxygen remained in the posterior air sac, but still no oxygen appeared in the anterior one. When the animal inhaled its next breath (this one of plain air, not pure oxygen), pure oxygen began appearing in the anterior sacs and disappearing from

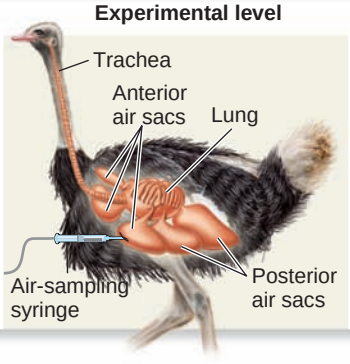
Figure 48.13 Schmidt-Nielsen and coworkers demonstrated the route that air travels in the avian (ostrich) lung.

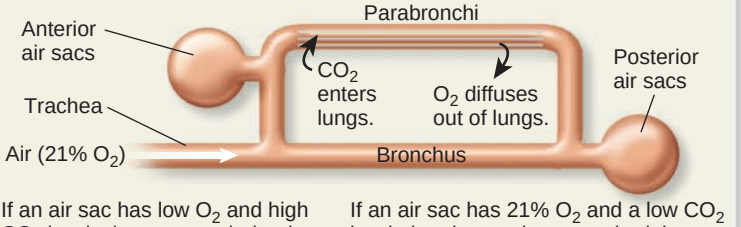
HYPOTHESIS Avian air sacs direct the flow of air through the lungs.

KEY MATERIALS Ostriches, gas analyzer, oxygen tank.

Experimental level | **Conceptual level**

1 Experiment 1: Analyze gas contents in anterior and posterior air sacs, using an air-sampling syringe.



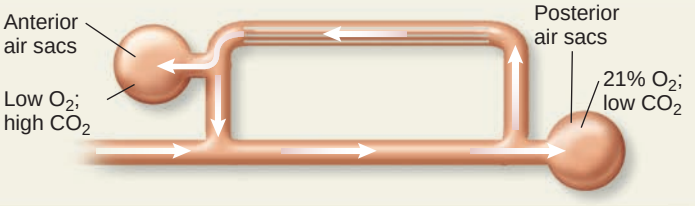


If an air sac has low O_2 and high CO_2 levels, it must get air that has already moved through the lungs.

If an air sac has 21% O_2 and a low CO_2 level, the air must have reached the sac before passing through the lungs.

2 THE DATA

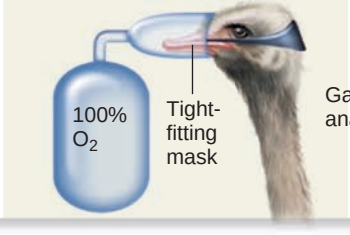
Results from Experiment 1:

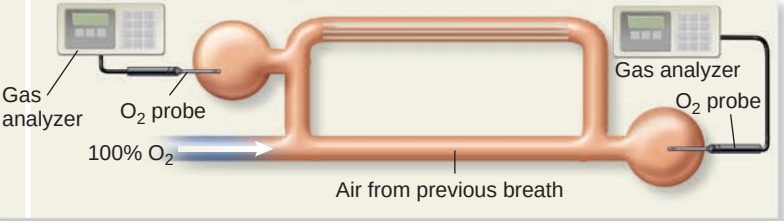


The researchers proposed that air moves directly to posterior sacs, then through the lungs, and then to the anterior sacs.

How can this be demonstrated?

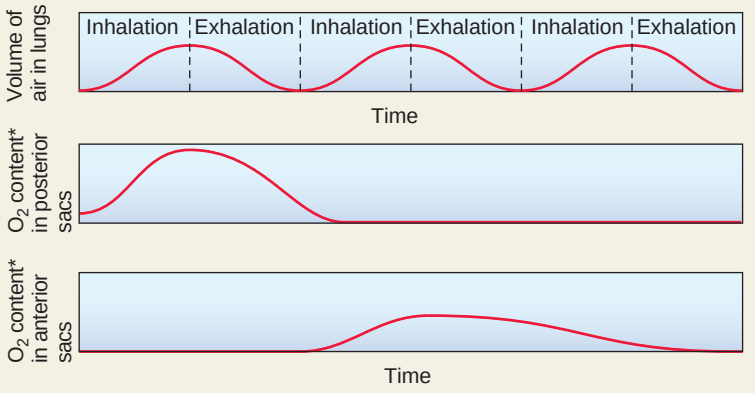
3 Experiment 2: Give ostriches a single breath of pure O_2, which can be tracked as it moves through the respiratory system. Then remove the mask and allow the bird to breathe normal air.





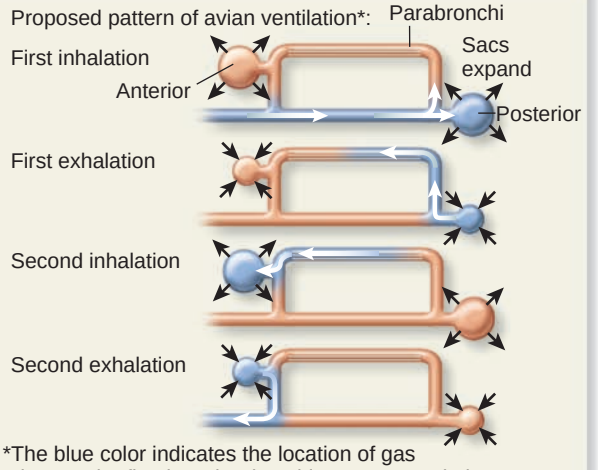
4 THE DATA

Results from Experiment 2: Pure O_2 appears first in the posterior sacs and does not appear in anterior sacs until the next breath.



*The O_2 shown in these graphs is from the pure O_2 inhaled on the first breath and is above the normal levels of O_2.

5 CONCLUSION



*The blue color indicates the location of gas taken on the first breath. The white arrows track the directional movement of air taken on the first breath.

6 SOURCE Schmidt-Nielsen, K. et al. 1969.Temperature regulation and respiration in the ostrich. *The Condor* 71:341–352.

the posterior sacs. Finally, as the ostrich exhaled a second time, the pure oxygen in the anterior sacs decreased.

Schmidt-Nielsen concluded from this study that air flows through the trachea, down the bronchi, and into the posterior air sacs during inhalation. As a bird exhales, air exits the posterior sacs and flows through the parabronchi in a posterior to anterior direction. During its passage through the lungs, some of the oxygen diffuses into the capillaries, while CO_2 diffuses out of the capillaries and into the lungs. During the next inhalation, air at the anterior part of the lungs flows through the remainder of the lungs and then into the anterior air sacs, which serve as a sort of holding chamber. Finally, a second exhalation causes this air from the previous inhalation to exit the anterior sacs and leave the animal's body through the trachea.

Therefore, it takes two complete breaths for air to move from the environment into the lungs and back out again to the environment. Air flows through the lungs during inhalation, as it is drawn by negative pressure through the parabronchi and into the expanding anterior sacs. Air is also forced through the parabronchi by positive pressure during exhalation, as the posterior air sacs are compressed. The efficiency of the avian flow-through system, together with its crosscurrent blood supply, is a major reason why many birds are able to fly at altitudes with extremely low atmospheric pressures (even over Mt. Everest—see Figure 48.2).

Experimental Questions

1. What was the purpose of these studies?
2. Considering the first experiment only, what were the results, and what conclusions did the researchers make based on these results?
3. Explain the purpose and procedure of the second experiment conducted by Schmidt-Nielsen and the conclusions he drew from his results.

48.4 Control of Ventilation in Mammalian Lungs

In the previous section, you saw that different vertebrates have adapted to air-breathing in very different ways. Now let's look at how the mechanisms of breathing are controlled, using mammals as our example.

Lungs are neither muscles nor electrically excitable tissue. Therefore, they cannot initiate or regulate their own expansion. Nonetheless, lungs require a mechanism to rhythmically expand and recoil, because animals cannot always consciously control breathing, such as during sleep. In this section, we examine the ways in which the nervous system and other structures control ventilation in mammals and how these control mechanisms are linked with metabolism.

The Nervous System Contains the Pacemaker for Ventilation

The pacemaker that initiates expansion of the lungs is a collection of nuclei in the nervous system. In mammals, these **respiratory centers** are located in the brainstem (Figure 48.14). Neurons within certain brainstem nuclei periodically generate action potentials. These electrical impulses then travel from the brainstem through two sets of nerves. The first set, called the intercostal nerves, stimulates the intercostal muscles, and the second set, the phrenic nerves, stimulates the diaphragm. When the lungs expand in response to the contraction of these muscles, stretch-sensitive neurons in the lungs and chest send signals to the respiratory centers, informing them that the lungs are inflated. This temporarily turns off the stimulating signal until the animal exhales, whereupon a new signal is sent to the breathing muscles.

Although the brainstem controls breathing automatically, it can be overridden. Animals that dive underwater—including humans when we go swimming—can hold their breath temporarily. We can also breathe faster than normal even while resting, at least for short periods of time. Normally, however, increased breathing occurs in response to physical activity. At such times, a variety of factors converge on the respiratory centers to increase the rate and strength of signals to the breathing muscles, resulting in faster and deeper breaths.

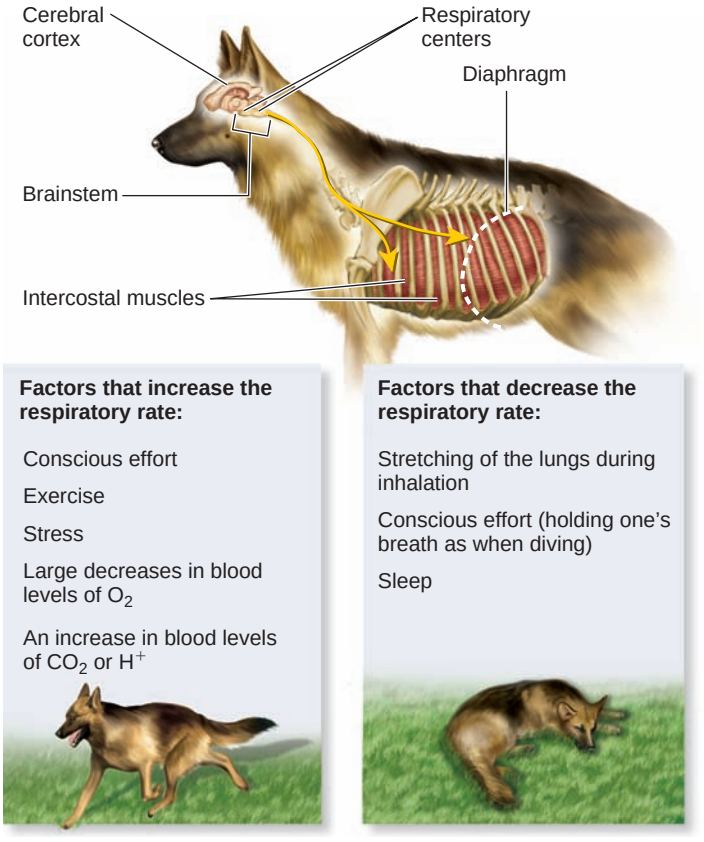


Figure 48.14 The control of breathing via respiratory centers in the mammalian brain. Neurons in the brainstem send action potentials along neurons in nerves that stimulate the intercostal muscles and diaphragm. The factors listed here can modulate the rate of action potential generation and therefore the respiratory rate.

Chemoreceptors Modulate the Activity of the Respiratory Centers

The respiratory centers are influenced by the concentrations of certain substances in the blood, including the partial pressures of oxygen and carbon dioxide, and the concentration of hydrogen ions (in other words, blood pH). **Chemoreceptors**—special cells located in the aorta, carotid arteries, and the brainstem—detect the circulating levels of these substances and relay that information through nerves or interneurons to the respiratory centers.

Normally, the oxygen level is not the most important variable monitored by chemoreceptors. However, if the oxygen level falls far below normal, as might occur at high altitude or in certain respiratory diseases, the chemoreceptors signal the respiratory centers to increase the rate and depth of breathing to increase ventilation of the lungs. This brings in more oxygen. Similarly, a buildup of carbon dioxide in the blood, which would occur if an animal's ventilation were lower than normal (again, often the result of respiratory disease), signals the respiratory centers to stimulate breathing. Not only does increased ventilation bring in more oxygen, it also helps eliminate more carbon dioxide. Finally, an increased level of hydrogen ions in the blood activates chemoreceptors, which signal the brain that the blood is too acidic. This leads to an increase in the rate of breathing.

What is the link between ventilation rate and hydrogen ion concentration? The concentrations of carbon dioxide and hydrogen ions in the blood are related, because the concentration of hydrogen ions in the fluid bathing the brainstem chemoreceptors reflects the amount of carbon dioxide produced by cells during metabolism. This is because roughly two-thirds of the carbon dioxide produced during metabolism is converted into a less toxic and more soluble form, bicarbonate ions (HCO_3^-). In the process, hydrogen ions are formed according to the following reaction, where H_2CO_3 is a short-lived compound called carbonic acid that immediately dissociates to a hydrogen ion and a bicarbonate ion:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

This reaction is readily reversible. The first step is catalyzed in both directions by the enzyme carbonic anhydrase, which is present in high amounts in red blood cells. As you learned in Chapter 2, reactions of this type proceed in a net "direction" according to the concentrations of the reactants and products. For example, if CO_2 levels were to increase for any reason, the forward reaction (from left to right as illustrated here) would be favored, and the pH of the blood would decrease because hydrogen ions would increase. Conversely, if the levels of CO_2 decreased, the reactions would proceed from right to left, and the pH of the blood would increase as hydrogen ions were removed from the blood and combined with bicarbonate ions.

So what happens when an animal exercises? During exercise, lactic acid—a by-product of metabolism—is released into

the blood, and this lowers the pH of the blood. The increase in hydrogen ion concentration that results from lactic acid activates chemoreceptors to stimulate increased ventilation. This, in turn, helps prevent CO_2 levels from increasing in the blood despite the increased metabolism that is occurring.

In body tissues, CO_2 levels are high because metabolism is generating the gas. As stated earlier, the reactions proceed largely to the right, and CO_2 and H_2O are converted to H^+ and HCO_3^-. As blood flows through the lungs, however, dissolved CO_2 diffuses into the alveoli and is exhaled. Therefore, CO_2 levels in the lung capillaries decrease, which favors the reverse reactions (right to left), so HCO_3^- and H^+ are converted back to CO_2 and H_2O; the CO_2 is then exhaled. These reactions are remarkably fast, occurring within the space of time required for blood to move through a capillary, typically less than 1 second.

The chemoreceptors in the brain are very sensitive to certain drugs, such as ethanol, opiates, and barbiturates. These drugs decrease the sensitivity of chemoreceptors to CO_2, for example, and thereby reduce ventilation to potentially life-threatening levels. Particularly when taken together, these drugs may be a lethal combination partly because of their inhibitory effects on ventilation.

Respiratory Center Activity Varies Among Species with Different Metabolic Rates

The respiratory centers are sensitive to a variety of other factors besides gases and hydrogen ions, such as sleep, stress, hormones, and body size. Recall from Chapter 46 that small animals tend to have higher metabolic rates than larger animals. Thus, small animals would be expected to require more oxygen per unit mass than would larger animals. This is not achieved by having disproportionately large lungs in small animals. Instead, small animals have higher breathing rates than do large animals. The respiratory centers are set at a higher rate in smaller, active animals. For example, a typical adult human takes about 12 to 14 breaths per minute at rest, whereas hummingbirds, small rodents, and shrews have astonishingly high rates of breathing, up to many hundreds of breaths per minute (see Table 48.1)! Thus, the respiratory activity of small, highly active animals is matched with their metabolism by increasing the resting breathing rate. This is similar to the differences in cardiac function among species. Small animals have hearts that are roughly proportional to their body size, but with higher heart rates than are found in larger animals (refer back to Table 47.1). Parallel changes in the heart and breathing rates are adaptations that allow small animals to have small hearts and lungs yet achieve high metabolic rates.

48.5 Mechanisms of Oxygen Transport in Blood

Gases such as oxygen are soluble in the plasma component of blood, but as with all solutes, there are limits to how much of a gas can dissolve in a volume of water. The amount of gas dissolved in the body fluids is not sufficient to sustain life in most animals. In nearly all animals, therefore, the amount of oxygen in the body fluid compartments must be increased above that which can be physically dissolved. This is made possible because of the widespread occurrence in animals of oxygen-binding proteins, which increase the total amount of oxygen available to cells. In this section, we examine the nature, function, and evolution of these molecules.

Oxygen Binds to Respiratory Pigments

The oxygen-binding proteins that have evolved in animals are called **respiratory pigments**, because they have a color (blue or red). In vertebrates, the pigments are contained within red blood cells, whereas many invertebrates have these pigments in their hemolymph. Enclosing the pigments within blood cells is an efficient way to package them, because this keeps the pigments in close proximity to various cellular enzymes that assist in binding and unbinding the gases to the pigments.

Respiratory pigments are proteins containing one or more metal atoms in their cores; the metal atom binds to oxygen. Typically, the metal is iron (Fe^{2+}) in vertebrates and many marine invertebrates, but in decapod crustaceans, arachnids, and many mollusks (including cephalopods and some gastropods), it is copper (Cu^{2+}). The copper-containing pigment, **hemocyanin**, gives the blood or hemolymph a bluish tint. **Hemoglobin** is the major iron-containing pigment and gives blood a red color when oxygen is bound.

Hemoglobin gets its name because it is a globular protein—which refers to the shape and water solubility of a protein—and because it contains a chemical group called a heme in its core. An atom of iron is bound within the heme group. In vertebrates, hemoglobin consists of four protein subunits, each with its own heme group and iron atom to which a molecule of oxygen can bind (refer back to Figure 47.6). Thus, a single hemoglobin protein can bind up to four molecules of oxygen.

Respiratory pigments share certain characteristics that make them ideal for transporting oxygen. First, they all have a high affinity for binding oxygen. Second, the binding between the pigment and oxygen is noncovalent and reversible. It would not be very useful for a protein to bind oxygen if it could not later unload the oxygen to cells that need it. The formula for the reversible binding of oxygen to a respiratory pigment is:

$$Hb + O_2 \leftrightarrow HbO_2$$

where Hb is hemoglobin, HbO_2 is called oxyhemoglobin, and the double arrows indicate that the reaction is reversible.

The amount of pigment present in the blood is great enough to provide sufficient oxygen to meet all but the most strenuous exertion. In humans, for example, the presence of hemoglobin gives blood about 45 times more oxygen-carrying capacity than would plasma alone.

Differences exist among respiratory pigments, however, at the molecular level. For example, the amino acid sequences of hemoglobins from different species vary, in some cases considerably. Human hemoglobin is similar but not identical to that of

other mammals, and mammalian hemoglobins have numerous amino acid differences from other vertebrate hemoglobins. The differences in amino acid sequences cause slight changes in the overall three-dimensional shape of hemoglobin, which alters its affinity for oxygen. As a general rule, animals with the highest metabolic rates tend to have hemoglobins with lower oxygen affinity, and animals with lower metabolic rates have higher affinities. That may sound paradoxical at first, but consider the preceding reactions again. Because the hemoglobin of small animals with high metabolic rates has lower oxygen affinity, the reverse reaction ($HbO_2 \rightarrow Hb + O_2$) will be more likely to occur when oxygen is diffusing from the blood to active cells. In other words, hemoglobin unloads its oxygen more readily in those animals whose cells use oxygen at the greatest rates.

The Amount of Oxygen Bound to Hemoglobin Depends on the P_{O_2} of Blood

Recall that the partial pressure of O_2 (P_{O_2}) is a measure of its dissolved concentration. When P_{O_2} is high, more O_2 binds to hemoglobin, whereas fewer O_2 molecules will be bound when P_{O_2} is low. Figure 48.15 shows the relationship between O_2 binding and P_{O_2}, known as an **oxygen-hemoglobin dissociation curve**, for humans. At a P_{O_2} of 100 mmHg, which is found in the blood leaving the lungs, each hemoglobin protein binds four O_2 molecules. It is 100% saturated with oxygen. The P_{O_2} of blood leaving the tissue capillaries of other parts of the body is lower and depends on metabolic activity and exercise. At rest, the P_{O_2} of blood capillaries in these other parts of the body is typically around 40 mmHg. At this P_{O_2}, hemoglobin releases some O_2 molecules, becoming less saturated with O_2. At high levels of exercise, P_{O_2} in the capillaries drops even further (as low as 20 mmHg), and hemoglobin releases even more O_2. In this way, hemoglobin performs its role of oxygen delivery. In the lungs, it binds O_2, and in other tissues of the body, it releases some of the O_2 as needed.

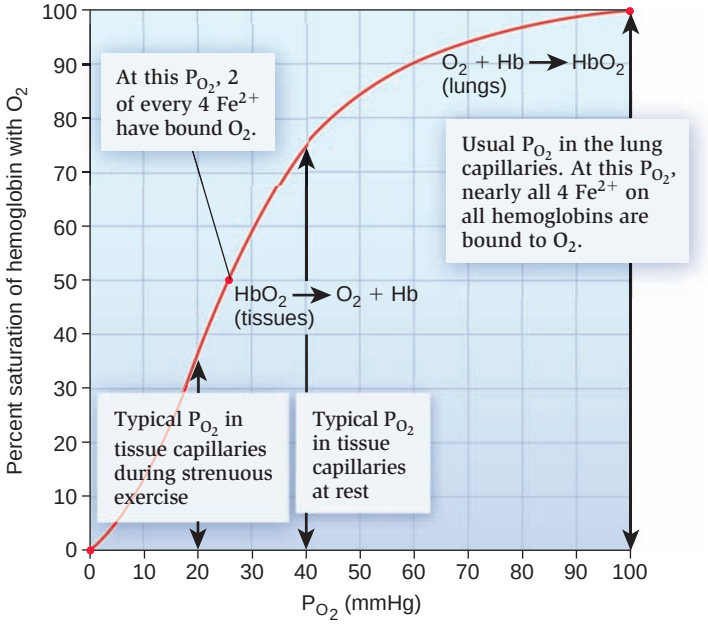

Figure 48.15 The human oxygen-hemoglobin dissociation curve. Depending on the partial pressure of oxygen, oxygen is either loaded onto hemoglobin, as in the lungs, or unloaded from hemoglobin, as in the rest of the body tissues. When P_{O_2} is high, more Fe^{2+} atoms are bound to O_2, and the hemoglobin is more saturated with O_2.

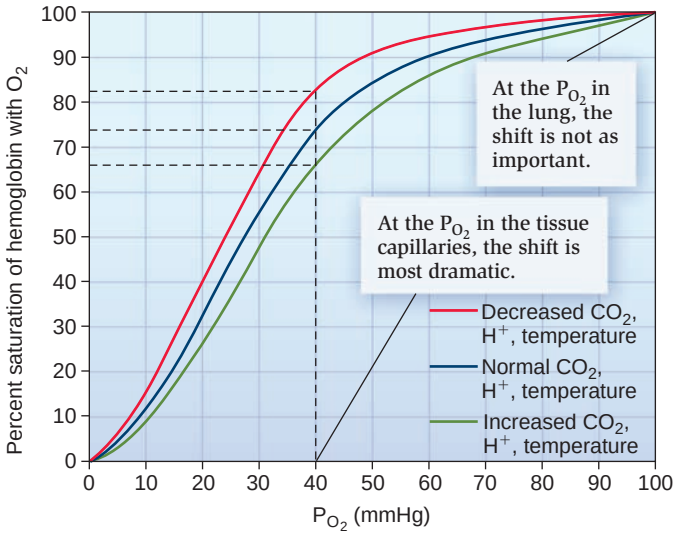
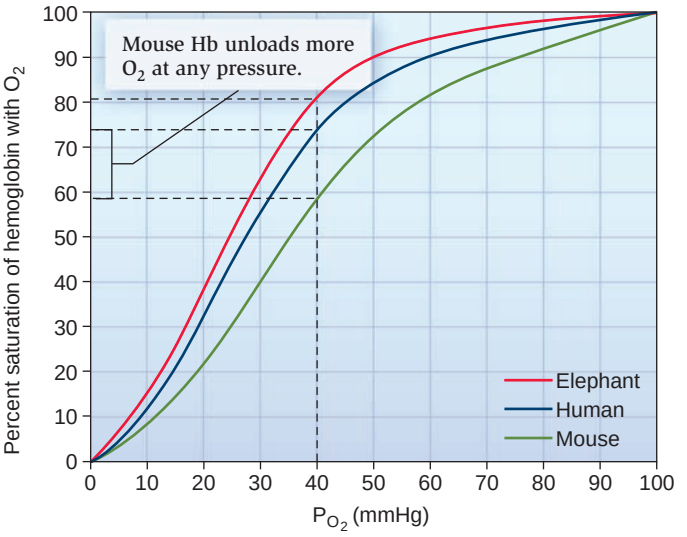
Concept check: Members of the Channichthyidae family of Antarctic icefish are the only vertebrates that do not have red blood cells and hemoglobin. Can you propose some mechanisms or adaptations that allow them to survive without the oxygen reservoir provided by hemoglobin? (Hint: Think about the effect of temperature on oxygen solubility and on an animal's metabolic rate.)

You may have noticed that the curve in Figure 48.15 is not linear but S-shaped (sigmoidal). This is because the subunits of hemoglobin are said to cooperate with each other in binding oxygen. Once a molecule of oxygen binds to one subunit's iron atom, the shape of the entire hemoglobin protein changes, making it easier for a second oxygen to bind to the next subunit, and so on. Thus, the relationship between oxygen pressure and the amount of oxygen bound to hemoglobin becomes very steep in the midrange of the curve, which represents the pressures that occur in the tissue capillaries throughout the body except in the lungs. This steepness allows O_2 release to be very sensitive to changes in P_{O_2}.

One of the remarkable features of the oxygen-hemoglobin binding relationship is that it can be influenced by metabolic waste products such as CO_2 and H^+ and also by temperature. In addition to being transported as bicarbonate ions, about 25% of the CO_2 in blood is bound to hemoglobin. The remainder—about 7–10%—exists dissolved in solution in the plasma and within red blood cells. Figure 48.16a shows three curves, one obtained under normal resting conditions and the others in the presence of low or high levels of CO_2. Carbon dioxide binds to amino acids in the hemoglobin protein (not to the iron, like O_2), and when it does, the ability of hemoglobin to continue binding oxygen decreases. Note how increased CO_2 shifts the curve to the right, such that at any P_{O_2}, less O_2 is bound to hemoglobin. Another way of saying this is that at any P_{O_2}, more O_2 has been released from hemoglobin, thus becoming available to cells. A similar shift in the curve occurs in the presence of H^+, which can also bind to hemoglobin; these effects of CO_2 and H^+ on the oxygen-hemoglobin dissociation curve are known as the Bohr effect, or Bohr shift, after their discoverer, the Danish physiologist Christian Bohr. Elevated temperature will also reduce the affinity of hemoglobin for oxygen, resulting in a shifted curve. Cells generate each of these products—CO_2, H^+, and heat—when they are actively metabolizing fuel. The metabolic products enter the surrounding blood vessels, where they disrupt the normal shape of hemoglobin, causing it to release more of its oxygen than would normally occur at that oxygen pressure. This phenomenon is a way in which individual body tissues can obtain more oxygen from the blood to match their changing metabolic demands. Thus, when an animal exercises, the skeletal muscles generate more waste products and heat than does,



(a) Shifts in the oxygen-hemoglobin dissociation curve



(b) Oxygen-hemoglobin dissociation curves of different animals

Figure 48.16 **Differences in oxygen-hemoglobin dissociation curves under different physiological conditions and among different species.** **(a)** Increasing or decreasing the amounts of carbon dioxide or hydrogen ions (acid), or the temperature of the blood, shifts the oxygen-hemoglobin dissociation curve. Actively metabolic tissues generate these products. The change in affinity of hemoglobin for oxygen allows different tissues to obtain oxygen in proportion to their metabolic requirements. **(b)** Oxygen-hemoglobin dissociation curves for three mammals with low (elephant), moderate (human), or high (mouse) relative metabolic rates. For any P_{O_2}, such as the one shown (40 mmHg), which is typical of the P_{O_2} of tissue capillaries, less oxygen is bound to mouse hemoglobin than to human or elephant hemoglobin, and less O_2 is bound to human hemoglobin than to elephant hemoglobin. Therefore, O_2 is unloaded from hemoglobin more readily in smaller animals.

Concept check: *What would happen to the position of the middle curve in part (a) following infusion of bicarbonate ions (HCO_3^-) into the blood of a resting, healthy individual?*

say, the skin. Therefore, the oxyhemoglobin in muscle blood vessels releases more oxygen to the cells where it is immediately required.

The shift in the oxygen-hemoglobin dissociation curve occurs in all classes of vertebrates (although not in all species), but it has different magnitudes in different species. Not surprisingly, perhaps, the most metabolically active animals, such as mice, show a greater shift for a given increase in CO_2, H^+, or heat than do less-active animals. Recall from Chapter 47 that these same waste products of metabolism also cause local vasodilation of arterioles. Thus, the more metabolically active a tissue is, the more blood flow it receives, which means more oxygen-bound hemoglobin. Moreover, the oxygen is unloaded from hemoglobin more readily due to the shift in the curve. This is another example of how adaptive changes in circulatory and respiratory functions often occur in parallel.

The hemoglobins of metabolically active animals also have a lower affinity for oxygen (Figure 48.16b). Small, active animals have curves that are displaced to the right of the human curve. In contrast, larger animals with slower metabolisms, such as the elephant, have curves shifted to the left of humans. At high oxygen pressures, such as those that occur in the lungs, these shifts have little relevance because nearly all the hemoglobin is bound to oxygen at those pressures. At lower oxygen pressures, however, such as those that would occur in the blood vessels of actively metabolic tissues, the difference in the curves becomes significant. For example, look at the three curves at an oxygen pressure of 40 mmHg, a typical value found in tissues that are using oxygen at a resting rate. The mouse hemoglobin has less oxygen bound (its hemoglobin is less saturated) at that pressure than does the human hemoglobin, which, in turn, has less oxygen bound than does the elephant hemoglobin. In other words, the mouse hemoglobin has released more of its oxygen to the active tissues than have the other animal hemoglobins.

Oxygen-carrying molecules are among the most ancient proteins found in animals. They appear to have begun as simple, single-subunit proteins such as muscle myoglobin, which stores oxygen in muscle cells. Around 500 million years ago, the gene for this ancient molecule duplicated, resulting in one gene that coded for myoglobin and the other for an early form of hemoglobin (refer back to Figure 21.8). Thus, animals gained the ability to not only store oxygen in tissues but also to transport it throughout the body via the circulation. Let's take a closer look at the molecular structure and evolution of hemoglobin and how a simple mutation in the sequence of one hemoglobin gene can have devastating consequences in humans.

Genomes & Proteomes Connection

Hemoglobin Evolved Over 500 Million Years Ago

Modern hemoglobin in adult mammals contains four subunits, designated $\alpha 1$, $\alpha 2$, $\beta 1$, and $\beta 2$. The two alpha and two beta

subunits are identical. Early in animal evolution, hemoglobin existed only as monomers (one subunit) or dimers (two subunits), which is still observed in lampreys. Later, gene duplication created the second set of subunits, leading to the four-subunit form, which first appeared in sharks and bony fishes. As we have seen in this chapter, the subunit structure of hemoglobin enables one hemoglobin protein to bind four oxygen molecules. Equally important, the subunits of hemoglobin cooperate with each other as shown by the sigmoidal shape of the oxygen-hemoglobin dissociation curve.

As noted earlier, modern hemoglobins differ among species within the same class of vertebrates and even more so between classes. This suggests that evolution of the hemoglobin genes continued even after the four-subunit structure appeared. The mutations that arose in the hemoglobin genes affected the structure of the hemoglobin protein. One consequence is that the affinity of hemoglobin for oxygen differs among animals, as discussed earlier. The differences in affinity may result, for example, in better oxygen-capturing ability of animals living in regions of low oxygen pressure, such as at high altitude. They also account, at least in part, for the ability of metabolically active animals to unload oxygen from hemoglobin more readily than less metabolically active organisms.

Despite the high frequency of mutations in the hemoglobin genes in vertebrates, certain regions of the molecule have remained well conserved. Not surprisingly, these are regions that are critically important for the function of the molecule. For instance, the amino acids that encase the heme group and iron atom of each subunit have changed little if at all during evolution. Similarly, the amino acid sequences associated with sites of subunit interactions have also resisted evolutionary change. Mutations that arise in these regions are typically not adaptive and may even be lethal.

Some mutations in the hemoglobin genes may appear to be detrimental because they negatively impact hemoglobin's function, and yet they provide a selective advantage under certain conditions. Consider the disease **sickle-cell disease** (also called sickle-cell anemia). In this case, substitution of a thymine for an adenine at one position in the hemoglobin gene results in a single amino acid substitution (refer back to Figure 14.1). This produces an abnormal form of hemoglobin that tends to form polymers and precipitate under low oxygen conditions, particularly in capillaries and veins. The protein forms long fibrous strands that may permanently deform the red blood cell, making it sickle-shaped. Sickled cells are less able to move smoothly through capillaries and can block blood flow, resulting in severe pain and cell death in the surrounding tissue.

The sickled red blood cells are also fragile and easily destroyed. The loss of those cells and their hemoglobin results in anemia, meaning that people with the disease have less oxygen-carrying capacity in their blood. Only individuals who are homozygous for this mutation show the dramatic phenotype of the disease. Heterozygotes are relatively unaffected.

The sickle-cell gene mutation is present in up to a third of individuals living in malaria-prone regions of Africa, to lesser extents in the Middle East and Eastern Europe, and in roughly 8% of African Americans (refer back to Figure 24.6). Why should such an obviously harmful mutation have persisted in the human population?

Malaria, a disease transmitted by bites from mosquitos of the genus *Anopheles*, is a global health threat that is responsible for over 300 million severe illnesses and 1 million deaths every year. When an infected mosquito bites, it injects a parasitic protozoan of the family Plasmodiidae (the most deadly being *Plasmodium falciparum*) into the circulation, where it spends part of its life cycle growing and multiplying within the host's red blood cells (refer back to Figure 28.29). The sickle-cell trait protects individuals from developing full-blown malaria, although the reason for this is uncertain. One favored hypothesis states that the parasite lowers the oxygen pressure in red blood cells by consuming oxygen to support its own metabolism. This may render the red blood cell susceptible to sickling even in heterozygous individuals. The damaged cells are destroyed and removed from the circulation, which also removes the parasite and limits its ability to multiply. Another hypothesis states that the heterozygotic condition results in a more efficient immune response of the body to the presence of the parasite. Thus, although both malaria and homozygous sickle-cell disease are life-threatening, heterozygotes for the sickle-cell trait develop neither pronounced anemia nor severe malaria and therefore have an advantage in areas where malaria is present. This heterozygote advantage explains why the sickle-cell mutation persists among certain human populations.

48.6 Adaptations to Extreme Conditions

Many animals are able to live permanently or temporarily in low-oxygen environments. Many humans, for instance, live in mountainous regions, and llamas and mountain goats spend most of their lives at extremely high altitudes. Other animals may only transiently encounter periods of oxygen deprivation, such as some reptiles, birds, and mammals that dive underwater to forage for food. As described in this section, several adaptations allow animals to exploit these environments, but all of them include changes in both cardiovascular and respiratory activities.

Life at High Altitudes Requires More Hemoglobin

Animals that live at high altitudes must have special adaptations that permit them to obtain the oxygen they need at such low atmospheric pressures. Llamas, such as the one shown in the chapter-opening photo, may live at altitudes up to 4,800 m, where the P_{O_2} is only about 85 mmHg (compared with 160 mmHg at sea level). Llama hemoglobin is quite different in amino acid sequence from that of other mammals, giving it an extraordinarily high affinity for binding oxygen even at very low atmospheric pressure. In other words, their hemoglobin curves are well to the left of a human's. In addition, llamas have larger hearts and lungs than would be predicted for their body size,

and a higher number of red blood cells in a given volume of blood. These adaptations provide the oxygen-carrying capacity and cardiac output needed to deliver sufficient oxygen to the tissues, even at low partial pressures of oxygen.

When animals that normally inhabit lowland areas temporarily move to higher altitudes, they develop some of these same features. In humans, for example, the number of red blood cells increases from about 5.1×10^{12} cells/L to about 6.4×10^{12} cells/L. This is stimulated by the hormone erythropoietin, which is secreted by the kidneys when the arterial P_{O_2} is low. This hormone acts on bone marrow to stimulate maturation of new red blood cells. Moving to higher elevations also increases ventilation due to a higher rate of breathing. The number of capillaries in skeletal muscle increases at high altitudes, a modification that facilitates oxygen diffusion into muscle cells. Finally, myoglobin content increases in muscle cells, expanding the reservoir of oxygen in the cytosol of those cells. Thus, after several days or weeks at high altitude, the cardiovascular and respiratory systems adapt together to maximize oxygen uptake, diffusion of oxygen into the blood, and the oxygen-carrying capacity of blood.

Diving Animals Rely on Anaerobic Respiration Once Their Oxygen Is Depleted

Many birds, reptiles, and several species of mammals spend time under water, foraging for food or escaping predators. During that time, the animal cannot breathe. In short dives, this is not a problem. We are all familiar with our own ability to stay under water for a minute or so. After that time, the oxygen level in the blood decreases, the carbon dioxide level in the blood increases, and we must surface for air. Some marine mammals, however, have an astonishing ability to remain under water for very long periods—up to nearly 2 hours in beaked whales and elephant seals. During that time, they continue to be active and search for food. How do they do it?

Like high-altitude animals, many diving animals have unusually high numbers of red blood cells, allowing them to store more oxygen in their blood than nondiving animals. In some species, such as seals, the extra blood cells are stored in the spleen until they dive, at which time the spleen contracts like wringing a wet washcloth and ejects the blood cells into the circulation. When seals resurface, the blood cells are sequestered again in the spleen until needed. In addition to having more erythrocytes, diving mammals typically have larger blood volumes than comparably sized mammals that live exclusively on land.

The muscles of diving mammals usually contain large quantities of myoglobin and its bound oxygen. This means that the muscles do not need to consume the precious stores of oxygen circulating in blood. Instead, the blood and its oxygen can be routed to other critical structures that lack myoglobin, such as the eyes, certain glands, the brain, and the placenta if the animal is pregnant.

Eventually, even with these adaptations, the oxygen in muscles and blood becomes so depleted that the only way to prolong the dive is for cells to begin respiring anaerobically. Most of a long dive, in fact, occurs under anaerobic conditions.

This concludes our examination of the ways in which animals obtain oxygen and eliminate carbon dioxide. We now address the importance of healthy lung function in humans and the ways in which humans are affected by respiratory diseases.

48.7 Impact on Public Health

Respiratory diseases afflict over 10% of the U.S. population and cause an estimated 500,000 deaths per year, making lung disease among the top three causes of death in the U.S. As many as 25 million Americans have impaired lung function. The economic impact of respiratory disorders on the U.S. economy is staggering, with recent estimates of $40–150 billion per year in health-related costs and lost work time. Many of these diseases are chronic—once they appear, they last for the rest of a person's lifetime. Lifestyle factors, such as smoking tobacco and exposure to air pollution, cause some respiratory disorders or make existing conditions worse. In this section, we examine a few of the most common respiratory disorders, as well as some of their causes and treatments.

Asthma Is a Disease of Hyperreactive Bronchioles

You learned earlier that the bronchioles deliver fresh air to the alveoli. Bronchioles are thin tubes surrounded by smooth muscle cells that can contract in the presence of airborne pollutants or other potentially damaging substances. In the disease **asthma**, however, the muscles around the bronchioles are hyperexcitable and contract more than usual. Contraction of these muscles narrows the bronchioles, a process called bronchoconstriction. This makes it difficult to move air in and out of the lungs, because resistance to airflow increases when the diameter of the airways decreases. Often, the resistance to airflow can be so great that the movement of air creates a characteristic wheezing sound.

Asthma tends to run in families and therefore has a genetic basis. Several known triggers can elicit wheezing, including exercise, cold air, and allergic reactions. The latter is of interest because asthma is believed to be partly the result of an imbalance in the immune system (see Chapter 53), which controls inflammation and other allergic responses. During flare-ups of asthma, a viscous, mucus-like fluid may inhibit the flow of air in and out of the airways and make symptoms worse.

The symptoms of asthma can be alleviated by inhaling an aerosol mist containing **bronchodilators**, compounds that bind to receptors located on the plasma membranes of smooth muscles that comprise the outer part of bronchioles. These compounds, which are related to the neurotransmitter norepinephrine, cause bronchiolar smooth muscles to relax. This, in turn, allows the bronchioles to dilate (widen). To help reduce the inflammation of the lungs, patients may inhale a mist

containing hormones with anti-inflammatory actions. Currently there is no cure for asthma, but with regular treatment and the avoidance of known triggers, most people with this disease can lead perfectly normal lives.

Tobacco Smoke Causes Respiratory Health Problems and Cancer

Smoking tobacco products is one of the leading global causes of death, contributing to about 430,000 deaths each year in the U.S. alone and over 5 million per year worldwide. According to the Centers for Disease Control and Prevention and the American Lung Association, people who smoke up to one pack of cigarettes each day live on average 7 years less than nonsmokers, and heavy smokers lose on average 15–25 years of life. Pregnant women who smoke run a high risk of their babies being born underweight, a potentially serious condition that may affect the newborn's long-term health.

Up to 85% of all new cases of lung cancer diagnosed each year are attributable to smoking, making lung cancer the leading cause of preventable death. Equally important, however, is that smoking is estimated to be responsible for nearly 30% of all cancers, including cancer of the mouth and throat, esophagus, bladder, pancreas, and ovaries. Smoking is also a leading cause of cardiovascular disease, high blood pressure, atherosclerosis, and stroke. Smoking as few as three to five cigarettes per day raises the risk of heart disease.

Because the products of tobacco smoke are inhaled directly into the lungs, the chemicals in smoke can do considerable damage to lung tissue. Even adolescents who have only recently started smoking have increased mucus (phlegm) production in their airways, shortness of breath, and reduced lung growth. Thousands of chemicals, including over 40 known cancer-causing compounds, have been identified in cigarette smoke. Some of these chemicals—such as formaldehyde—are toxic to all cells. Others, like the odorless gas carbon monoxide (CO), have harmful effects on lung function in particular. CO competes with oxygen for binding sites in hemoglobin, thereby reducing hemoglobin saturation. Heavy smokers who smoke more than a pack of cigarettes each day may have as much as 15% less oxygen-carrying capacity in their blood.

In addition to its effects on cancer, cardiovascular disease, and lung function, long-term smoking is the major cause of the serious and irreversible disease emphysema.

Emphysema Causes Permanent Lung Damage

Unlike asthma, in which the major problems are inflamed airways and hyperreactive bronchioles, **emphysema** involves extensive lung damage (Figure 48.17). The disease reduces the elastic quality of the lungs and the total surface area of the alveoli, which cuts the rate of oxygen diffusion from the lungs into the circulation. Consequently, one sign of emphysema is a lower than normal partial pressure of oxygen in the arteries. It is also physically harder to exhale because of the loss of elasticity, and therefore, arterial CO_2 levels increase. Finally, the terminal ends of the bronchioles are often damaged, which increases resistance to airflow and creates asthma-like symptoms and shortness of breath.

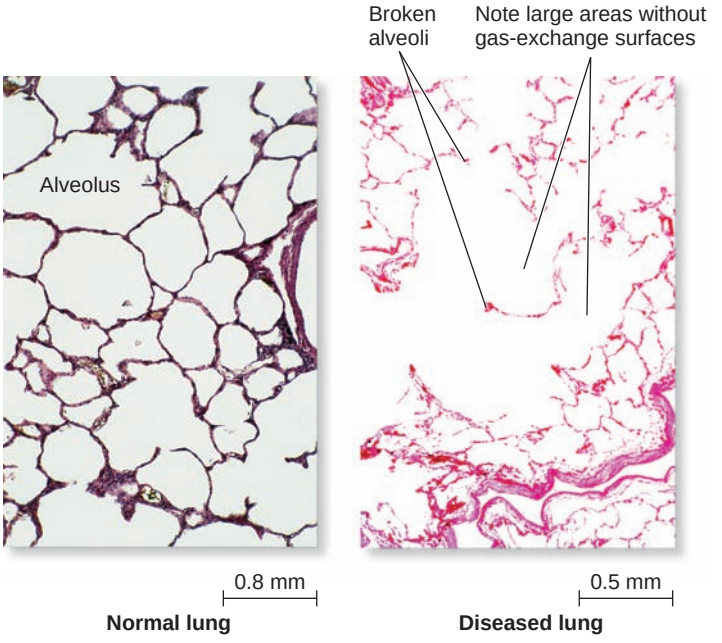


Figure 48.17 **The effects of emphysema.** These light micrographs compare a section of a normal lung (left) with that of a lung from a person who died of emphysema (right). The destruction of alveoli caused by this disease reduces the surface area for gas exchange in the lungs.

Reduced blood oxygen and poor lung function limit the patient's ability to function, and in its late stages, emphysema results in a person being essentially bedridden. Oxygen therapy, in which the person breathes a mixture of air and pure oxygen from a portable gas tank, can provide some help. The extra oxygen increases the pressure gradient for oxygen from the alveoli to the lung capillaries, promoting oxygen diffusion into the blood.

Estimating how many people have emphysema is difficult because the symptoms appear gradually, but more than 3 million people have severe cases of the disease, and about 120,000 people die from it each year in the U.S. Emphysema is a progressive disease that does not go away. As the years go by, the disease worsens, although medical care can slow the rate at which this happens.

In some cases, emphysema results from an enzyme deficiency in the lungs that destroys the protein that provides the recoil during exhalation, or it may result from chronic exposure to air pollution. However, the overwhelming majority of cases, 85%, are due to smoking. Toxins in cigarettes and other tobacco products damage the lungs by stimulating white blood cells to release proteolytic enzymes that degrade lung tissue. The likelihood of developing emphysema is strongly correlated with the quantity of cigarettes smoked during a person's lifetime.

Summary of Key Concepts

48.1 Physical Properties of Gases

- Gas exchange is the process of moving oxygen and carbon dioxide in opposite directions between the environment, body fluids, and cells. The partial pressure of oxygen in the environment provides the driving force for its diffusion from air or water across a respiratory organ and into the blood. Atmospheric pressure decreases at higher elevations. (Figure 48.2)
- Three factors—the pressure of the gas, temperature of the water, and presence of any other solutes—are particularly important for affecting the solubility of a gas in water.

48.2 Types of Respiratory Systems

- Ventilation is the process of bringing oxygenated water or air into contact with a respiratory organ. All respiratory organs have moist surfaces in which gases can dissolve and diffuse, as well as other adaptations that increase the amount of surface area and blood flow. Water-breathing and air-breathing animals face different gas exchange challenges.
- The body surface is permeable to gases in some invertebrates and in amphibians, eels, and a few other species of fishes. (Figure 48.3)
- Water-breathing animals use external or internal gills for gas exchange. (Figures 48.4, 48.5, 48.6)
- Air-breathing animals have evolved two major mechanisms to exchange gas with the environment: tracheal systems in insects and lungs in terrestrial vertebrates. In insects, air moving down the tracheoles comes into contact with fluid at the tracheole tips. Oxygen from the air dissolves in this fluid and diffuses across the tracheole wall and into nearby cells. (Figure 48.7)
- Except for some rare amphibians, all air-breathing vertebrates use lungs to bring oxygen into the circulatory system and remove carbon dioxide. All lungs receive deoxygenated blood from the heart and return oxygenated blood to the heart.
- Frogs and most other amphibians ventilate their lungs with positive pressure filling, which uses the principles of Boyle's law. (Figure 48.8)

48.3 Structure and Function of the Mammalian and Avian Respiratory Systems

- The mammalian respiratory system includes the nose, mouth, airways, lungs, and muscles and connective tissues that encase these structures within the thoracic (chest) cavity. (Figure 48.9)
- Most reptiles and all birds and mammals ventilate their lungs by negative pressure filling. In mammals, the work is provided by the intercostal muscles and diaphragm.
- Mammals breathe by tidal ventilation. Tidal volume is proportional to body size within and between species. (Figure 48.10, Table 48.1)
- The avian respiratory system, a flow-through system, is unique among vertebrates because it is supplemented with numerous air sacs. Inhaled air is stored in air sacs before passing through the lungs. Blood flows through the lungs in a crosscurrent direction with respect to the movement of oxygen. This is less efficient in extracting oxygen than the countercurrent flow in fish gills, but more efficient than the tidal ventilation system of mammals. (Figures 48.11, 48.12, 48.13)

48.4 Control of Ventilation in Mammalian Lungs

- In mammals, respiratory centers in the brainstem initiate the rhythmic expansion of the lungs. (Figure 48.14)
- Chemoreceptors detect blood levels of hydrogen ions and the partial pressures of carbon dioxide and oxygen. They relay this information through nerves to the respiratory centers, which, in turn, affect the breathing rate. The respiratory centers are also sensitive to other factors, such as sleep, stress, hormones, and body size.

48.5 Mechanisms of Oxygen Transport in Blood

- There are limits to how much of a gas can dissolve in water. These limits are overcome in nearly all animals by either transporting a gas reversibly bound to a protein carrier or by transforming the gas into a more soluble form.
- Animals have evolved a way to carry a reservoir of oxygen on respiratory pigments, large proteins containing one or more metal atoms that bind to oxygen. Typically, the metal is iron in vertebrates and many marine invertebrates, and copper in decapod crustaceans, arachnids, and many mollusks, including cephalopods and some gastropods.
- The amount of oxygen bound to hemoglobin depends on the partial pressure of oxygen in the blood. Metabolic waste products can influence the oxygen-hemoglobin binding relationship. (Figures 48.15, 48.16)
- The evolution of the globin gene family has resulted in several specialized hemoglobin proteins. Heterozygotes for the sickle-cell allele are resistant to malaria.

48.6 Adaptations to Extreme Conditions

- Several adaptations in cardiovascular and respiratory activities allow animals to exploit low-oxygen environments. Animals that inhabit high altitudes have larger hearts and lungs and have hemoglobin with a high affinity for binding oxygen. Many diving animals have unusually high numbers of red blood cells and also muscles with large quantities of myoglobin.

48.7 Impact on Public Health

- In asthma, the muscles around the bronchioles contract more than usual, increasing resistance to airflow.
- Smoking tobacco products is one of the leading global causes of death. Smoking is strongly linked to cancer, cardiovascular disease, stroke, and emphysema. (Figure 48.17)

Assess and Discuss

Test Yourself

1. The driving force for diffusion of oxygen across the cells of a respiratory organ is
   a. the difference in the partial pressure of oxygen in the environment and in the blood.
   b. the humidity.
   c. the partial pressure of carbon dioxide in the blood.
   d. the air temperature.
   e. the partial pressure of carbon dioxide in the atmosphere.
2. Carbon dioxide is considered a harmful by-product of cellular respiration because it
   a. lowers the pH of the blood.
   b. lowers the hydrogen ion concentration in the blood.
   c. competes with oxygen for transport in the blood.
   d. does all of the above.
   e. a and b only
3. The process of bringing oxygenated water or air into contact with a gas-exchange surface is
   a. respiration. c. ventilation. e. exhalation.
   b. gas exchange. d. gas transport.
4. The group of vertebrates with the greatest capacity for gas exchange across the skin is
   a. the fishes. d. the birds.
   b. the reptiles. e. the mammals.
   c. the amphibians.
5. The countercurrent exchange mechanism in fish gills
   a. maximizes oxygen diffusion into the bloodstream.
   b. is a less efficient mechanism for gas exchange compared to mammalian lungs.
   c. occurs because the flow of blood is in the same direction as water flowing across the gills.
   d. is the same phenomenon observed in birds' lungs.
   e. requires that the fish swallow water.
6. The tracheal system of insects
   a. consists of several tracheae that connect to multiple lungs within the different segments of the body.
   b. consists of extensively branching tubes that are in close contact with all the cells of the body.
   c. allows oxygen to diffuse across the thin exoskeleton of the insect to the bloodstream.
   d. cannot function without constant movement of the wings to move air into and out of the body.
   e. provides oxygen that is carried through the animal's body in hemolymph.
7. _____ is secreted by Type II alveolar cells in the mammalian lung to prevent the collapse of alveoli due to surface tension at the interface of air and extracellular fluid.
   a. Hemoglobin c. Mucus e. Surfactant
   b. Myoglobin d. Water
8. In negative pressure filling, air moves into the lungs when
   a. the volume of the thoracic cavity increases.
   b. the pressure in the thoracic cavity decreases.
   c. air is forced down the trachea by muscular contractions of the mouth and pharynx.
   d. all of the above
   e. a and b only
9. Which of the following factors does <u>not</u> alter the rate of breathing by influencing the chemoreceptors?
   a. carbon dioxide partial pressures in the blood
   b. oxygen partial pressures in the blood
   c. blood pH
   d. blood glucose levels
   e. hydrogen ion concentration in the blood
10. With rare exceptions, the majority of oxygen is transported in the blood of vertebrates
    a. by binding to plasma proteins.
    b. by binding to hemoglobin in erythrocytes.
    c. as dissolved gas in the plasma.
    d. as dissolved gas in the cytoplasm in the erythrocytes.
    e. by binding to myoglobin.

Conceptual Questions

1. Define countercurrent exchange as it relates to gas exchange in fishes.
2. Explain the special features of the avian respiratory system that make birds so well-adapted to air-breathing.
3. Explain some of the special adaptations for life at high altitudes; why are such adaptations necessary?

Collaborative Questions

1. Discuss two ways in which animals exchange gases in an aqueous environment. What special adaptations facilitate this exchange?
2. Discuss the components of the mammalian respiratory system.

Excretory Systems and Salt and Water Balance

49

The human kidneys could filter the volume of water of this pool in a few months.

Chapter Outline

If you have ever noticed how quickly the water in an aquarium or a swimming pool becomes dirty if the filter is not functioning, you will have a good idea of the importance of filtering the wastes from the blood of an animal. The human kidneys, for example, are remarkable filtration devices. Although each one is only about the size of a computer mouse, the kidneys are able to filter blood at a rate of 150–200 liters/day. Considering that there are only five or so liters of blood in a typical adult, that is an astonishingly effective filtration mechanism. Despite their small size, our kidneys could filter the entire contents of a medium-sized swimming pool in a few months. By the time a person reaches 50 years of age, their kidneys have filtered roughly 3,000,000 liters of blood! Even more impressive is that the kidneys not only remove waste products of metabolism from that filtered blood, but recapture useful substances such as sodium ions and water that form part of the liquid being filtered. In this way, the kidneys and other excretory organs found in animals contribute to homeostasis.

Homeostasis has been a common theme of the previous several chapters. Animals maintain a variety of physiological processes—including energy intake and usage, blood pressure, body temperature, and blood oxygen levels—within normal and often narrow ranges. Homeostasis is also critical in the regulation of salt and water levels in body fluid compartments. As described in Chapter 2, the general term "salt" is used to refer to a compound formed from an attraction between a positively charged ion, such as Na^+, and a negatively charged ion, such as Cl^-. These ions are held together by ionic bonds, which are broken when the salt is dissolved in water. Changes in the concentrations of ions resulting from dissolved salts in the extracellular and intracellular fluids have the potential to disrupt proper cellular function; for example, they may alter the difference in electrical potential across plasma membranes in the heart and brain. Salt (ion) concentrations and water volumes in the different body fluid compartments are related to each other, because a major way in which water moves between compartments is by osmosis, which, in turn, depends on the numbers of dissolved solutes in water. Consequently, changes in salt concentrations in body fluids may also affect cell volume, which then can cause cell disruption or death.

As we have learned, homeostasis is an energy-requiring process. A significant portion of most animals' daily energy expenditures goes toward maintaining salt and water homeostasis. The ability to do so is complicated by many factors, such as the environment and climate in which an animal lives and its access to sufficient supplies of drinking water.

In this chapter, we examine why salt and water balance is vital for survival, how it is affected by the requirement to eliminate metabolic wastes, and how different excretory organs participate in these processes. We then highlight some of the major features of the vertebrate and mammalian kidney, explore challenges posed by an animal's life history and environment, examine how the kidney eliminates wastes and regulates salt and water balance, and consider how kidney disease affects human health.

49.1 Principles of Homeostasis of Internal Fluids

As we saw in Chapter 47, an animal's internal fluids exist in compartments within the body. In invertebrates, these fluids include the hemolymph and the intracellular fluid, whereas in vertebrates, it includes the plasma component of blood, the

interstitial fluid surrounding cells, and the intracellular fluid. A description of the major salts found in animals' bodies and some of their chief functions was included in Chapter 45 (refer back to Table 45.3). As stated earlier, salts dissociate in solution to form charged ions. Because ions are electrically charged, such salts are referred to as electrolytes. In this section, we will examine why water and electrolyte homeostasis is so important and how an animal's electrolyte concentration and water volume are maintained within normal ranges.

The Balance of Water and Electrolytes Is Critical for Survival

Maintenance of normal body water levels is of great importance for all animals. Not only is water the major portion of an animal's body mass, it is also the solvent that permits dissolved solutes to participate in chemical reactions. As described in Chapters 2 and 3, water also participates in many important chemical reactions, notably hydrolysis reactions. In addition, water is the transport vehicle that brings oxygen and nutrients to cells and removes wastes generated by metabolism.

When an animal's water volume is reduced below the normal range, we say the animal is dehydrated. In terrestrial animals, dehydration may occur if sufficient drinking water is not available or when water is lost by evaporation (perspiring or panting). Dehydration can be a serious, potentially life-threatening condition. For example, because blood is roughly 50% plasma (water), blood volume may decrease in dehydrated animals. Reduced blood volume compromises the ability of the circulatory system to move nutrients and wastes throughout the body and to assist in the regulation of body temperature on hot days (see Chapters 46 and 47).

Electrolyte balance is also very important for animals. A change of only a few percent in the extracellular fluid concentrations of K^+, for example, can trigger changes in nerve, heart, and skeletal muscle function by altering membrane potentials (see Chapter 41). Other electrolytes, such as Ca^{2+}, Mg^{2+}, PO_4^{3-}, and SO_4^{2-}, also participate in various biological activities. These functions include serving as cofactors for enzyme activation, participating in bone formation, forming part of the extracellular matrices around cells, and activating cellular events such as exocytosis and muscle contraction. An imbalance in any of these ions can seriously disrupt cellular activities.

Water and Salts Move Between Fluid Compartments by Different Mechanisms

Water moves between adjacent body compartments by osmosis down an osmotic gradient (see Chapter 5). Changes in the salt concentration in one compartment will lead to changes in fluid distribution between the compartments. These changes can cause cells to shrink or swell. When, for example, the salt concentration of extracellular fluid increases, water moves by osmosis from inside cells to the extracellular fluid, causing the cells to shrink. Shrinking or swelling of cells in the brain, heart, and other vital organs can rupture plasma membranes, leading to cell death.

Whereas water moves between fluid compartments by osmosis, ions from dissolved salts such as sodium chloride move by different mechanisms. All ions have very limited ability to diffuse across plasma membranes, because of their high water solubility and low lipid solubility. As described in Chapter 5, ions may cross membranes through channels formed by proteins that create a pore in the membrane. Alternatively, ions may be actively transported across epithelial cells that line tube-like structures such as those in the kidneys. Still other epithelia, such as those in gills, can actively transport ions between the surrounding salt or fresh water and the animal's body fluids. As this type of transport is an active process, it requires energy stored in the chemical bonds of ATP. Animals that face exceptional challenges to maintaining salt balance, such as marine fishes, must expend a considerable share of their daily energy budget to transport ions across epithelial cells.

Salt and Water Balance Occurs Despite Obligatory Exchanges with the Environment

Many vital processes—eliminating nitrogenous wastes, obtaining oxygen and eliminating carbon dioxide, consuming and metabolizing food, and regulating body temperature—have the potential to disturb salt and water balance. Therefore, these processes require additional energy expenditure to minimize or reverse the disturbance. Exchanges of salt and water with the environment that occur as a consequence of such vital processes are called obligatory exchanges (because the animal is "obliged" to make them) (Figure 49.1). Next we will examine these and other obligatory exchanges and how they are related to an animal's environment and life history.

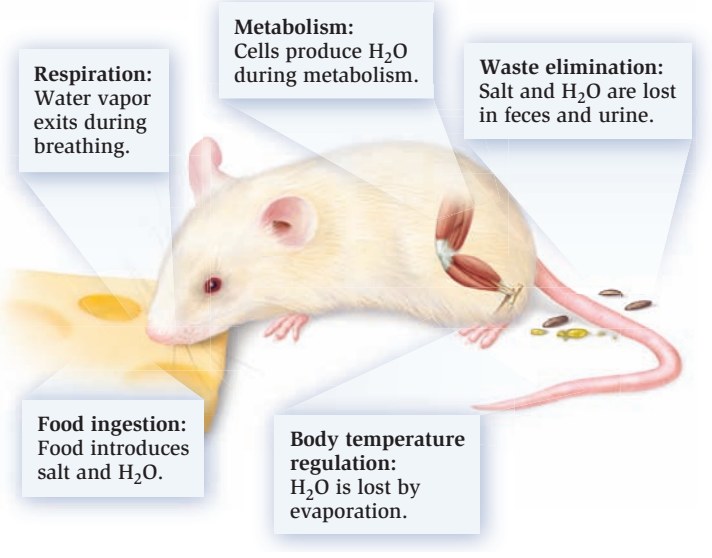

Figure 49.1 Types of obligatory salt and water exchanges in a terrestrial animal. Obligatory exchanges with the environment occur as the result of necessary life processes.

Concept check: Can animals completely avoid all the losses resulting from obligatory exchanges?

Elimination of Nitrogenous Wastes When carbohydrates and fats are metabolized by animal cells, the major waste product is carbon dioxide gas, which is exhaled or diffuses across the body surface. By contrast, proteins and nucleic acids contain nitrogen; when these molecules are broken down and metabolized, nitrogenous wastes are generated. **Nitrogenous wastes** are molecules that include nitrogen from amino groups (NH_2). These wastes are toxic at high concentrations and must be eliminated from the body but, unlike carbon dioxide gas, cannot be eliminated by exhaling or diffusion. The elimination of nitrogenous wastes occurs via excretory organs such as the kidneys or other specialized structures, such as gills.

Nitrogenous wastes are usually found in three forms—ammonia (and ammonium ions), urea, or uric acid (Figure 49.2). Different animal groups produce a particular form of waste, depending on the species and the environment in which they live.

Ammonia (NH_3) and ammonium ions (NH_4^+) are the most toxic of the nitrogenous wastes because they disrupt pH, ion electrochemical gradients, and many chemical reactions that involve oxidations and reductions. Animals that excrete wastes in this form typically live in water. In marine invertebrates, ammonia and ammonium ions are continually excreted across the skin, whereas in freshwater and most saltwater fishes, these wastes are excreted via the gills and kidneys. Because ammonia is so toxic, aquatic animals excrete it as quickly as it is formed. However, some terrestrial snails and crustaceans can excrete ammonia in its gaseous form, which is less toxic and does not require water for elimination. The chief advantage of excreting nitrogenous wastes as NH_3 or NH_4^+ is that energy is not required for their conversion to a less toxic product, such as urea and uric acid, as described next.

All mammals, most amphibians, some marine fishes, some reptiles, and some terrestrial invertebrates convert ammonia into **urea**, which is then excreted. In addition to being less toxic than ammonia, urea does not require large volumes of water to be excreted. Animals can tolerate some accumulation of urea in their blood, tissues, and storage organs such as the urinary bladder. This conserves water, removes the necessity for constant excretion, and reduces the likelihood of toxicity. One drawback of producing urea is that the enzymatic conversion of ammonia into urea requires a moderate expenditure of ATP and thus uses up part of an animal's total daily energy budget.

Birds, insects, and most reptiles produce **uric acid** or other nitrogenous compounds called purines. Like urea, these compounds are less toxic than ammonia, but they are even more energetically costly to synthesize from ammonia. However, because they are poorly soluble in water, they are not excreted in a watery urine but instead are packaged with salts and other waste products into a semisolid, partly dried precipitate that is excreted. The energy investment required to produce uric acid, therefore, is balanced against the water conserved by excreting nitrogenous wastes in this form.

Respiration-Related Water and Electrolyte Exchanges The requirements for both respiration and water and electrolyte balance present different challenges to air- and water-breathing animals. To ventilate its lungs, an air-breathing animal moves air in and out of its airways. Water in the form of water vapor in the mouth, nasal cavity, and upper airways exits the body with each exhalation. As an animal becomes more active, it requires more oxygen and produces more carbon dioxide. These changes are met by an increase in respiratory activity. Breathing becomes deeper and more rapid, which, in turn, increases the rate of water loss from the body. Therefore, respiration in animals with lungs is associated with significant water loss, as you can observe in cold weather when you can "see your breath."

As described in Chapter 46, small, active animals with high metabolic rates have higher breathing rates than do larger, less

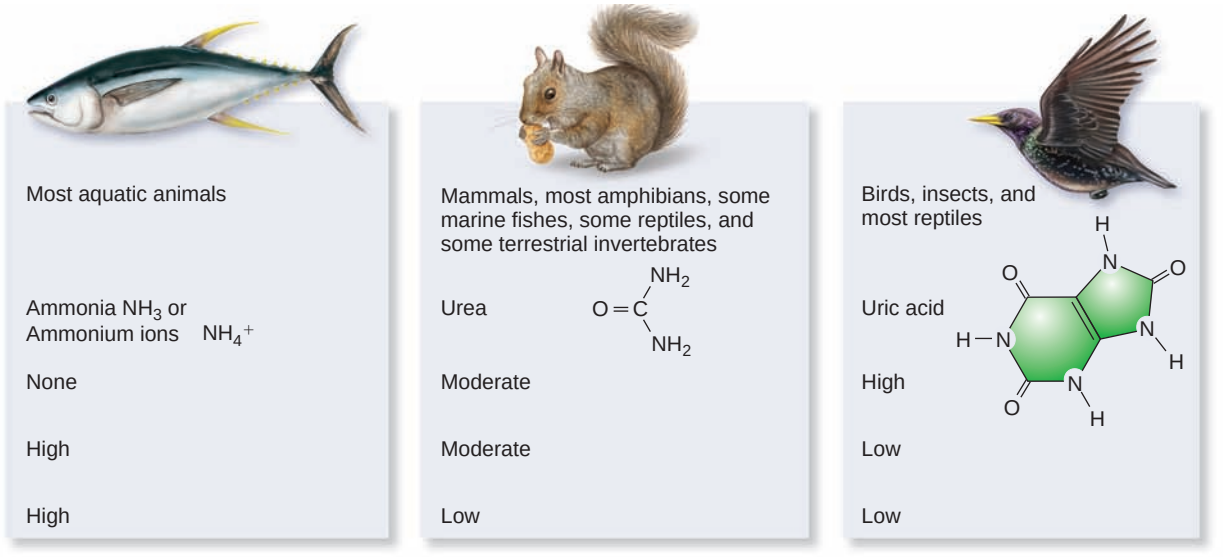

Figure 49.2 Nitrogenous wastes produced by different animal groups. The three forms of nitrogenous wastes, which are derived from the breakdown of proteins or nucleic acids, have different properties.

active animals. Consequently, the potential for water loss due to respiration is considerably greater in small animals, particularly in endotherms. Hummingbirds, for example, may have 15 to 20 times the water loss per gram of body mass than would a large goose.

In water-breathing animals, the challenge of water and salt balance is more complex, because such animals move water, not air, over their respiratory organs (gills). Recall from Chapter 48 that gills, like all respiratory organs, are thin structures with large amounts of surface area and an extensive network of capillaries. Although these features make gills ideal for gas exchange by diffusion between the capillaries and the surrounding water, they also make them ideal for salt and water movement by diffusion and osmosis, respectively.

The solute concentration of a solution of water is known as the solution's **osmolarity**, expressed as milliosmoles/liter (mOsm/L). The number of dissolved solute particles determines a solution's osmolarity. For example, a 150 mM NaCl solution has an osmolarity of 300 mOsm/L, because each NaCl molecule dissociates into two ions, one Na^+ and one Cl^- ($2 \times 150 = 300$).

When differences occur in salt concentration between a water-breathing animal's body fluids and the surrounding water, respiration via the gills has the potential to disrupt salt and water balance. The internal fluid osmolarity of most fishes is usually within the range of 225–400 mOsm/L, similar to that of most other vertebrates. Fishes or other water-breathing animals that live in fresh water and those that live in salt water face opposite challenges in maintaining this balance (Figure 49.3). Because freshwater lakes and rivers have very little salt content (usually <25 mOsm/L), a high concentration gradient for salts could promote the loss of salts from a fish's body into the fresh water. Likewise, a high osmotic gradient favors the movement of water into a freshwater fish. Freshwater fishes, therefore, gain water and lose salt when ventilating their gills (Figure 49.3a). If left uncorrected, this would cause a dangerous decrease in blood salt concentrations.

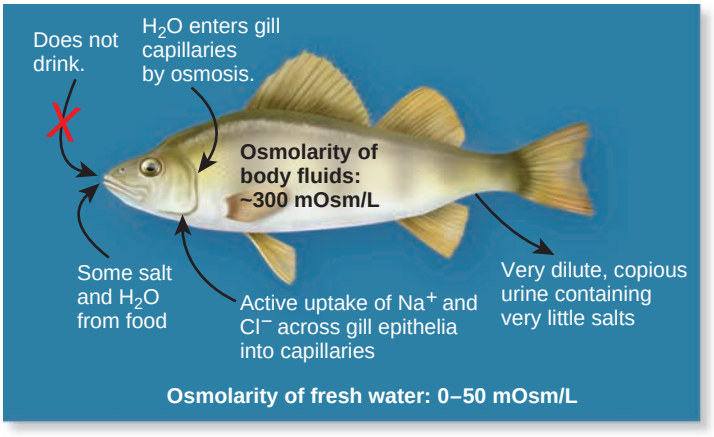
Freshwater fishes avoid this problem with two different mechanisms. First, their kidneys are adapted to producing copious amounts of dilute urine—up to 30% of their body mass per day (an amount that would be equivalent to about 25 L per day in an average-sized man!). Second, specialized gill epithelial cells actively transport Na^+ and Cl^- from the surrounding water into the fish's capillaries. Thus, these two important ions are recaptured from the water. As the preceding discussion suggests, freshwater fishes rarely, if ever, drink water, except for any that might be swallowed with food.

Other freshwater animals, such as frogs and other adult amphibians, have body surfaces that are permeable to water and are used in gas exchange. Like freshwater fishes, therefore, they tend to gain water by osmosis and compensate by excreting a copious dilute urine. Epithelial cells of the skin actively transport necessary electrolytes from the water into the blood.

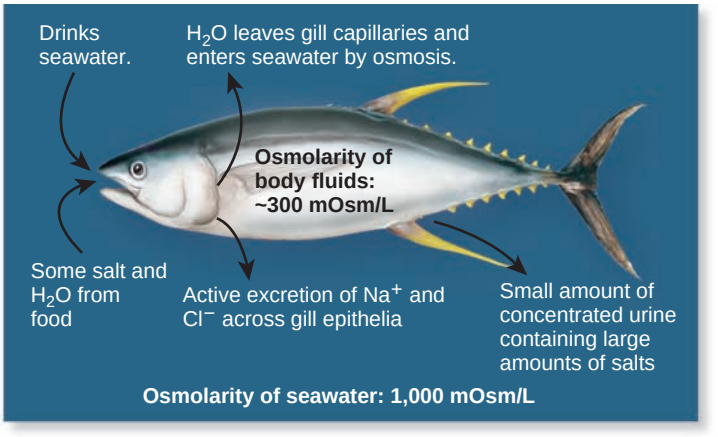
Saltwater fishes have the opposite problem. They tend to gain salts and lose water across their gills, because seawater has a much higher osmolarity (about 1,000 mOsm/L) than that of their body fluids (Figure 49.3b). The gain of salts and the loss of water from the body are only partly offset by the kidneys, which in marine fishes produce very little urine so water can be retained in the body. The urine that is produced has a higher salt concentration than that of freshwater fishes.

To prevent dehydration from occurring, marine fishes must drink. However, the only water available to them is seawater, which has a very high salt content. Paradoxically, therefore, marine fish drink seawater to replenish the water lost by osmosis through their gills. This creates a new problem: What does the fish do with all of the salt it ingested?

The ingested salt must be eliminated, and this process is accomplished by gill epithelial cells. In contrast to the gills of freshwater fishes, which pump salt from the water into the fluids of the fish, the gills of marine fishes pump salt out of the fish and into the ocean. Thus, marine fishes drink seawater to replace the water lost through their gills by osmosis and then expend energy to transport the excess salt out of the body.



(a) Freshwater fish



(b) Saltwater fish

Figure 49.3 **Salt and water balance in water-breathers.** Water-breathing creates osmoregulatory challenges due to diffusion of salts and osmosis of water across gills. These challenges differ between **(a)** freshwater and **(b)** saltwater fishes and are met by drinking or not drinking water, by active transport of salts across the gills, and by alterations in urine output.

Ingestion-Related Fluid and Electrolyte Balance Because foods contain minerals and water, eating also involves an obligatory exchange of salt and water. Some plant products are over 95% water by weight, and other foods may contain high amounts of sodium or other minerals. Therefore, the type of diet an animal consumes determines how much salt and water it ingests.

Once food has been digested and absorbed, the unusable parts of food are excreted as solid wastes. Some salt and water are lost by this route in most animals, but exceptions exist. Desert-dwelling kangaroo rats such as *Dipodomys panamintensis* produce fecal pellets that are almost completely dry, which helps these animals conserve water.

As noted earlier, marine fishes drink seawater. Other animals besides marine fishes may also consume seawater, either because fresh water is unavailable or because they ingest some with the food they eat. Many marine reptiles and birds, for example, ingest seawater when consuming prey or, in some cases, when they spend prolonged periods at sea and have no access to fresh water for drinking. These animals have specialized epithelial cells that line structures called salt glands, located in groups around the nostrils, mouth, and eyes (Figure 49.4). Salts move from the blood into the interstitial fluid, from where they are actively transported by the epithelial cells of the salt glands into the tubules of the gland. The salts and a small amount of fluid then collect into a central duct and are excreted as highly concentrated solutions. In general, vertebrates without salt glands cannot survive by drinking seawater, because they have no means of creating and excreting such a highly concentrated salt solution. Some marine mammals have been observed to occasionally drink small amounts of seawater, but most appear to never drink at all. These animals get their water from the food they eat.

Regulation of Body Temperature with Water Endotherms use body water to cool off (see Chapter 46). For example, sweating and panting are used to cool the body. These behaviors use the evaporation of water to draw heat out of the body. In the process, however, the animal loses water and, in sweat, some salts. You know from tasting sweat that it is salty, but the saltiness of sweat and that of blood are not the same. Sweat is a hypoosmotic (more dilute) solution compared to blood, so the fluid left behind in the body after perspiration has both a lower volume and a higher salt concentration.

Other than perspiration and panting, very little water is gained or lost directly across the body surface of most terrestrial vertebrates, because their skin is impermeable to water. Exceptions include amphibians (and also some invertebrates). In invertebrates, the rate of water loss across the body surface depends on whether the animal is soft-bodied, like worms, or covered in a waxy, water-impermeable cuticle, like most insects.

Metabolism and Water Balance When food molecules are metabolized to provide energy that will be stored in the chemical bonds of ATP, oxygen captures electrons and combines with hydrogen ions, thereby making water. This water is sometimes called "metabolic water" to indicate its origin. Some animals—especially desert dwellers, which lack ready access to drinking water—depend on this water to provide all or nearly all of their water requirements. In other animals, the production of metabolic water may sometimes result in more water than is required at that time. This excess water is eliminated by the excretory organs or through other routes. Because metabolism is always ongoing and is required for survival, the excretion or retention of metabolic water can be considered a type of obligatory exchange.

As described next, the significance of obligatory exchanges and their effects on homeostasis was dramatically illustrated by a long-term investigation by a research team at the University of Florida. Their discovery would lead to a revolution in our understanding of exercise physiology in humans.

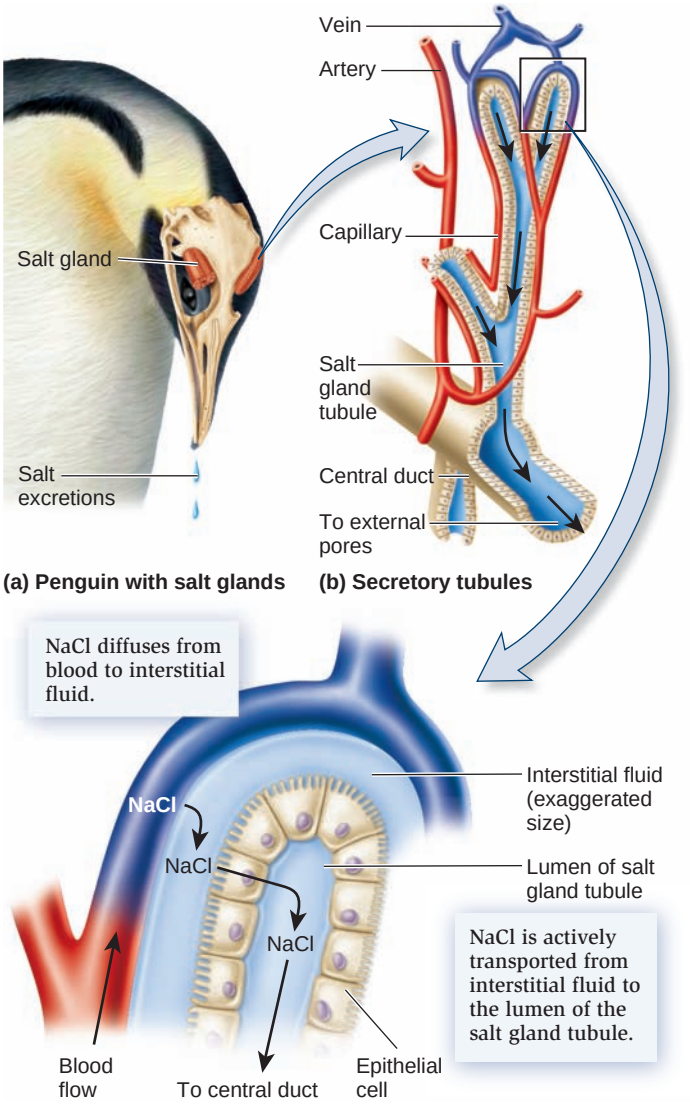


Figure 49.4 **Salt glands as an adaptation for marine life.** Many marine birds and reptiles have salt glands, which contain a network of secretory tubules that actively transport NaCl from the interstitial fluid into the tubule lumen. The viscous solution then moves through a central duct and to the outside environment through pores in the nose, around the eyes, and in other locations. The black arrows indicate direction of flow of blood or salt gland excretions.

Concept check: *Why can't humans survive by drinking seawater?*

Feature Investigation

Cade and Colleagues Discovered Why Athletes' Performance Wanes on Hot Days

On a typically hot summer day in the mid-1960s in Gainesville, Florida, the University of Florida football team was practicing in full equipment. The players were rapidly becoming dehydrated and, unbeknownst to them, the osmolarity of their body fluids was increasing as their bodies produced copious amounts of dilute sweat in an effort to maintain body temperature. The athletes became aware of two things. First, they discovered that they did not need to urinate for long periods after a tough practice session, and second, their performance on the field suffered as they became increasingly fatigued and more susceptible to severe muscle cramps. Often, players would need to receive medical treatment or even hospitalization for their symptoms. In extreme cases, athletes exercising in these conditions have been known to occasionally develop seizures—uncontrolled activity of neurons in the brain. This situation did not escape the notice of the team physicians and, notably, university faculty member and kidney specialist Robert Cade.

Many of the symptoms experienced by the players could be readily explained. The fatigue was directly related to loss of water from the body, which put a strain on the circulatory system and reduced blood flow to muscles and other organs. It was worsened by a decrease in blood glucose levels that were not being replenished during the long practices or games. The muscle cramps and even occasional seizures arose from an imbalance in extracellular electrolytes—notably sodium and potassium ions—which are secreted outside the body by sweat glands in the process of perspiration. The resulting imbalance in extracellular electrolyte concentrations caused a change in the electrical potential across muscle and neuronal cell membranes, which triggered the spasms. Lastly, the decreased urine production is one of the body's mechanisms for reducing fluid loss when body water is decreasing.

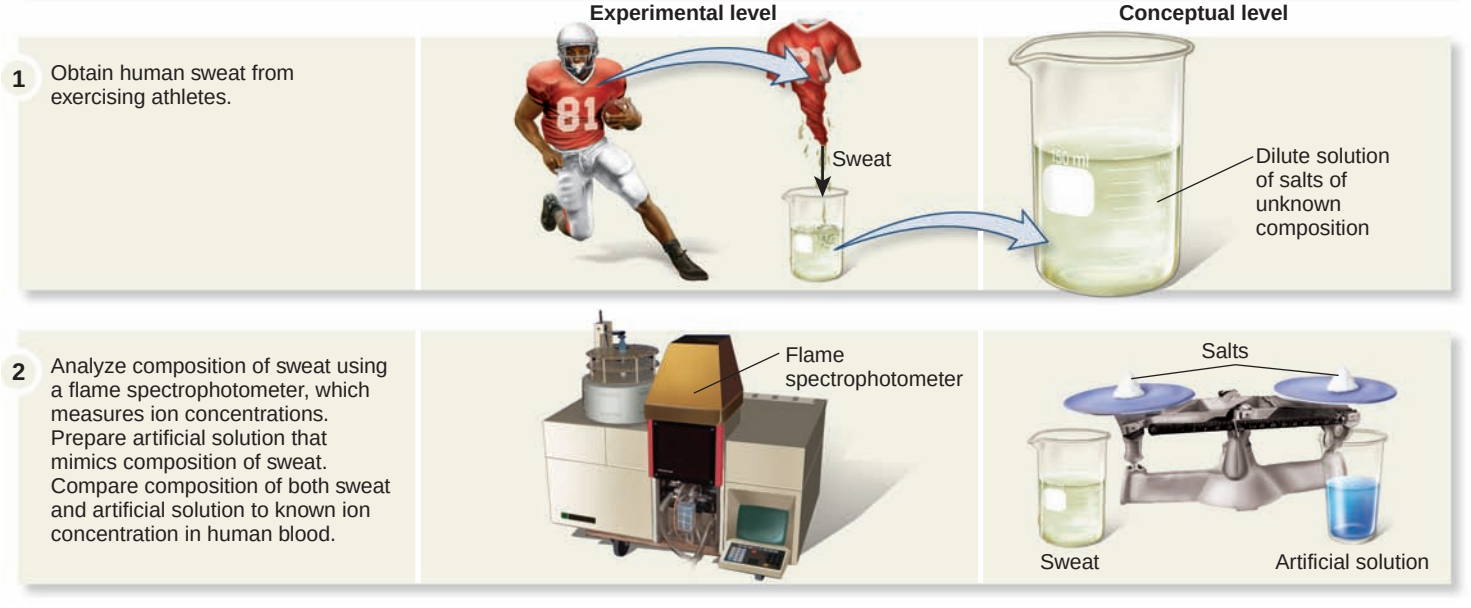
The key question was, How can these effects of extreme exercise best be reversed or prevented? The answer was simple and clever. Cade and his colleagues rejected the prevailing view that drinking any fluids during heavy exercise somehow contributed to cramps and other problems. Instead, they hypothesized that the best way to maintain salt and water homeostasis in a profusely sweating person is to restore to the body exactly what was lost; that is, the person should drink a solution that resembles sweat!

The first thing Cade needed to do was analyze precisely how much sodium, potassium, and other ions are actually present in sweat. Fortunately, he had an abundance of human sweat at his disposal to analyze. Once the players left the field, their jerseys were wrung out, and the composition of the sweat was determined with an ion analyzer such as one called a flame spectrophotometer, as shown in Figure 49.5. The concentrations could then be compared with known values of ion concentrations in human blood. The composition of human sweat is now known to change under certain conditions and to vary among people, but Cade's results were typical. The sweat of the athletes contained mostly Na^+, K^+, and Cl^- at concentrations

Figure 49.5 **Cade and colleagues discovered a way to improve athletic performance and prevent salt and water imbalance during strenuous exercise.**

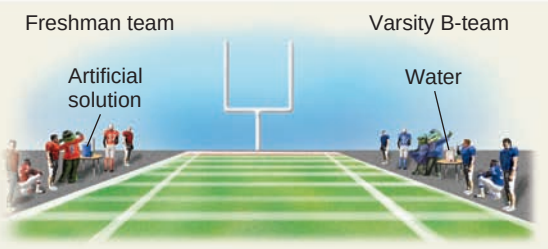
HYPOTHESIS Athletic performance can be enhanced by maintaining the body's salt and H_2O balance during exercise.

KEY MATERIALS Supply of human sweat for analysis, ion analyzer, salt solution.

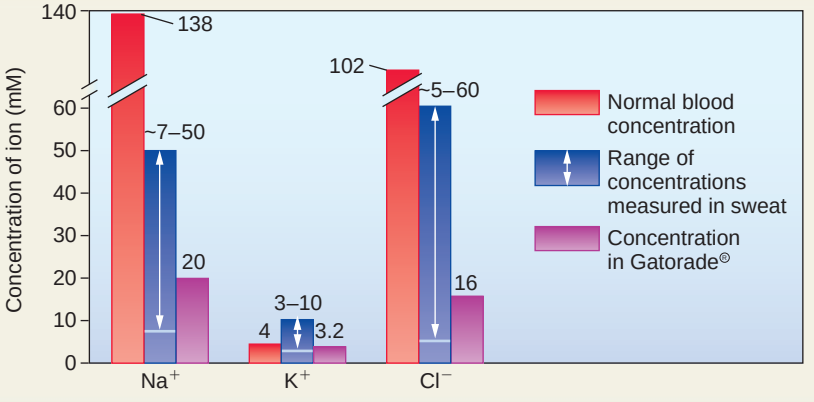


3 Add flavoring and sugar to artificial solution.

4 Provide freshman team with the artificial solution and varsity B-team with water. Hold scrimmage.



5 **THE DATA**



6 **CONCLUSION** Replacement of fluid with solute concentrations similar to those found in human sweat improves athletic performance compared to water replacement alone.

7 **SOURCE** Most of the original studies described here were published in expanded form in a later report. See Cade, R. et al. 1972. Effect of fluid, electrolyte and glucose replacement during exercise on performance, body temperature, rate of sweat loss, and compositional changes of extracellular fluid. *Journal of Sports Medicine and Physical Fitness* 12:150–156.

that indicated the solution was dilute compared to blood. Once Cade completed this analysis, he simply made an artificial solution of a composition similar to human sweat. The next step was to have the players ingest the solution before and during the practice sessions and games. Improving its taste—adding some lemon flavoring and sugar—removed any inhibitions the players may have had about drinking it, while also providing an energy boost.

For the first trial, Cade gave the solution to the freshman players during an intrasquad scrimmage against the more experienced varsity B-team, whose members received only pure water to drink as a control. At first, the freshman team appeared overmatched by the B-team, as might be expected. In the second half of the scrimmage, however, the freshman team vastly outperformed the more experienced players and did not suffer the characteristic late-game fatigue the B-team experienced. Based on this test, the varsity A-team was given a similar solution to drink the next day during a game against a heavily favored opponent, whom they beat handily on a hot 39°C day. In subsequent years, Cade and other researchers would conduct carefully controlled experiments with humans and laboratory animals to confirm that a balanced solution of

electrolytes similar to that present in sweat effectively improves exercise performance and reduces the possibility of dehydration and its consequences.

Because the solution was envisioned as "aid" for the team known as the University of Florida "Gators," the drink eventually came to be called Gatorade®. The year after its introduction, the Gators enjoyed their most successful season. In 1965, the Kansas City Chiefs of the former American Football League became the first professional sports team to try the drink, and shortly thereafter, the team enjoyed its greatest success. Nowadays, Gatorade® is used at sporting events around the world, and for good scientific reason.

The effectiveness of a solution like Gatorade® is due to its ability to restore the correct amounts of both water and ions lost during exercise. Importantly, it is very rapidly absorbed because its osmolarity is close to that of body fluids. Many of the other sports drinks subsequently invented contain additional solutes, such as vitamins and other minerals, and many contain higher amounts of sugar. Because of the presence of these other solutes, these drinks may be very hyperosmotic relative to body fluids. Therefore, when ingested, they initially tend to draw water out of the interstitial fluid and into the gut lumen by osmosis. This slows down the rate at which the water from the drink gets absorbed into the blood.

The story of Gatorade® is one of good common sense based on solid scientific principles of osmolarity and salt and water homeostasis. You can now understand why drinking a dilute salt solution during strenuous exercise is better than drinking water. Although drinking pure water prevents dehydration, if drunk in excess, it will actually reduce plasma salt concentrations to below normal. In other words, it will replace one type of salt imbalance with another.

Experimental Questions

1. What symptoms are sometimes seen in athletes after prolonged, strenuous exercise, particularly in hot weather? How are these symptoms related to water loss during exercise, and what did Cade and his colleagues hypothesize about this?
2. How did the researchers test their hypothesis?
3. What was the result of consuming the drink during exercise?

Animals Adapt to Osmotic Challenges by Regulating or Conforming

Animals adapt to osmotic challenges posed by the environment in one of two major ways. Some animals regulate their internal osmolarity at a very stable level, whereas others conform to the osmolarity of their environment (for example, the sea). Animals that maintain very stable internal salt concentrations and osmolarities, even when living in water with very different osmolarities than their body fluids or on land, are called **osmoregulators**. Such animals drink or excrete water and salt as necessary to maintain an internal osmolarity that is generally about 300 mOsm/L, or about one-third that of seawater and at least 10 times that of fresh water. All terrestrial animals are osmoregulators, as are all freshwater animals and many marine animals, including bony fishes and some crustaceans. Osmoregulators maintain stable cellular levels of ions and fluid, but this requires considerable expenditure of energy, primarily to pump ions into and out of epithelial cells.

Most marine invertebrates and some vertebrates—notably sharks—use a different means to control body fluid composition. In this case, the osmolarity of extracellular and intracellular fluids is matched with seawater. These animals are called **osmoconformers**, because their osmolarity conforms to that of their environment. The osmolarity of blood and other fluids of marine osmoconformers is like seawater, around 1,000 mOsm/L. An advantage of having body fluids conform to the osmolarity of the surrounding seawater is that there is much less tendency to gain or lose water by osmosis across the skin or gills. Thus, sharks and other osmoconformers expend less energy to compensate for water gain or loss than do other aquatic animals. However, osmoconformers are generally limited to the marine environment, whereas many species of osmoregulators such as salmon can migrate between waters of different salinities.

Vertebrate osmoconformers have a high concentration of uncharged molecules in their extracellular fluids. This allows the extracellular fluids and seawater to have similar osmolarities, but it prevents the excessive accumulation of ions in the body. The body fluids of sharks and other osmoconformers contain sugars, amino acids, and metabolic waste products—notably urea and an organic compound called trimethylamine oxide (TMAO). The total amount of salt and organic compounds in a shark's extracellular fluids produces an osmolarity very similar to that of seawater, even though the salt concentration is similar to that of osmoregulators.

Vertebrate osmoconformers cannot tolerate high ion concentrations in their body fluids any better than osmoregulators. One reason is because a proper ion balance is required for normal electrical signaling in their neurons and muscle cells. In addition, very high salt concentrations tend to disrupt the three-dimensional structure of many proteins, rendering them inactive. Consequently, the body fluids of vertebrate osmoconformers are less salty—that is, they have fewer ions—than seawater, as is also the case in all osmoregulators. Therefore, vertebrate osmoconformers tend to gain salt by diffusion across their gills. That excess salt is eliminated by the kidneys and a type of salt gland called the rectal gland.

Animals that cannot survive wide changes in the salinity of their surroundings—including most marine invertebrates and many types of fishes—are said to be stenohaline (from the Greek, meaning narrow salt). Other animals, such as migratory fishes and some species of shellfish (oysters and mussels), can tolerate certain changes in the salinity of their surroundings and are said to be euryhaline (from the Greek, meaning

broad salt). One of the most dramatic examples of euryhaline animals is salmon, which migrate between fresh water and the sea without any ill effects. Although the mechanisms by which such animals adapt to changing salinities are not entirely understood, exposure to a sudden change in salinity is associated with large-scale changes in gene expression. A recent study in nematode worms, for example, reported that the expression of well over 100 genes was altered by changing the salt concentration of the medium on which the worms were living. Presumably, some of the genes are associated with such functions as ion transport in skin and other tissue.

Next we will examine the excretory organs found in different animals and how such organs not only function to eliminate wastes but also are involved in salt and water homeostasis.

49.2 Principles of Fluid Filtration and Waste Excretion

Most excretory organs operate by using one or more of the following processes: filtration, reabsorption, secretion, and excretion (Figure 49.6). In **filtration**, an organ acts like a sieve or filter, removing some of the water and its small solutes from the blood, interstitial fluid, or hemolymph, while retaining blood cells and large solutes such as proteins. A typical filtration system is that seen in the mammalian kidney, in which the plasma component of the blood is forced under pressure through leaky capillaries and into the kidney tubules. The material that passes through the filter and enters the excretory organ for either further processing or excretion is called a **filtrate**.

Some of the material in the filtrate can be recaptured and returned to the blood. This is an important feature of many excretory organs, because the formation of a filtrate is not selective, apart from the exclusion of proteins and blood cells. In other words, in order to filter the blood and remove soluble wastes, necessary molecules such as salts, sugars, and amino acids also get filtered in the process. Recapturing these useful solutes requires active transport pumps or other transport systems and is known as **reabsorption**. Much of the filtered water also gets reabsorbed along with useful solutes by osmosis.

In some cases, solutes may get excreted from the body in quantities greater than those found in the filtrate. How is this possible? Some solutes are actively transported from the interstitial fluid surrounding the epithelial cells of the tubules into the tubule lumens. This process, called **secretion**, supplements the amount of a solute that would normally be removed by filtration alone. This is often a way in which excretory organs eliminate particularly toxic compounds from an animal's body, and it can be very effective. Some marine fishes, for example, use secretion as the sole means of cleansing the blood. These animals do not form a filtrate at all.

Excretion is the process of expelling waste or harmful materials from the body. In animals that form a filtrate, the excreted part of the filtrate that remains after reabsorption has been completed is called **urine**. Now let's take a comparative look at some of the organ systems that perform these vital functions in different animals.

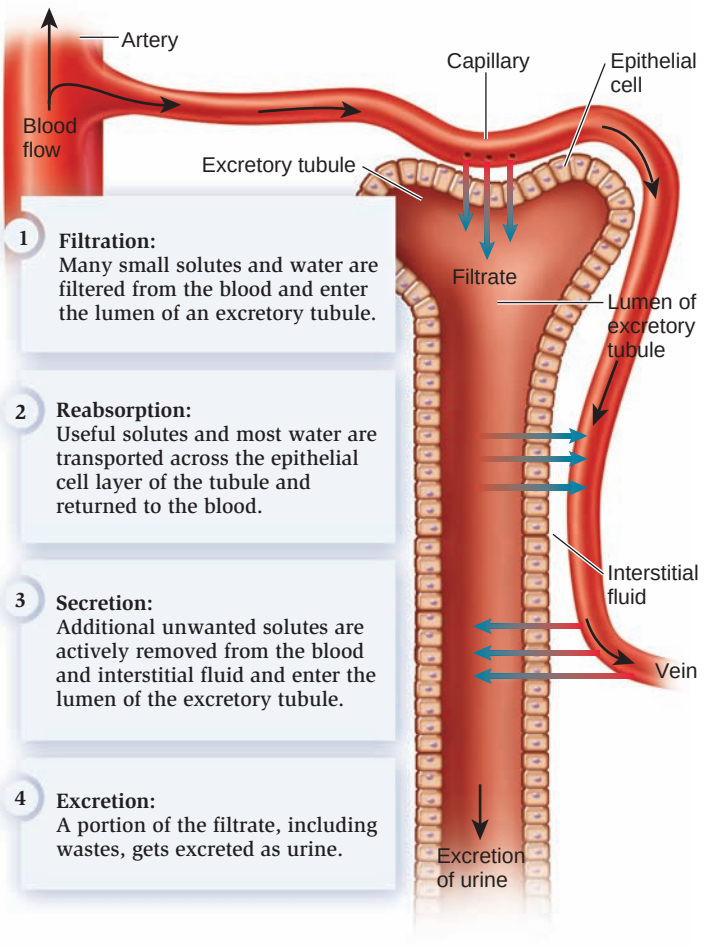


Figure 49.6 Basic features of the function of many excretory systems.

Concept check: *What is the benefit of secreting substances into the tubule?*

49.3 Comparative Excretory Systems

Although the mammalian kidney, and in particular that of humans, has been especially well studied, enough is known about other classes of animals to make general statements regarding the regulation of salt, water, and waste levels in the fluid compartments of an animal's body. This is an ancient and important function that arose early in evolution.

As described, animals make use of one or more different organs to rid themselves of metabolic wastes, excess water and salts, and toxins from their environment. Most excretory organs contain tubular structures lined with epithelial cells that have the capacity to actively transport ions across their membranes. Wastes are excreted out of the body by means of these tubes.

In some cases, animals may have considerable ability to regulate the rate at which waste is secreted and how much water is lost in the process. For example, even though a thirsty mammal on a hot, sunny day must continue to rid its body of soluble waste products, it must also conserve water. In this section, we consider invertebrate and vertebrate excretory organs.

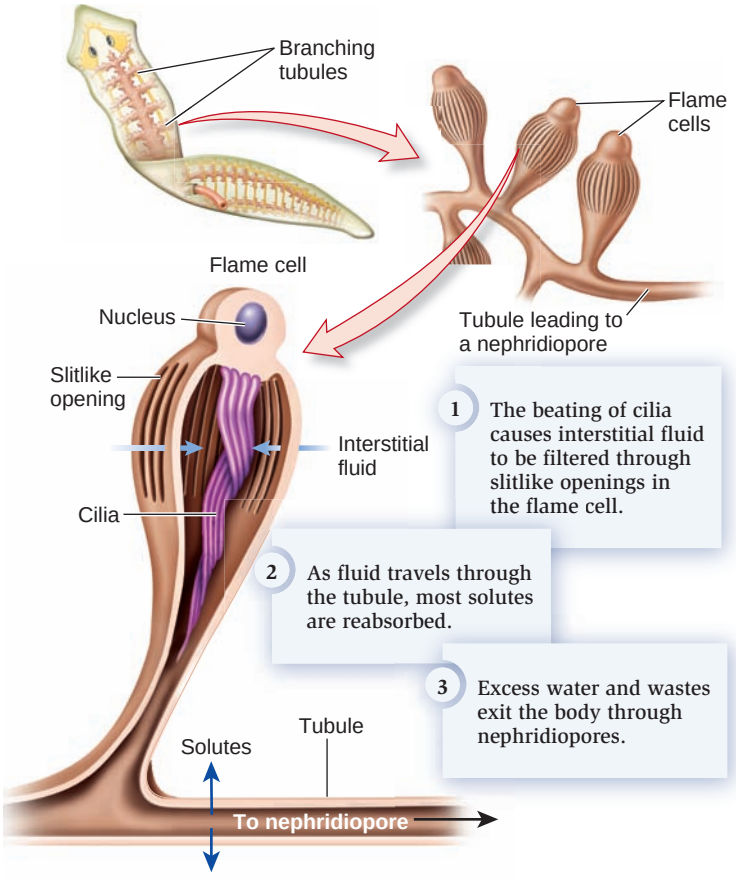

Figure 49.7 The protonephridial filtration system of flatworms. As the filtrate moves along the tubules, the composition of the filtrate can be changed by the action of the tubule epithelial cells. The final excreted fluid is typically hypoosmotic to body fluids.

Most Invertebrates Use a Filtration Mechanism to Cleanse the Blood

The simplest filtration mechanism in invertebrates is the **protonephridia** system of flatworms (Figure 49.7). A series of branching tubules filters fluids from the body cavity into the tubule lumens by means of ciliated cells that cap the ends of the tubule branches. The beating of the cilia bears some resemblance to a flickering flame, which is why these cells are known as flame cells. As fluid is drawn through slitlike openings of the flame cells and into the lumen, it percolates through the tubule, where most solutes are reabsorbed back into the interstitial fluid. Excess water and some wastes travel through the tubules and are emptied through tiny openings in the body wall called nephridiopores. Much of the nitrogenous waste in flatworms actually diffuses across the body surface into the surrounding water; therefore, the protonephridia are primarily osmoregulatory organs. The urine is generally hypoosmotic compared to the rest of the body fluids, an adaptation for life in fresh water.

Annelids use a different filtration mechanism, called a **metanephridial system** (Figure 49.8). In annelids, pairs of metanephridia are located in each body segment. They consist of a tubular network that begins with a funnel-like structure called a nephrostome. The nephrostomes are open to the body cavity and collect coelomic fluid, which contains nitrogenous wastes, through tiny pores that exclude large solutes. Na^+, Cl^-, and other solutes are reabsorbed by active transport along the length of the tubules that extend from the nephrostomes, and from there diffuse into nearby capillaries. The nitrogenous wastes remain behind in the tubules and are excreted through nephridiopores in the body wall. Many annelids live in watery environments and thus, like flatworms, excrete a hypoosmotic urine.

Filtration mechanisms also operate in the metanephridia of many mollusks and in the crustacean excretory organs called antennal glands. As in worms, reabsorption of useful solutes occurs along the length of the excretory system. Research has clearly indicated that mollusks can reabsorb organic nutrients well enough that under most conditions, these nutrients do not appear at all in the urine. As in the protonephridial and metanephridial systems just discussed, urine is excreted via nephridiopores in mollusks and crustaceans.

Insects Excrete Wastes by Means of Secretory Organs Rather Than Filtration

The insect excretory system is quite different from other invertebrates, because it involves secretion rather than filtration of body fluids. In insects, a series of narrow, extensive tubes called **Malpighian tubules** arises from the midgut and extends into the surrounding hemolymph (Figure 49.9). The cells lining the tubules actively transport potassium ions, along with uric

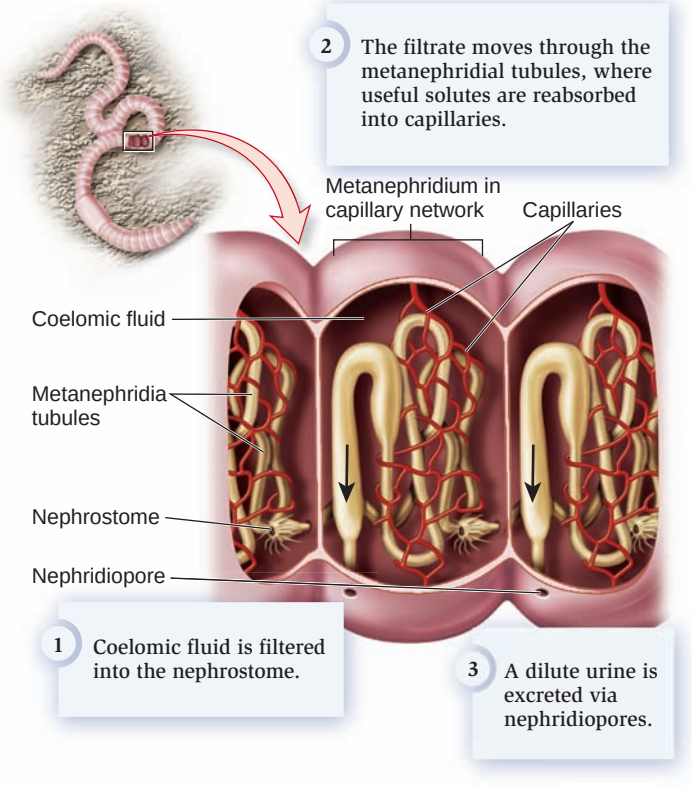

Figure 49.8 The metanephridial filtration system of annelids. Most internal body structures have been omitted for clarity. Only one of the two metanephridia in each segment is shown.

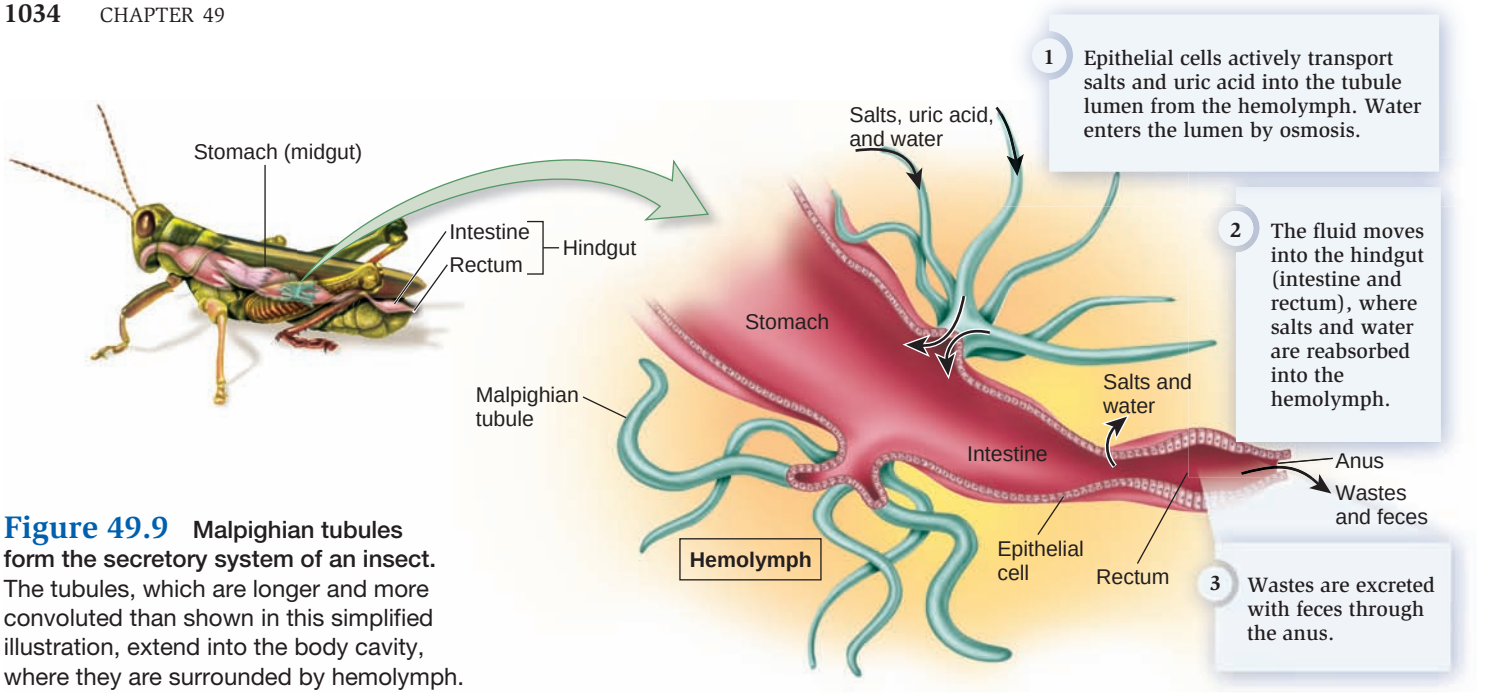

Figure 49.9 **Malpighian tubules form the secretory system of an insect.** The tubules, which are longer and more convoluted than shown in this simplified illustration, extend into the body cavity, where they are surrounded by hemolymph.

acid and other purines from the hemolymph, into the tubule lumen. This secretion process creates an osmotic gradient that draws water into the tubules. The fluid moves from the tubules into the hindgut—the intestine and rectum—where much of the useful salt and water is reabsorbed. The nitrogenous wastes and other waste compounds are excreted together with the feces through the anus.

Unlike other invertebrates, most terrestrial insects, apart from blood-sucking ones, excrete urine that is either isoosmotic or hyperosmotic to body fluids. This is a testament to the efficiency with which the insect hindgut reabsorbs water, and reflects the fact that life in dry environments is associated with a risk of dehydration.

The Kidney Is the Major Excretory and Filtration Organ in Vertebrates

The major excretory organ found in all vertebrates is the **kidney**. The kidneys of all vertebrates have many features in common. They typically contain specialized tubules composed of epithelial cells that participate in both salt and water homeostasis by promoting active transport of sodium, potassium, and other ions across their membranes. In addition, all kidneys participate in the excretion of wastes. In response to an animal's changing salt and water requirements, these processes can be controlled, that is, sped up or slowed down, by the actions of nerves and hormones. Most vertebrate kidneys are filtration kidneys, with the exception of purely secretory kidneys found in some marine fishes. Finally, filtration in the kidneys is controlled by mechanical forces, such as the hydrostatic pressure exerted by blood entering the capillaries of the kidneys. The mammalian kidney has been especially well studied and is examined in detail later in this chapter. Note that when we refer to kidneys, we use the adjective renal, meaning "pertaining to the kidneys." For example, we refer to renal physiology and renal functions.

The need to eliminate waste products while simultaneously maintaining salt and water homeostasis occurs in all animals. How animals achieve this balance in highly disparate environments, and with different life histories, is the subject of our next discussion.

49.4 Renal Function and Vertebrate Life History

As previously mentioned, not all animals have similar requirements for salt and water. Table 49.1 summarizes some of the special requirements of different vertebrates and some major behavioral and physiological adaptations that allow them to maintain homeostasis.

The demands placed on an animal by its environment can often be predicted by examining the activities of that animal's kidneys. For example, the kidneys of freshwater fishes are specially adapted for rapid, large-scale filtering of the blood and producing a very dilute urine. Amphibians, because of their permeable skin, absorb fresh water from their environments, and consequently they have kidneys with an appearance and activity that resemble those of freshwater fishes. By contrast, the kidneys of marine fishes and desert mammals are adapted to produce urine that is more concentrated than that of freshwater fishes and amphibians. This is an important adaptation that helps conserve as much water as possible.

Some animals have a diet that is extreme in one way or another. This is often associated with differences in renal structure and function. Many mammals and insectivores, for example, subsist entirely or almost entirely on sporadic, high-protein meals. These animals consume so much protein at a single meal that the rate at which they generate nitrogenous waste is very high. Not surprisingly, perhaps, the rate at which blood is filtered through the kidneys of such animals tends also to be very high, an adaptation that helps eliminate the toxic waste.

At the other extreme, polar bears may go 4 to 5 months without feeding. During the nonfeeding periods, polar bears neither defecate nor urinate and subsist by breaking down stores of fat and protein in their bodies. Thus, even though they are not eating, they generate nitrogenous wastes such as urea. Despite not urinating during this time, the concentration of urea in their blood may actually decrease! The explanation for this surprising phenomenon appears to be that polar bears have the extraordinary ability to recycle nitrogenous waste into synthesis of new protein. This ability is of great interest to researchers who study the health consequences of kidney disease and consequent accumulation of urea in the bloodstream of humans.

We turn now to an examination of one of the best understood excretory organs: the mammalian kidney.

Table 49.1 A Comparison of the Vertebrate Mechanisms of Osmoregulation in Different Environments

Animal group		Blood concentration relative to environment	Urine concentration relative to blood	Main nitrogenous waste	Osmoregulatory mechanisms and special features
Marine fish		Hypoosmotic	Isoosmotic or hyperosmotic	Ammonia	Drinks seawater; secretes salt from gills
Freshwater fish		Hyperosmotic	Strongly hypoosmotic	Ammonia	Drinks no water; transports salt across gills
Amphibian (fresh water)		Hyperosmotic	Strongly hypoosmotic	Most secrete urea	Absorbs water through skin
Marine reptile		Hypoosmotic	Isoosmotic	Ammonia, urea, uric acid	Drinks seawater; hyperosmotic salt-gland secretion
Terrestrial reptile		—	Isoosmotic	Uric acid	Drinks fresh water
Marine bird		Hypoosmotic	Weakly hyperosmotic	Uric acid	Drinks seawater; hyperosmotic salt-gland secretion
Terrestrial bird		—	Weakly hyperosmotic	Uric acid	Drinks fresh water
Desert mammal		—	Strongly hyperosmotic	Urea	Drinks no water; very long loops of Henle; depends on water generated by cellular metabolism
Marine mammal		Hypoosmotic	Strongly hyperosmotic	Urea	Drinks no water
Other mammals		—	Strongly hyperosmotic	Urea	Drink fresh water

49.5 Structure and Function of the Mammalian Kidney

All mammals have kidneys that are similar in structure and function, although some are more adapted to one type of life history and environment than another. Much of what we know today about the human kidney arose from observations made on the kidneys of rodents, dogs, and other mammals.

The two kidneys lie in the abdomen (Figure 49.10a). The urine formed in each kidney collects in a central area called the renal pelvis. From there it flows through tubes called the **ureters** into the **urinary bladder**. Urine is eliminated via the **urethra**, in a process called micturition, or urination. Collectively, the kidneys, ureters, urinary bladder, and urethra constitute the **urinary system** in humans.

Each kidney is composed of an outer portion called the renal cortex and an inner portion called the renal medulla, which, in turn, is composed of outer and inner regions (Figure 49.10b). The cortex is the primary site of blood filtration. In the medulla, the filtrate becomes concentrated by the reabsorption of water back into the blood. In this section, we will examine the structural features of the kidney that allow it to function as a filtration system.

The Functional Units of the Kidney Are Called Nephrons

Depending on its size, the mammalian kidney contains as many as several million similar, single-cell–thick structures called **nephrons**. (We get the name of the medical specialty nephrology from the word nephron.) As shown in Figure 49.10c, each nephron consists of an initial filtering component called the **renal corpuscle** and a narrow tubule that extends out from the renal corpuscle. This tubule empties into a larger tubule called a **collecting duct**.

The renal corpuscle forms a filtrate from blood that is free of cells and proteins. This filtrate then leaves the renal corpuscle and enters the lumen of the tubule. As it flows through different regions along the length of the tubule, substances are reabsorbed from it or secreted into it. Ultimately the filtrate remaining at the end of each nephron combines in the collecting

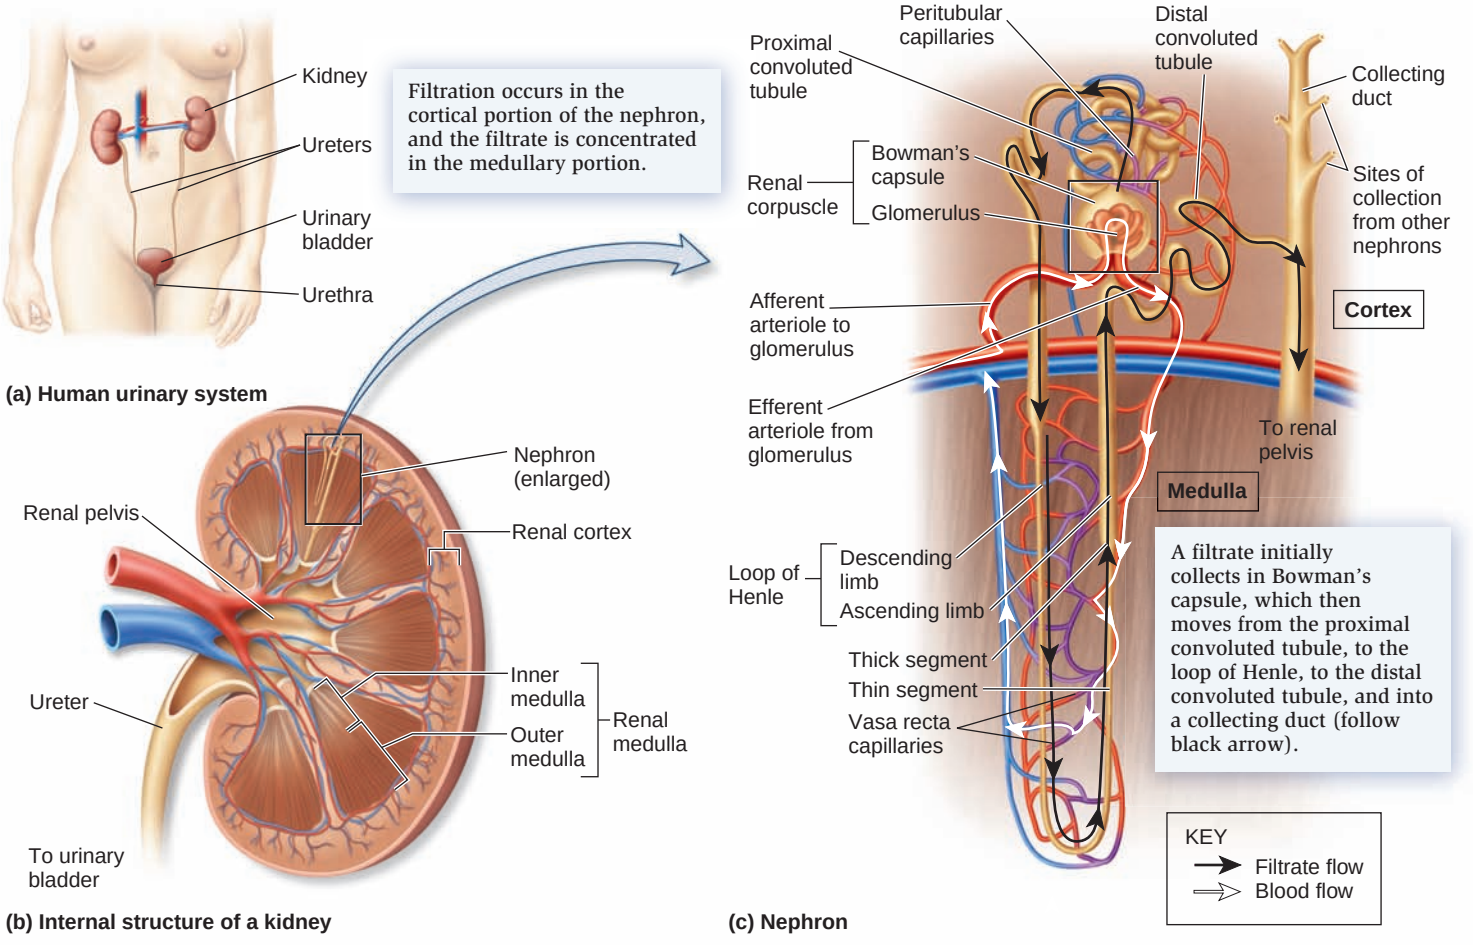

Figure 49.10 **The mammalian urinary system, including the basic functional unit of the nephron.** **(a)** The human urinary system in a woman. In the male, the urethra passes through the penis. **(b)** Enlarged view of a section through a kidney, showing the locations of the major internal structures and a single nephron (enlarged; at the scale of this illustration, nephrons would be microscopic). **(c)** Structure of a nephron. The nephron begins at Bowman's capsule and empties into a collecting duct. Many nephrons empty into a given collecting duct. Surrounding the nephron are capillaries, called peritubular capillaries in the cortex and vasa recta capillaries in the medulla.

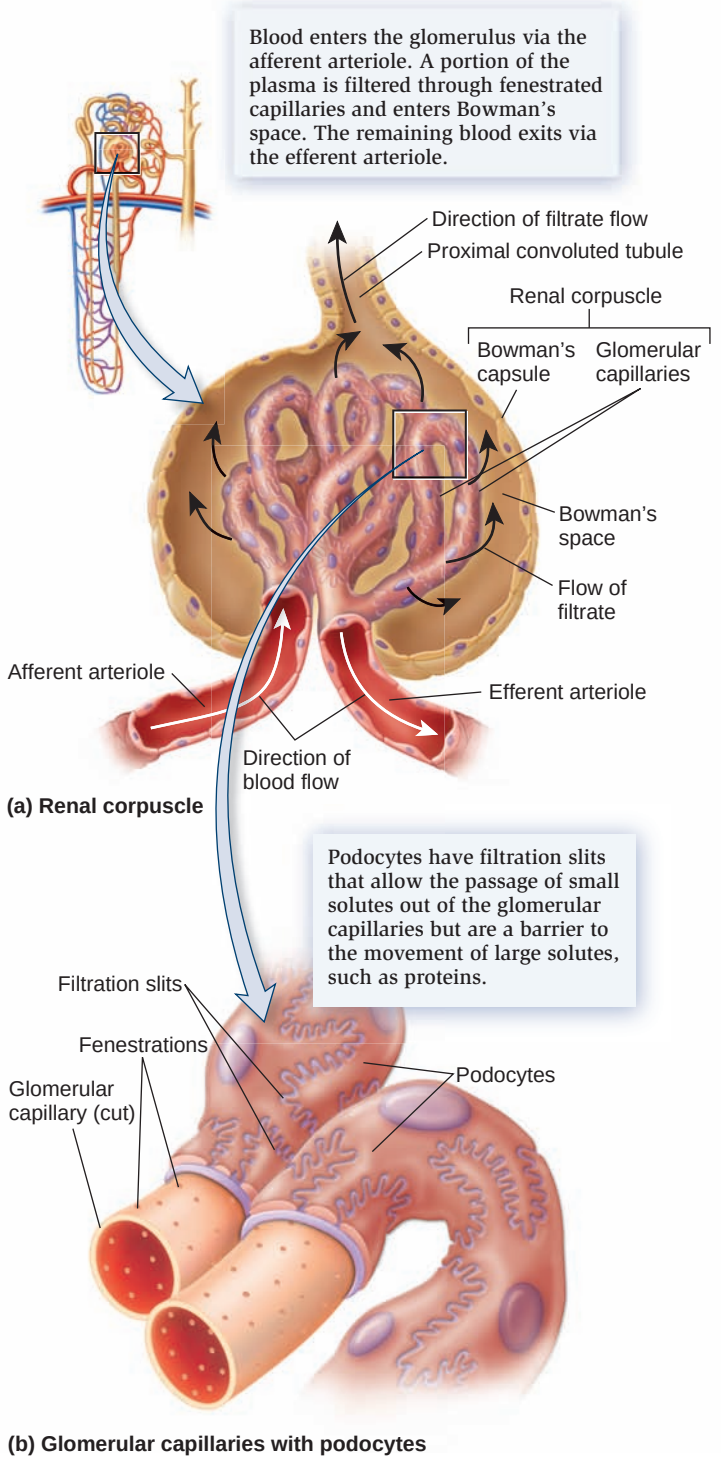

Figure 49.11 The structure and function of the renal corpuscle.

ducts. Let's look more closely at each part of the nephron and its associated structures.

The Renal Corpuscle Each renal corpuscle contains a cluster of capillaries called the **glomerulus** (plural, glomeruli), or glomerular capillaries (Figure 49.11a). Each glomerulus is supplied with blood under pressure by an **afferent arteriole**, and blood exits the glomerulus via an **efferent arteriole**. The glomerulus protrudes into a fluid-filled space called Bowman's space, which lies within a capsule called **Bowman's capsule** (first identified by the English physiologist William Bowman in 1841). The combination of a glomerulus and a Bowman's capsule constitutes a renal corpuscle. The glomerular capillaries contain fenestrations, tiny holes that permit rapid flow of plasma out of the capillaries. This filtration is modified by cells called podocytes that surround the capillaries and form filtration slits that allow the passage of small solutes, but are believed to help prevent proteins from entering the filtrate (Figure 49.11b).

The Tubular Part of the Nephron The tubule of the nephron, which is continuous with Bowman's capsule, is made of a single layer of epithelial cells resting on a basement membrane. The epithelial cells differ in structure and function along the tubule's length, and several distinct segments are recognized. The segment of the tubule that drains Bowman's capsule is the **proximal convoluted tubule** ("proximal" means adjacent to, with respect to the Bowman's capsule) (see Figure 49.10c). The next portion of the tubule is the **loop of Henle**, discovered by the German physician Friedrich Henle in 1861. It is a long, hairpin-like loop consisting of a descending limb coming from the proximal tubule and an ascending limb. The ascending limb has two segments, a thin and a thick segment. The thick segment leads to the next tubular segment, the **distal convoluted tubule** ("distal" means away from the Bowman's capsule). Fluid flows from the distal convoluted tubule into one of the many collecting ducts in the kidney.

Capillaries of the Nephron All along its length, each tubule is surrounded by capillaries. These include the **peritubular capillaries** in the cortex and the **vasa recta capillaries** in the medulla (see Figure 49.10c). Both sets of capillaries carry away reabsorbed solutes and water from the filtrate in the nephron and return them to the bloodstream. However, only the peritubular capillaries secrete solutes into the tubules.

Now that we have learned about the structural units of the mammalian kidney, we turn our attention to the mechanisms by which nephrons filter blood and produce urine for excretion and how these activities are controlled under different conditions.

Filtration: A Filtrate Is Produced in Bowman's Space

Filtration begins as blood flows through the glomerulus and a portion of the plasma leaves the glomerular capillaries and filters into Bowman's space. Only about 15–20% of the plasma is filtered from the blood as it circulates through the glomerulus. Most of the blood, therefore, exits the glomerulus by an efferent arteriole (see Figure 49.11a). Proteins and blood cells are prevented from leaving the glomerular capillaries because of the small diameter of the fenestrations and the presumed actions of the filtration slits mentioned earlier. The fluid that enters Bowman's space is called the glomerular filtrate. The rate at which the filtrate is formed is called the **glomerular filtration rate** (**GFR**). GFR can be increased by dilation (widening) of the afferent arteriole. When the afferent arteriole dilates, more blood enters the glomerulus, increasing the hydrostatic

pressure in those capillaries and forcing more plasma through the fenestrations in the glomerular capillaries and into Bowman's space. This might happen, for example, when there is an excess of water in the body that must be excreted in the urine.

By contrast, constriction of the afferent arteriole would reduce the amount of blood entering the glomerular capillaries and therefore would reduce GFR. This might occur following a loss of blood due to a severe injury. In such a scenario, reducing GFR results in less urine production, which, in turn, minimizes how much water is lost from the body and helps compensate for the blood lost due to the injury.

Reabsorption and Secretion: Useful Solutes Are Reabsorbed from, and Toxic Solutes Are Secreted into, the Filtrate in the Proximal Tubule

The filtrate flows from the renal corpuscle to the proximal convoluted tubule. Anywhere from two-thirds to 100% of a particular useful solute is reabsorbed from the filtrate in the proximal tubule. This includes Na^+, K^+, Cl^-, HCO_3^-, and organic molecules such as glucose and amino acids. Some ions diffuse through channels in the membranes of the epithelial cells that form the single-cell–thick proximal tubule. Others are actively transported across the tubule. Organic molecules generally are reabsorbed by being coupled to transport of ions such as Na^+. The absorption of solutes and water is enhanced by microvilli that extend from the luminal surface of the epithelial cells of the proximal tubule. This anatomical adaptation, called a brush border, creates an enormous surface area for transporters and channels to be localized (Figure 49.12).

Most of the water in the filtrate leaves by osmosis as the ions and organic molecules are transported from the lumen of the proximal tubule to the interstitial fluid outside the tubules. The amount of water reabsorbed is proportional to the amount of solutes reabsorbed. From the interstitial fluid, the solutes and water enter peritubular capillaries to return to the blood.

Many of the reabsorptive mechanisms in the renal tubule have a limit to the amounts of material they can transport in a given amount of time—called the transport maximum (T_m). This occurs because the binding sites on the membrane-transport proteins become saturated with their ligands. Occasionally, certain molecules may reach such high concentrations in the blood that they exceed the T_m for that molecule in the renal tubule and consequently get excreted in the urine. For example, people who ingest very large quantities of water-soluble vitamins, such as vitamin C, have increased plasma concentrations of vitamin C. Eventually, the filtered load may exceed the tubular reabsorptive T_m for this vitamin, and any additional ingested vitamin C is excreted in the urine.

In addition to reabsorption, secretion also occurs in the proximal tubule. Some solutes that are either not required by an animal or that are potentially toxic at high concentrations are secreted by active transport mechanisms from the extracellular fluid into this tubule. Examples of such substances include foreign compounds (for example, penicillin), naturally occurring toxins, nucleoside metabolites, and ions such as K^+ and H^+. These solutes are excreted in the final urine.

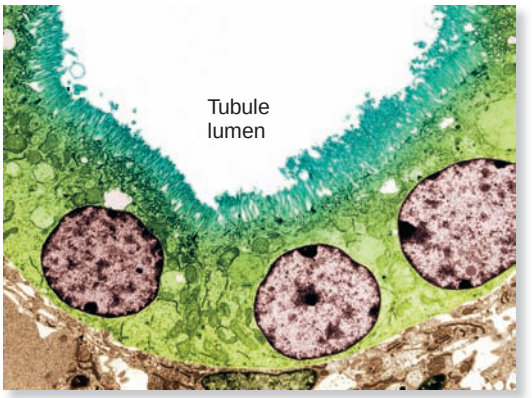

Figure 49.12 **Electron micrograph of cuboidal epithelial cells of the proximal convoluted tubule of a rat nephron.** Note the extensive brush border microvilli on the luminal surface of the cells.

Concept check: *In what other organ have you learned about a brush border? Can you draw general conclusions about the function of such specialized epithelia?*

By the time the filtrate leaves the proximal tubule, its volume and composition have changed considerably. The amount of salts and water it contains is much reduced, and the organic molecules have all been removed. However, the final osmolarity of the filtrate is still about the same as blood.

Reabsorption: Water and Salt Continue to Be Reabsorbed from the Filtrate by a Countercurrent Osmotic Gradient Along the Loop of Henle

In the loop of Henle in the mammalian kidney, filtrate moves down the descending limb of the loop, makes a U-turn at the bottom, and then moves back up the ascending limb of the loop. The permeabilities and transport characteristics of the epithelial cells lining the loop change over its length as it descends from the cortex into the medulla and then ascends to the cortex again (Figure 49.13).

As we have seen, the filtrate that leaves the proximal convoluted tubule has had some solutes and water reabsorbed from it; the osmolarity of the initial filtrate is about 300 mOsm/L. This filtrate enters the descending limb of the loop of Henle, which is very permeable to water but not to solutes. Water leaves the filtrate by osmosis in this region because the surrounding interstitial fluid is hyperosmotic compared to the tubule contents. The hyperosmolarity of the interstitial fluid originates from three sources. First, the initial upturn of the thin segment of the ascending limb of the loop of Henle is very permeable to sodium and chloride but not to water. Therefore, these ions diffuse at high rates out of the loop into the interstitial fluid, significantly increasing the osmolarity of the inner medulla. Second, the epithelial cells of the thick segment of the ascending limb of the loop of Henle actively transport some of the remaining sodium and chloride ions out of the filtrate and into the interstitial fluid of the outer medulla. Third, although urea is a waste product that gets excreted, some of the urea that is present in the filtrate does not get excreted in the urine, but instead diffuses out of the lower ends of the collecting ducts and into the inner medulla interstitial fluid. Collectively, these solutes create the osmotic force that draws water out of the

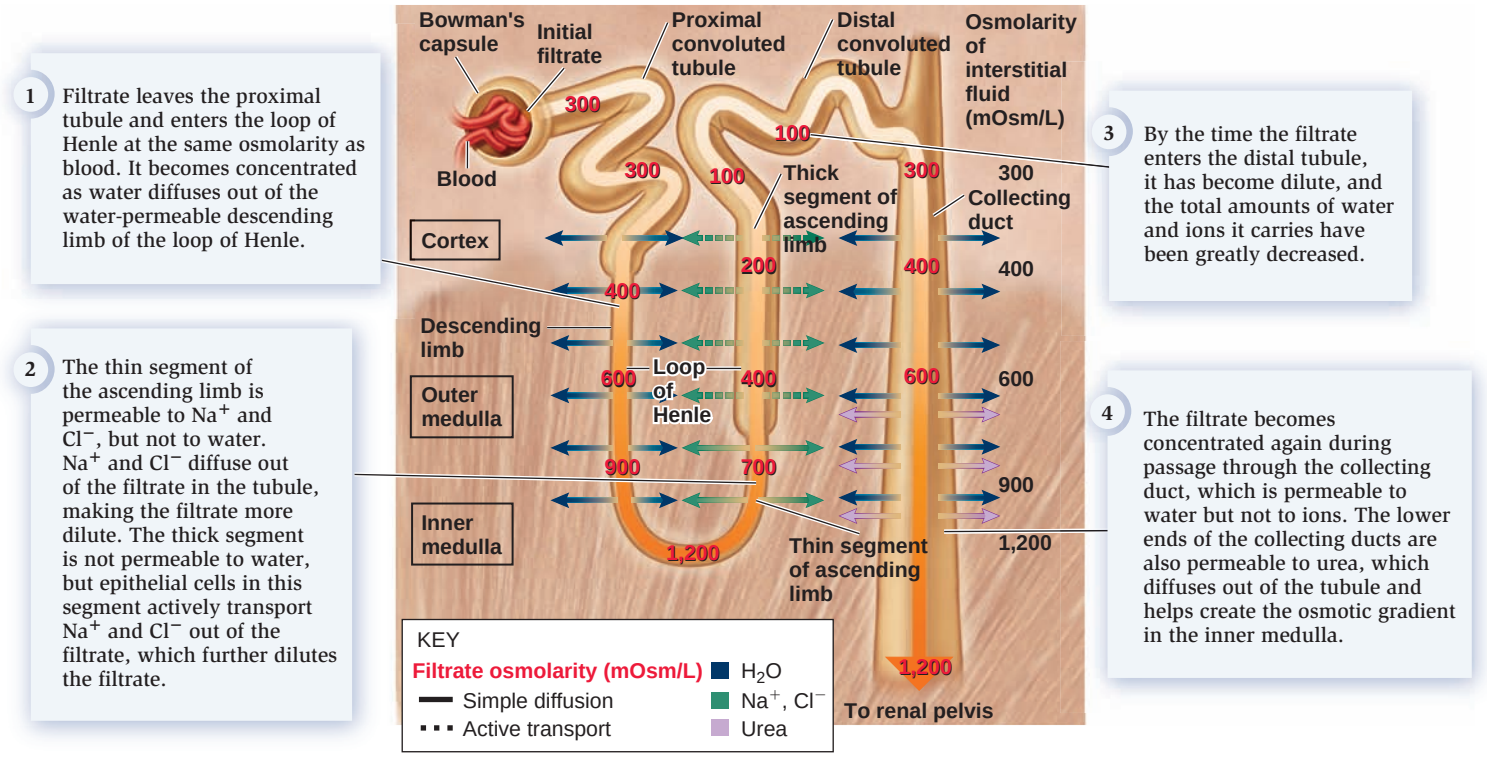

Figure 49.13 Tubule permeabilities and concentrations of the filtrate in the nephron and collecting duct.

filtrate in the descending limb. The water then enters local capillaries and rejoins the blood circulation.

As water diffuses out of the filtrate in the descending limb of the loop of Henle, the osmolarity of the filtrate increases from 300 to about 1,200 (or higher in some species) mOsm/L. During its passage up the ascending limb, however, the osmolarity of the filtrate decreases to about 200 mOsm/L as ions diffuse out and are transported out of the tubule. The thin segment of the ascending limb is permeable to Na^+ and Cl^-, but not water, so Na^+ and Cl^- diffuse out of the filtrate in the tubule. This begins to dilute the filtrate. The thick segment is also not permeable to water, but epithelial cells in this segment actively transport Na^+ and Cl^- out of the filtrate, further diluting the filtrate.

As a consequence of ion movement out of the ascending limb, the osmolarity of the kidney interstitial fluid increases from cortex to inner medulla. This extracellular osmolarity gradient is what allows water to diffuse by osmosis from the descending limb of the loop of Henle all along its length. In other words, this is an example of a countercurrent exchange system, like those that operate in heat and gas exchange in some animals (see Chapters 46 and 48). A major difference between those countercurrent exchange systems and the one in the loop of Henle, however, is that the latter requires energy-dependent ion pumps to maintain the necessary gradient. Energy-requiring systems such as that in the kidney are referred to as countercurrent multiplication systems, because energy is used to increase—or multiply—the gradient. Energy is not used to establish a heat or oxygen gradient in those other countercurrent exchange systems.

The chief advantage to an animal provided by the loop of Henle is that the final volume of urine produced can be reduced and its contents concentrated by the recapture of water along the osmotic gradient. This is especially important in animals in which total body water stores are regularly in danger of being depleted. For example, desert mammals such as the kangaroo rat tend to have longer loops of Henle than other mammals. The extra length of the loop provides for a very large osmotic gradient in the medulla and, therefore, more water-reabsorbing capacity. At the other extreme, animals that generally must eliminate excess water have reduced or absent loops of Henle. Freshwater fishes, for example, have no loops of Henle in their nephrons. In their case, it is advantageous to excrete as much water as possible to compensate for the large amounts of water constantly entering the body by osmosis across the gills.

Reabsorption: The Vasa Recta Capillaries Help to Maintain the Medullary Osmotic Gradient and So Minimize the Loss of Useful Solutes from the Filtrate

Why does the blood flowing through the vasa recta capillaries of the medulla not eliminate the countercurrent osmotic gradient set up by the loops of Henle? One would think that as plasma, having the usual osmolarity of ~300 mOsm/L, enters the highly concentrated environment of the medulla, two types of massive net diffusion or osmosis would occur: of sodium and chloride into the capillaries and of water out of them. Thus, the interstitial gradient would be "washed away." However, this does not happen because the vasa recta form hairpin loops that run parallel to the loops of Henle and medullary collecting ducts (see Figure 49.10c). Near the top of the loop of Henle, blood in the vasa recta has a normal osmolarity. As the blood flows down the loop deeper and deeper into the inner medulla, sodium and chloride do indeed diffuse into, and water moves

out of, the vasa recta. However, after the bend in the loop is reached, the blood then flows up the ascending vessel loop, where the process is almost completely reversed. Thus, the hairpin-loop structure of the vasa recta minimizes excessive loss of solutes from the interstitial fluid by diffusion. At the same time, both the salt and water being reabsorbed from the loops of Henle and collecting ducts are carried away in equivalent amounts by the movement of water and solutes between fluid compartments. Therefore, the steady-state countercurrent gradient set up by the loops of Henle is maintained.

Reabsorption and Secretion: Salt and Water Concentrations of the Filtrate Are Fine-Tuned in the Distal Tubule and Collecting Duct

By the time the filtrate reaches the distal convoluted tubule, most of the reabsorbed salt and water have already been restored to the blood, so the filtrate has been diluted to an osmolarity of about 100 mOsm/L (Figure 49.13). However, the remaining concentrations of sodium, chloride, and potassium in the filtrate can still be fine-tuned. This process is mediated by the actions of two hormones called aldosterone and antidiuretic hormone (ADH).

Aldosterone and Sodium Reabsorption and Potassium Secretion **Aldosterone** acts on the basolateral surface of epithelial cells of the distal tubule and upper part of the collecting duct. There it stimulates the active transport of three molecules of Na^+ out of the filtrate in the tubule into the interstitial fluid (reabsorption) for every two molecules of K^+ it pumps into cells from the interstitial fluid and ultimately into the filtrate (secretion) (Figure 49.14). Water from the filtrate follows the Na^+ by osmosis into the interstitial fluid and blood. This makes the filtrate that moves to the lower part of the collecting duct a bit more concentrated than it was before, with an osmolarity of about 400 mOsm/L. Aldosterone levels increase in the blood whenever the Na^+ concentration of the blood is lower than normal or the K^+ concentration is higher than normal. Through its actions on the nephron, aldosterone corrects such imbalances.

ADH and Water Reabsorption The lower part of the collecting duct is the final place where urine composition can be altered. The osmolarity of the filtrate increases further during passage along the collecting duct, which is permeable to water but not to ions, allowing water to diffuse out of the tubules by osmosis. As previously described, the cells of the collecting duct in the inner medulla are permeable to urea, which contributes to the osmotic gradient there.

In addition, however, the permeability of the epithelial cells of the collecting ducts to water (but not ions) can be regulated, depending on the body's requirement at that moment for retaining or excreting water. This happens under the influence of **antidiuretic hormone** (**ADH**). When ADH is present in the blood, it acts to increase the number of water channels in the membranes of the collecting duct cells. Because the collecting ducts travel through the hyperosmotic medulla of the kidney, an osmotic gradient draws water from the filtrate in the duct into

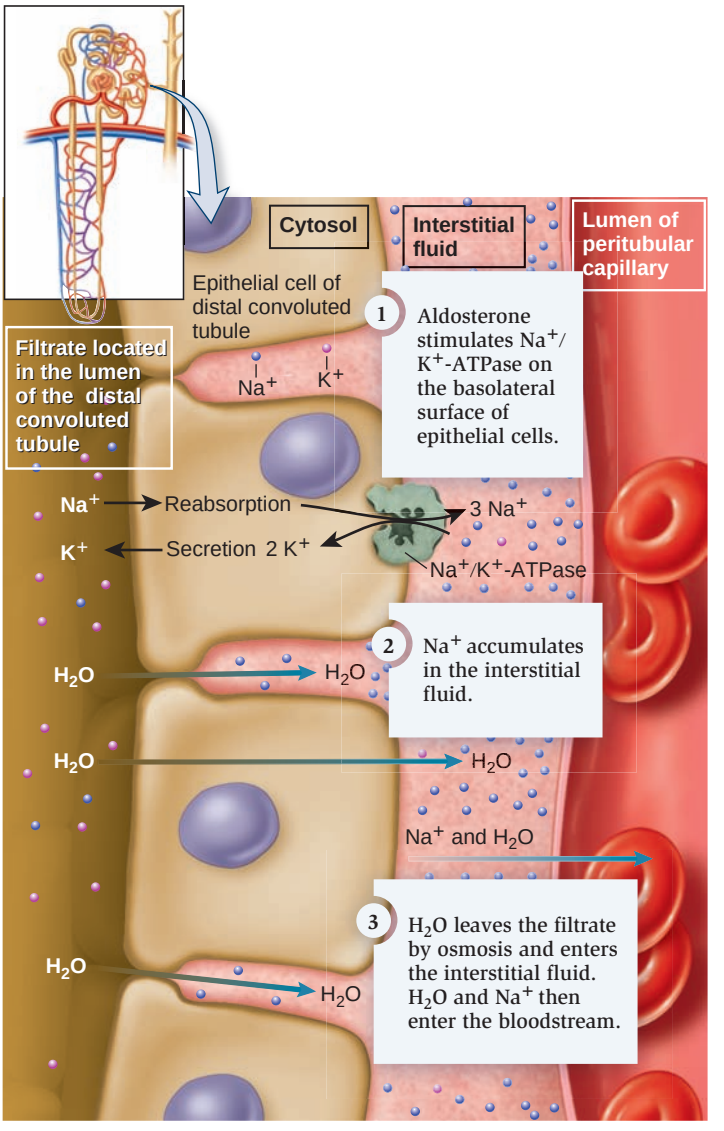

Figure 49.14 **Action of aldosterone on distal convoluted tubule epithelial cells.** Aldosterone stimulates the Na^+/K^+-ATPase activity of distal tubule cells on the side facing the interstitial fluid (the basolateral membrane). This activity creates an osmotic gradient, as three Na^+ are reabsorbed from the filtrate for every two K^+ secreted into it. Water then leaves the tubule by osmosis. The net effect is reabsorption of Na^+ and water, and secretion of K^+, which gets excreted in the urine. Na^+ and water enter the peritubular capillaries and are carried away in the bloodstream.

Concept check: *What special property of epithelial cells is demonstrated by the action of aldosterone?*

the surrounding interstitial fluid, from where it enters the vasa recta capillaries and the blood. In this way, as the filtrate travels through the collecting ducts, it becomes greatly concentrated (hyperosmotic) compared to blood—as much as four to five times more concentrated in humans, for example. The ability of the kidneys to produce hyperosmotic urine is a major determinant of an animal's ability to survive in conditions where water availability is limited. When the body's stores of water are plentiful, the level of ADH in the blood decreases. This, in turn, decreases the water permeability of the collecting ducts. In such a case, urine increases in volume and becomes more dilute because less water diffuses out of the collecting ducts.

Biological membranes such as the plasma membranes of animal cells are composed of a lipid bilayer that inhibits the movement of water. The mystery of how water moves rapidly across membranes like those of the collecting ducts and loop of Henle was solved by the discovery in the early 1990s of a family of molecules that came to be known as aquaporins (from the Latin, meaning water pores), as described next.

Genomes & Proteomes Connection

Water Channels Called Aquaporins Comprise a Large Family of Proteins That Are Ubiquitous in Nature

In the early 1990s, the American physiologist Peter Agre and colleagues discovered the first of what would eventually be recognized as a new family of proteins, called aquaporins, a discovery that earned Agre the Nobel Prize in Chemistry in 2003 (see Chapter 5). Scientists now know that aquaporins are a subfamily of an even larger family of proteins with membrane transport capabilities, found in all kingdoms of living organisms. The functions of all the members of this family are not yet known, but some aquaporins can transport other small molecules, such as glycerol and urea. There are currently 11 known members of the aquaporin family in the human genome.

Aquaporins are proteins with six transmembrane domains and two short loops in the membrane (Figure 49.15). In animals, the two short loops come together to form the three-dimensional core of the water channel. The importance of the loops is reflected in the observation that these portions are the most highly conserved sequences of the protein among different species. Water must pass through a zone of constriction, created by the loops, that reduces the channel opening to about 30 picometers (30×10^{-12} meters), or just about the width of a water molecule. Scattered along the inner part of the channel are arginine amino acids, which are positively charged. The charged arginines participate in hydrogen bonding with water molecules, facilitating their single-file movement through each channel at rates that have been estimated to be up to billions of water molecules per second!

Within the various extracellular and intracellular domains of aquaporins are sites that can be modified by enzymes, such as kinases. This suggests that the opening and closing of these channels may be gated by stimuli, like the way ion channels are gated in neurons and other cells. In addition, the promoter region of certain aquaporin genes contains a site that is recognized by transcriptional activator proteins that are responsive to the presence of cAMP, a common intracellular signaling molecule and one that is generated by cells stimulated by ADH. Thus, one mechanism by which ADH promotes osmosis of water out of the renal collecting ducts appears to be by stimulating the transcription of one or more aquaporin genes.

Our understanding of aquaporin function has allowed us to explain the molecular basis of one form of an inherited human disease called hereditary nephrogenic diabetes insipidus. Patients with this disease are unable to produce a concentrated urine and consequently lose large amounts of water. A mutation in one aquaporin gene results in a form of the protein expressing any of several abnormalities: improper folding into its correct shape, impaired ability of the molecule to enter the plasma membrane, or impaired ability of the molecule to form a channel core. In addition, Agre's discovery may have widespread implications for other areas of biology and human health. For example, certain types of plant disease are associated with abnormal aquaporin expression in roots. In addition, some scientists are investigating the possibility that drugs that inhibit bacterial aquaporins may someday be useful antibiotics. The use of drugs to inhibit one class of aquaporins has even been suggested as a possible antiperspirant!

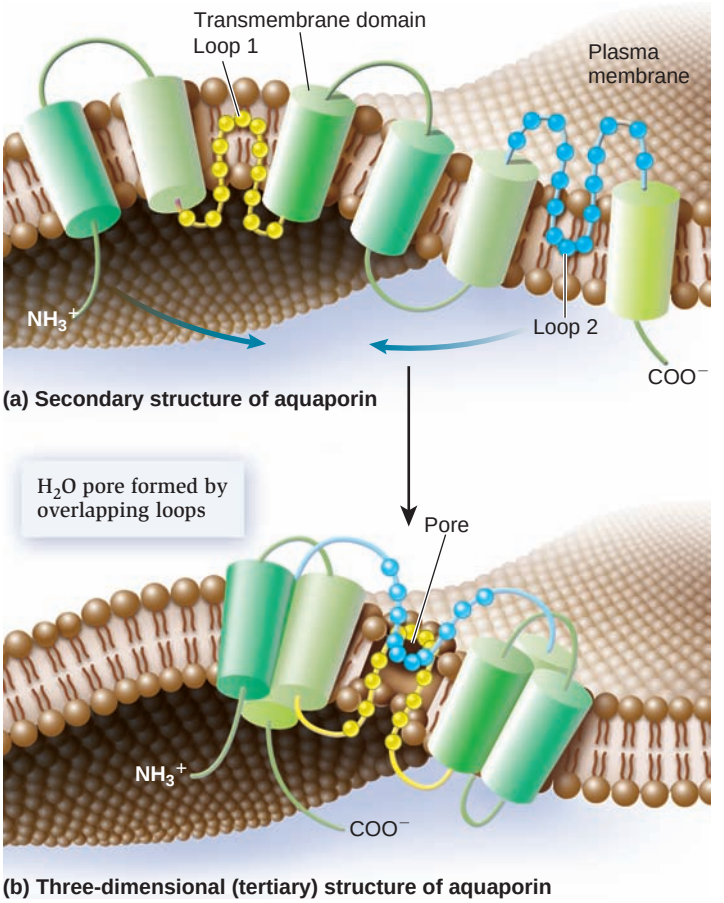

Figure 49.15 **Detailed aquaporin structure.** All proteins of the aquaporin family share a similar structure, with six membrane-spanning domains (represented as cylinders) and two loops that come together to form a water channel. **(a)** Secondary structure of aquaporin. This highly schematic representation highlights the two separate regions of the molecule that come together to form the water pore. **(b)** Tertiary structure of aquaporin showing pore formation.

The mammalian kidney is a remarkably efficient organ serving many functions, most of them related to various aspects of homeostasis. Because of its central role in homeostasis, it should not be surprising that kidney damage or disease can have devastating consequences. In the final section, we consider kidney diseases in humans.

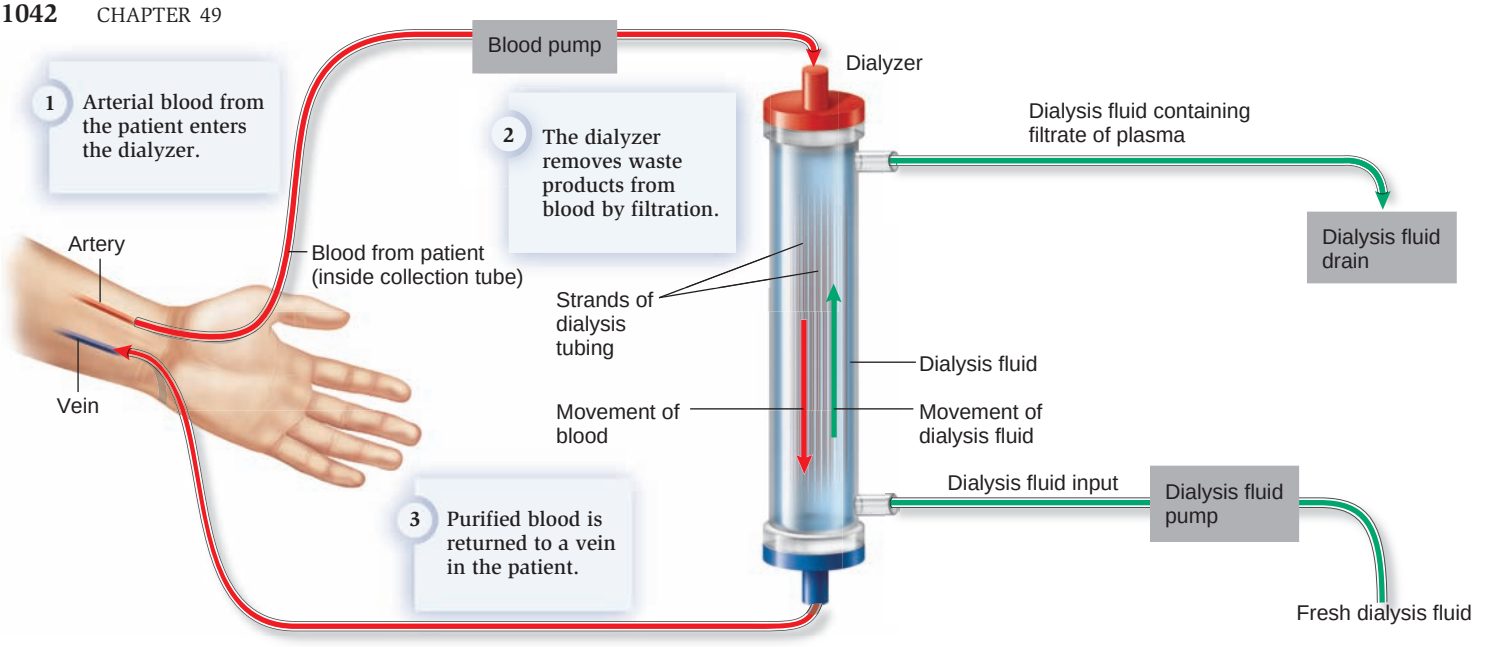

Figure 49.16 Simplified diagram of hemodialysis. The dialyzer is composed of many strands of very thin, sievelike tubing. In the dialyzer, blood within the dialysis tubing and the dialysis fluid bathing the tubing move in opposite directions (a countercurrent). The dialyzer provides a large surface area for diffusion of waste products out of the blood and into the dialysis fluid.

49.6 Impact on Public Health

Diseases and disorders of the kidney are a major cause of illness in the human population. According to statistics released by the Centers for Disease Control and Prevention, up to 4.5% of the U.S. population—or about 13 million people—suffers from one form of kidney disease or another, with approximately 15,000 individuals requiring kidney transplants each year. This section gives an overview of kidney diseases and disorders in humans and also discusses some of the available treatments for these conditions.

Kidney Damage and Disease Are Caused by Many Factors and Result in Disruption of Homeostasis

Many diseases affect the kidneys. Diabetes, bacterial infections, allergies, congenital defects, kidney stones (accumulation of mineral deposits in nephron tubules), tumors, and toxic chemicals are some possible sources of kidney damage or disease. A buildup of pressure due to obstruction of the urethra or a ureter may damage one or both kidneys and increase the likelihood of a bacterial infection.

The symptoms of renal malfunction are similar regardless of the cause of the disease, and all stem from the condition known as **uremia**—from the Greek, meaning urine in the blood. Assuming that a person with diseased kidneys continues to ingest a normal diet containing the usual quantities of nutrients and electrolytes, what problems might arise? Potentially toxic waste products that would normally enter the nephron tubules by filtration instead build up in the blood, because kidney damage significantly reduces the number of functioning nephrons. In addition, the excretion of potassium is impaired because too few nephrons remain capable of normal tubular secretion of this ion. Increased K^+ in the blood is an extremely serious condition, because of the importance of stable extracellular concentrations of K^+ in the control of heart and nerve function.

The kidneys are still able to perform their homeostatic functions reasonably well as long as at least 10% of the nephrons are functioning normally. The remaining nephrons undergo alterations in function—filtration, reabsorption, and secretion—to compensate for the missing nephrons. For example, each remaining nephron increases its rate of potassium secretion so that the total amount of potassium excreted by the kidneys can be maintained at normal levels. The kidneys' regulatory abilities are limited, however. If, for example, someone with severe renal disease were to eat a diet high in potassium, the remaining nephrons might not be able to secrete enough potassium to prevent its concentrations from increasing in the extracellular fluid.

Kidney Disease May Be Treated with Hemodialysis and Transplantation

Diseased kidneys may eventually reach a point where they can no longer excrete and reabsorb water and ions at rates that maintain salt and water homeostasis, nor excrete waste products as fast as they are produced. Adjusting a person's diet can help reduce the severity of these problems; for example, lowering potassium intake reduces the amount of potassium to be excreted. However, such alterations may not eliminate the problems. In that case, doctors must use various procedures to artificially perform the kidneys' excretory functions.

The most important of these procedures is **hemodialysis**. The general term dialysis means to separate substances in solution using a porous membrane. An artificial kidney is an apparatus that removes excess substances from the blood by hemodialysis (Figure 49.16). During this procedure, blood from one of the patient's arteries flows into the dialysis machine, which is called

a dialyzer. Within the dialyzer, blood flows through cellophane tubing that is surrounded by a special dialysis fluid. The tubing is highly permeable to most solutes but relatively impermeable to protein and completely impermeable to blood cells. These characteristics are designed to be quite similar to those of the body's own capillaries. The dialysis fluid has ion concentrations similar to those in normal plasma but contains no urea or other substances that are to be completely removed from the plasma.

As blood flows through the tubing in the dialyzer, small solutes diffuse out into the dialysis fluid until an equilibrium is reached. If, for example, the patient's plasma potassium concentration is above normal, potassium diffuses out of the blood across the cellophane tubing and into the dialysis fluid. Similarly, waste products and excess amounts of other substances also diffuse into the dialysis fluid and thus are eliminated from the body. Note in Figure 49.16 that blood and dialysis fluid flow in opposite directions through the dialyzer. This establishes an artificial countercurrent exchange system that increases the efficiency with which the blood is cleansed. The dialyzed, purified blood is then returned to one of the patient's veins through another type of tubing that leaves the dialyzer.

Some patients with reversible, temporary forms of kidney disease may require hemodialysis for only days or weeks. However, patients with chronic, irreversible kidney disease require treatment for the rest of their lives, unless they receive a kidney transplant. Such patients undergo hemodialysis several times a week. Each year nearly 300,000 Americans undergo some type of dialysis.

The treatment of choice for most patients with permanent kidney disease is kidney transplantation. Rejection of the transplanted kidney by the recipient's body is a potential problem with transplants, but great strides have been made in reducing the frequency of rejection. Many people who might benefit from a transplant, however, do not receive one, because the number of people needing a transplant exceeds the number of donors. Currently, the major source of kidneys for transplanting is from recently deceased persons. Improved public understanding may lead many more individuals to give permission to have their kidneys and other organs used following their death. Recently, donation from a living, related donor has become more common, particularly with improved methods for preventing rejection. As noted earlier in this chapter, the mammalian kidney can perform its functions with only a fraction of its nephrons intact. Due to this large safety factor, a person who donates one of his or her kidneys can function quite normally with only one kidney.

Summary of Key Concepts

49.1 Principles of Homeostasis of Internal Fluids

- Exchanges of salt and water with the environment resulting from vital processes, such as respiration or the elimination of wastes, are called obligatory exchanges. (Figure 49.1)
- Among the important products of the breakdown of proteins and nucleic acids are nitrogenous wastes, molecules that include nitrogen from amino groups (NH_2). Most aquatic animals produce ammonia (NH_3) and ammonium ions (NH_4^+), which are the most highly toxic nitrogenous wastes but require no energy to produce. Many animals, including all mammals, convert ammonia into urea, which is less toxic than ammonia and requires moderate expenditures of water and energy. Birds, insects, and most reptiles produce uric acid or other nitrogenous compounds called purines. These nitrogenous wastes conserve water and are less toxic but energetically costlier than ammonia. (Figure 49.2)
- The solute concentration of a solution of water is known as the solution's osmolarity, expressed as milliosmoles/liter (mOsm/L). Fishes and other water-breathing animals that live in fresh water and those that live in salt water face opposite osmoregulatory challenges. (Figure 49.3)
- Salt glands are adaptations found in marine birds and reptiles that permit these animals to eliminate excess salt from the body. (Figure 49.4)
- Robert Cade and coworkers discovered that fluid replacement during exercise is particularly beneficial if the fluid contains solutes at concentrations resembling those in sweat. (Figure 49.5)
- Animals that maintain constant internal salt concentrations and osmolarities, even when living in water with very different osmolarities than their body fluids, are called osmoregulators. Animals in which internal osmolarity conforms to the osmolarity of the environment are called osmoconformers.

49.2 Principles of Fluid Filtration and Waste Excretion

- Most excretory organs operate by one or more of the following processes: (1) filtration, the removal of water and small solutes from the body fluids such as blood or hemolymph; (2) reabsorption, in which useful filtered solutes are returned to the body fluids via transport systems; (3) secretion, in which toxic or unnecessary solutes are actively transported from the blood or interstitial fluid and into the excretory tubule, and (4) excretion, in which wastes and unnecessary materials are passed out of the body. (Figure 49.6)

49.3 Comparative Excretory Systems

- In the protonephridial system of flatworms, a series of branching tubules filters fluids from the body cavity into the tubule lumens via the actions of ciliated flame cells. (Figure 49.7)
- In the metanephridial system of annelids, pairs of metanephridia located in each body segment filter interstitial fluid through funnel-like structures called nephrostomes. A dilute urine is excreted via nephridiopores in the body wall. (Figure 49.8)
- In insects, cells of Malpighian tubules secrete salts and uric acid from hemolymph into the tubule lumen; water follows by osmosis. After useful salts and water are reabsorbed into the hemolymph, wastes are excreted from the body. (Figure 49.9)

49.4 Renal Function and Vertebrate Life History

- The mechanisms by which vertebrates osmoregulate vary depending on the animal's environment. (Table 49.1)

49.5 Structure and Function of the Mammalian Kidney

- The urinary system in humans consists of the kidneys, ureters, urinary bladder, and urethra. Urine is excreted through the

urethra. Each kidney is composed of an outer renal cortex and an inner renal medulla. (Figure 49.10)

- The functional units of the kidney, called nephrons, are composed of a filtering component, called the renal corpuscle, and a tubule that empties into a collecting duct. Each renal corpuscle contains a cluster of interconnected, fenestrated capillaries called the glomerulus within a structure called Bowman's capsule. Each glomerulus is supplied with blood under pressure by an afferent arteriole. Filtration occurs in the renal corpuscle. Each tubule of a nephron is composed of a proximal convoluted tubule, a loop of Henle, and a distal convoluted tubule. Tubules are surrounded by peritubular capillaries in the cortex and by the vasa recta capillaries in the medulla. (Figure 49.11)
- Different portions of the tubule have different permeabilities to solutes and water. Most reabsorption of useful solutes occurs in the proximal convoluted tubule. Water and ion reabsorption continues along the loop of Henle, using a medullary countercurrent osmotic gradient. The reabsorption of solutes by the vasa recta minimizes the loss of solutes from the renal medulla. Fine-tuning of urine composition by the hormone aldosterone occurs in the distal convoluted tubule and upper collecting duct, and the final concentration of urine is determined by ADH in the lower collecting duct. (Figures 49.12, 49.13, 49.14)
- Agre and coworkers discovered that water moves through plasma membranes through protein channels. Agre called these channels aquaporins. Aquaporins regulate water reabsorption in the kidneys. (Figure 49.15)

49.6 Impact on Public Health

- Regardless of the cause of renal malfunction, the symptoms are similar and stem from the condition known as uremia, which literally means "urine in the blood."
- One important treatment for kidney disease is hemodialysis, in which wastes in blood diffuse across a selectively permeable artificial membrane into a dialysis fluid. Hemodialysis uses a countercurrent exchange system. (Figure 49.16)

Assess and Discuss

Test Yourself

1. A change in electrolyte levels in the body may result in
   a. altered membrane potentials that disrupt normal cell function.
   b. disruption of certain biochemical processes that occur in the cell.
   c. cell death.
   d. a and b only.
   e. a, b, and c.
2. Nitrogenous wastes are the by-products of the metabolism of
   a. carbohydrates.
   b. lipids.
   c. nucleic acids.
   d. proteins.
   e. both c and d.
3. Marine fishes avoid water balance problems by
   a. producing a large volume of dilute urine.
   b. not drinking water.
   c. having gill epithelial cells that recapture lost salts from the environment.
   d. producing small volumes of concentrated urine.
   e. a, b, and c.
4. Metabolic water is water
   a. necessary to stimulate the process of cellular respiration.
   b. found within cells.
   c. produced during cellular respiration.
   d. produced by sweat glands.
   e. used by cells during the uptake of glucose.
5. Animals that maintain a constant water balance despite changes in water concentrations in the environment are
   a. osmoregulators.
   b. osmoconformers.
6. The excretory system found in insects is composed of
   a. protonephridia.
   b. metanephridia.
   c. Malpighian tubules.
   d. a filtration kidney.
   e. a secretory kidney.
7. In the mammalian kidney, filtration is driven by
   a. solute concentration in the tubular filtrate.
   b. solute concentration in the blood.
   c. water concentration in the blood.
   d. water concentration in the tubular filtrate.
   e. hydrostatic pressure in the blood vessels of the glomerulus.
8. In the mammalian urinary system, the urine formed in the kidneys is carried to the urinary bladder by
   a. the collecting duct.
   b. the renal tubule.
   c. the renal pelvis.
   d. the ureters.
   e. the urethra.
9. Which of the following causes an increase in sodium reabsorption in the distal convoluted tubule?
   a. an increase in aldosterone levels
   b. an increase in antidiuretic hormone levels
   c. a decrease in aldosterone levels
   d. a decrease in antidiuretic hormone levels
   e. none of the above
10. Aquaporins are
    a. ion channels.
    b. water channels.
    c. receptors for aldosterone.
    d. small pores in the fenestrated capillaries of the glomerulus.
    e. both a and c.

Conceptual Questions

1. Define nitrogenous wastes, and list four types. What are some advantages and disadvantages of excreting different types of nitrogenous wastes?
2. Explain how salt glands are an adaptation for marine life.
3. List and define the three processes involved in urine production. Do all three processes occur for every substance that enters an excretory organ such as the kidney?

Collaborative Questions

1. Discuss two different types of filtration mechanisms found in invertebrates.
2. Briefly discuss the parts and functions of the nephron in the mammalian kidney.

Chapter Outline

Endocrine Systems

50

A section through a human brain, highlighting the pituitary gland and its connection to the hypothalamus (white). Both of these structures secrete numerous hormones. (Image is a three-dimensional MRI.)

A 22-year-old man was seen by his physician because of a complaint of hair loss and the appearance of severe acne over much of his face, neck, back, and shoulders. Upon examination, the man was found to have additional symptoms, including hypertension (high blood pressure), an elevated cholesterol level, an increased hematocrit (red blood cell count; see Chapter 47), and, alarmingly, shrunken testes. When questioned, the patient admitted that for 6 months he had been taking an oral form of the illegal drug stanozolol in an effort to improve his physique by building more muscle mass. Stanozolol is a synthetic version of a hormone known as an androgen (from the Greek, *andros*, meaning man, and *genein*, meaning to produce). A **hormone** is a chemical produced by cells in the body, which circulates throughout the body in the bloodstream and acts on one or more target tissues to effect a wide range of functions.

In males, androgens are normally produced by the testes, the endocrine organs that are also responsible for producing sperm. In normal amounts, androgens play a key role in the physiological events associated with puberty and reproduction (see Chapter 51), including the characteristic changes in the male physique that accompany puberty. Our patient hoped to accentuate those characteristics by consuming large amounts of androgens to build more muscle. At high concentrations, however, androgens promote increased red blood cell production, which, in turn, makes the heart work harder and can lead to hypertension. Likewise, high concentrations of androgens increase the cholesterol level in the blood, promote fluid retention, damage the liver, cause hair loss, and increase the activity of the sebaceous glands (the oil-producing glands in the skin that make acne worse). At such concentrations, androgens also strongly inhibit the activity of the testes. The latter phenomenon can be thought of for now as arising because the body senses that sufficient androgens are already available in the blood; therefore, the testes are not required to make more androgens, and the glands shrink in size.

Fortunately, this person was educated by his doctor about the consequences of misuse of these powerful hormones, and he discontinued the practice. Had he continued to take androgens, all of his symptoms would have worsened, and he would have run the risk of serious and irreversible damage to his heart, liver, and other organs, while increasing his risk of cancer and other diseases.

Androgens are not unique to humans, or even to mammals, but are found in all vertebrates. Nor are hormones unique to vertebrates; most invertebrates require hormones to maintain homeostasis and to time when key events occur during their life history. Hormones are often produced in response to a homeostatic challenge, such as a change in an animal's blood pressure or body temperature. A chief function of hormones is to counter these challenges and maintain the body's homeostasis. Therefore, hormones affect a wide range of body functions, including gastrointestinal activity, blood pressure, cholesterol balance, fluid and mineral balance, and reproduction, among others.

Hormones are made by cells in nearly all the body's organs. In addition, hormone-producing cells are often found in specialized glands, called **endocrine glands**, whose primary function is hormone synthesis and secretion. An example is the pituitary gland highlighted in the chapter-opening photo. Collectively, all the endocrine glands and other organs with hormone-secreting cells constitute the **endocrine system**, as depicted for a human in Figure 50.1. Unlike some other organ systems such as the urinary or respiratory system, the endocrine system does not consist of a small number

of physically connected tissues and organs. Rather, the endocrine system consists of glands and tissues that produce hormones and that are scattered throughout the body. Please take a moment to read through the information presented in Figure 50.1, in preparation for the rest of the chapter.

In this chapter, we will first learn about the chemical nature of hormones and their mechanisms of action, how the endocrine and nervous systems interact, and the ways in which hormones influence such diverse functions as metabolism, growth, and reproduction. We conclude with a discussion of how hormones impact the human condition, including how synthetic hormones are misused, as in the example just described.

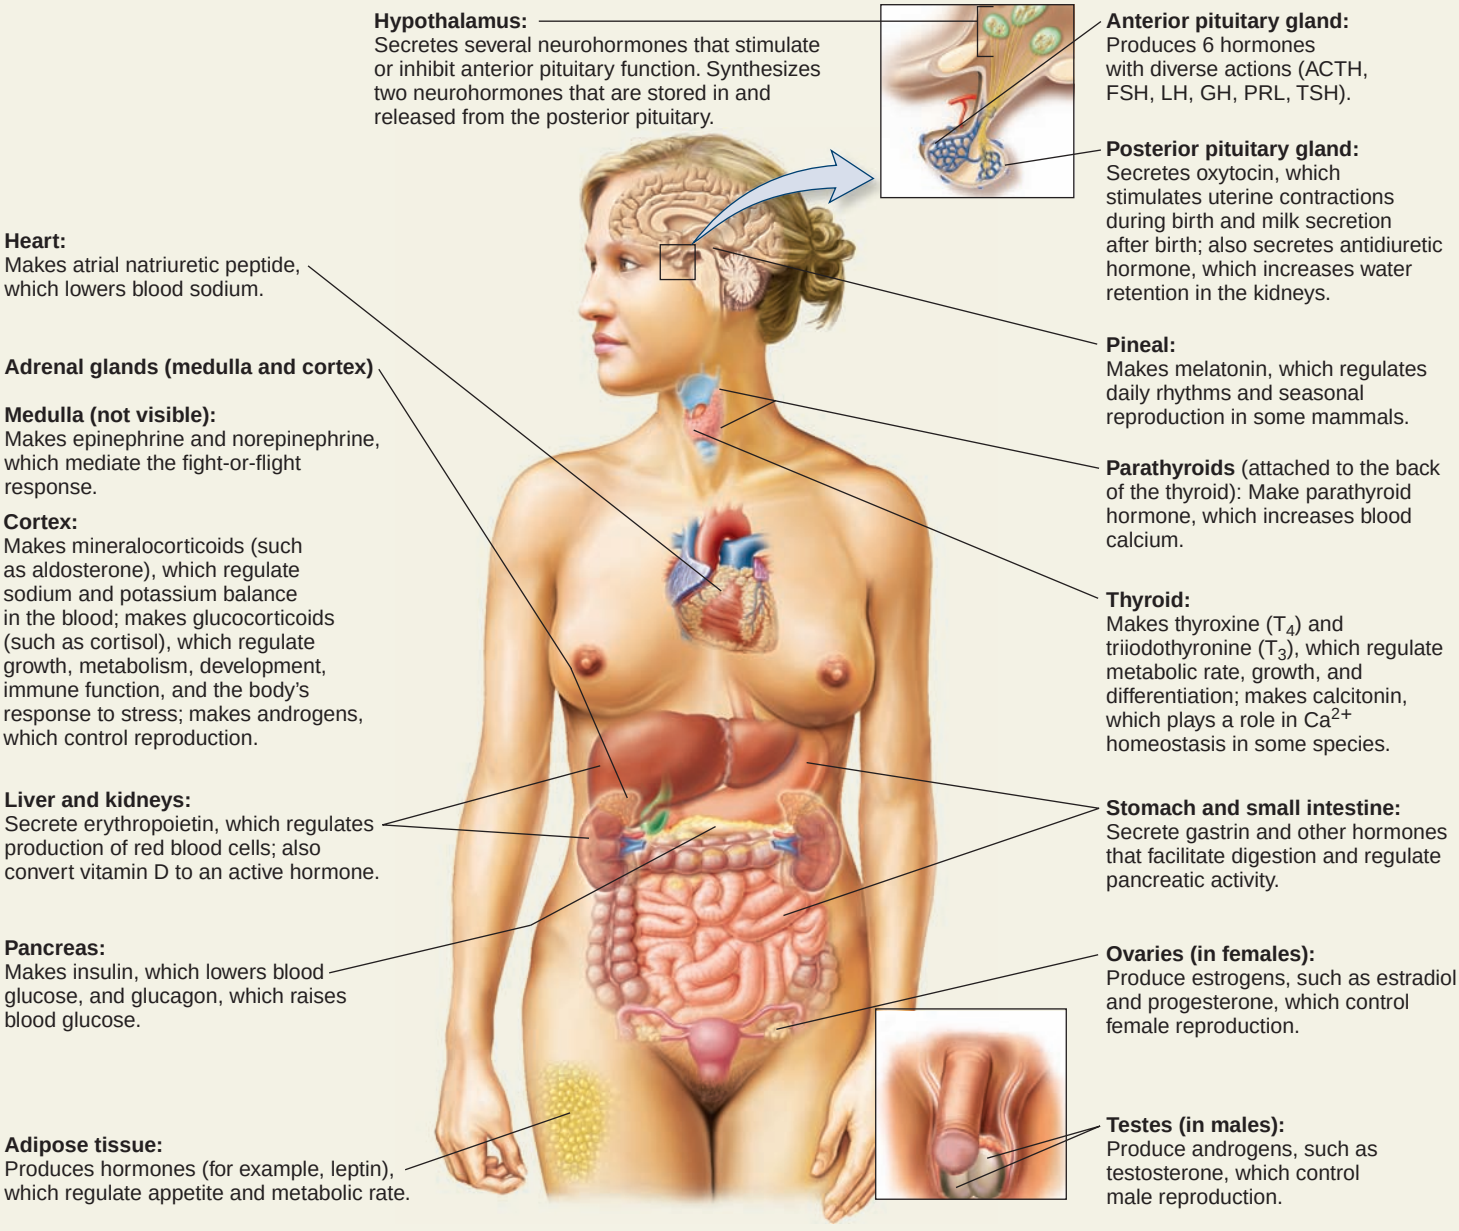

Figure 50.1 **Overview of the endocrine system in humans.** This figure shows many of the major endocrine glands and other structures that constitute the human endocrine system, as well as some major functions of the hormones produced by those glands.

50.1 Mechanisms of Hormone Action and Control

In this section, we will examine some of the general characteristics of hormones, how they act, and how they are controlled. Before proceeding, you might look at Figure 9.3 for a review of the different types of cell-to-cell communication mechanisms found in animals, of which hormones are only one.

Long-Distance Signaling Allows Remote Organs and Tissues to Communicate

Suppose an animal is injured and bleeding badly, which decreases the total amount of fluid in its body significantly. Therefore, the animal's heart would not fill adequately with blood. As a consequence, blood pressure would decrease, creating a potentially life-threatening situation. In vertebrates, the major organs capable of minimizing the loss of fluid from the

body during such times are the kidneys. After a loss of blood, the heart communicates with the kidneys to improve their ability to retain water that would otherwise be lost in the urine. This helps prevent the fluid level of the body from dropping further. In this type of communication between organs, signaling molecules (hormones) must be released from the heart—which detects the loss of blood—into the bloodstream, where they can be carried to the kidneys to exert their effects.

Hormones Can Have Short-Term or Long-Term Effects

The effects of a given hormone may occur within seconds or require several hours to develop, and they may last for as short as a few minutes or as long as days. This is a key difference between the communication processes in the nervous and endocrine systems. In the nervous system, signals are transmitted from one cell to another within milliseconds, and the effect on the postsynaptic cell occurs immediately. In the endocrine system, one hormone may act on a cell quickly and for a very short time, while another may act very slowly and have a lingering action. The explanation for these differences lies in the mechanisms by which different hormones act. This principle is further illustrated by the fact that several hormones, including norepinephrine and dopamine, act as both hormones and neurotransmitters depending on where they are synthesized and how they are released. To understand this, we first examine the different chemical types of hormones, because it is the chemical nature of hormones that determines their mechanisms of action.

The Three Classes of Hormones Differ in Composition

Hormones fall into three broad classes: the amines, proteins/peptides, and steroid hormones (Table 50.1). The amines and the proteins/peptides generally share similar chemical properties and mechanisms of action, whereas the steroid hormones act very differently from the other two classes. Let's look in more detail at each of these three types of hormones.

The amine hormones are derived from an amino acid, either tyrosine or tryptophan. As shown in Figure 50.2, tyrosine is the precursor for the hormones epinephrine and norepinephrine, which are produced in the adrenal medulla and are important in the body's response to stress (the fight-or-flight reaction; see Chapter 42), and for dopamine, a hormone made by the brain. Tyrosine is also the chemical backbone of the hormones made by the thyroid gland, which are important regulators of metabolic rate, growth, and differentiation. The major hormone derived from tryptophan is melatonin, which is produced within an endocrine gland called the pineal gland located in the brain. Melatonin is important for controlling seasonal reproduction in certain mammals such as sheep and hamsters.

The proteins and peptides (small polypeptides) class of hormones is the most abundant. These hormones participate in numerous body functions such as metabolism, mineral balance, growth, and reproduction. Examples include insulin and glucagon made by the pancreas, leptin made by adipose tissue, and many others.

Steroid hormones are synthesized from cholesterol, and thus all steroid hormones are lipids, unlike the other classes of hormones. Steroids are less soluble in water than are amines or protein/peptide hormones. Due to this limited solubility, steroids are usually bound to large, soluble proteins in the blood that serve as carriers. By combining with these proteins, steroids can reach high concentrations in the blood. The major steroid hormones found in vertebrates include aldosterone and cortisol made by the adrenal cortex, androgens made by the testes, and estrogens and progesterone made by the ovaries. In insects, the steroid hormone ecdysone is produced in the prothoracic gland located in the thorax. How do these different characteristics affect the function of hormones?

Hormones Act Through Membrane or Intracellular Receptors

The amine and protein/peptide hormones are generally water-soluble, and the steroid hormones are lipid-soluble. Therefore, the amines and proteins/peptides are not able to cross plasma membranes and must use receptors on the cell surface. Steroid hormones, however, being lipids, can diffuse across plasma membranes and access receptors in either the cytosol or nucleus. Hormones that work through membrane receptors tend to be those that elicit fast responses, whereas those that require a response from the genetic machinery may take longer. Let's look at each of these.

Water-Soluble Hormones and Their Membrane Receptors
All the amine and protein/peptide hormones, with one exception

Table 50.1 Chemical Classes of Hormones

Class	Chemical properties	Location of target cell receptor	Mechanism of action	Examples
Amines	Derived from tyrosine or tryptophan; small, water-soluble	Plasma membrane (except thyroid hormones, which act via intracellular receptors)	Stimulate second messenger pathways (except thyroid hormones which act via changes in gene transcription)	Epinephrine, norepinephrine, dopamine, thyroid hormones, melatonin
Proteins/Peptides	Water-soluble	Plasma membrane	Stimulate second messenger pathways	Insulin, glucagon, leptin
Steroids	Derived from cholesterol, mostly lipid-soluble	Cytosol or nucleus	Usually stimulate gene transcription directly	Aldosterone, cortisol, testosterone, estradiol

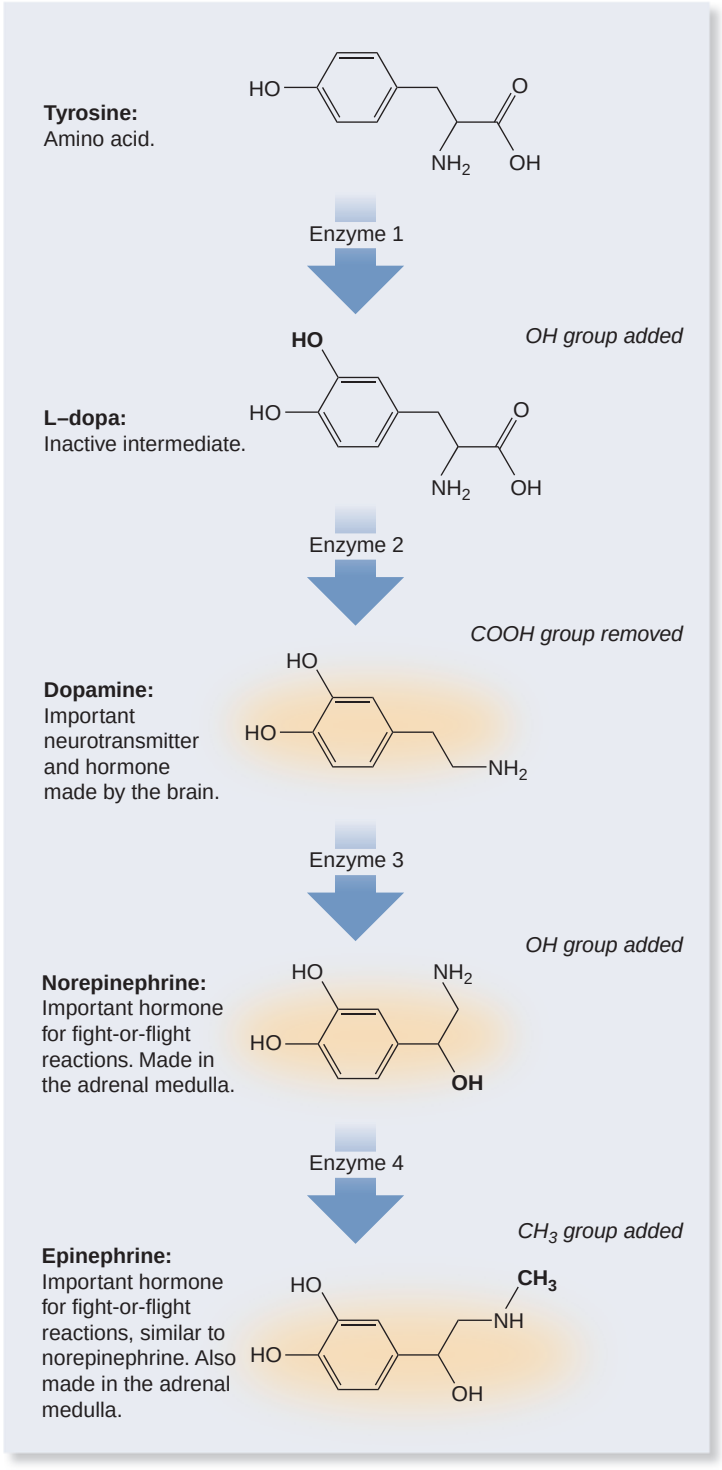

Figure 50.2 **Synthesis of the amine hormones dopamine, norepinephrine, and epinephrine.** The synthesis of thyroid hormones also begins with tyrosine but follows a different mechanism, as described later.

(thyroid hormones, discussed later), act by binding to a receptor protein located in the plasma membrane (refer back to Figure 9.5). As these hormones diffuse from the blood into the interstitial fluid, they must bind to a specific receptor protein located on a cell surface. Only cells having the proper receptors on their surfaces can respond to the hormone. Thus, although a hormone travels throughout the entire circulatory system, it activates only specific cells. The hormone interacts noncovalently and reversibly with the receptor. The reversibility of the binding between hormone and receptor is one way in which cells are prevented from being permanently stimulated.

Among cells throughout the body, different receptor proteins may recognize the same hormone. These different receptors, called subtypes or isoforms, may be the product of different genes or may be produced by alternative splicing, described in Chapter 13. By binding to receptor isoforms, the same hormone is able to elicit differing, sometimes even opposite, responses, depending on where it binds in the body. These isoforms may have different affinities for the hormone, such that low concentrations of a hormone may cause one type of effect by binding to high-affinity receptors on one cell, and higher concentrations may cause entirely different actions by binding to low-affinity receptors on another cell. In this way, most hormones are able to serve more than one function.

The binding of a water-soluble hormone to its plasma membrane receptor initiates intracellular signaling pathways that often involve second messengers (refer back to Figure 9.12). Three major signaling pathways that are activated by water-soluble hormones are the cyclic AMP pathway, the calcium/phosphatidylinositol pathway, and the tyrosine kinase pathway. These signal transduction processes may be rapid, occurring in some cases within seconds, and involve changing the activity of enzymes. Both of these features are important, because occasionally the rapidity of the cell response to a hormone can mean the difference between life and death, as may occur, for example, under conditions of extreme danger. The presence of enzymes in the signaling process ensures that the signal from a small amount of hormone is greatly amplified, because a single signaling molecule results in the production of many intracellular messengers. In this way, endocrine glands may synthesize and secrete relatively small amounts of hormone while still producing biological effects; this conserves energy and resources.

Activation of signaling pathways may also lead to changes in cellular activities that occur more slowly. These slower changes usually require activation or inhibition of genes in the nucleus, and are mediated by transcription factors (see Chapter 12) that are activated by the same signaling pathways described earlier. However, another means of activating gene transcription is through activation of receptors for lipid-soluble hormones.

Lipid-Soluble Hormones and Their Intracellular Receptors

All steroid hormones and the thyroid hormones are lipophilic and bind to intracellular receptors. The complex of a steroid or thyroid hormone bound to its intracellular receptor functions as a transcriptional activator (or less frequently as an inhibitor) by binding to enhancers of particular genes (refer back to Figure 9.9). Once bound, transcription of a gene is increased, which increases the amount of that gene's protein product. These proteins may be important in a variety of cellular activities, such as regulating the number of ion pumps in membranes, controlling cell differentiation, secretory activity, and growth.

Steroid and thyroid hormones can influence several genes within a single cell or different cells. In this way, one hormone can exert a variety of actions throughout the body. The physical changes that accompany puberty in mammals result from the actions of two steroid hormones—androgens in males and estrogens in females—and are among the most striking and commonly recognized examples of this widespread action.

We have learned that hormones act in all cases by binding to receptor proteins located on the cell surface, in the cytosol, or in the nucleus. This raises an intriguing question: Which evolved first, a given hormone or its receptor? There would appear to be no selection pressure to evolve one without the other. However, recent research has generated intriguing new hypotheses regarding the evolution of these signaling systems, as described next.

Genomes & Proteomes Connection

Hormones and Receptors Evolved as Tightly Integrated Molecular Systems

All hormones act by binding to receptors. Without a receptor, a hormone has no function, and without a hormone, the receptor has no function. Hormones and their receptors function as tightly integrated molecular systems. Each molecule depends on the other for biological activity. How such systems could have evolved, or whether they evolved together, has long been a major puzzle.

American biologist and environmental scientist Joseph Thornton and colleagues recently addressed this puzzle by examining how two structurally related steroid hormones evolved separate activities and distinct receptors. **Aldosterone**, as noted, is a steroid hormone made by the adrenal cortex. Because it regulates the balance of two minerals (Na^+ and K^+) in the body, it is known as a **mineralocorticoid**. **Cortisol** is another steroid hormone made by the adrenal cortex and is known as a **glucocorticoid** because one of its major functions is to regulate glucose balance. The actions of these hormones are mediated by intracellular receptors known as the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), respectively. Phylogenetic analysis of the gene sequences that code for these two receptors suggests that they arose at least 450 million years ago by duplication of an ancient corticoid receptor (CR) gene.

The researchers analyzed the known sequences of the genes for the MR and GR of many vertebrate species, including the most ancient vertebrates, to deduce the theoretical sequence of an ancestral CR. They then synthesized this CR and tested its ability to bind aldosterone and cortisol. They discovered that the CR was capable of binding both hormones, particularly aldosterone. This was surprising, because aldosterone is only present in tetrapods, which arose long after the proposed gene duplication event that created the MR. Therefore, it appears that a receptor with high affinity for aldosterone was present long before animals acquired the capacity to synthesize aldosterone. The receptor seems to have evolved to bind other steroids. Around 450 million years ago, the gene for the CR duplicated, and then the two resulting genes seem to have evolved such that one receptor gained high affinity primarily for mineralocorticoids and the other for glucocorticoids.

These studies suggest that the ability of an animal to respond to aldosterone evolved long before aldosterone did, because a receptor with high affinity was already in place in animals. When aldosterone evolved in tetrapods, it was able to use the MR derivative of the ancestral CR. In this example, therefore, the answer to "which came first" appears to be that the receptor evolved first and the hormone later.

Hormone Levels in Blood Depend on Rates of Synthesis and Removal

When hormones are produced by endocrine cells, they are released into the interstitial space between the cell and adjacent blood vessels. The hormones then diffuse into the blood vessel. Although most hormones circulate in the blood at all times, their concentrations can increase or decrease dramatically when necessary. This can be accomplished in two major ways: by changing the rate of hormone production and release by an endocrine cell and by changing the rates at which hormones are removed from the blood or inactivated.

How hormones are synthesized and the rate of that synthesis differ for each of the three classes, amine, protein/peptide, and steroid. Synthesis of amine hormones is mediated by enzymatic conversion of either tyrosine or tryptophan into their respective hormones. These reactions require several enzymes that add or remove chemical side groups and achieve the final product (Figure 50.2). The synthesis of the hormone depends on the amounts and activities of the synthesizing enzymes. These enzymes are always present in the cell, but they can be greatly stimulated when additional hormone is required.

The protein and peptide hormones are synthesized at a steady rate in an unstimulated cell, until additional hormone is required. In that case, transcription factors within the cell direct the increased transcription of the gene coding for the hormone in question. Conversely, when less hormone is required, gene transcription is slowed or stopped. These hormones are too large and hydrophilic to diffuse across the plasma membrane and then into the extracellular fluid. Instead, they are packaged into secretory vesicles much the same way as neurotransmitters are packaged in neuron terminals. This packaging provides a ready means of secreting the hormones by exocytosis and a reservoir of stored hormone available for immediate release when required. When a cell is stimulated to secrete its stored protein or peptide hormones, it also is typically stimulated to synthesize new hormone molecules to replace them.

As noted earlier, the steroid hormones are derived from cholesterol, as depicted in Figure 50.3. To form steroid hormones, a cell must express enzymes capable of adding hydroxyl groups to specific carbons in the cholesterol skeleton. Other enzymes carry out reduction reactions, and still others can both

hydroxylate a carbon and split carbon-carbon bonds. The activities and amounts of many of these enzymes change if more or less hormone is required. Steroid hormones, unlike water-soluble hormones, are not packaged into secretory vesicles because the steroid can diffuse out across the lipid membrane of the vesicle. Instead, steroid hormones are made on demand, and no significant storage exists for them.

Although hormones carry out vital functions, excessive stimulation of cells by hormones may produce detrimental effects. For example, hormones that are activated if an animal loses blood typically help restore blood volume and pressure. This cannot continue indefinitely, however, because once blood volume and pressure are restored, it would be harmful if they continued to increase until their levels were above normal. Therefore, once a hormone enters the blood and performs its functions, it is usually prevented from exerting its effects indefinitely. This is accomplished in one or more ways:

- Hormones that bind to plasma membrane receptors may be engulfed by endocytosis into a cell, where lysosomal enzymes degrade the hormones.
- Small, water-soluble hormones are excreted in the urine.
- The liver chemically modifies many hormones to render them inactive and more easily excretable via the kidneys.
- Negative feedback processes (see Chapter 40) turn off the signals that were responsible for stimulating the synthesis and secretion of the hormone.

Generally, these processes ensure that hormone levels in the blood remain within a normal range under most circumstances,

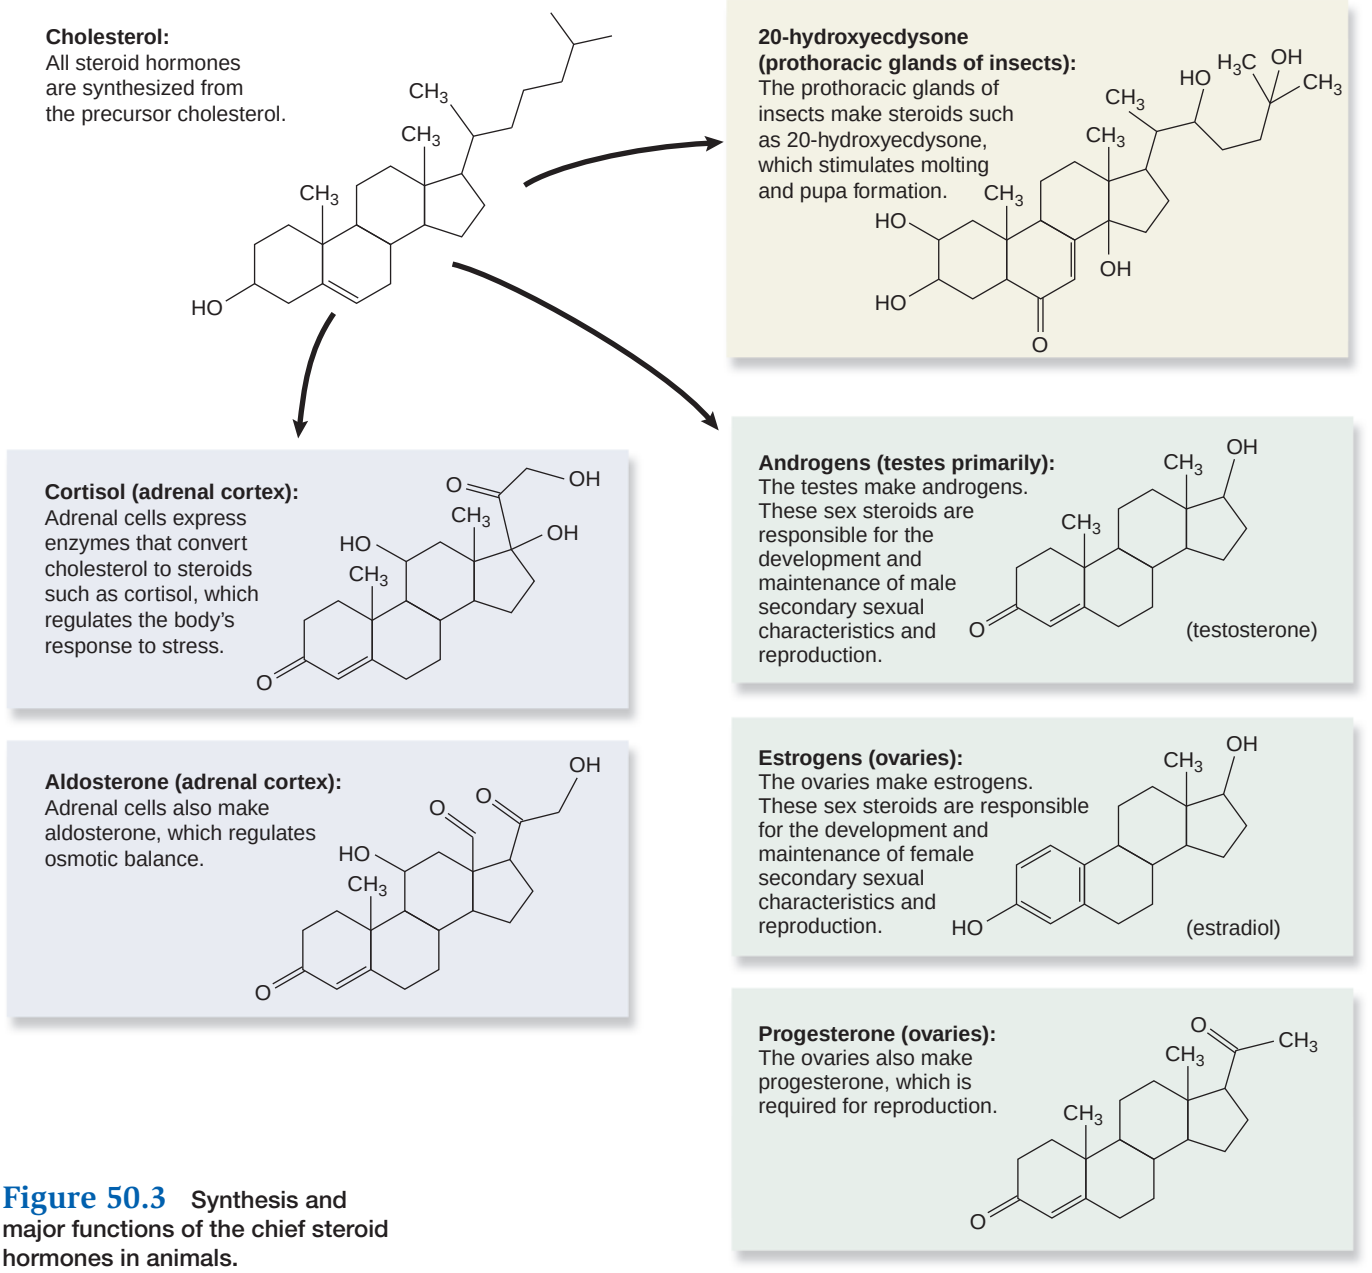

Figure 50.3 Synthesis and major functions of the chief steroid hormones in animals.

but have the capacity to be increased or decreased beyond that range if required. One of the ways in which changes in hormone levels are initiated is through sensory input to an animal's brain. As we see next, the nervous system and endocrine system are functionally linked in many animals, including all vertebrates.

50.2 Links Between the Endocrine and Nervous Systems

A key feature of the endocrine system in most animals is that the concentrations of many hormones in the extracellular fluid rise and fall with changes in an animal's environment. For this to happen, the endocrine system must somehow be informed of environmental changes. This often occurs when sensory input is received by an animal's nervous system, which, in turn, modulates the activity of one or more endocrine glands.

Sensory stimuli detected by the nervous system can activate the endocrine system. For example, when an antelope detects the presence of a nearby lioness, visual and olfactory sense information is relayed to the antelope's brain. The brain initiates responses in certain endocrine glands that release hormones to prepare the antelope for the possibility of an attack. As another example, the levels of certain hormones fluctuate in the blood of certain fishes as they migrate back and forth between feeding grounds in the sea and freshwater spawning sites. These hormones are activated by different salinities in the environment, which are detected by sensory cells of the fish's nervous system. The hormones act to prepare the gills of the fish to handle the large changes in salinity of the water.

The common feature of these examples and many others is that a sensory cue, such as a predator or the salinity of water, must be perceived by a sensory receptor and converted into an endocrine response. Electrical signals are transmitted from the sensory receptors to different parts of the brain, including the hypothalamus. In this section, we explore how the hypothalamus and pituitary gland play the major roles in linking the nervous and endocrine systems.

The Hypothalamus and Pituitary Gland Are Physically Connected

The **hypothalamus** is a collection of several nuclei that are located at the bottom surface of the vertebrate brain (Figure 50.4a). Neurons in these nuclei are connected to an endocrine gland sitting directly below the hypothalamus, called the **pituitary gland** (see the bottom part of the highlighted structure in the chapter-opening photo). The pituitary gland in humans is made up of two lobes, the anterior and posterior lobes. Some vertebrate species have an intermediate lobe that is believed to be vestigial in primates. The hypothalamus and pituitary are connected by a thin piece of tissue called the **infundibular stalk**. These two structures are also connected by a system of blood vessels called portal veins.

Portal veins differ from ordinary veins because not only do they collect blood from capillaries—like all veins do—but they then also form another set of capillaries, as opposed to returning the blood directly to the heart like other veins. The portal veins extend through the length of the infundibular stalk before forming new capillaries. Within the anterior lobe of the pituitary gland—often simply called the anterior pituitary gland—the portal veins empty into a second set of capillaries. This arrangement of blood vessels bypasses the general circulation and allows the hypothalamus to communicate directly with the anterior pituitary gland. Let's now explore the nature of this communication.

The Hypothalamus and Anterior Pituitary Gland Have Integrated Functions

As described in Chapter 42, the hypothalamic nuclei are vital for such diverse functions as reproduction, bodily rhythms, appetite, metabolism, and responses to stress. The hypothalamus has such wide-ranging effects in part because it acts as a master control, signaling the pituitary gland when to produce and secrete its many hormones. However, the hypothalamus communicates differently with the anterior and posterior pituitary glands. Let's look at the interaction between the hypothalamus and anterior pituitary first.

Within the different nuclei of the hypothalamus are neurons that synthesize a class of hormones called neurohormones. A **neurohormone** is any hormone that is made in and secreted by neurons. All neurohormones are either amines or peptides. Although they are produced within neurons, these molecular signals are not referred to as neurotransmitters, because the endings of the neurons do not terminate in a synapse with another cell. Instead, the neuron terminals from the hypothalamus end near capillaries. Here, the neurons secrete their neurohormones into the capillaries, which, in turn, collect into the portal veins. This allows neurohormones to be delivered directly from the hypothalamus to the cells of the anterior pituitary gland in a quick, efficient manner (Figure 50.4b).

In response to the presence of these hypothalamic neurohormones, the anterior pituitary gland synthesizes several different hormones. Table 50.2 lists the six major anterior pituitary hormones that have well-defined functions in vertebrates and the neurohormones that regulate them. As shown in the table, five of the anterior pituitary gland hormones are activated by neurohormones, one is inhibited by dopamine, and one is under both stimulatory and inhibitory control by the hypothalamus. Recent research suggests the possibility for dual control of some of the other pituitary gland hormones, but this remains uncertain. The stimulatory actions of several of the hypothalamic neurohormones has historically led to them also being known as "hypothalamic-releasing hormones," because they cause the release, or secretion, of other hormones from the anterior pituitary. The six hormones of the anterior pituitary gland are secreted into the general blood circulation, where they act on other glands or structures.

Adrenocorticotropic hormone (ACTH) stimulates the cells of the adrenal cortex to synthesize and release cortisol or related steroid hormones. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) act on the ovaries or testes to

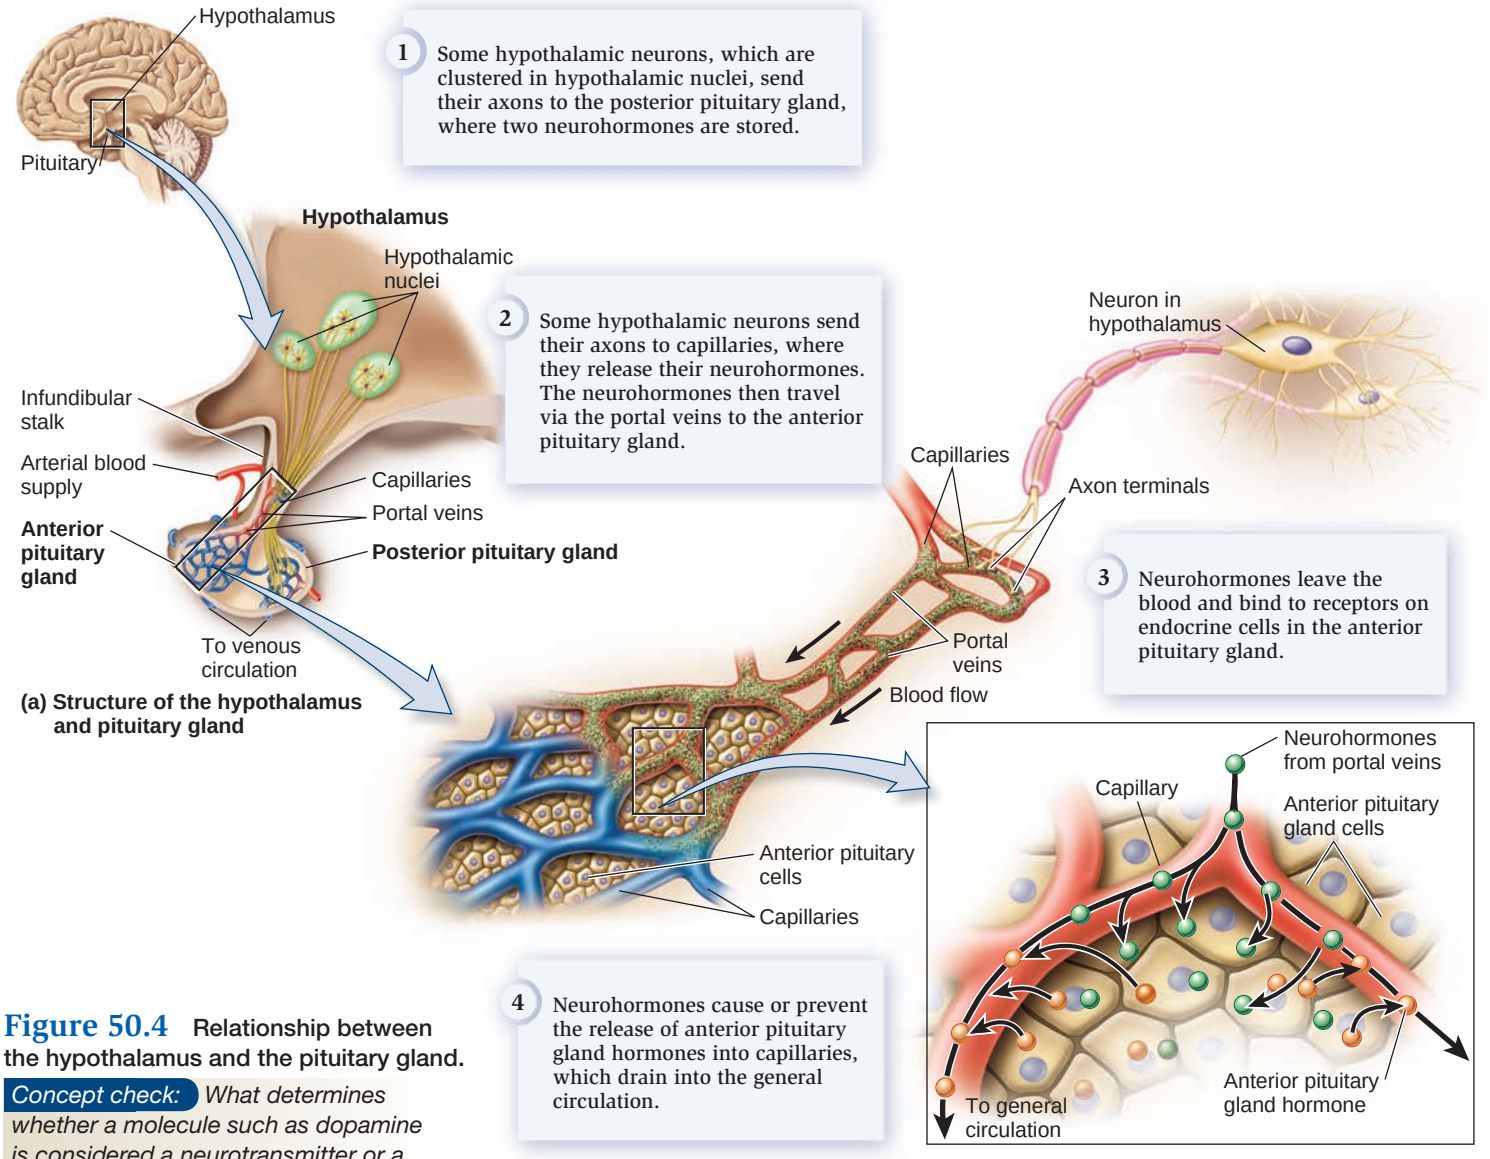

Figure 50.4 Relationship between the hypothalamus and the pituitary gland.

Concept check: What determines whether a molecule such as dopamine is considered a neurotransmitter or a hormone?

Table 50.2 Hormones of the Anterior Pituitary Gland and Hypothalamus

Anterior pituitary gland hormone	Stimulatory neurohormone from hypothalamus	Inhibitory neurohormone from hypothalamus	Major functions
Adrenocorticotropic hormone (ACTH)	Corticotropin-releasing hormone (CRH)	None known	Stimulates adrenal cortex to make glucocorticoids
Follicle-stimulating hormone (FSH)	Gonadotropin-releasing hormone (GnRH)	None known	Stimulates germ cell development and sex steroid production in gonads
Luteinizing hormone (LH)	Gonadotropin-releasing hormone (GnRH)	None known	Stimulates release of eggs in females; stimulates sex steroid production from gonads
Growth hormone (GH)	Growth hormone-releasing hormone (GHRH)	Somatostatin	Promotes linear growth; regulates glucose and fatty acid balance in blood
Prolactin (PRL)	TRH and other factors have been suggested as stimulators of PRL, but this is not unequivocal	Dopamine	Stimulates milk formation in mammals; participates in mineral balance in other vertebrates
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH)	None known	Stimulates thyroid gland to make thyroid hormones

stimulate egg or sperm development, as well as the synthesis and release of estrogens and androgens from these gonads. Growth hormone (GH) stimulates growth of immature animals and also participates in control of energy balance. The prolactin (PRL) level in the blood is increased in mammals during late pregnancy and during lactation. This hormone stimulates milk production in mammals but affects salt and water balance in other vertebrates. Finally, thyroid-stimulating hormone (TSH) acts on cells of the thyroid gland to stimulate growth of the gland and production of thyroid hormones.

Understanding the function of the hormones of the anterior pituitary gland is an ongoing and active area of research. Several other peptides from the anterior pituitary have been characterized and suggested to be hormones, but their functions have not yet been clearly defined in any vertebrate species. One example is β-endorphin, which is released into the blood during times of stress. Because it is related in structure to the opiate-type molecules such as morphine, it has been suggested that β-endorphin may act in some species as a painkiller during times of stress, but this is uncertain.

The Posterior Pituitary Gland Contains Axon Terminals from Hypothalamic Neurons That Store and Secrete Oxytocin and Antidiuretic Hormone

The posterior pituitary gland has a blood supply, but, in contrast to the anterior pituitary gland, it is not connected to the hypothalamus by portal veins and does not respond to neurohormones from the hypothalamus. Instead, the posterior pituitary gland is an extension from the hypothalamus that lies in close contact with the anterior pituitary gland (Figure 50.4). Axons from neurons extend from the hypothalamus into the posterior pituitary. In mammals, the axon terminals in the posterior pituitary store one of two hormones, oxytocin or antidiuretic hormone (ADH), which are produced by the cell bodies of those neurons. When the hypothalamus receives information that these hormones are required, they are released directly from the neuron axon terminals into the bloodstream.

Oxytocin concentrations increase in the blood of pregnant mammals just prior to birth. It stimulates contractions of the smooth muscles in the uterus, which facilitates the birth process. After the offspring are born, oxytocin becomes important in the let-down of milk. When the mother's nipples are stimulated by the suckling of a newborn (or the thought, sight, sound, or smell of a newborn), neurons transmit a signal from the breast to the mother's hypothalamus, which stimulates the cells that produce oxytocin. Oxytocin is released from the posterior pituitary gland into the blood where it travels to smooth muscle cells surrounding the milk glands and ducts of the breast. This stimulates the release of milk. Thus, oxytocin has two important and different functions, one during birth and one during lactation. In both cases, the hormone stimulates contraction of muscle cells.

Antidiuretic hormone (**ADH**) gets its name because it acts on kidney cells to decrease urine production—a process known as antidiuresis. Diuresis is an increased loss of water in the urine, as happens, for example, when you drink large amounts of fluids. If the fluid content of the body is low, such as during dehydration or after blood loss, ADH is secreted into the blood from the posterior pituitary gland. It acts to increase the number of water-channel proteins called aquaporins present in the membranes of kidney tubule cells; water is recaptured from the forming urine through these aquaporins (see Chapter 49). Minimizing the volume of water used to form urine is an adaptation that conserves body water when necessary.

At high concentrations, ADH also increases blood pressure by stimulating vasoconstriction of blood vessels. Like oxytocin, therefore, ADH has more than one function. Both of its major functions are related in that they contribute to maintaining blood pressure and fluid levels in the body. The two actions of ADH are mediated by different receptor isoforms, a feature that has proven to be of medical value in humans. Researchers have synthesized versions of ADH that have been chemically modified to activate ADH receptors in the kidney but not those in blood vessels. One such compound is sometimes used to treat **nocturnal enuresis** (bed wetting) in children by decreasing urine production without the unwanted side effect of increasing blood pressure.

Oxytocin and ADH are well-studied examples of the evolution of hormones. These two hormones are found only in mammals. However, many invertebrates and all nonmammalian vertebrates secrete one or more peptides that share chemical similarities with oxytocin and ADH but are not identical to the mammalian hormones. One of these is **vasotocin**, which combines some of the chemical structure of both oxytocin and ADH. Research indicates that an ancestral vasotocin gene duplicated at some point, and then the two genes evolved into the oxytocin and ADH genes found in mammals. Because only mammals lactate, the role of vasotocin must be different in birds, fishes, and other vertebrates than that of oxytocin in mammals. Research has shown that vasotocin is responsible for regulating salt and water balance in the blood of nonmammalian vertebrates.

The observation that members of the vasotocin/oxytocin/ADH gene family arose early in animal evolution also suggests that oxytocin and ADH may have additional, unrecognized actions that have been retained in mammals. For example, human males have oxytocin in their blood, but its role cannot be the same as in females because, of course, only females give birth and lactate. The key roles of oxytocin in male humans and other animals have not been unequivocally identified.

50.3 Hormonal Control of Metabolism and Energy Balance

An important function of the endocrine system is to control metabolic rate and energy balance. Hormones are partly responsible for regulating energy use by modulating appetite, digestion, absorption of nutrients, and the levels of energy sources like glucose in the blood and its transport into cells. Although many hormones are involved in these processes, those from the

thyroid gland, pancreas, adipose tissue, and the adrenal glands play particularly important roles, as described in this section.

Thyroid Hormones Contain Iodine and Regulate Metabolic Rate

The thyroid gland lies within the neck of vertebrates. In mammals, it straddles the trachea just below the larynx (Figure 50.5a). It consists of many small, spherical structures called follicles that consist of a shell of epithelial cells called follicular cells and a core of a gel-like substance called the **colloid**. The colloid consists primarily of large amounts of the protein **thyroglobulin** (**TG**), which plays a major role in the synthesis of thyroid hormones.

Thyroid hormones are produced when the hypothalamic neurohormone thyrotropin-releasing hormone (TRH; see Table 50.2) stimulates the anterior pituitary gland to secrete thyroid-stimulating hormone (TSH) into the blood. TSH stimulates the follicular cells of the thyroid gland to begin the process of making thyroid hormones. The thyroid hormones have a negative feedback effect on the hypothalamus and anterior pituitary, preventing them from producing too much TRH and TSH.

Figure 50.5b shows the pathway leading to thyroid hormone synthesis. First, iodide—converted by the gut from dietary iodine—diffuses from the bloodstream into the interstitial fluid, from where it is transported across the basolateral membrane of the thyroid follicular cells. The iodide then diffuses through the apical membrane and enters the colloid, where it is oxidized and bonds to tyrosine side chains in thyroglobulin. When the thyroid follicular cells are stimulated by TSH, the apical membranes undergo endocytosis (see Chapter 5), bringing colloid with its iodinated thyroglobulin into the cell. The endocytotic vesicles fuse with lysosomes; there, lysosomal enzymes cleave the iodinated tyrosines from thyroglobulin to form two thyroid hormones, called **thyroxine** and **triiodothyronine**. These molecules are unique among hormones in that they contain iodine molecules: four in the case of thyroxine, also called T_4, and three in triiodothyronine, or T_3. Both T_4 and T_3 then diffuse out of the follicular cells across the basolateral membrane into the bloodstream. These hormones are carried throughout the body and diffuse into cells. Inside cells, most T_4 is converted by enzymes that remove one iodine, forming T_3. It is T_3 that actually binds to cellular receptor proteins. T_4 can be considered, therefore, as a circulating precursor of the active hormone T_3.

A major action of thyroid hormones in adult animals is to stimulate energy consumption by many different cell types. This occurs in large part by increasing the number and activity of the Na^+/K^+-ATPase pumps in plasma membranes. As these pumps hydrolyze ATP, the cellular level of ATP decreases. This decrease is compensated for by increasing the cell's metabolism of glucose. Whenever metabolism is increased, heat production is increased. Consequently, a person with a hyperactive thyroid gland (**hyperthyroidism**; from the Greek *hyper*, meaning over or above) generally feels warm, whereas the opposite condition (**hypothyroidism**; from the Greek *hypo*, meaning under or below) results in a sensation of coldness. Scientists have estimated that up to 70% of the heat produced by some homeotherms is attributable solely to the actions of thyroid hormones on metabolic rate.

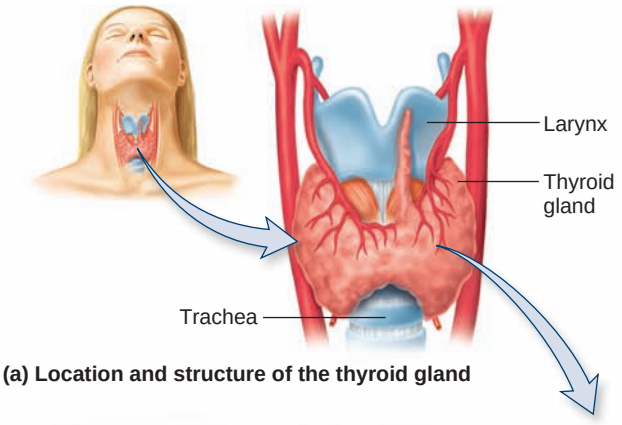
The observation that thyroid hormones cannot be made without iodine presents some interesting and unique features of these hormones. The availability of iodine in the diet of most animals is variable. As a consequence, the ability to store large amounts of thyroglobulin in the colloid of the thyroid was an important evolutionary adaptation. In this way, during times when iodine ingestion is high, many thyroglobulin molecules have their tyrosine amino acids bound to iodines, one of the first steps in forming T_4 and T_3. During times of low iodine availability, this reservoir of iodinated tyrosines in thyroglobulin molecules can be tapped. Humans, for example, have at least a 2-month supply of thyroid hormones even if dietary iodine were to become unavailable. In most industrialized countries, iodine deficiency is rarely a problem since the introduction of iodized salt in the mid-20th century. However, in some regions of the world, this is still a major health problem.

The left side of Figure 50.6a shows the pattern of T_4 and T_3 production from a normal thyroid gland when iodine ingestion is adequate. The right side of the figure shows the consequences when thyroid hormones are not produced in normal amounts, for example, due to a lack of iodine in the diet. In such a case, the decreased T_4 and T_3 levels provide less negative feedback on the hypothalamus and anterior pituitary gland, resulting in elevated TRH and, consequently, TSH levels. The thyroid gland responds to the increased TSH by increasing the cellular machinery needed to produce more and more thyroglobulin, even though in the absence of iodine, no additional T_4 or T_3 will be synthesized. What results is an overgrown gland that still lacks the resources to make thyroid hormone. This condition is known as an **iodine-deficient goiter** (Figure 50.6b). In humans, the problem can be alleviated either by adding iodine to the diet or by taking T_4 pills. Goiters are not unique to humans. Iodine deficiency is relatively common among vertebrates, and goiters are found frequently in reptiles and birds, particularly those that subsist on all-seed diets, which are generally low in iodine.

Hormones of the Pancreas and Adrenal Glands Regulate Fuel Levels in the Blood

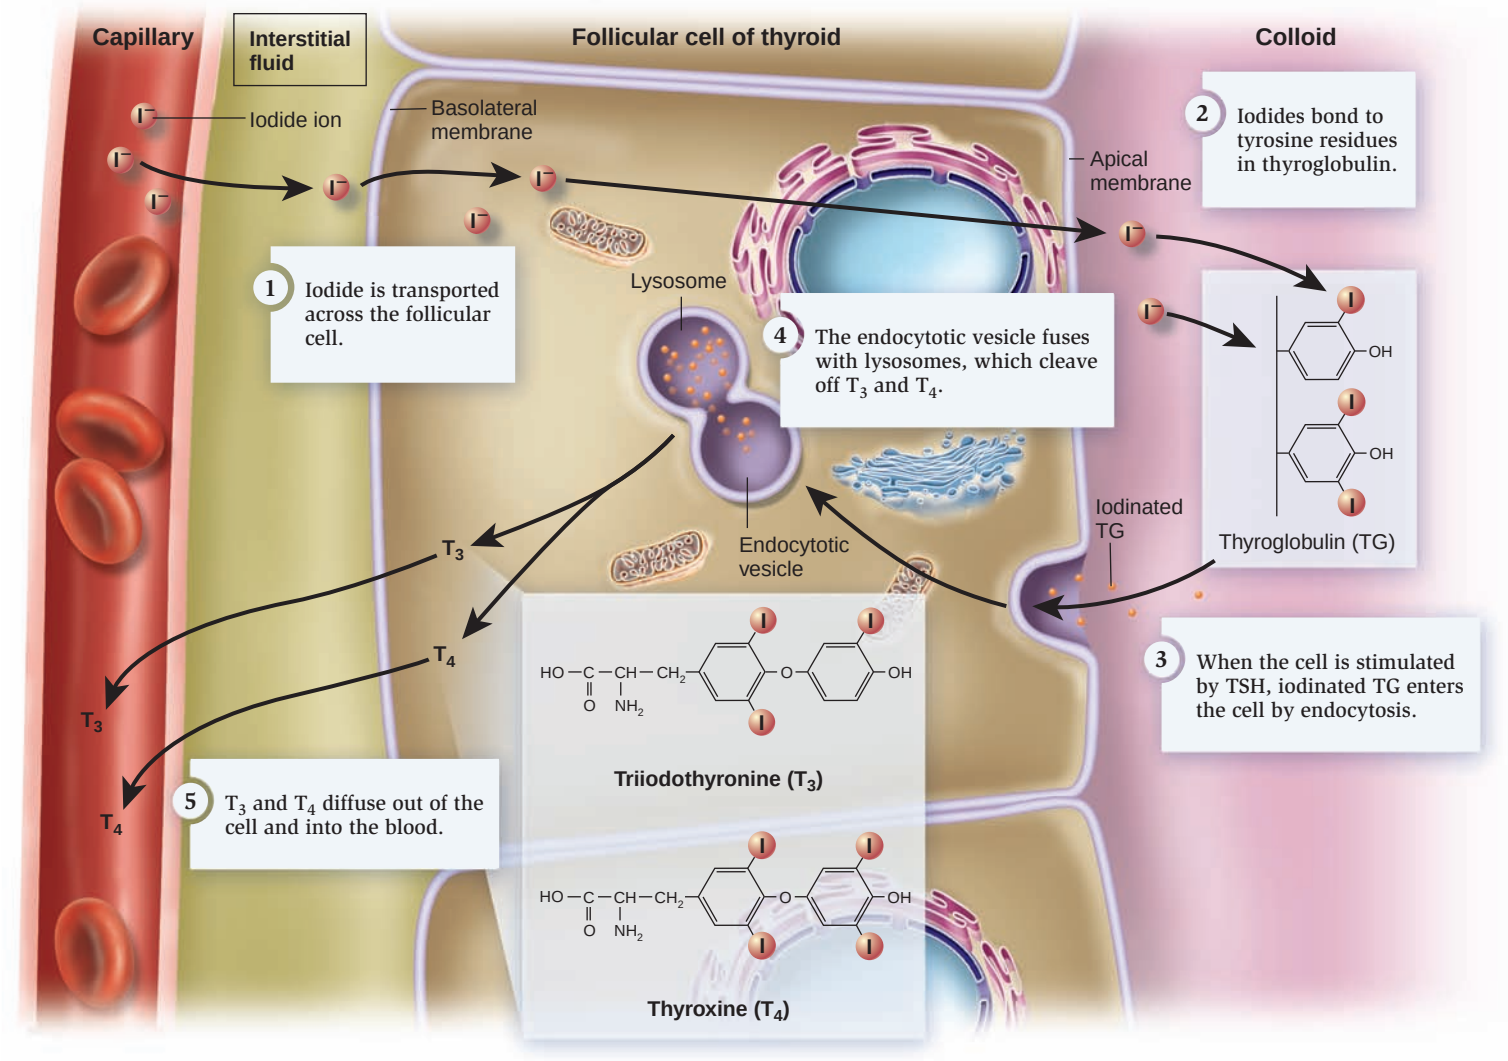
Thyroid hormones regulate an animal's metabolism. For metabolism to proceed normally, however, body cells must have adequate sources of energy available, usually in the form of glucose and fatty acids. The brain, in particular, must have a constant supply of glucose because brain cells have relatively limited storage capacity for fuel. Regulation of energy availability to cells is in large part the job of the hormones of the pancreas and the adrenal glands.

The pancreas is a complex organ consisting of two parts, exocrine and endocrine cells (Figure 50.7). Most of the mass of the pancreas comprises exocrine glands. An **exocrine gland** is one in which epithelial cells secrete chemicals into a duct, which carries those molecules directly to another structure or to the outside surface of the body. Examples of exocrine glands



(a) Location and structure of the thyroid gland

Figure 50.5 **The thyroid gland and synthesis of thyroid hormones.** **(a)** Location and structure of the gland in a human. Vertebrates contain thyroid tissue in the neck region, but it is not always consolidated into a single structure as shown here. **(b)** The steps involved in production of thyroid hormones. Shown is a cross section through a small part of a single follicle in a thyroid gland, with a nearby capillary (not to scale). The blood delivers iodide to the gland and picks up thyroid hormones secreted by the gland.



(b) Synthesis of thyroid hormones

include the sweat glands, salivary glands, liver, and pancreas. The secretions of the exocrine pancreas empty into the small intestine, where they aid digestion. The non-exocrine portion of the pancreas consists of endocrine cells that produce peptide hormones, notably insulin and glucagon.

Spherical clusters of endocrine cells called **islets of Langerhans** are scattered in great numbers throughout the pancreas. Within the islets are alpha cells, which make **glucagon**, and beta cells, which make **insulin**. The actions of these two hormones are antagonistic with respect to each other—insulin lowers and glucagon raises blood glucose concentrations.

Maintaining normal glucose and other nutrient levels in the blood is a vital process that keeps cells functioning optimally. When an animal has not fed for some time, its energy stores become depleted, and the blood glucose level falls. Under these conditions, glucagon is secreted into the blood, where it acts on the liver (Figure 50.8, right side). The liver contains a limited supply of glucose in the form of stored glycogen. Glucagon

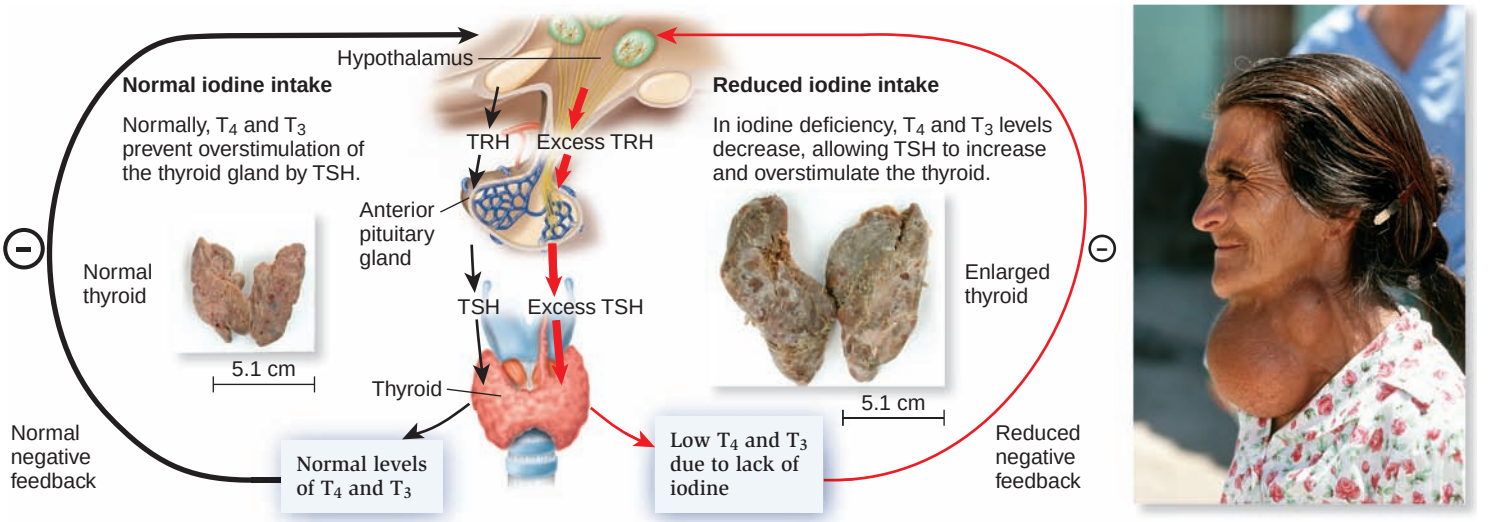


Figure 50.6 **Consequences of normal and inadequate iodine in the diet.** **(a)** With normal iodine intake, as shown on the left, T_4 and T_3 levels inhibit TSH secretion. Without enough iodine, as shown on the right, less T_4 and T_3 are synthesized, and the TSH level increases. This leads to the enlargement of the thyroid gland. **(b)** An extreme example of an enlarged thyroid gland, or goiter, due to iodine deficiency.

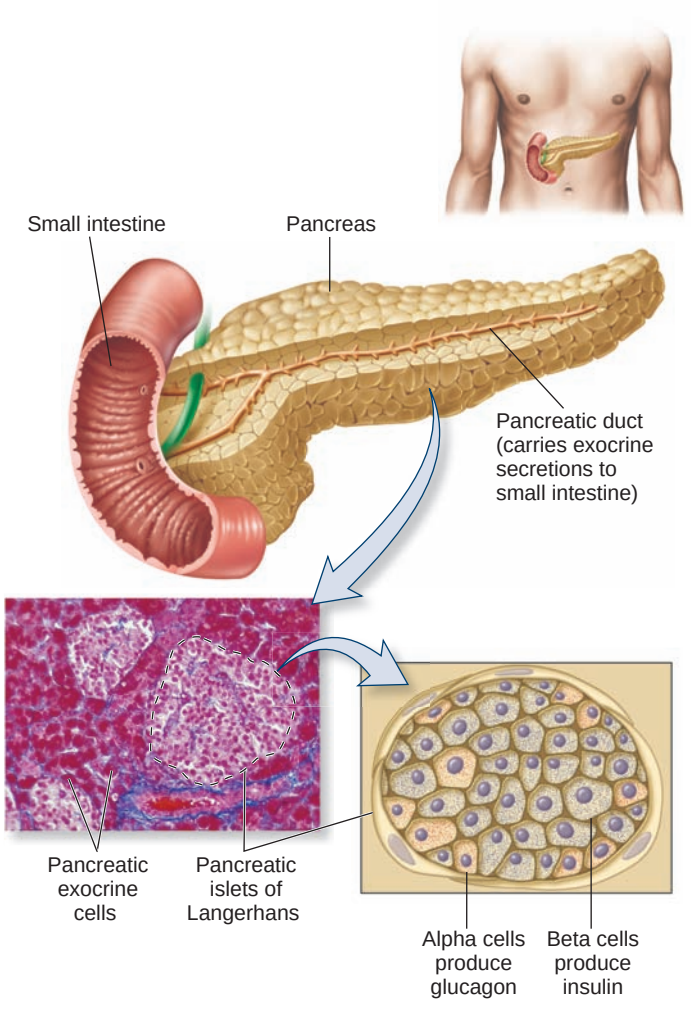

stimulates the breakdown of glycogen into many molecules of glucose, which are then secreted into the blood. This process, known as glycogenolysis (see Chapter 46), is stimulated within seconds by glucagon. A second action of glucagon on the liver is important for responses to prolonged fasting. In that case, glucagon stimulates the process of gluconeogenesis (see Chapter 46), by which noncarbohydrates are converted into glucose, which is then released into the blood.

The adrenal glands, which sit atop the kidneys, also play a role in glucose metabolism by producing amine and steroid hormones. When blood glucose levels are lower than normal, neurons from the sympathetic nervous system activate the secretion of epinephrine by the adrenal medulla. Like glucagon, epinephrine also stimulates glycogenolysis and gluconeogenesis. In addition, cortisol is released from the adrenal cortex. Once in the blood, cortisol also activates gluconeogenesis in the liver. These processes are vital to long-term survival in the absence of food. Because of the combined short-term and long-term actions of glucagon, epinephrine, and cortisol, the blood glucose level rarely falls or remains significantly below normal except in extreme circumstances.

In contrast to fasting, after an animal eats a meal, the levels of glucose and other nutrients in the blood become elevated.

Figure 50.7 **Location, appearance, and internal structure of the mammalian pancreas.** Amidst the exocrine pancreas are scattered islets of Langerhans, which are endocrine tissue. Only the exocrine products are secreted into the intestine; the hormones from the islets of Langerhans are secreted into the blood (not shown).

Concept check: *The pancreas contains both exocrine and endocrine tissue. Is this property ever observed in other organs?*

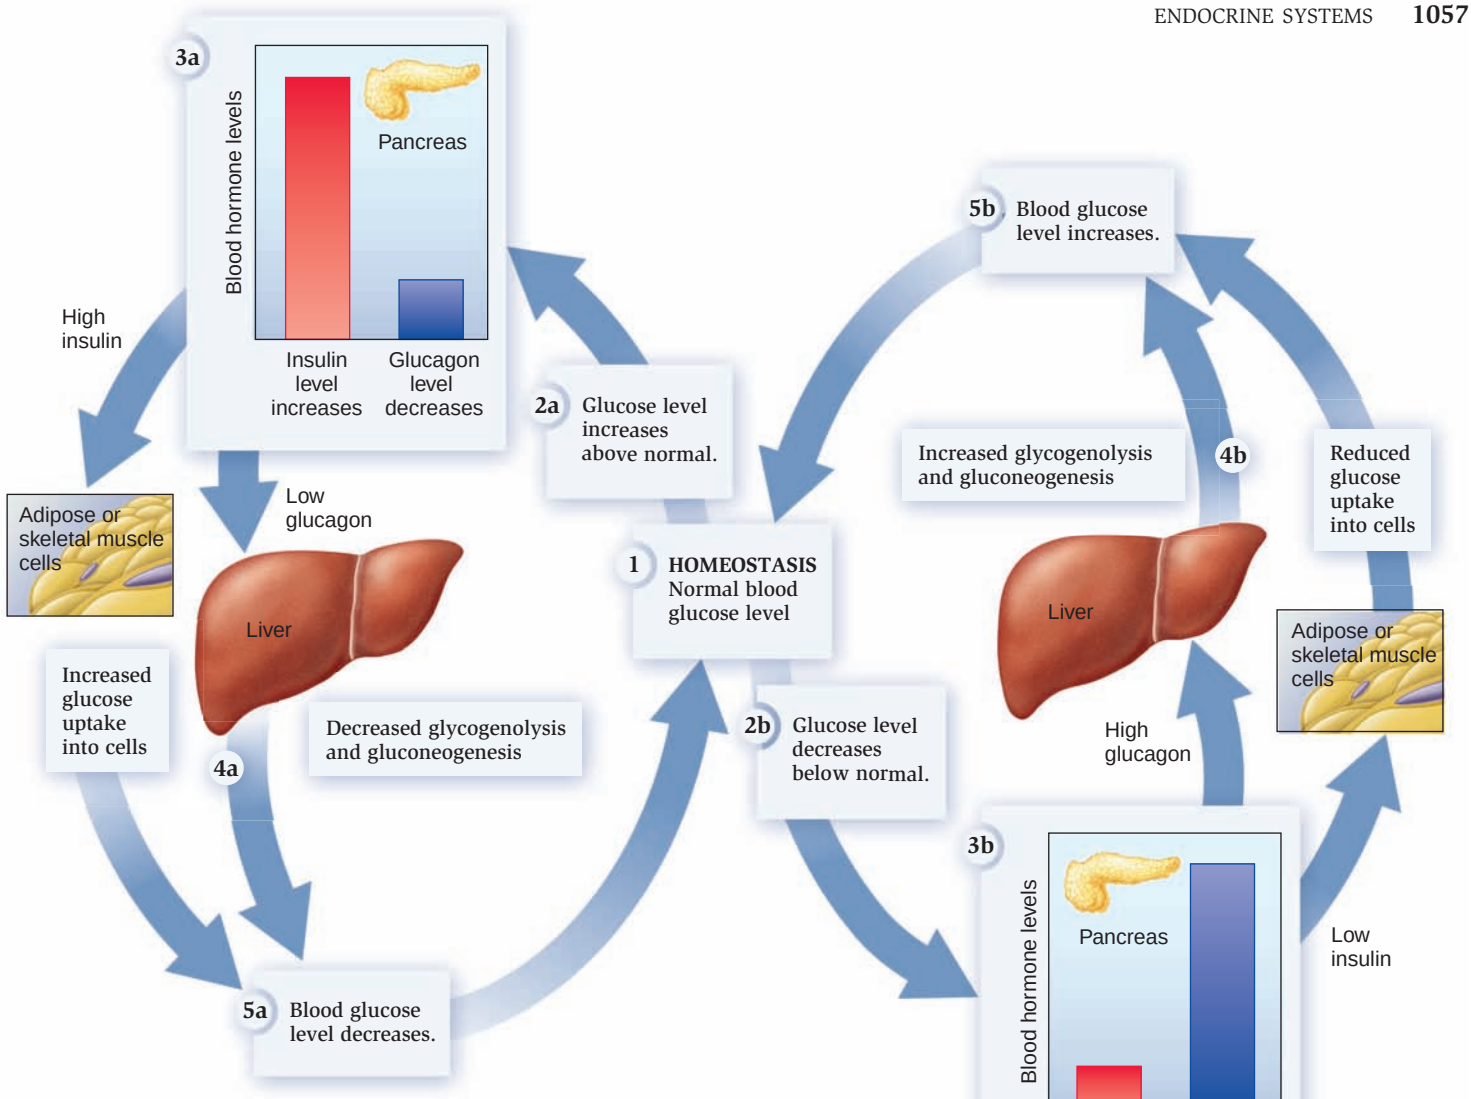

Figure 50.8 **Mechanisms that help maintain glucose homeostasis in the blood.** Glucagon and insulin respond in opposite ways to changes in plasma glucose concentrations. When the plasma glucose concentration decreases below normal (right), the insulin level decreases, and glucagon increases. When the plasma glucose concentration increases above normal (left), the insulin level increases, and glucagon decreases. Both of these mechanisms return the plasma glucose concentration to normal. In addition, through their action on the liver, hormones from the adrenal medulla and adrenal cortex play significant roles in elevating glucose levels (not shown).

Restoring the normal blood concentrations of glucose, fats, and amino acids is almost exclusively under the control of insulin, one of the few hormones that are absolutely essential for survival in animals. The secretion of insulin is directly stimulated by an increased concentration of glucose in the blood (Figure 50.8, left side). Once in the blood, insulin acts on plasma membrane receptors located primarily in cells of adipose and skeletal and cardiac muscle tissues to facilitate the transport of glucose across the plasma membrane into the cytosol. Once in the cell, glucose is used for cellular functions or converted to stored energy forms such as fat. As discussed in Chapter 46, the process of glucose transport involves the actions of proteins called glucose transporters (refer back to Figure 46.3). These proteins exist in cytosolic membrane vesicles. The major function of insulin is to stimulate movement of the vesicles with their glucose transporters to the plasma membrane. Once the vesicle fuses with the plasma membrane, the transporters begin transporting glucose from the extracellular fluid into the cell.

When the blood glucose level returns to normal, the stimulus for insulin secretion disappears, and the insulin level in the blood decreases. This results in a decrease in the number of glucose transporters in plasma membranes, because the glucose transporters are subjected to endocytosis and thereby return to membrane vesicles in the cytosol. The actions of insulin are not limited to glucose transport, however, because the hormone also stimulates transport of amino acids into cells and promotes fat deposition in adipose tissue. In other words, the broader role of insulin in the body is to facilitate the transfer of energy from the extracellular fluid into storage sites primarily in muscle and fat.

In the absence of sufficient insulin, as occurs in the disease **type 1 diabetes mellitus** (**T1DM**), less extracellular glucose can cross plasma membranes, and consequently, glucose accumulates to a very high concentration in the blood. T1DM occurs in many mammals and other vertebrates. It is caused when the body's immune system mistakenly attacks and destroys the insulin-producing cells of the islets of Langerhans. One consequence of the disease is that muscle and fat cells cannot receive their normal amount of glucose to provide the ATP they require. In addition, the unusually large amount of glucose in the blood overwhelms the kidneys' ability to reabsorb it from the kidney filtrate, and glucose appears in the urine. Fortunately, this form of the disease is treatable with regular monitoring of blood glucose level and daily administration of insulin.

In humans, the more common form of diabetes, which accounts for roughly 90–95% of all cases (estimates range between 15 and 20 million people in the U.S. alone), is **type 2 diabetes mellitus** (**T2DM**). In T2DM, the pancreas functions normally and is not attacked by the immune system. However, the cells of the body lose much of their ability to respond to insulin for reasons that are still unclear. T2DM is linked to obesity and can often be prevented or reversed with weight control. Drugs are also available that improve the ability of cells to respond to insulin. Formerly, T2DM was known as "adult-onset" diabetes, because it usually appeared in middle age. This name is no longer used, because the rising tide of childhood obesity in developed countries like the U.S. has sparked a dramatic increase in the number of young people with the disease.

The discovery of insulin and its application to the human condition was one of the greatest and most influential achievements in the history of medical research. Next, we describe how this occurred.

Feature Investigation

Banting, Best, MacLeod, and Collip Were the First to Isolate Active Insulin

In the 19th century, scientists discovered that in addition to the exocrine part of the pancreas, the organ contains spherical clusters of cells that are not associated with its exocrine digestive functions. These clusters were called islets by their discoverer, German physiologist Paul Langerhans. By the early 20th century, German scientists had discovered that in dogs, complete removal of the pancreas resulted immediately in T1DM. Researchers assumed, therefore, that cells of the islets of Langerhans produced a factor of some kind that prevented diabetes—in other words, it helped maintain glucose homeostasis by preventing the blood glucose level from getting too high. The factor, however, proved impossible to isolate using the chemical purification methods available at the time. Researchers assumed that during the process of grinding up a pancreas to produce an extract, the factor was destroyed by the digestive enzymes of the exocrine pancreas.

This problem was eventually solved in 1921 by a team of Canadian scientists working at the University of Toronto: surgeon Frederick Banting, medical student Charles Best, and biochemist James Bertram Collip. The work was performed in the laboratory of John MacLeod, a renowned expert in carbohydrate metabolism at the time. Banting had read a paper in a medical journal that described a deceased patient in whom the pancreatic duct, which carries digestive juices to the small intestine, had become clogged due to calcium deposits. The closed duct caused pressure to build up behind the blockage, which eventually caused the exocrine part of the pancreas to atrophy and die. The islets of Langerhans, however, survived intact. Banting hypothesized that if he were to tie off, or ligate, the pancreatic ducts of an animal, and then wait a sufficient time for the exocrine pancreas to die, he could more easily obtain an active glucose-lowering factor from the remaining islets without the problem of contamination by digestive enzymes.

Banting and Best proceeded to ligate the pancreatic ducts of several dogs as shown in Figure 50.9. After waiting 7 weeks, an amount of time they previously had determined was sufficient for the exocrine part of the pancreas to atrophy, they prepared extracts of the remaining parts of the pancreas, including its islets of Langerhans. This was done by removing the atrophied pancreas from each dog and grinding it up with a mortar and pestle in an acid solution. The extract was then injected into a second group of dogs in which diabetes had previously been induced by surgically removing the pancreas. The researchers discovered that the extract was capable of keeping the diabetic dogs alive for a brief time. However, they were unable to isolate sufficient quantities of the active factor in the extract to keep the experiments going longer than a day or so, nor were they able to obtain sufficiently pure factor to prevent side effects such as infection and fever.

This is where Collip's expertise came in. Collip developed a method to precipitate contaminating proteins from the extract by adding alcohol to the acid (step 3, Figure 50.9). Different proteins will precipitate from a solution in response to different concentrations of alcohol. Using a concentration too low to cause the active factor to precipitate, Collip was able to remove most of the contaminating proteins, leaving behind a much more purified and safe extract. The extract was then filtered to remove debris and further extracted to remove lipids. In this step, a hydrophobic solvent was added to the partially purified extract; the lipids in the extract dissolved in the solvent, which could then be decanted and removed. This was done because the researchers believed that the factor was either a peptide or a small protein and by removing lipids, they would obtain a more purified preparation. Finally, the purified extract was concentrated by evaporating the alcohol, which increased its potency. When increasing amounts of this purified factor were injected into diabetic dogs, their blood glucose levels decreased and even returned to normal, and there was no longer any glucose in their urine. Diabetic dogs that received only a control

solution that did not contain the factor continued to show a high glucose level in the blood and urine, compared to healthy controls.

In an ironic twist, scientists later recognized that the ligation procedure was not necessary to obtain the active factor. In fact, previous attempts to obtain the factor probably failed not because of enzymatic actions of the exocrine pancreas, but rather because the purification steps were too crude to yield a sufficient amount of purified compound. In later experiments, two subsequent innovations enabled the researchers to obtain larger amounts of the factor and more accurately assess its potency without using the ligation procedure. First, the researchers chose the very large pancreases of cows, obtained at a local slaughterhouse, for the starting material from which to prepare the extracts. Second, Collip developed a highly sensitive assay to more precisely measure the concentration of glucose in the blood of an animal before and after injection of the purified factor. The combination of the improved chemical purification steps, large amounts of starting material, and improved assays for testing the extract proved to be the keys that enabled the team to test the factor, which they eventually named insulin, on human patients. The first successful test came in 1922 on a 14-year-old boy in Toronto, who was seriously ill from T1DM. In 1982, recombinant human insulin first became available for widespread use.

The success of the team in rapidly isolating insulin and proving its effectiveness was so significant that Banting and MacLeod were awarded the Nobel Prize the following year, in 1923. The Nobel committee felt that Banting and MacLeod were the leaders of the project and that it was they who deserved

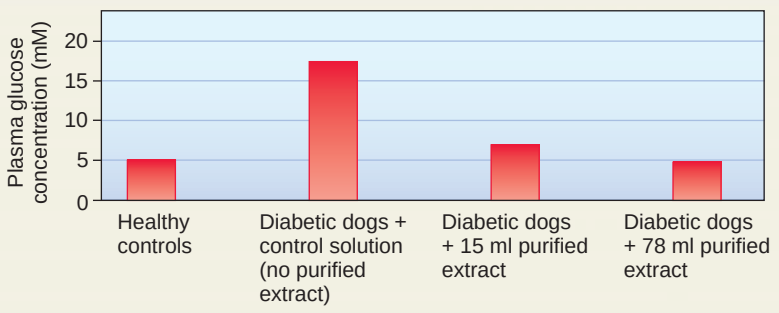
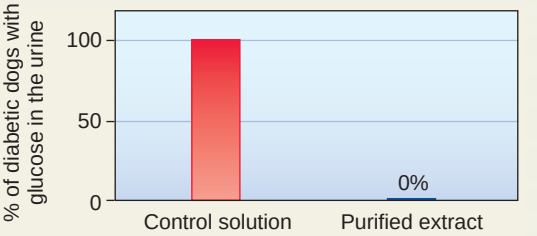
5 Inject either purified extract or control solution into the diabetic dogs. Determine the levels of glucose in the blood and in the urine.

6 **THE DATA**





7 **CONCLUSION** Atrophy of the exocrine portion of the pancreas eliminated digestive enzymes that would have degraded the glucose-lowering factor (insulin) during its purification from the pancreas. Along with improved chemical purification procedures, this atrophy step allowed researchers to obtain a highly purified and fully active glucose-lowering factor.

8 **SOURCE** Banting, F.G., and Best, C.H. 1922. The internal secretion of the pancreas. *Journal of Laboratory and Clinical Medicine* 7:256–271.

the prize, but the two scientists disagreed. Banting shared the monetary portion of his award with Best, and MacLeod shared his with Collip.

Experimental Questions

1. How did Banting and Best propose to obtain the glucose-lowering factor produced by the pancreas?
2. What was Collip's contribution to the isolation of insulin?
3. What subsequent innovations led to large-scale production of insulin for human patients?

Adipose Tissue Secretes the Hormone Leptin That Regulates Appetite

Hormones also contribute to metabolism by exerting effects on appetite and, as a consequence, on food consumption. As you might imagine from its importance as the body's major storage site for energy-yielding fat, a chief source of appetite-regulating hormones is adipose tissue. One such hormone introduced in Chapter 46 is the protein leptin, which has been observed in species from all vertebrate classes. Leptin is released by adipose cells into the blood in direct proportion to the amount of adipose tissue in the body, and it acts on the hypothalamus to inhibit appetite (refer back to Figure 46.9). When adipose stores are low, however, leptin secretion from adipose cells decreases, resulting in a reduced blood level of leptin. This removes the inhibitory effect of leptin on appetite, resulting in increased food consumption by the animal. In these ways, the amount of energy stored in an animal's body in the form of fat is communicated to the brain to regulate how hungry an animal feels.

We have seen that hormones influence energy homeostasis by regulating appetite, nutrient levels in the blood, transport of nutrients into cells, and metabolic rate. In the next section, we consider how hormones control another feature of homeostasis, that of regulating concentrations of key minerals in the blood.

50.4 Hormonal Control of Mineral Balance

All animals must maintain a proper balance in their cells and fluids of minerals such as Ca^{2+}, Na^{+}, and K^{+}. These ions participate in numerous functions common throughout much of the animal kingdom. For example, the partitioning of ions across plasma membranes determines in large part the electrical

properties of cells like neurons. In this section, we will see how maintaining a homeostatic balance of these ions in an animal's body is coordinated in large part by hormones.

Vitamin D and Parathyroid Hormone Regulate the Calcium Ion Level in Blood

Calcium ions play critical roles in neuronal transmission, heart function, muscle contraction, and numerous other events. Therefore, the concentration of Ca^{2+} in the blood is among the most tightly regulated variables in an animal's body.

Calcium is obtained from the diet and absorbed through the small intestine. Like all charged molecules, Ca^{2+} cannot readily cross plasma membranes, including those of the epithelial cells of the small intestine, and thus its transport must be facilitated. This process is controlled by the action of a derivative of **vitamin D**. In most mammals that receive regular exposure to the sun, skin cells produce vitamin D from a precursor called 7-dehydrocholesterol, a reaction that requires the energy of ultraviolet light (Figure 50.10). In addition, many animals obtain vitamin D from food or, in people today, from milk supplemented with the vitamin. This is especially important for people who live at latitudes that receive little sunlight for much or part of the year.

Before it can act, vitamin D must first be modified by two enzymes that both add one hydroxyl group to specific carbon atoms, first in the liver and then in the kidney. The final active product is called 1,25-dihydroxyvitamin D. This molecule is a hormone because it is secreted into the extracellular fluid by one organ—the kidneys—and then circulates in the blood and acts on a distant target tissue—the small intestine. The major function of 1,25-dihydroxyvitamin D in the intestine is to activate a Ca^{2+} transporter in the intestinal epithelium, thereby stimulating the absorption of Ca^{2+}. The calcium ions then enter the blood, from where they are delivered to tissues for such activities as building bone and maintaining nerve, muscle, and heart functions. If the active form of vitamin D is not present in the blood, the bones lose calcium and become weakened. In children, this results in the weight-bearing bones of the legs becoming deformed, a condition called rickets.

Even when calcium is not present in the diet, or when 1,25-dihydroxyvitamin D is not formed in normal amounts because of insufficient exposure to sunlight, the blood level of Ca^{2+} does not normally decrease dramatically, because of a hormone called **parathyroid hormone** (**PTH**). This hormone is secreted from several small glands called parathyroid glands, which in humans are attached to the back of the thyroid gland (Figure 50.11a). PTH acts on bone to stimulate the activity of cells that dissolve the mineral part of bone. This releases Ca^{2+}, which then enters the blood (Figure 50.11b). Typically, only a very small fraction of the total Ca^{2+} in bone is removed in this way. Therefore, besides providing a skeletal framework for the vertebrate body, bone also serves as an important reservoir of Ca^{2+}. PTH also acts to increase reabsorption of Ca^{2+} in the kidneys, such that less Ca^{2+} is excreted in the urine. Without PTH, calcium homeostasis is not possible. The total absence of PTH is fatal in humans and other mammals.

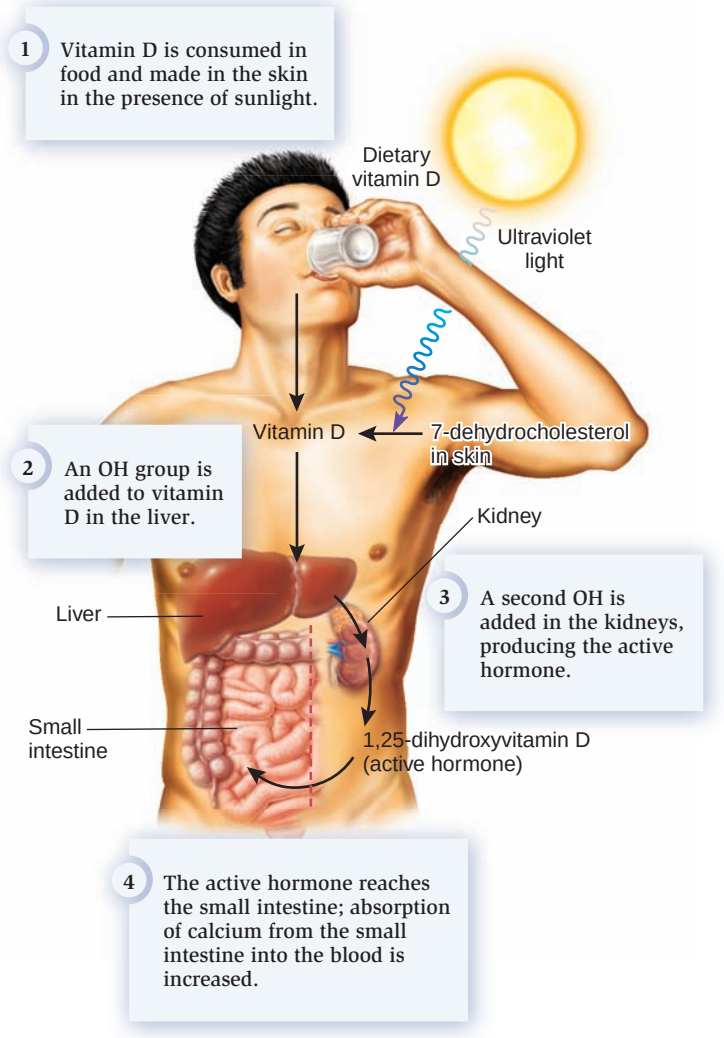


Figure 50.10 **Synthesis of the active hormone formed from vitamin D or its precursor in the skin.**

Concept check: *Would you predict that all mammals synthesize the active form of vitamin D using the energy of sunlight?*

In addition to 1,25-dihydroxyvitamin D and PTH, another hormone called **calcitonin** plays a role in Ca^{2+} homeostasis in some vertebrates, notably fishes and possibly some mammals, including young children (but not adult humans). Calcitonin is produced in and secreted from cells in the thyroid gland. Its function is the opposite in many respects to that of PTH. Calcitonin promotes excretion of Ca^{2+} via the kidneys and deposition of Ca^{2+} into bone, thereby lowering blood Ca^{2+} levels. This is especially important in marine fishes, because of the high Ca^{2+} content of seawater and the entry of this ion into the body fluids of the animals.

Several Hormones Regulate Sodium and Potassium Ions in Vertebrates

Like calcium, concentrations of sodium and potassium ions in the body fluids of most animals are tightly regulated, because

Concept check: *Why is there more than one hormone that regulates sodium and potassium balance?*

these ions play crucial roles in membrane potential formation and action potential generation (see Chapter 41), among other functions. Like calcium, sodium and potassium are ingested in the diet and excreted in the urine in vertebrates. Unlike calcium, however, no large reservoirs exist in the body for sodium and potassium. One of the key mechanisms that regulates the concentrations of these ions in the blood is altering the rate of sodium, potassium, and water reabsorption from the urine as it is being formed in the kidneys. This is accomplished in large part by the actions of three hormones: ADH, aldosterone, and atrial natriuretic peptide (Figure 50.12). All three of these hormones exert their effects on the kidneys.

The vertebrate kidney normally reabsorbs most sodium and potassium from the fluid filtered through the kidney glomerulus (see Chapter 49). However, dietary and other changes can alter the concentrations of these ions in the blood. When this happens, the kidney works to restore the ions to their normal concentrations. For example, if the blood sodium

level increases above normal, the osmolarity of the blood will increase. Osmoreceptors in the brain detect this and stimulate ADH secretion from the posterior pituitary gland. Recall from Chapter 49 that ADH acts on the kidney to reabsorb water from the forming urine. By increasing the amount of ADH available to act on the kidneys, less water is excreted in the urine. In addition, the synthesis and secretion of the adrenal steroid hormone aldosterone is directly inhibited in response to an increase in Na^+ concentration. Normally, aldosterone increases sodium reabsorption in the kidney, and therefore, its absence results in more sodium excretion in the urine. Finally, **atrial natriuretic peptide** (**ANP**) is secreted from the atria of the heart whenever the blood level of sodium increases. ANP causes a natriuresis (a loss of sodium in the urine; from the Latin *natrium*, meaning sodium) by decreasing sodium reabsorption. Thus, ANP and aldosterone have opposite effects on sodium balance in the body, which is why their concentrations in the blood tend to rise and fall in opposite directions. The combined effect of decreasing water loss in the urine and reabsorbing less sodium is to decrease the concentration of sodium in blood and other body fluids, returning its concentration to normal.

50.5 Hormonal Control of Growth and Differentiation

Hormones play a nearly universal role in controlling growth and differentiation in animals. Growth can occur slowly over long periods or in brief spurts, with some animals exhibiting both types of growth. Many mammals, for example, grow slowly but steadily until puberty, then experience a period of rapid growth, followed by slower rates of growth, and finally cessation of growth. Many insects, however, grow and develop in spurts during molting periods. Although growth is determined by many factors, notably adequate nutrition, it is regulated in large part by the endocrine system.

Growth is distinguished from differentiation, which is the process by which cells form tissues with specific functions, and tissues develop into larger and more complex structures. In this section, we will examine how both processes depend in part on the endocrine system.

Vertebrates Require a Balance of Several Hormones for Normal Growth

Several hormones stimulate growth in vertebrates. The anterior pituitary gland produces **growth hormone** (**GH**), which is under the control of the hypothalamus (see Table 50.2). GH acts on the liver to produce another hormone, called **insulin-like growth factor-1** (**IGF-1**). In mammals, IGF-1 stimulates the elongation of bones, especially during puberty, when mammals become reproductively mature. This growth is further accelerated by the steroid hormones of the gonads, leading to the rapid pubertal growth spurt. Eventually, however, the gonadal hormones cause the growth regions of bone to seal, preventing any further bone elongation.

GH, IGF-1, and gonadal steroid hormones continue to be produced in adult vertebrates—including humans—even though growth has ceased. In adulthood, GH serves metabolic functions, such as helping to regulate the levels of glucose and fatty acids in the blood. The gonadal steroids are important for reproduction in adults (see Chapter 51).

In rare cases, a tumor of the GH-secreting cells of the anterior pituitary gland produces excess GH. If this occurs during childhood, a person with this disorder can grow very tall and is known as a **pituitary giant**. Soon after puberty, growth stops. If a tumor causes a high GH level after puberty, the excess GH causes many bones, such as those of the hands and feet, to thicken and enlarge, a condition known as **acromegaly** (Figure 50.13). People with acromegaly are generally treated with a synthetic form of somatostatin, which as you may recall from Table 50.2 is the inhibitor of GH made by the hypothalamus. In many cases, however, the tumor must be surgically removed.

By contrast, if the pituitary fails to make adequate amounts of GH during childhood, the concentrations of GH and IGF-1 in the blood will be lower than normal. In such cases, growth is stunted, resulting in **short stature** (formerly called **pituitary dwarfism**). Individuals with this condition can be treated with injections of recombinant human GH and will grow to relatively normal height, as long as treatment begins before puberty ends so that the bones may still elongate.

Hormones are also required during fetal life, not for growth but for development of the brain, lungs, and other organs into fully mature, functional structures. For example, cortisol from the fetal adrenal gland is vital for proper lung formation. Premature babies born before the adrenal glands have matured have lungs that are not capable of expanding normally; therefore such babies require hospitalization to survive.

As another example, thyroid hormones impact differentiation among all vertebrates. In amphibians, thyroid hormones play a critical role in metamorphosis, notably in tadpoles, where they promote the resorption of the tail and development of the legs (Figure 50.14). This effect can be dramatically demonstrated by experimentally decreasing or increasing the tadpole's thyroid hormone level, which results respectively in a tadpole that does not transform into a frog or in a tadpole in which metamorphosis occurs sooner than normal resulting in a tiny frog. In fishes, thyroid hormones play an equally critical role in differentiation. For example, among species of flatfish such as flounder that live on the ocean floor, thyroid hormones are responsible for the characteristic change in appearance that occurs in these species as they settle into a sedentary existence on the ocean bottom. The fins and gill covers migrate to the dorsal surface facing the water; the dorsal body surface becomes pigmented; and most remarkably, the eyes migrate to the same side of the head such that one eye is not unused on the side facing the ocean floor. Each of these metamorphic events is under the direct control of thyroid hormones.

Invertebrates Grow and Develop in Spurts Under the Control of Three Major Hormones

Like vertebrate endocrine pathways, hormonal control systems in insects and other invertebrates often involve multiple glands and neural structures acting in concert. In insects, for example,

Figure 50.13 **Acromegaly in one individual from a pair of identical twins.** This disease is caused by a high level of growth hormone, which leads to the enlarged bones in the hands and feet.

Concept check: *Did the individual on the left develop a growth hormone disorder before or after puberty?*

the endocrine system is critical for the growth and development of larvae and their eventual differentiation into pupae (Figure 50.15). In the case of larval growth and metamorphosis, specialized neurosecretory cells periodically secrete a hormone called **prothoracicotropic hormone** (**PTTH**), which then stimulates a pair of endocrine glands called the prothoracic glands. These glands, located in the thorax, synthesize and secrete into the hemolymph a steroid hormone called **20-hydroxyecdysone** (not found in vertebrates). This hormone is secreted only periodically. In response to each burst of secretion, the larva undergoes a rapid differentiation and molts (sheds its cuticle) and begins a new developmental period until it molts again in response to another episode of secretion. The molting process is known as ecdysis, from which the name of the hormone is derived.

Throughout larval development, paired neurosecretory structures behind the brain, called the corpus allata, secrete

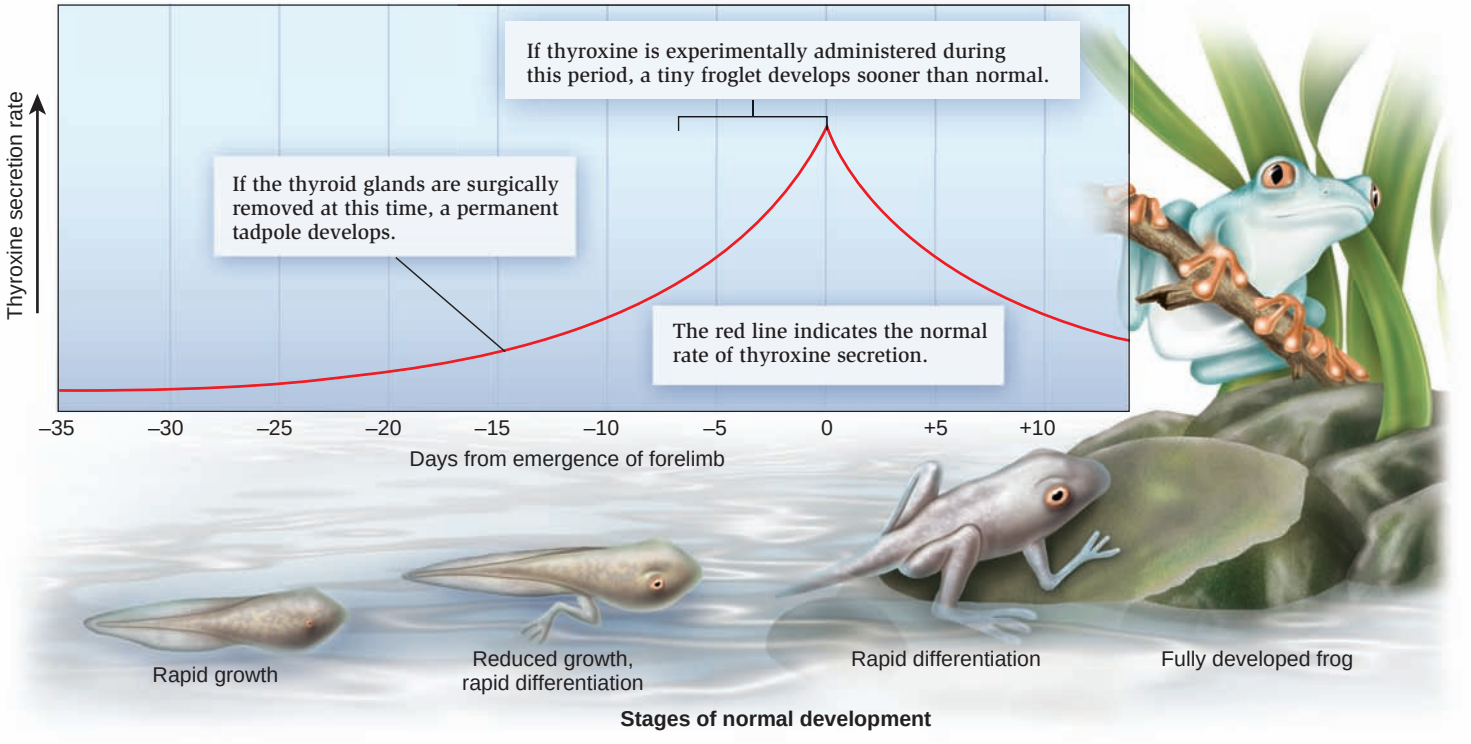

Figure 50.14 **The effect of thyroid hormones on tadpole development.** Experimental manipulation of thyroid hormone levels can retard or accelerate this development.

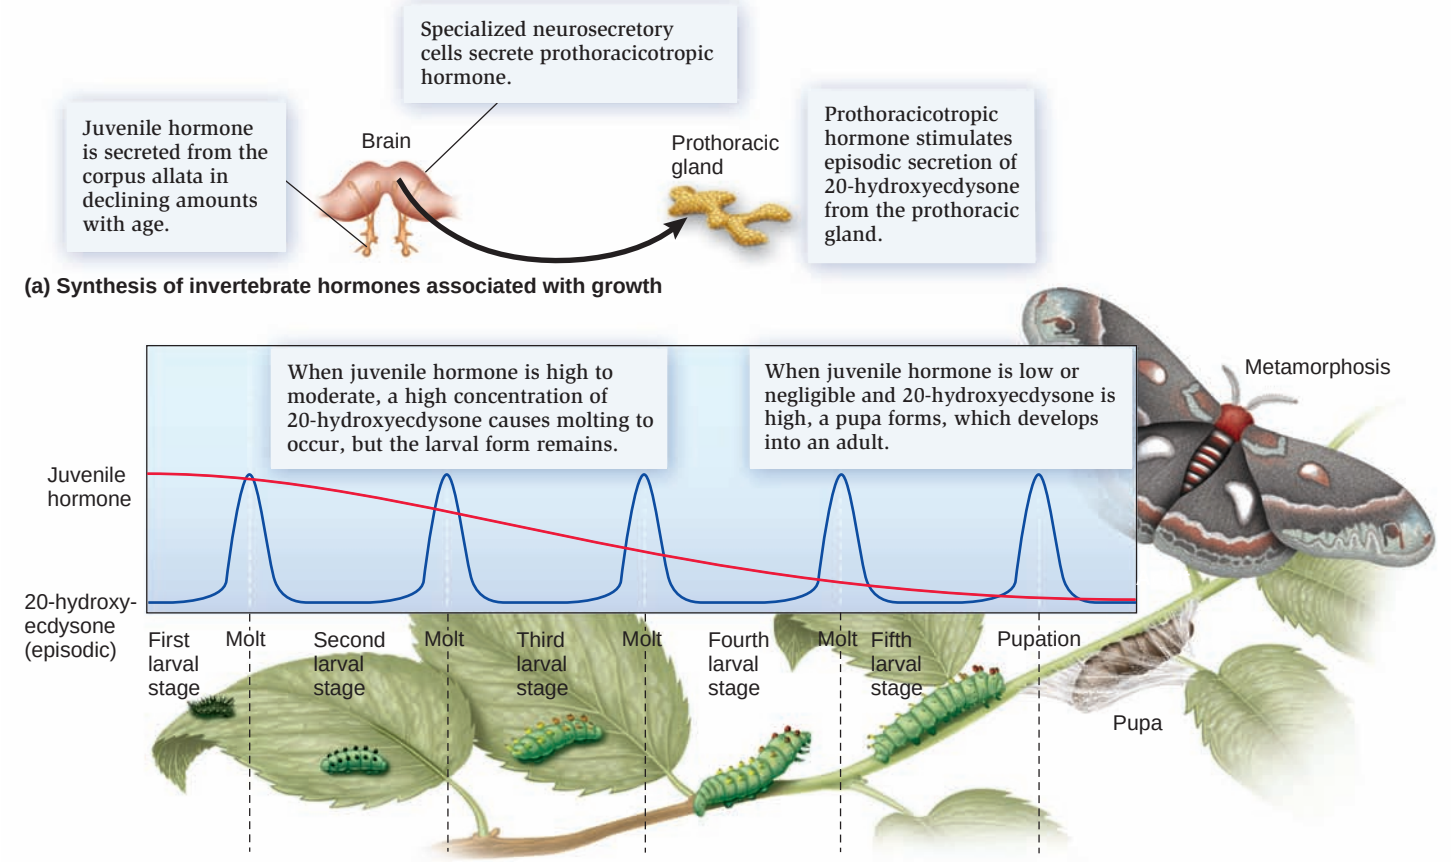

Figure 50.15 **Hormonal control of insect development.** Development of insects requires the coordinated actions of three hormones. Note: The relative levels and patterns of 20-hydroxyecdysone and juvenile hormone in this figure are schematic and not representative of all insects.

Concept check: *In what part of a cell do you predict the receptor for the steroid 20-hydroxyecdysone would be located?*

another hormone, a protein called **juvenile hormone** (**JH**). JH determines the character of the molt that is induced by 20-hydroxyecdysone, by acting to prevent metamorphosis into an adult (hence the name "juvenile," which reflects that fact that JH fosters the larval stage). As the larva ages, however, the amount of JH it produces gradually declines until its concentration is nearly zero. During this time, 20-hydroxyecdysone continues to be periodically secreted. The decline in JH below a certain concentration results in the transition from larva to pupa in response to a burst of 20-hydroxyecdysone; the near absence of JH is a prerequisite for the final step of metamorphosis into an adult.

50.6 Hormonal Control of Reproduction

The topic of reproduction is covered in Chapter 51, but it is worth noting here that in all vertebrates and probably most invertebrates, reproduction is closely linked with endocrine function. In this section, we explore the most common reproductive hormones and their actions in male and female animals.

The Gonads Secrete Sex Steroids That Influence Most Aspects of Reproduction

Hormones produced by the gonads of animals play vital roles in nearly all aspects of reproduction, from reproductive behaviors to the ability to produce offspring. In males, the gonads are called testes. They produce and house the gametes, called sperm cells. In addition, the testes produce several related steroid hormones collectively termed **androgens**. In many vertebrates, including humans, the primary androgen is **testosterone**. The gonads of females are called the ovaries, which contain the female gametes, or egg cells. Other cells within the ovaries secrete two major steroid hormones, **progesterone** and a family of related hormones called **estrogens**. The major estrogen in many animals, including humans, is **estradiol**. Collectively, the male and female gonadal steroid hormones are referred to as the sex steroids.

The sex steroids are responsible for male- or female-specific reproductive behaviors associated with courtship and mating. In vertebrates, androgens from the developing testes are required for development of the male phenotype. Exposure of fetuses to abnormal levels of male or female hormones can lead to ambiguous phenotypes and sexual behavior after birth. Sex steroids

are also chiefly responsible for development of secondary sex characteristics for each sex, which in humans include such things as growth of the appropriate external genitals, growth of the breasts in women, development of facial hair in men, and distribution and amount of fat and muscle in the body (see Chapter 51). Finally, sex steroids are required for maturation of gametes, the transition of young animals to reproductive maturity, and the ability of females to produce young.

The ability of the testes and ovaries to produce sex steroids depends on the presence of the gonadotropins secreted by the anterior pituitary, which are the same in both sexes and include **follicle-stimulating hormone** (**FSH**) and **luteinizing hormone** (**LH**) (see Table 50.2). Therefore, identical anterior pituitary gland hormones control the gonads in both male and female animals.

Nutrition and Reproduction Are Linked Through Hormones

An interesting feature of the endocrine control of reproduction is the long-noted observation that puberty is delayed in mammals, including humans, that are very undernourished. Similarly, fertility—the ability to produce offspring—is reduced in women and other adult female mammals under such conditions. This makes sense, because supporting the nutritional demands of a growing fetus would be difficult without good nutrition and energy stores. In such a case, it is more advantageous for an animal to delay reproduction until sufficient food is available.

How does the brain of a female mammal determine when sufficient energy is stored in her body to support pregnancy? The answer appears to be partly the result of hormonal signals. For example, if the amount of fat in a woman's body decreases, so does the concentration of leptin in her blood, as described earlier. Leptin has been demonstrated to stimulate synthesis and secretion of reproductive hormones such as FSH and LH. Consequently, undernourishment that causes a decrease in leptin results in reduced production of reproductive hormones, thereby contributing to a loss of fertility. Therefore, leptin acts as a link between adipose tissue and the reproductive system.

50.7 Hormonal Responses to Stress

Stress in animals is often defined as any real or perceived threat to survival. This can take many forms depending on the species. To a crab, a passing shadow may indicate a hungry shark passing overhead, but to a human, a shadow may simply mean that a cloud has passed in front of the sun. Similarly, a severe storm can be extremely stressful for birds in exposed nests, but not to animals that live in sheltered environments. Crowding is adaptive for penguins trying to keep warm on ice floes, but it is stressful to mice and rats.

In the 1920s, Canadian physiologist Hans Selye made the remarkable discovery that regardless of the nature of the stress in any given species, a mammal's adaptive responses to stress were highly similar. Later this was determined to be true because these responses depend on hormones from the adrenal glands. The adrenal glands, so named because they sit atop the kidneys (from the Latin *ad*, meaning toward, and *renis*, meaning kidney), are multifunctional glands containing an inner region called the adrenal medulla and an outer region called the adrenal cortex (Figure 50.16a). These two regions produce different hormones that affect the vertebrate response to stress. In this section, we will examine how these hormones function and how they act to prepare an animal to confront or escape a challenge—the fight-or-flight response.

The Inner Core of the Adrenal Glands Makes the Fight-or-Flight Hormone Epinephrine

The cells of the adrenal medulla secrete the amine hormones norepinephrine and epinephrine (Figure 50.16b). Together, these two hormones are responsible for most of the fight-or-flight reactions that were described earlier in Chapter 42 and are summarized here in Table 50.3. These include improved heart and lung function, increased production of energy sources by the liver, and increased alertness.

The Outer Regions of the Adrenal Glands Make Steroid Hormones in Response to Stress

The outer part of the adrenal gland, the cortex, is itself subdivided into three zones: the glomerulosa, the fasciculata, and the reticularis (Figure 50.16b). The outer zone, the glomerulosa, is the region that makes aldosterone. As mentioned, this mineralocorticoid hormone acts to maintain mineral balance. The innermost cortical zone is known as the reticularis, which functions in humans to make certain androgens, but whose function in other animals is not as clear. The bulk of the cortex is the middle zone, the fasciculata. The glucocorticoid hormones are made here, among them cortisol and other structurally related steroids.

Table 50.4 summarizes some of the major actions of glucocorticoids in vertebrates. Glucocorticoids are catabolic hormones; that is, they promote the breakdown of molecules and macromolecules. For example, they act on bone, immune, muscle, and fat tissue to break down proteins and lipids to provide energy for the body's cells. This is important for an animal that is facing an acute stress, because feeding and digestion both stop during fight-or-flight reactions, leaving internal stores as the only source of energy. These adrenal steroids are called glucocorticoids because one of their major actions is to promote gluconeogenesis in the liver during times of stress, thus providing glucose to the blood.

Responding to acute stress is an important function of glucocorticoids, but excessive production of these steroids can create serious problems. Such a situation might arise if an animal were chronically stressed for some reason, for example, due to habitat destruction, intraspecies competition and aggression, or chronic infection. Glucocorticoids, together with amine hormones such as epinephrine, increase the activity of the heart and can raise blood pressure. Therefore, prolonged stress can lead to disorders of the heart and blood vessels. In addition, a chronic increase in the glucocorticoid level can suppress the

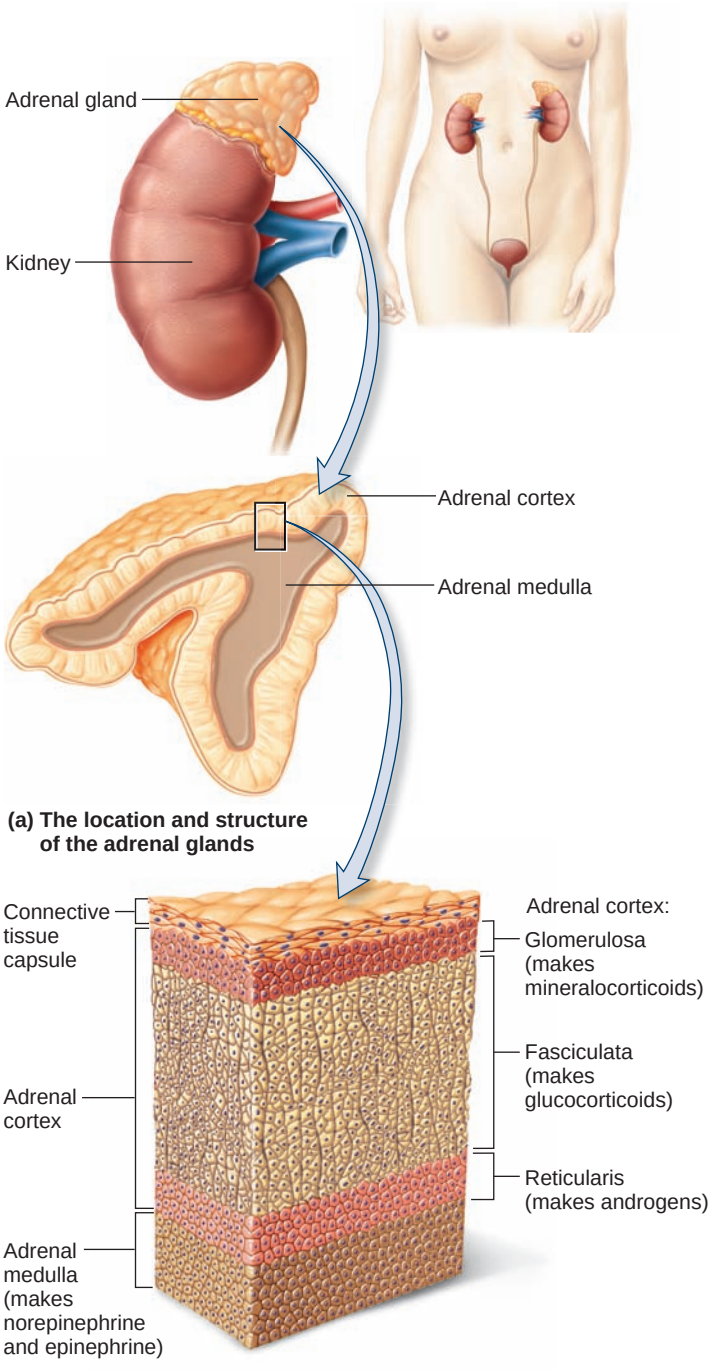

Figure 50.16 Location, cellular organization, and function of the adrenal glands.

immune system because of the catabolic actions of glucocorticoids on immune tissue. This may compromise an animal's ability to fight infection. For example, the prolonged stress a salmon experiences when it makes its exhausting swim upriver to its spawning grounds causes massive suppression of its immune system, and many mature salmon that die after spawning are found to be riddled with infections. People who are chronically stressed also tend to be susceptible to infections or to having dormant viruses suddenly flare up, such as the type of herpesvirus that causes cold sores.

Even an animal's ability to reproduce and grow is negatively affected by chronic stress, as noted most dramatically in medical situations involving humans. In children, for example, chronic exposure to a high level of glucocorticoids may stunt growth, at least temporarily. In women, chronic stress may result in the loss of monthly reproductive cycles. The explanation for this may be understood from an evolutionary perspective. Chronic stress generally suggests that an animal's fitness or survival is in jeopardy. Therefore, it is advantageous to have all energetically demanding activities—such as growth, reproduction, and even immune activity—come to a halt if these activities are not immediately required for staying alive.

The preceding discussion illustrates only a few ways in which the endocrine system can affect health and fitness in many animals, including humans. In the last section of this chapter, we highlight some aspects of hormones that are exerting a large impact on public health in humans.

Table 50.3 The Fight-or-Flight Response to Stress

System	Responses
Cardiovascular	Increases heart rate and strength of heart contractions to maximize pumping of blood to all parts of the body; dilates blood vessels entering tissues requiring more oxygen—such as skeletal muscle—and constricts blood vessels to regions of less immediate importance—such as the gut and kidney
Respiratory	Dilates small airways (bronchioles) to reduce resistance to airflow in mammals; increases rate and depth of breathing to maximize oxygen intake and carbon dioxide elimination
Metabolic	Increases glycogenolysis in muscle to provide glucose for muscle cells and in the liver to provide glucose to the blood, where it can reach all body cells; increases breakdown of adipose triglycerides into usable fuel (fatty acids) that can then enter the bloodstream; stimulates glucagon secretion, which acts on the liver to promote gluconeogenesis
Nervous	Increases arousal and alertness; inhibits nonessential functions such as appetite

Table 50.4 The Major Actions of Glucocorticoids in Stress

Site	Actions
Liver	Stimulate gluconeogenesis, thus providing glucose to the blood
Adipose tissue	Stimulate breakdown of triglycerides into fatty acids and glycerol for fuel
Muscle and adipose tissue	Inhibit sensitivity to insulin, making more glucose available to brain cells, which do not require insulin to move glucose across their plasma membranes
Bone	Inhibit bone growth and formation, because such processes require large amounts of nutrients that could be used to combat stress instead
Lungs	Stimulate lung maturation in the fetus
Immune	Suppress immune system function and reduce inflammation
Other	Regulate sodium and chloride balance in migratory fishes; stimulate nervous system development in most vertebrates; stimulate protein breakdown to provide amino acids to the liver for gluconeogenesis; inhibit reproduction

50.8 Impact on Public Health

The list of endocrine-related diseases in the human population is a long one, ranging from relatively common disorders such as diabetes and thyroid disease to rare ones that may affect only 1 in every 100,000 or more individuals. Hormones can be used to treat many of these diseases, but they can also be misused in ways that cause health problems. Also, the widespread industrial use of chemicals with hormone-like actions and their possible environmental consequences have become very much a part of the news. Let's consider how hormones are used therapeutically as well as misused, and then look at an example of how factors that alter the function of the human endocrine system can have important health implications.

Hormones Are Used to Treat Millions of People

Since the advent of synthetic hormone production, doctors have been able to provide individuals with hormones that their own bodies fail to produce. For example, millions of people self-administer insulin each day or take thyroxine to supplement their insufficient levels of thyroid hormones. Many women undergo hormone therapy to help induce pregnancy or control the symptoms of menopause. A growing number of men, too, are administered gonadal hormones if the levels produced by their bodies decline significantly in later life. Other examples include recombinant human growth hormone to treat abnormally short stature in prepubertal children, epinephrine inhalers to treat asthma, and glucocorticoids to treat inflammation, lung disease, and skin disorders, to name just a few.

Hormone Misuse Can Have Disastrous Consequences

Some individuals, typically those in competitive sports, self-administer hormones such as androgens. This practice may increase muscle mass and improve athletic performance. However, the price is steep. First, androgens exert negative feedback actions on FSH and LH secreted by the anterior pituitary gland. As a consequence, the anterior pituitary gland stops producing and secreting FSH and LH while the user is taking supplements containing androgens. In males, this causes the testes to shrink, as they no longer are making sperm, and the man becomes infertile; this is what happened to our case subject described at the beginning of the chapter. Androgen administration has also been linked to extreme aggressive behavior (**"roid" rage**), cardiovascular disease and heart attacks, skin problems, and certain cancers. Women using androgens run similar health risks as men but, in addition, develop masculinizing traits, including growth of body hair and thinning scalp hair.

Another example of hormone misuse is when they are used to boost the number of red blood cells in the circulation to increase the oxygen-carrying capacity of the blood (often called **blood-doping**). This has become common among athletes participating in long-distance aerobic activities, such as cycling and cross-country skiing. It has replaced the former practice of actually transfusing suspensions of red blood cells into a person's circulation. The hormone used is **erythropoietin** (**EPO**), which acts by stimulating the maturation of red blood cells in the bone marrow and their release into the blood. EPO is normally made by the liver and kidneys in response to any situation where additional blood cells are required, such as following blood loss or when a person lives at high altitudes, where the oxygen pressure is low. When used abusively, however, the concentration of red blood cells reaches such a high level that the blood becomes much thicker than normal. This puts a serious strain on the heart, which must work harder to pump the thickened blood. Since the 1990s, the international cycling community has been rocked by an alarming trend of world-class European cyclists who died of heart attacks in the prime of their lives. These individuals had been using EPO to gain an unfair and, as it turns out, unwise advantage over their peers. Testing continues to detect injected EPO in the blood of some cyclists and other endurance athletes.

Synthetic Compounds May Act as Endocrine Disruptors

A recent phenomenon—disturbing because of its potential to impact reproduction in animals and people—is the growing amount of so-called **endocrine disruptors** found in lakes, streams, ocean water, and soil exposed to pollution runoff. These chemicals are derived in many cases from industrial waste and have molecular structures that in some cases resemble estrogen sufficiently to bind to estrogen receptors. If these compounds make their way into drinking water or food, they can exert estrogen-like actions or inhibit the actions of the body's own estrogen. This can lead to dramatic consequences on fertility and on the development of embryos and fetuses. The extent of the risk from these **xenoestrogens** (from the Greek *xeno*, meaning foreign) is hotly debated, but the number of mature, functional germ cells produced in animals as diverse as mollusks and human males has declined dramatically during the past 50 years in the U.S. In addition, researchers throughout the world have noted feminization of freshwater fishes downstream of wastewater facilities. For example, male fishes that were exposed to such conditions during development show increased production of proteins normally made by females bearing eggs. They also show changes in gonadal structures that resemble the female appearance. Further research is urgently needed to provide more information on the consequences of these contaminants to animal endocrine systems.

Summary of Key Concepts

50.1 Mechanisms of Hormone Action and Control

- The endocrine glands and other organs with hormone-secreting cells constitute the endocrine system.
- Endocrine glands contain epithelial cells that secrete hormones into the bloodstream, where they circulate throughout the body. Although slower than the electrical signaling of nervous

systems, chemical signaling complements nervous system regulation through its varying actions in multiple locations across widely ranging time frames.

- The effects of a hormone may occur within seconds or require several hours to develop, and it may last for as short as a few minutes or as long as days.
- Hormones fall into three broad classes that include the amines, proteins/peptides, and steroids. The amines and the proteins/peptides generally share similar chemical properties and modes of action, whereas the steroid hormones act very differently from the other classes. (Table 50.1)
- Water-soluble hormones (amines and proteins/peptides) act on receptor molecules located in the plasma membrane, whereas lipid-soluble hormones (steroids) act on intracellular receptors.
- Blood levels of hormones can increase or decrease through two mechanisms: changing the rate of hormone synthesis by an endocrine cell and changing the rates at which hormones are removed or inactivated. (Figures 50.2, 50.3)

50.2 Links Between the Endocrine and Nervous Systems

- Sensory input from an animal's nervous system modulates the activity of certain endocrine glands and influences blood levels of many hormones.
- The hypothalamus is physically connected to the pituitary gland; the two lobes of the pituitary are the anterior and posterior pituitary glands. (Figure 50.4)
- Within the hypothalamus are numerous neurons that synthesize neurohormones and stimulate the anterior pituitary.
- The anterior pituitary gland synthesizes six different hormones that respond to the presence of hypothalamic neurohormones. They are adrenocorticotropic hormone, follicle-stimulating hormone, luteinizing hormone, growth hormone, prolactin, and thyroid-stimulating hormone. (Table 50.2)
- In mammals, the neuron terminals in the posterior pituitary gland store and secrete one of two hormones, oxytocin or antidiuretic hormone (ADH).

50.3 Hormonal Control of Metabolism and Energy Balance

- Hormones are partly responsible for regulating energy use by cells, that is, for modulating appetite, digestion, absorption of nutrients, and blood levels of energy sources such as glucose. Although many hormones are involved in these processes, two from the thyroid gland (thyroxine and triiodothyronine), two from the pancreas (insulin and glucagon), and one from adipose tissue (leptin) play especially important roles.
- The thyroid gland makes thyroid hormones, which contain iodide. A major action of thyroid hormones in adult animals is to stimulate energy consumption by many different cell types. (Figures 50.5, 50.6)
- The endocrine pancreas produces the peptide hormones insulin and glucagon, which have opposite effects on the blood glucose level. The adrenal glands produce steroid hormones known as glucocorticoids, which increase the blood glucose level. (Figure 50.7)
- Maintaining normal glucose and other nutrient levels in the blood is a vital process that keeps cells functioning optimally. The combined short-term and long-term actions of insulin, glucagon, epinephrine, and cortisol help maintain normal blood glucose levels during fasting. (Figure 50.8)
- Groundbreaking research by Banting, Best, MacLeod, and Collip isolated insulin for therapeutic use in treating diabetes mellitus. (Figure 50.9)
- Adipose tissue is an important source of appetite-regulating hormones, including the protein leptin, which acts on the hypothalamus to inhibit appetite. Adipose cells release leptin into the blood in direct proportion to the amount of adipose tissue in the body.

50.4 Hormonal Control of Mineral Balance

- Because of the important roles that calcium plays in neuronal transmission, heart function, muscle contraction, and numerous other events, the concentration of Ca^{2+} in the blood is among the most tightly regulated variables in an animal's body. Vitamin D and parathyroid hormone, produced by the parathyroid glands, regulate the blood concentration of Ca^{2+}. (Figures 50.10, 50.11)
- Sodium and potassium play crucial roles in membrane potential formation, action potential generation, and other functions. A key mechanism that regulates blood concentrations of these ions is to alter the rate of sodium, potassium, and water reabsorption from the urine as it is being formed in the kidneys. This is accomplished in large part by the actions of ADH, aldosterone, and atrial natriuretic peptide (ANP). (Figure 50.12)

50.5 Hormonal Control of Growth and Differentiation

- Hormones play a crucial role in regulating growth and differentiation. In vertebrates, normal growth depends on a balance between growth hormone, insulin-like growth factor-1 (IGF-1), and gonadal hormones. Thyroid hormones affect differentiation among all vertebrates. (Figures 50.13, 50.14)
- In insects, prothoracicotropic hormone, 20-hydroxyecdysone, and juvenile hormone control the growth of larvae and their differentiation into pupae. (Figure 50.15)

50.6 Hormonal Control of Reproduction

- Hormones produced by the gonads play vital roles in nearly all aspects of reproduction. The ability of the testes and ovaries to produce the sex steroids depends on the gonadotropins, which are the same in both sexes and include follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
- Leptin is required for fertility in mammals.

50.7 Hormonal Responses to Stress

- Regardless of the nature of the stress, animals' bodies respond to stress in similar ways. In vertebrates, hormones produced by the adrenal glands are the common denominator of the response to stress. Norepinephrine and epinephrine, produced by the adrenal medulla, are responsible for most fight-or-flight reactions. (Figure 50.16, Table 50.3)
- Glucocorticoids promote breakdown of storage compounds to provide energy for cells during stress. (Table 50.4)

50.8 Impact on Public Health

- Hormones are used therapeutically to treat a variety of human disorders, such as infertility and growth disorders.
- Androgen misuse can disrupt normal hormone levels and cause health risks such as aggression; cardiovascular disease; skin problems; cancer; and, in women, masculinizing traits. Blood-doping with erythropoietin can make blood dangerously thick.
- Endocrine disruptors, such as chemicals derived from industrial waste, may bind to estrogen receptors in animals' bodies. They may exert estrogen-like actions or inhibit the actions of the body's own estrogen.

Assess and Discuss

Test Yourself

1. Which is the defining feature of hormones?
   a. They are only produced in endocrine glands.
   b. They are secreted by one type of cell into the blood, where they may simultaneously reach many distant target cells and thereby alter cell function throughout the body.
   c. They are released only by neurons.
   d. They are never released by neurons.
   e. They are secreted into ducts, where they diffuse to another nearby gland or other structure.
2. Steroid hormones are synthesized from _____ and bind _____.
   a. proteins; membrane receptors
   b. fatty acids; membrane receptors
   c. tyrosine; intracellular receptors
   d. proteins; intracellular receptors
   e. cholesterol; intracellular receptors
3. Which of the following is not true about protein and peptide hormones?
   a. Most of them bind to receptors located on the cell membrane.
   b. Most of them are lipophilic.
   c. They are the most abundant class of hormones.
   d. They normally activate second messengers and intracellular signaling pathways.
   e. They bind noncovalently to receptors.
4. Which is not correct about the control of hormones?
   a. Many are regulated by negative feedback.
   b. In some cases, they may be controlled by changes in blood levels of certain nutrients such as glucose.
   c. In some cases, they may be controlled by changes in blood levels of certain minerals such as Ca^{2+}.
   d. Their blood levels are controlled by their rates of synthesis and degradation.
   e. The rate of degradation of a hormone may go up or down, but synthesis is always constant.
5. The hypothalamus and the pituitary gland are physically connected by
   a. arteries.
   b. the infundibular stalk and portal veins.
   c. the adrenal medulla.
   d. the spinal cord.
   e. the intermediate lobe.
6. Antidiuretic hormone
   a. increases water reabsorption in the kidneys.
   b. regulates blood pressure by constricting arterioles.
   c. decreases the volume of urine produced by the kidneys.
   d. increases blood pressure during times of high blood loss.
   e. does all of the above.
7. Which of the following pairs of hormones are involved in the regulation of blood calcium ion level in vertebrates?
   a. aldosterone and ANP
   b. insulin and glucagon
   c. parathyroid hormone and 1,25-dihydroxyvitamin D
   d. prolactin and oxytocin
   e. thyroxine and TSH
8. In invertebrates, molting of larvae is stimulated by
   a. growth hormone.
   b. cortisol.
   c. juvenile hormone.
   d. 20-hydroxyecdysone.
   e. aldosterone.
9. Which of the following is not true of glucocorticoids?
   a. They stimulate maturation of the fetal lungs.
   b. They promote a decrease in the blood glucose level.
   c. They inhibit the sensitivity of cells to insulin.
   d. They are lipophilic (lipid soluble).
   e. They reduce inflammation.
10. Endocrine disruptors are
    a. chemicals released by the nervous system to override the endocrine system.
    b. chemicals released by the male of a species to decrease the fertility of other males.
    c. drugs used to treat overactive endocrine structures.
    d. chemicals derived from industrial waste that may alter endocrine function.
    e. all of the above.

Conceptual Questions

1. What is the function of leptin, and what is the benefit of an adipose-derived signaling molecule in this context? Why does an animal have an appetite?
2. Describe the major functions of insulin and glucagon. When are they released into the blood? What might happen to a nonfasting mammal that was injected with a high dose of glucagon?
3. Distinguish between type 1 and type 2 diabetes mellitus.

Collaborative Questions

1. Discuss the role of hormones in insect development.
2. Discuss the role of the different steroid hormones and where they are produced in the human body.

Chapter Outline

Animal Reproduction

51

Most animals reproduce by sexual reproduction. These mud daubers, shown here mating, reproduce by sexual reproduction, which favors genetic variation in species.

Over a span of 40 years in the early 18th century, a woman known to history only as the "wife of Feodor Vassilyev," a Russian peasant, reportedly gave birth 27 times to a total of 69 children! If accurate, it is safe to say that this is about the uppermost realistic limit of human fertility, considering a pregnancy length of about 40 weeks, the rarity of a woman producing multiple births such as twins, and the reproductive life span of an adult woman. Impressive as such a number is, however, it pales in comparison to the numbers of offspring produced by many other animals. For example, many invertebrate species, such as the mud daubers shown in the chapter-opening photo, lay anywhere from several to dozens of eggs in 1 day. As an extreme example, a single female cod fish can lay several million eggs during one spawning season (although not all the eggs will result in offspring).

Indeed, when we examine all forms of life, we discover that individuals of every species are part of an unbroken cycle of life and death. Perpetuation of all life requires **reproduction**—the processes by which organisms replicate themselves and multiply. Because reproduction is the only way in which a species can perpetuate itself, enormous evolutionary pressure has been exerted on the processes of reproduction, and demands made on organisms by their environments have influenced how reproduction occurs.

The biological mechanisms that favor successful reproduction in the animal kingdom are extraordinarily diverse. Many of the observable differences in animal behavior and anatomy are the result of adaptations to environmental pressures that increase an animal's chances of reproducing. Both the behaviors and the anatomical specializations that promote reproduction are under the control of a variety of factors, particularly hormones.

In this chapter, we will initially focus on the diverse means of reproduction that occur throughout the animal kingdom, including asexual and sexual reproduction. Then we will highlight some of the anatomical, hormonal, and behavioral aspects of reproduction in mammals, including humans. We will conclude with a discussion of some key issues related to fertility (the ability to reproduce) in the human population today. We begin by examining the different ways animals reproduce.

51.1 Asexual and Sexual Reproduction

Asexual reproduction occurs when offspring are produced from a single parent, without the fusion of genetic material from two parents. The offspring are therefore clones of the parent. **Sexual reproduction** is the production of a new individual by the joining of two haploid reproductive cells called **gametes**, one from each parent. This produces offspring that are genetically different from both parents. In this section, we will consider the processes of asexual and sexual reproduction, as well as their advantages and disadvantages.

Asexual Reproduction

Asexual reproduction occurs in some invertebrates and in a small number of vertebrate species. Animals use one of three major forms of asexual reproduction: budding, regeneration, or parthenogenesis. **Budding**, which is seen in cnidarians, occurs

(a) Budding (b) Regeneration

Figure 51.1 Examples of asexual reproduction. (a) A hydra with a bud on its left side. (b) A sea star regenerating a complete new body from a single arm.

when a portion of the parent organism pinches off to form a complete new individual (Figure 51.1a). In this process, cells from the parent undergo mitosis and differentiate into specific types of structures before the new individual breaks away from the parent. At any one time, a parent organism may have one, two, or multiple buds forming simultaneously. Budding continues throughout such an animal's lifetime.

Some animals, including certain species of sponges, echinoderms, and worms, reproduce by the **regeneration** of a complete organism from small fragments of their body. In the sea star, for example, an arm removed by injury or predation can grow into an entirely new individual (Figure 51.1b). Similarly, a flatworm bisected into two pieces will regenerate into two new individuals.

The asexual process called **parthenogenesis** (from the Greek, meaning virgin birth) is the development of offspring from an unfertilized egg. It occurs in several invertebrate classes and in a few species of fishes and reptiles. Animals produced by parthenogenesis are usually haploid. Some species—such as rotifers, many social insects, and the freshwater crustacean *Daphnia*—may reproduce either parthenogenically or sexually, depending on the time of year or environmental conditions. In honeybees, ants, and wasps, for instance, haploid males (drones) are produced by parthenogenesis, and diploid females (workers and queens) by sexual reproduction. Production of drones, whose major function is to mate with a queen, usually occurs in late spring. The queen stores sperm cells from several drones for up to 2 years, during which time she may lay hundreds of thousands of eggs, only some of which will be fertilized. As stored sperm runs out, the unfertilized eggs become new drones.

Sexual Reproduction

Sexual reproduction occurs in most animal species, invertebrate and vertebrate. As mentioned, sexual reproduction involves the joining of two gametes. The gametes are spermatozoa (usually shortened to **sperm cell**) from the male and **egg cells**, or **ova**, (singular, **ovum**) from the female. When a sperm unites with an egg—a process called **fertilization**—each haploid gamete contributes its set of chromosomes to produce a diploid cell called a fertilized egg, or **zygote**. As the zygote undergoes cell divisions and begins to develop, it is called an **embryo**.

Advantages and Disadvantages of Asexual and Sexual Reproduction

Asexual reproduction provides a relatively simple way for an organism to produce many copies of itself, whereas sexual reproduction requires two individuals to produce offspring. What are the advantages and disadvantages of each?

Asexual reproduction has numerous advantages over sexual reproduction. First, an animal can reproduce asexually even if it is isolated from others of its own species, either because the animal is sessile (nonmotile) or rarely encounters another member of its species. Another advantage is that individuals can reproduce rapidly because they need not seek out, attract, and mate with an opposite sex. Asexual reproduction, therefore, is an effective way of generating large numbers of offspring. Although many kinds of animals reproduce asexually, it is more prevalent in species that live in very stable environments, with little selection pressure for genetic diversity in a population.

Compared with asexual reproduction, sexual reproduction is associated with unique costs. Two types of gametes (sperm and eggs) must be made, males and females require specialized body parts to mate with each other, and the two sexes must be able to find each other. Yet given that most eukaryotic species reproduce sexually, a question has intrigued biologists since the time of Darwin: What is the advantage of sexual reproduction for the perpetuation of a species?

In the context of species survival, the major difference between asexual and sexual reproduction is that sexual reproduction allows for greater genetic variation due to genetic recombination. Only certain alleles from each parent are passed on, and when a set of genes from one parent mix with a different set from the other parent, the offspring are never exactly like either of their parents. Thus, a hallmark of sexual reproduction is increased genetic variation between successive generations. One prevalent hypothesis about why sex evolved is that sexual reproduction allows more rapid adaptation to environmental changes than does asexual reproduction.

In particular, sexual reproduction allows alleles within a species to be redistributed via crossing over and independent assortment across many generations. As a result, some offspring carry combinations of alleles that promote survival and reproduction, while other offspring may carry less favorable combinations. As described in Chapter 24, natural selection can favor those combinations that promote greater reproductive success while eliminating offspring with lower fitness. By comparison, the alleles of asexual organisms are not reassorted from generation to generation. As a result, it is more difficult to accumulate potentially beneficial alleles within individuals of these species. Also, as described next, sexual reproduction may facilitate elimination of harmful alleles from a population.

Feature Investigation

Paland and Lynch Provided Evidence That Sexual Reproduction May Promote the Elimination of Harmful Mutations in Populations

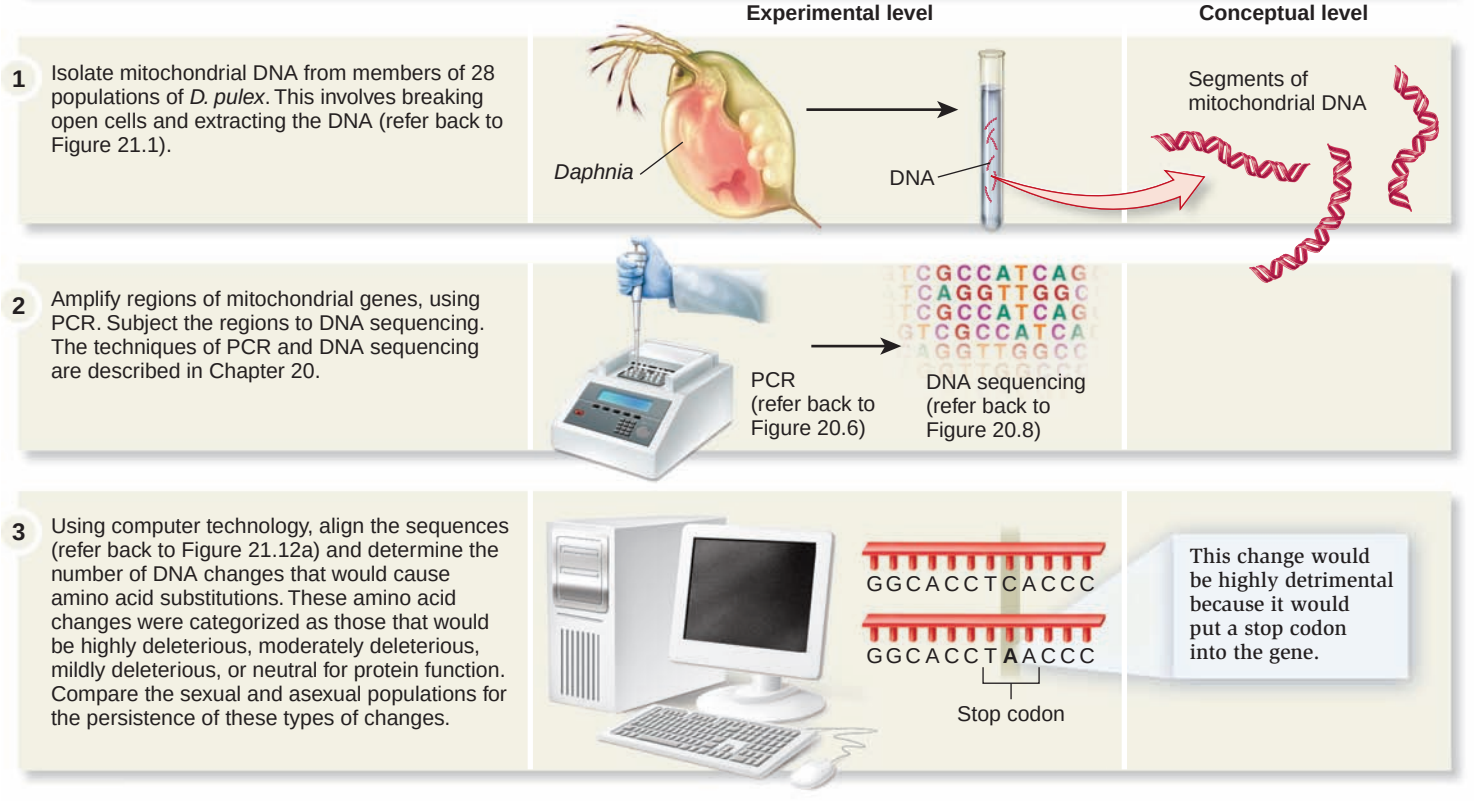
Evolutionary biologists have suggested that the inability of asexual species to reassort alleles may be a key disadvantage compared to sexually reproducing species. To investigate this question, American researchers Susanne Paland and Michael Lynch recently studied the persistence of mutations in populations of *Daphnia pulex*, a freshwater organism commonly known as the water flea. The researchers chose this organism because some natural populations reproduce asexually, and others reproduce sexually.

In their experiment, shown in Figure 51.2, Paland and Lynch studied the sequences of several mitochondrial genes in 14 sexually reproducing and 14 asexually reproducing populations of *D. pulex*. The researchers hypothesized that asexual populations would be less able to eliminate harmful mutations. As discussed in Chapter 24, random gene mutations that change the amino acid sequence of the encoded protein are much more likely to be harmful than beneficial. As we discussed, the alleles of sexually reproducing populations can be reassorted from generation to generation, thereby producing succeeding generations in which the detrimental alleles are lost from the population. As you can see in the data, the researchers discovered that both the sexual and asexual populations could eliminate highly deleterious mutations. Organisms harboring such mutations probably died rather easily. In addition, the sexual and asexual populations both retained mildly deleterious and neutral mutations. However, moderately deleterious mutations were eliminated from the sexual populations but not from the asexual ones. One interpretation of these data is that sexual reproduction allowed for the reassortment of beneficial and detrimental alleles, making it easier for sexual populations to eliminate those mutations that are moderately detrimental.

Figure 51.2 **Paland and Lynch demonstrated the importance of sexual reproduction in reducing the frequency of maladaptive genetic mutations.**

HYPOTHESIS Sexual reproduction allows for greater mixing of alleles of different genes and thereby may prevent the accumulation of detrimental alleles in a population.

KEY MATERIALS The researchers collected samples of *Daphnia pulex* from many natural populations. A total of 14 sexual populations and 14 asexual populations were studied.



4 THE DATA

Results from step 3:

Types of amino acid substitutions (The amino acid substitutions were due to rare mutations that occurred in the natural populations of *D. pulex*.)	% of total amino acid substitutions	Allowed to persist in	
		Sexual populations	Asexual populations
Highly deleterious	73.2	No	No
Moderately deleterious	13.3	No	Yes
Mildly deleterious	4.4	Yes	Yes
Neutral	9.1	Yes	Yes

5 CONCLUSION Moderately deleterious mutations are less likely to persist in populations of animals that reproduce sexually.

6 SOURCE Paland, S., and Lynch, M. 2006. Transition to asexuality results in excess amino acid substitutions. *Science* 311:990–992.

Experimental Questions

1. How did Paland and Lynch propose to test the hypothesis that sexual reproduction allowed for the reduction in deleterious mutations?
2. What did they discover?
3. What is the proposed evolutionary benefit of sexual reproduction?

51.2 Gametogenesis and Fertilization

This section covers how and where gametes are formed, and how two gametes join to form a new organism.

Sperm and Eggs Are Produced During the Process of Gametogenesis

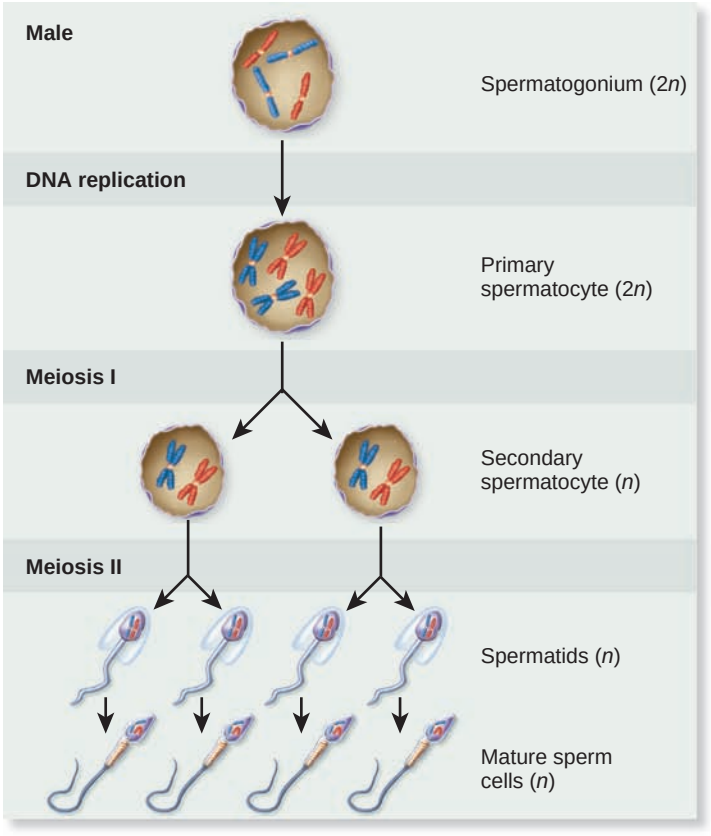
Male and female gametes are formed within the **gonads**—the **testes** (singular, **testis**) in males and the **ovaries** (singular, **ovary**) in females. Some similarities are found in the ways gametes develop in the testes and the ovaries, as well as some differences.

Gametogenesis—the formation of gametes—begins with primordial cells called germ cells, which multiply by mitosis, resulting in diploid cells (carrying two copies of each gene; denoted as $2n$) called **spermatogonia** (singular, **spermatogonium**) in males and **oogonia** (singular, **oogonium**) in females (Figure 51.3). Some of these cells become **primary spermatocytes** or **primary oocytes** that may begin the process of meiosis. Until this point, the development of sperm and eggs is similar. From then on, gametogenesis differs between the two types of gamete.

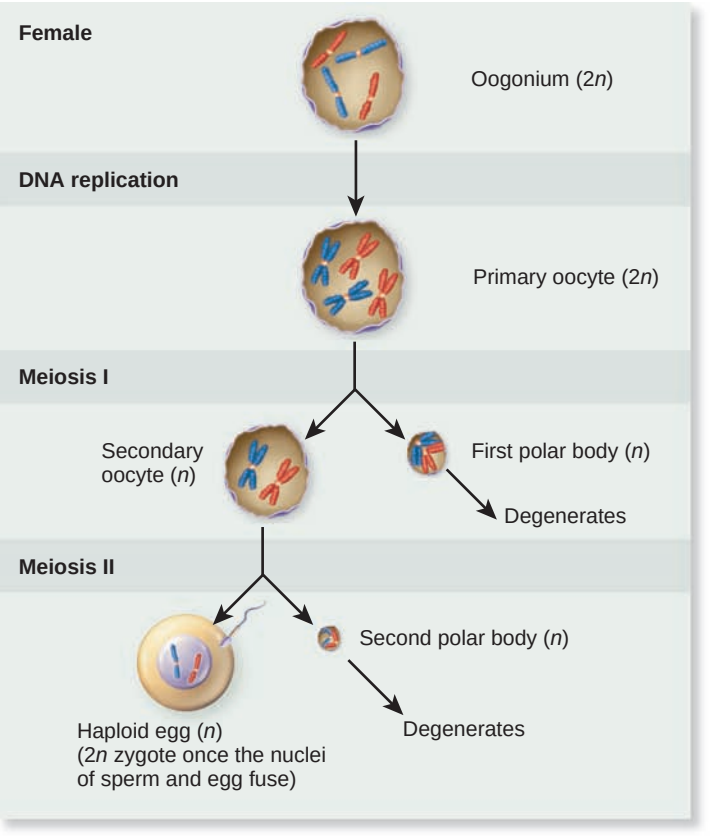
Spermatogenesis The formation of haploid sperm from the original diploid germ cell is called **spermatogenesis**. As shown in Figure 51.3a, primary spermatocytes begin this process by undergoing the first of two meiotic divisions (meiosis I). (For a review of the processes of mitosis and meiosis, see Chapter 15.) Meiosis I in the primary spermatocyte produces two haploid (n) cells called **secondary spermatocytes**. These cells also undergo meiosis (meiosis II), producing four haploid **spermatids** that eventually differentiate into mature sperm cells. Gametogenesis in males, therefore, results in four gametes from each spermatogonium.

The most striking change in each spermatocyte as it differentiates into a sperm is the formation of a flagellum, also called the tail (Figure 51.3b). The movements of the tail require cellular energy and make the sperm motile. The sperm also has a head, which contains the nucleus that carries the chromosomes. The head and tail are separated by a midpiece containing one or more mitochondria, depending on the species, that produce the ATP required for tail movements. At the tip of the head is a special structure called the **acrosome** that contains proteolytic enzymes that help break down the protective outer layers surrounding the ovum.

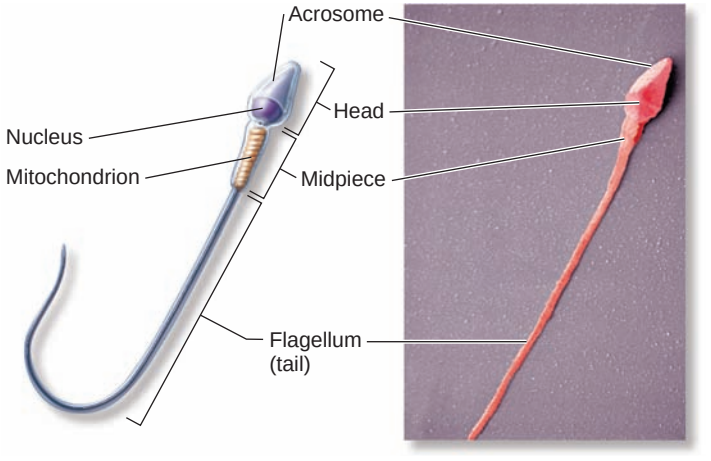
Oogenesis Whereas spermatogenesis produces four gametes from each primary spermatocyte, gametogenesis in the female, called **oogenesis**, results in the production of a single gamete from each primary oocyte (Figure 51.3c). Each meiotic division in oogenesis results in one large cell—either a **secondary oocyte** (meiosis I) or (because meiosis II is not complete until fertilization) a fertilized egg (meiosis II)—plus a smaller cell, called a polar body, that eventually degenerates. Only the larger of the two daughter cells resulting from meiosis II (that is, the fertilized egg) contains the cellular components needed for development after fertilization.



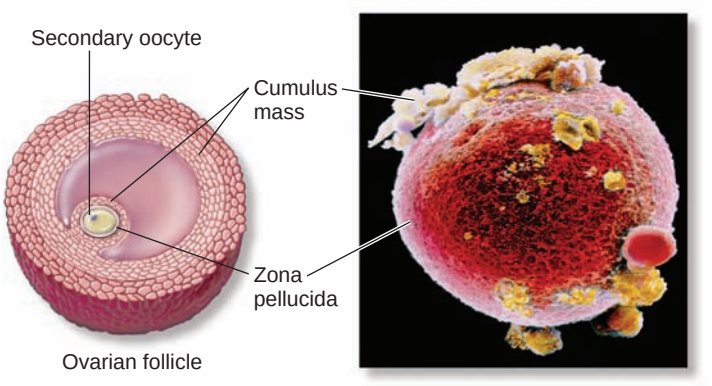
(a) Spermatogenesis



(c) Oogenesis



(b) Mature human sperm



(d) Mature human follicle and oocyte

Figure 51.3 **Gametogenesis and gametes in males and females.** **(a)** In the process of spermatogenesis, male diploid (2*n*) germ cells undergo two meiotic divisions to produce mature haploid (*n*) sperm. **(b)** The characteristic head, midpiece, and tail (flagellum) of a mature human sperm, as seen in a drawing and the accompanying scanning electron micrograph (SEM). **(c)** The process of oogenesis in females, which produces a haploid secondary oocyte that enters but does not complete meiosis II until it is fertilized. **(d)** Mature follicle and oocyte. The drawing depicts a secondary oocyte within its follicle; the SEM shows an isolated human oocyte covered by its zona pellucida and remnants of the cumulus mass.

Depending on the species, one or many oocytes can develop at a time. Within the ovaries, each oocyte undergoes growth and development within a structure called a **follicle** before it leaves the ovary in the process of **ovulation**. Once ovulated, a secondary oocyte can become fertilized if sperm are available. In mammals, the secondary oocyte is surrounded by two layers: an inner layer composed of glycoproteins called the **zona pellucida**, which surrounds the surface of the secondary oocyte, and an outer layer of cells called the cumulus mass (Figure 51.3d). These two layers play important roles in the fertilization of the secondary oocyte.

In mammals, oogenesis begins in the female fetus before birth: A cohort of germ cells develop into primary oocytes and enter meiosis I, which is arrested partway through the process.

Meiosis I does not resume until puberty, the time when a mammal first becomes capable of reproducing. In selected primary oocytes, meiosis I is completed, producing haploid secondary oocytes. These cells then begin but do not complete meiosis II. A secondary oocyte will complete meiosis II and become a haploid egg if it is fertilized by a sperm. Once the haploid egg nucleus fuses with a haploid sperm nucleus, a diploid zygote is produced.

In a Given Species, Fertilization Occurs Either Outside or Inside the Female

For sperm to fertilize eggs, the two gametes must physically come into contact. This can occur either outside or inside the female's body. When this occurs outside of the female, the process is called **external fertilization**. This type of fertilization occurs in aquatic environments, when eggs and sperm are released into the water in close enough proximity for fertilization to occur. The aqueous environment protects the gametes from drying out.

Animals that reproduce by external fertilization show species-specific behaviors that bring the eggs and sperm together. For instance, very soon after a female fish lays her eggs, a male deposits his sperm in the water such that they spread over the clump of eggs. When frogs mate, the clasping behavior of the male stimulates the female to release her eggs into the water (Figure 51.4); the male then releases sperm onto the eggs. The fertilized eggs then develop outside the mother's body.

Although the aqueous environment protects against desiccation, fertilized eggs can be eaten by predators, washed downstream by currents, or subjected to potentially lethal changes in water temperature. Such environmental challenges have led to selection for some species, including many aquatic or amphibious animals, to release very large numbers of eggs at once, as noted previously for cod fish.

In contrast to external fertilization, most terrestrial animals and some aquatic animals use **internal fertilization**, in which sperm are deposited within the reproductive tract of the female during the act called **copulation**, as seen in the mud daubers in the chapter-opening photo. Internal fertilization protects the delicate gametes from environmental hazards and predation and also guarantees that sperm are placed and remain in very close proximity to eggs. Once fertilization occurs within the female, the zygotes then develop into offspring.

The behaviors and anatomical structures involved in achieving internal fertilization are extremely varied among species. Typically, mating involves accessory sex organs, which are reproductive structures other than the gonads. The external accessory sex organs involved in copulation are the genitalia (for example, the **penis** and the **vagina**), which are used to physically join the male and female so that sperm can be deposited directly into the female's reproductive tract. A penis or analogous structure is present in most insects, reptiles, some species of birds (rattites), and all mammals. However, males of other vertebrate species—such as most birds—that reproduce by internal fertilization lack a structure that can be inserted into the female, so they deposit sperm in the female by cloacal contact. The cloaca is a common opening for the reproductive, digestive, and excretory systems in these animals.

Figure 51.4 An example of external fertilization. The male frog (*Rana palustris*) clasps the female, which stimulates her to release her eggs. He then releases his sperm (not visible here) over the eggs. This process occurs in aquatic environments, which protect gametes from drying out.

Concept check: What kinds of aquatic environments are most suitable for external fertilization?

Another form of internal fertilization involves an indirect means of depositing sperm. In this case, males produce small packets of sperm, called spermatophores, that are deposited externally and then inserted into the female's reproductive tract by either the male or the female. During copulation in cephalopods, the male uses a tentacle to transfer a spermatophore into the mantle cavity of the female. In spiders, the male places a droplet of sperm on a web and then uses a foreleg to insert the droplet into the female's reproductive tract. Subsequently the eggs are fertilized internally and deposited on the web or elsewhere in the environment.

Some Hermaphroditic Species Can Fertilize Themselves or Each Other

In some species, individuals have both male and female reproductive systems. This is called **hermaphroditism** (after the male and female Greek gods, Hermes and Aphrodite). In some hermaphroditic species, individuals can fertilize their own eggs with their own sperm, but in most hermaphroditic species, individuals exchange sperm with another individual. The latter situation has the selective advantage of creating additional genetic diversity in the population. An advantage of hermaphroditism is that all individuals of a sexually reproducing species can produce offspring.

There are two main types of hermaphroditism, in which animals are simultaneously both male and female or alternately male or female. This first type of hermaphroditism is known as synchronous hermaphroditism. Such hermaphrodites are often sessile animals or burrowing animals such as earthworms, which may live for long periods without encountering sexual partners. A single earthworm can fertilize its own eggs, or two earthworms can join together for several hours during which sperm from each worm fertilize the eggs of the other. In the

latter case, individual worms act both as females (receiving sperm to fertilize their eggs) and males (giving sperm to fertilize another worm's eggs), so the offspring carry genes from both individuals.

The second type of hermaphroditism, called sequential hermaphroditism, involves sex reversal, in which a female may change into a male, or vice versa. In such animals, individuals express specific genes and therefore develop and maintain reproductive structures of either a male or a female, but not at the same time. This kind of sex reversal occurs in some species of animals with strong social hierarchies. In some reef-dwelling species of fishes, for example, a single dominant male defends a harem of several females within a specific territory. When that dominant male dies, the largest of the females reverses sex and becomes a male. Thus, these fishes are protogynous—that is, female first but capable of becoming males later during their life cycle. Oysters and clownfish are also sequential hermaphrodites, but they are protandrous; that is, they are males first and only later become females. An advantage of protandrous hermaphroditism is that males change into females when they are older and larger—and so likely to be capable of producing a greater number of eggs.

Fertilization Involves the Union of Sperm with Egg

Fertilization is a complex series of events by which the haploid male and female gametes unite and become a diploid zygote. Several important cellular and molecular processes must occur before the nuclei of the gametes can fuse. The mechanism by which the egg and sperm make contact has been studied extensively in sea urchins, and some evidence suggests that a similar process occurs in humans and other mammals. When chemical attractant molecules emitted by sea urchin eggs bind to nearby sperm, cellular respiration (that is, the breakdown of nutrients to synthesize ATP) within the sperm increases, which helps increase sperm motility. The sperm then swim toward the egg by following the attractant's concentration gradient. The attractants are species-specific; that is, sperm will respond to the attractants produced by eggs of only their own species.

For a sperm to physically contact the egg, it must first penetrate the layers surrounding the egg's plasma membrane. In mammals, when the head of a sperm contacts the layers surrounding a secondary oocyte, chemicals in the cumulus mass stimulate the breakdown of the membrane covering the acrosome of the sperm. Proteolytic enzymes released from the acrosome digest a local area of the zona pellucida, allowing the sperm to contact the plasma membrane of the secondary oocyte. The plasma membrane of the secondary oocyte then fuses with the sperm head, facilitating its movement into the secondary oocyte's cytoplasm.

Once a sperm fuses with the secondary oocyte, other sperm must be prevented from also fusing with the fertilized egg to avoid the formation of a polyploid zygote, a condition that few zygotes survive. In most mammals, the penetration of one sperm induces metabolic changes within the egg that prevent additional sperm from penetrating the zona pellucida and entering the egg (see Chapter 52).

Offspring Are Born Live or Hatch from Eggs That Are Laid or Retained Within the Mother

As we have seen, internal fertilization occurs within the female, and the resulting zygotes then continue their development into offspring. This occurs by three main processes. First, when most of embryonic development occurs within the mother and the animal is born alive, as in most mammals, the process is called **viviparity**. Second, if all or most of embryonic development occurs outside the mother and the embryo depends exclusively on yolk from an egg for nourishment, the process is called **oviparity**. Oviparity is the rule in avian species and is common in reptiles, fishes, amphibians, and insects. Among mammals, only the echidna and the platypus are oviparous. In some cases, embryos of oviparous animals grow within a protective covering, such as a shell, from which they hatch. Terrestrial animals lay eggs with shells that protect the future offspring from desiccation. Such eggs may have leathery shells, as in most reptiles and insects, or hard shells containing calcium carbonate, as in birds and many turtles. These eggs contain all the nutrients necessary for the development of the embryo. Oxygen enters, and carbon dioxide exits, through tiny pores in the shell. The eggs of aquatic species lack shells so that external fertilization may occur. Such eggs are protected from drying out by their environment.

Although some animals lay only a single egg at one time, some animals lay many more. For example, snakes and turtles lay between several and hundreds of eggs at a time, frogs and fishes can lay thousands or even millions of eggs, and honeybee queens produce as many as 250,000 eggs during a nearly continuous laying cycle over 1–2 years!

Although oviparity reduces the female's metabolic investment in the young, it increases the incidence of predation. In many amphibian and reptile species, the large number of eggs laid increases the chances of some young surviving even if predation occurs. The energetic cost to the female of producing numerous eggs is high, but usually little or no parental care is involved, freeing the parent to devote energy to other activities. In birds, some fish, and some reptiles (crocodilians), however, incubation of the eggs after laying requires to varying degrees additional energy expenditure in the form of parental care, which typically continues after the eggs have hatched, and thus relatively few eggs are laid.

Third and finally, some animals develop by a process called **ovoviviparity**, which features aspects of the first two modes of development. In this case, fertilized eggs covered with a shell that is little more than a thin sheath hatch inside the mother's body, but the offspring receive no nourishment from the mother. Ovoviviparity occurs in sharks, lizards, some snakes, and some invertebrates.

51.3 Mammalian Reproductive Structure and Function

We turn now to a detailed look at the mammalian reproductive system. For both sexes, we will begin with a description of the anatomy of the reproductive system, including the gonads

and the accessory sex structures. We will then examine the hormones that control the production of the gametes and the preparation for and establishment of pregnancy.

The Male Reproductive Tract Is Specialized for Production and Ejaculation of Sperm

The external structures of the male reproductive tract—the genitalia—consist of the penis and the scrotum, the sac that contains the testes and holds them outside the body cavity (Figure 51.5). The testes develop within the body cavity, and just before birth in human males, they descend into the scrotum, where the temperature is approximately 2°C lower than core body temperature. The lower temperature is optimal for spermatogenesis.

Each testis is composed of tightly packed **seminiferous tubules**, encased in connective tissue (Figure 51.6). Surrounding the tubules are Leydig cells—scattered cells that secrete the steroid hormone testosterone. Spermatogenesis begins at puberty and continues throughout life. It occurs all along the walls of the seminiferous tubules. Cells at the earliest stages of spermatogenesis, the spermatogonia, are located nearest the wall. Cells of more advanced stages are located progressively inward, such that the sperm are released into the tubule lumen. Cells within the seminiferous tubules are continuously developing from spermatogonia into spermatocytes and eventually to sperm, so at any one time, all types of cells are present along the seminiferous tubule. Support cells, called Sertoli cells, surround the developing spermatogonia and spermatocytes, providing them with nutrients and protection and playing a role in their maturation into sperm.

Sperm moving out of the seminiferous tubules are emptied into the **epididymis**, a coiled, tubular structure located on the surface of the testis (Figure 51.6). The epididymis is very long—approximately 6 m in humans—and in humans, it takes about 20 days for new sperm to reach its end. Here the sperm complete their differentiation by becoming motile and gaining the capacity to fertilize ova.

Sperm leave the epididymis through the **vas deferens** (or ductus deferens), a muscular tube leading to the **ejaculatory duct**, which then connects to the urethra (see Figure 51.5). As noted in Chapter 49, the urethra originates at the bladder and extends to the end of the penis. In males, the urethra not only conducts urine but also carries **semen**, a mixture containing fluid and sperm, that is released during **ejaculation**—the movement of semen through the urethra by contraction of muscles at the base of the penis. These contractions during ejaculation contribute to the pleasurable sensation of orgasm.

The liquid components of semen are important for the survival and movement of sperm through the female reproductive tract. This liquid is formed by three paired accessory glands that secrete substances into the urethra to mix with the sperm.

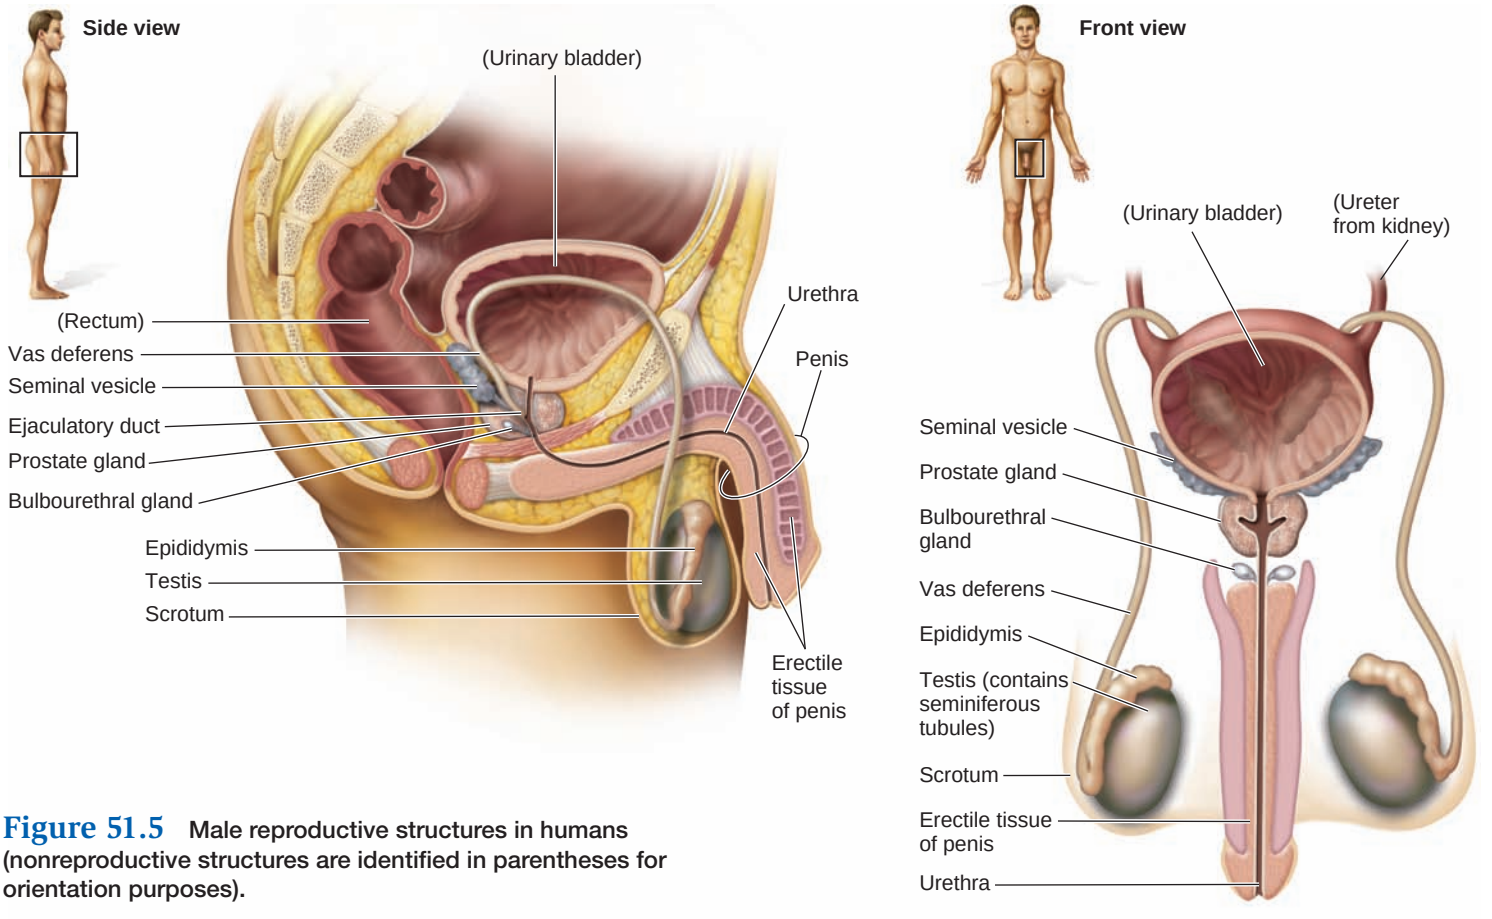


Figure 51.5 Male reproductive structures in humans (nonreproductive structures are identified in parentheses for orientation purposes).

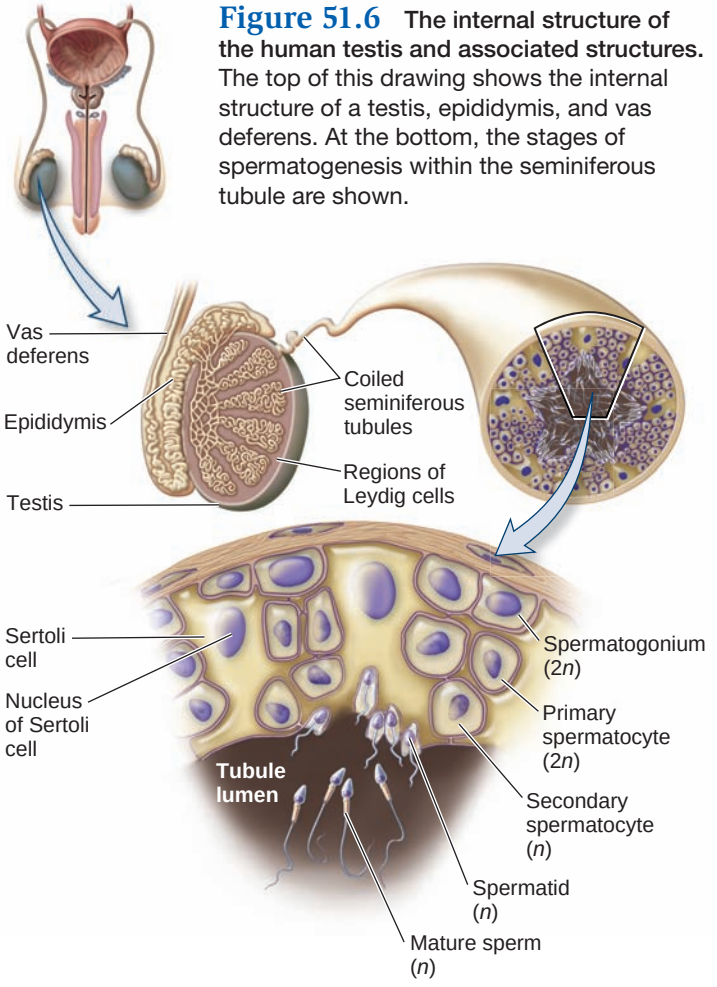

Figure 51.6 **The internal structure of the human testis and associated structures.** The top of this drawing shows the internal structure of a testis, epididymis, and vas deferens. At the bottom, the stages of spermatogenesis within the seminiferous tubule are shown.

The **seminal vesicles** secrete the monosaccharide fructose, the main nutrient for sperm, as well as other factors that enhance sperm motility and survival. The **prostate gland** secretes a thin, alkaline fluid that protects sperm from acidic fluids in the urethra and within the female reproductive tract. An additional small amount of alkaline fluid is secreted by the **bulbourethral glands**. Secretions constitute about 95% of semen, while sperm make up only about 5% of total semen volume. The volume of semen released at ejaculation in humans is about 2–5 ml and contains 20–130 million sperm per milliliter. Although this seems like a huge excess of sperm to fertilize a single ovum, relatively few sperm actually reach the egg.

Introduction of sperm into the female reproductive system during copulation is made possible by erection of the penis. Erection occurs when blood fills spongy erectile tissue located along the length of the penis (see Figure 51.5). In a number of mammals (excluding humans, but for example, in whales), the firmness of the erection is aided by the presence of a bone in the penis called a baculum.

Sexual arousal stimulates release of the gaseous neurotransmitter nitric oxide (NO) in the penis, causing vasodilation of arteries. The pressure of the blood flowing into the penis constricts nearby veins, causing a reduction in venous drainage from the penis, engorging it with blood. After ejaculation, NO release is reduced, causing a reversal of the vascular changes responsible for erection. Both physiological and psychological factors can result in an inability to achieve an erection, a medical condition known as erectile dysfunction (also called impotence). Orally administered drugs are available that increase the occurrence of erections by stimulating the same intracellular signaling events as NO in the smooth muscle cells of penile blood vessels.

Male Reproductive Function Requires the Actions of Testosterone

The role of hormones in male reproductive function is diagrammed in Figure 51.7. Recall from Chapter 50 that the hypothalamus is a structure at the base of the brain containing neurosecretory cells (see Table 50.2). One of the neurohormones produced by some of these cells is gonadotropin-releasing hormone (GnRH). GnRH stimulates the anterior pituitary gland to release two gonadotropic hormones: luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

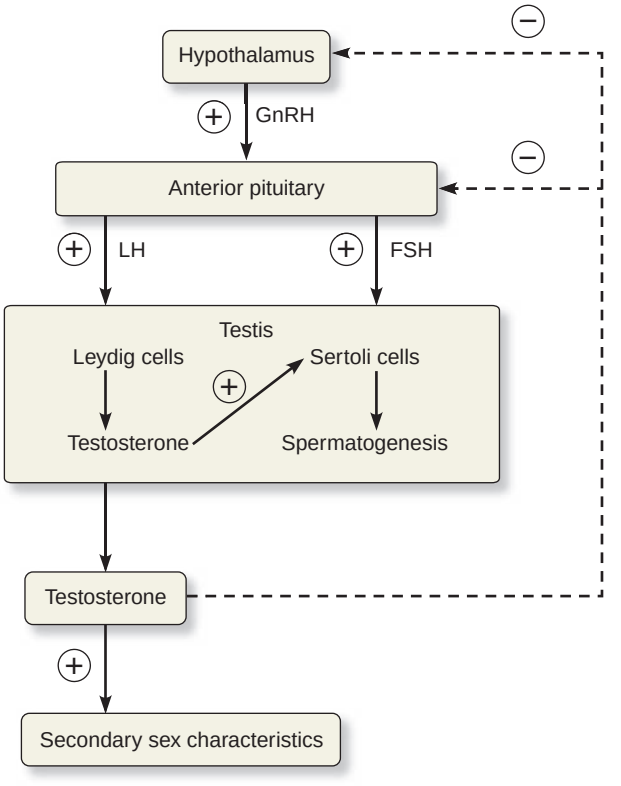

Figure 51.7 **The endocrine control of spermatogenesis.** In response to LH, Leydig cells in the testes secrete testosterone, which, along with FSH, acts on Sertoli cells to facilitate spermatogenesis. Negative signs indicate inhibitory effects via negative feedback, and plus signs indicate stimulatory effects. Not shown: Sertoli cells also secrete the protein hormone inhibin, which inhibits secretion of GnRH and FSH.

Concept check: *What would happen to spermatogenesis in a man taking testosterone to increase muscle mass or improve athletic performance?*

LH stimulates the Leydig cells of the testes to produce androgens, particularly testosterone. In turn, testosterone acts on Sertoli cells and germ cells to stimulate spermatogenesis. Testosterone also stimulates the growth of the male reproductive tract and the genitalia during development and puberty and the development of male secondary sex characteristics. In humans, these include facial hair growth, increased muscle size, and deepening of the voice. In other male mammals, they include such things as growth of the horns of a bull, enlargement of the nose of proboscis monkeys, and formation of cheek pads in some apes. Testosterone-dependent secondary sex characteristics are not unique to mammals, however. One familiar example is the bright coloration of extensive plumage in male birds such as the peacock.

The other pituitary gonadotropin, FSH, functions along with testosterone to stimulate spermatogenesis. FSH does this by stimulating the activity of the Sertoli cells within the seminiferous tubules. The Sertoli cells provide the nutritional and structural support necessary for development of the sperm. They also respond to testosterone produced by the Leydig cells, by stimulating mitosis and meiosis of the germ cells associated with them in the tubules.

Production of sperm and testosterone is kept in check by negative feedback mechanisms that control the amount of gonadotropins produced (Figure 51.7). Testosterone in high concentrations inhibits the secretion of GnRH from the hypothalamus, so both LH and FSH are inhibited when the blood concentration of testosterone is high. Testosterone also directly inhibits LH secretion by the anterior pituitary gland. In addition, when Sertoli cells are activated by FSH, they secrete a protein hormone called inhibin, which enters the blood and inhibits further secretion of GnRH and FSH. These feedback mechanisms maintain homeostatic levels of FSH and LH in the blood.

Before puberty, LH is not released in sufficient amounts to stimulate significant testicular production of testosterone, and the reproductive system is quiescent—spermatogenesis does not occur. Although the mechanisms that initiate puberty in mammals are still not completely understood, research has shown that increased GnRH production at that time initiates increased LH and FSH secretion from the pituitary. The testosterone induced by LH stimulates development of adult male characteristics. Testosterone is also responsible for an increased sex drive (libido) at this time.

The Female Reproductive Tract Is Specialized for Production and Fertilization of the Egg and Development of the Embryo

The female genitalia differentiate from the same embryonic tissues as the male genitalia. The female genitalia are composed of the larger, hair-covered outer folds called the **labia majora** (from the Latin, meaning major lips), which surround the external opening of the reproductive tract, plus the smaller, inner folds, called the **labia minora** (from the Latin, meaning minor lips; Figure 51.8). The labia majora originate from the same embryonic tissue as the scrotum of the male, whereas the labia minora originate from urethral primordial tissue. At the anterior part of the labia minora is the **clitoris**, which is erectile tissue of the same origin as the penis. Like the penis, the clitoris becomes engorged with blood during sexual arousal (as do the labia minora) and is very sensitive to sexual stimulation. Unlike males, however, the openings of the reproductive tract and the urethra are separate in females. The opening of the urethra is located between the clitoris and the opening of the reproductive tract.

In mammals alone, the external opening of the reproductive tract leads to the vagina, a tubular, smooth muscle structure into which sperm are deposited. At the end of the vagina is the **cervix**, the opening to the **uterus**, which in humans is about the size and shape of an inverted pear. Sperm pass through the cervix into the uterus, which is specialized for carrying the developing fetus. It consists of an inner lining of glandular and secretory cells, called the endometrium, and a thick muscular layer, called the myometrium. We will discuss the functions of the uterus later in the chapter.

Oocytes develop within one of the two bilateral ovaries (Figure 51.8), which are suspended within the abdominal cavity by connective tissue. In humans, each ovary is typically a little larger than an almond. Usually, one secondary oocyte leaves the ovary and is quickly drawn into a thin tube, the **oviduct** (also called the fallopian tube), by the actions of undulating fimbriae (fingers) of the oviduct that extend out to the ovary.

The secondary oocyte is moved down the length of the oviduct by cilia on the oviduct's inner surface. For fertilization to take place, sperm must travel through the cervix and uterus and then into the oviduct where fertilization typically occurs. Upon contact with a sperm, the secondary oocyte completes meiosis II, and the union of sperm and secondary oocyte creates a fertilized egg, or zygote. The zygote undergoes several cell divisions to become a **blastocyst**, a ball of approximately 32 to 150 cells that enters the uterus, where it will develop into an embryo (the details of this development are covered in Chapter 52).

Gametogenesis in Females Is a Cyclical Process Within the Ovaries

The process of oogenesis occurs within the ovaries (Figure 51.9). In contrast to spermatogenesis, which continues throughout postpubertal life in the testes in males, most female mammals appear to be born with all the primary oocytes they will ever have, although limited recent evidence in mice suggests that new oocytes may form later in life. At birth, each ovary in a human female has about 1 million primary oocytes, which are arrested in prophase of meiosis I. Most of these degenerate before the onset of puberty, when each ovary contains about 200,000 primary oocytes. Other than this degeneration, the ovaries are quiescent until puberty, when they begin to show cyclical activity.

The major estrogen produced by mammalian ovaries is **estradiol**, which plays a critical role in ovulation and influences the secondary sex characteristics of females. The secondary sex characteristics, which begin to develop at puberty, include development of breasts, widening of the pelvis (an adaptation for giving birth), and a characteristic pattern of fat deposition.

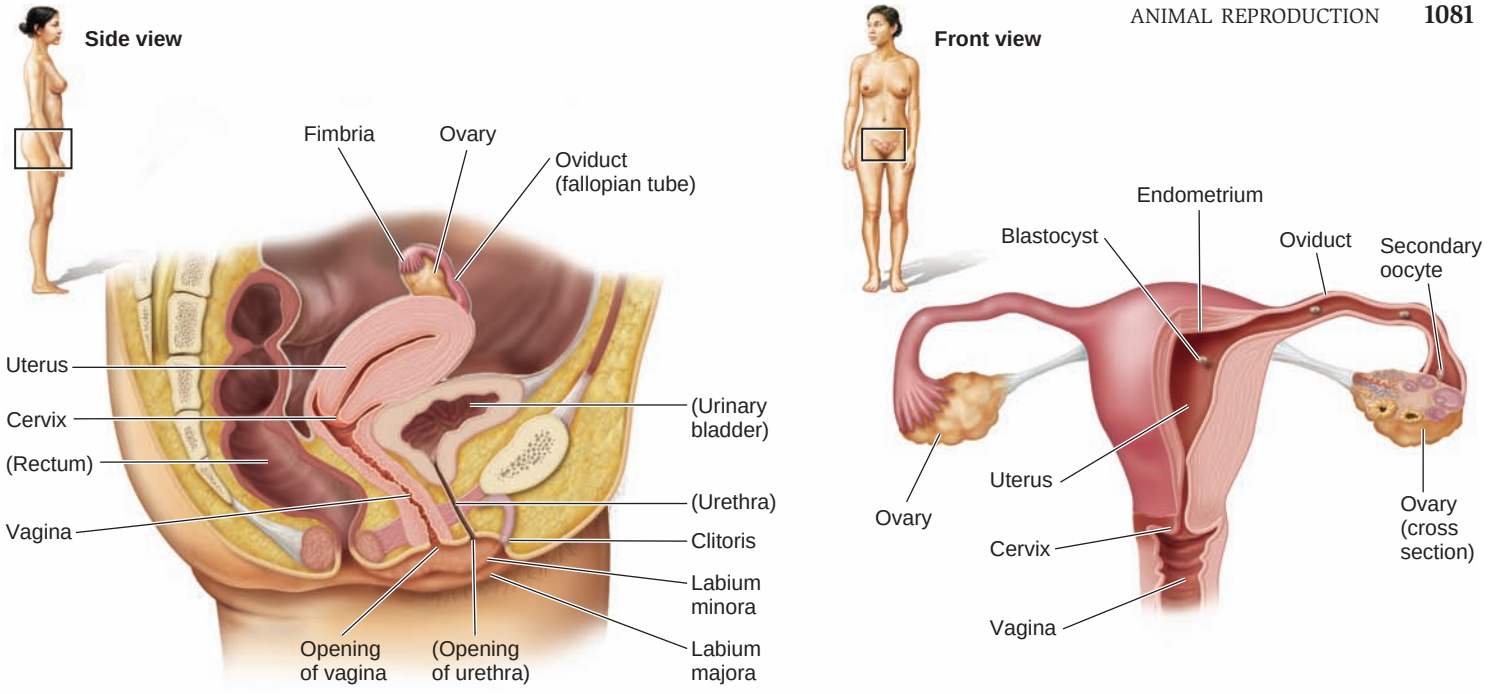

Figure 51.8 **Female reproductive structure and function in humans.** Side and front views of the female reproductive system (nonreproductive structures are identified in parentheses for orientation purposes). An oocyte moves from the ovary into the oviduct (also called the fallopian tube), where it may be fertilized and develop into a blastocyst. Subsequently, the blastocyst enters the uterus, where it may implant in the endometrium, the inner lining of the uterus.

In an adult female, the process of producing mature oocytes occurs as a cycle that may be as brief as a few days in small rodents or as lengthy as 15–16 weeks in elephants. In humans, a typical cycle lasts approximately 28 days, during which time several oocytes in each ovary begin to mature. However, all but one of these oocytes usually degenerates, and only a single secondary oocyte fully matures and gets released (ovulated) from the ovary each cycle. Thus, only 300 to 500 secondary oocytes are ovulated over a woman's 30- to 40-year reproductive lifetime.

Ovulation and degeneration of additional primary oocytes continue throughout adulthood. Eventually, the oocytes become nearly depleted, and a woman stops having ovarian cycles, an event called **menopause**. The average onset of menopause in the U.S. is approximately 51 years of age. After menopause, a woman is no longer capable of becoming pregnant. Until 1900, the average life expectancy of a woman in the U.S. was no higher than 47 years; therefore, menopause was once much less common than it is today. At one time, scientists thought menopause was unique to humans, but it now appears that other female mammals, if they survive long enough, also become incapable of ovulation at some point.

The **ovarian cycle** involves the development of an ovarian follicle, the release of a secondary oocyte, and the formation and subsequent regression of a corpus luteum (Figure 51.9). During the first week of the ovarian cycle in humans, several primary oocytes begin to mature, each within a follicle. At the beginning of the second week, all but one of the growing follicles and its primary oocyte degenerate, and the single remaining follicle continues to develop and enlarge. During that time, the primary oocyte of that follicle completes meiosis I, becomes a secondary oocyte, and begins meiosis II. The developing

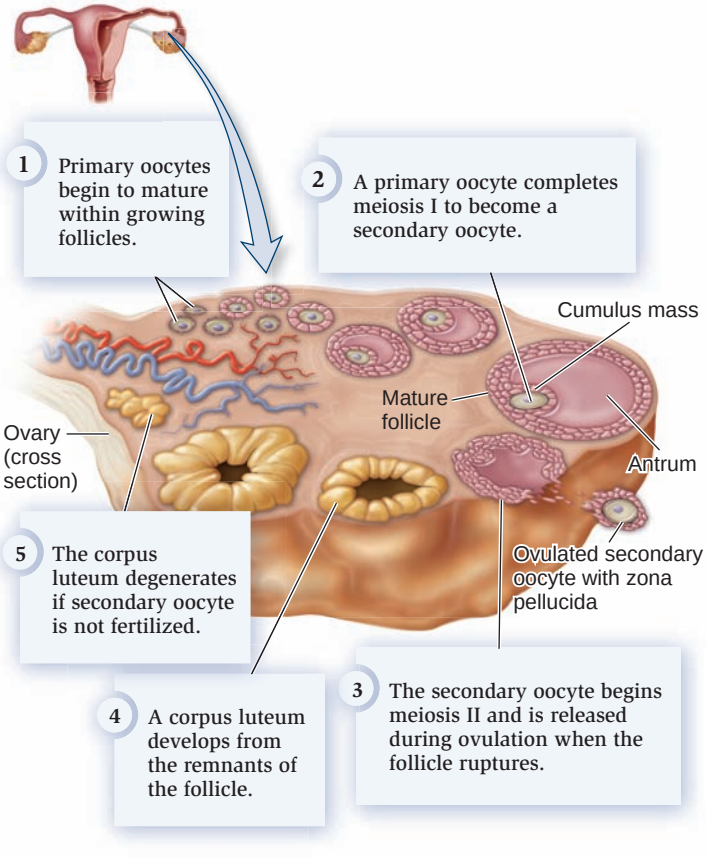

Figure 51.9 **Follicle and oocyte development.** Development of an oocyte and corpus luteum within the ovary, illustrating the events that occur during a single ovarian cycle.

secondary oocyte is surrounded by cells of the cumulus mass, which both protect and nurture it and which secrete estradiol. The estradiol is secreted into the blood, where it functions to control the secretion of LH and FSH from the anterior pituitary gland. Some estradiol is also secreted into the follicle, where it stimulates fluid secretion into the inner core of the follicle, called the antrum. As the follicle grows in response to continued stimulation by LH and FSH, the fluid pressure inside the antrum increases, until the follicle begins to form a bulge. Eventually, ovulation occurs as the follicle ruptures, and the secondary oocyte, zona pellucida, and some surrounding supportive cells of the cumulus mass are released from the ovary.

Cells in the empty follicle subsequently proliferate and develop into a structure called the **corpus luteum**. In humans, the corpus luteum is active for approximately the second half of the ovarian cycle. It is responsible for secreting hormones that stimulate the development of the uterus needed for sustaining the embryo in the event of a pregnancy. If pregnancy does not occur, the corpus luteum degenerates, and a new group of follicles with their primary oocytes develops.

The Ovarian Cycle Results from Changes in Hormone Secretion

We saw that in males, testosterone produced in the testes exerts a negative feedback on secretion of GnRH and LH. In females, however, the situation is more complicated. Although GnRH also stimulates release of LH and FSH, the resulting estradiol can have both negative and positive feedback effects on the gonadotropic hormones. To understand this, let's examine hormone changes during the ovarian cycle in a human female (Figure 51.10).

The first half of the ovarian cycle is called the follicular phase of the cycle, because this is when the growth and differentiation of the follicles are occurring. The relatively low level of LH that exists during follicular development stimulates the cells of the follicle to make estradiol. The estradiol that is produced is important for enlargement and growth of the oocytes and it also is secreted into the blood, where it can influence the secretion of LH and FSH.

As the follicles develop, estradiol (and to a lesser extent, another steroid hormone called progesterone) production continues, and consequently, the level of estradiol in the blood slowly but steadily increases. Initially, estradiol exerts a negative feedback action on LH and FSH secretion, inducing death of all but the largest of follicles. When the follicle is fully developed and ready for ovulation, its production of estradiol increases, such that the blood concentration of estradiol increases sharply. At that time, the feedback action of estradiol on LH and FSH switches from negative to positive, by mechanisms that are still being investigated but involve increased GnRH secretion from the hypothalamus. This results in a sudden, sharp surge in gonadotropin levels in the blood, particularly LH.

The LH released from the pituitary as a result of positive feedback by estradiol induces rupture of the follicle and ovulation. This type of ovulation is known as spontaneous ovulation,

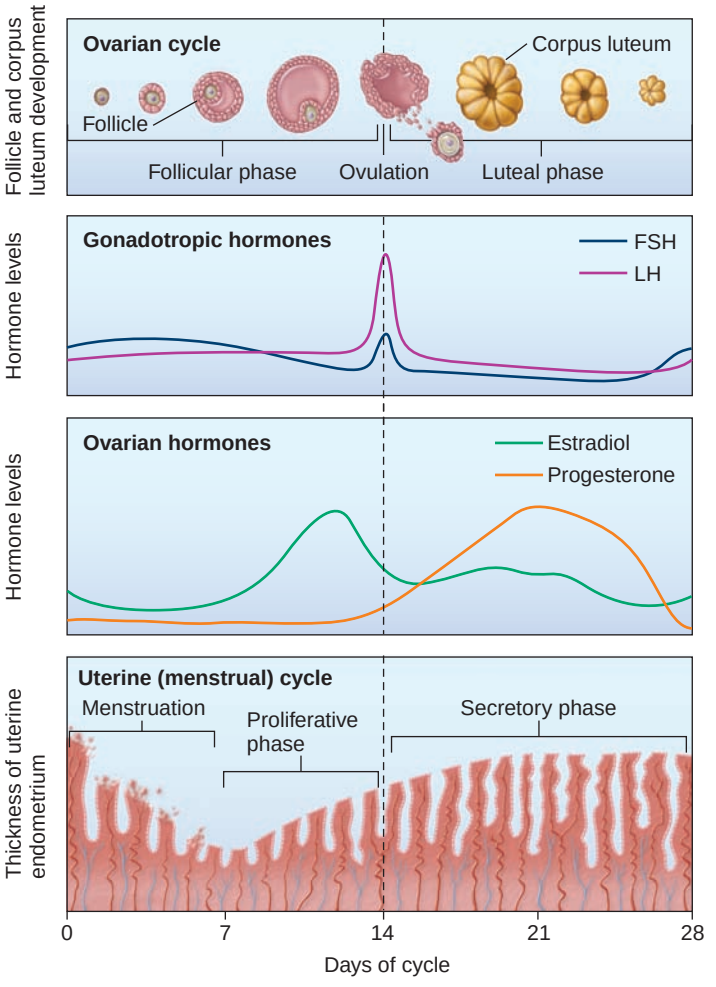

Figure 51.10 The ovarian and uterine cycles in a human female. The ovarian cycle is divided into the follicular and luteal phases. The uterine cycle is divided into menstruation and the proliferative and secretory phases.

Concept check: Would similar surges in the levels of FSH and LH be expected to occur in human males?

because it happens regularly on a cyclical basis without requiring any external stimulus. Some mammals, including rabbits, cats, and camels, undergo ovarian cycles that turn off unless mating occurs. If mating occurs at a time in the ovarian cycle when oocytes are ready, the mating act itself triggers ovulation. This mechanism, called induced ovulation, helps ensure that oocytes are not wasted by being ovulated when the female has not mated with a male.

Ovulation marks the end of the follicular phase and the beginning of the luteal phase of the ovarian cycle, named after the corpus luteum. Estradiol production decreases, and the continuing high LH level initiates development of the corpus luteum. The corpus luteum secretes progesterone, the dominant ovarian hormone of the luteal phase, plus some estradiol. Progesterone inhibits LH and FSH secretion, and it further prepares the uterus for receiving and nourishing the embryo. If fertilization of the secondary oocyte does not occur, the corpus luteum degenerates after 2 weeks, allowing LH and FSH to initiate development of a new set of oocytes. However, if fertilization does occur, the blastocyst develops a surrounding layer of

cells that secrete an LH-like hormone, called **chorionic gonadotropin**, which maintains the corpus luteum and its ability to secrete progesterone. Chorionic gonadotropin is the hormone that is tested for by home pregnancy tests.

Maternal Hormones Prepare the Uterus to Accept the Embryo

In humans, the ovarian cycle occurs in parallel with changes in the lining of the uterus called the **uterine cycle**, or **menstrual cycle**. The hormones produced by the ovarian follicle influence the development of the endometrium, the glandular inner layer of the uterus. As depicted at the bottom left of Figure 51.10, a period of bleeding called **menstruation** (from the Latin *mensis*, meaning month) marks the beginning of the uterine cycle and the follicular phase of the ovarian cycle. During menstruation, a portion of the well-developed uterine wall, including the blood vessels that grew during the previous cycle, is sloughed off and released from the body.

Menstrual cycles are found in many primates, including humans. Other mammals also have uterine cycles but without the bleeding associated with menstruation. These cycles are called estrous cycles and are usually associated with a period of sexual receptivity in females that is timed to coincide with the preovulatory period. Cyclical changes in female sexual receptivity may be present in some primates with menstrual cycles but have never been documented to occur in humans.

By about the end of the first week of the menstrual cycle in humans, the endometrium is ready to grow again in response to the newly increasing level of estrogen secreted by a developing follicle. This phase of the menstrual cycle, which corresponds to the latter part of the ovarian follicular phase, is called the proliferative phase (Figure 51.10). During this time, the endometrium becomes thicker and more vascularized. During the subsequent luteal phase of the ovarian cycle, progesterone from the corpus luteum initiates further endometrial growth, including the development of glands that secrete nutritive substances that sustain the embryo during its first 2 weeks in the uterus. This part of the menstrual cycle is called the secretory phase. If fertilization does not occur, degeneration of the corpus luteum and the associated decrease in progesterone and estrogen levels initiate menstruation and the beginning of the next uterine cycle. If fertilization does occur, however, and the blastocyst becomes embedded in the endometrium, pregnancy begins, as described in the next section.

51.4 Pregnancy and Birth in Mammals

Pregnancy, or gestation, is the time during which a developing embryo and fetus grows within the uterus of the mother. Physiologically, pregnancy is considered to begin not at fertilization but when the embryo is established in the uterine lining. This occurs within days of fertilization in animals with short gestation lengths but may take weeks in large animals with long gestations.

In mammals, gestation length varies widely and is roughly related to the size of adults in a particular species. Small animals such as hamsters and mice have gestation periods of 16–21 days, canines have longer pregnancies of about 60–65 days, humans average about 268 days, and the Asian elephant carries its fetus up to 660 days. The advantages of prolonging prenatal development are twofold: The embryo is protected while it is developing in the uterus, and the offspring can be more fully developed at birth. This is especially important for animals whose survival depends on mobility shortly after birth, such as horses and ruminants.

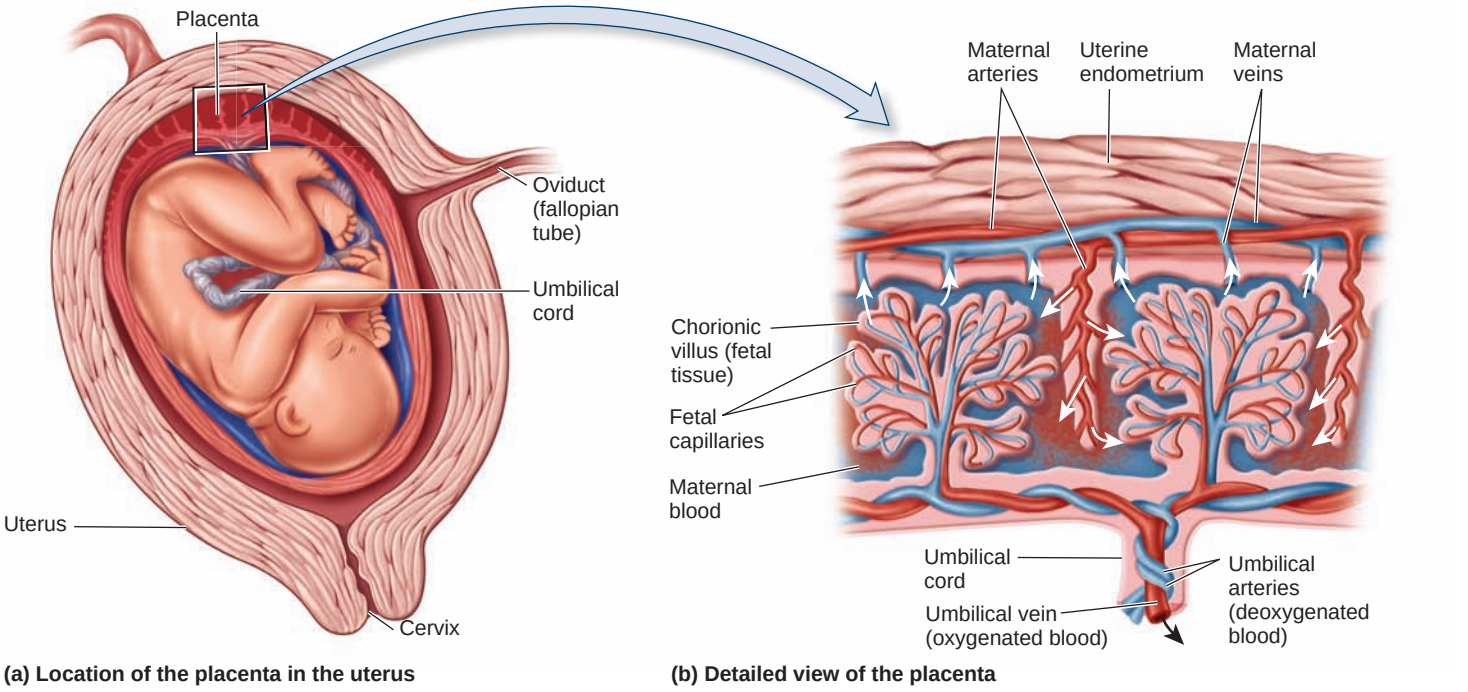
Gestation length is influenced not only by adult body size but also by the number of offspring in a single pregnancy. Rats, for example, which bear up to 12 or so offspring per litter, have a short gestation period and produce young that are relatively undeveloped at birth and are totally dependent on the mother. Horses, by contrast, have a long gestation period and typically give birth to a single, highly developed offspring. In this section, we will examine how mammals have evolved to retain their young in the uterus for extended periods, the structure and function of the nourishing placenta, and the role of hormones in pregnancy and birth.

Most Mammals Retain Their Young in the Uterus and Nourish Them via a Placenta

Three types of pregnancies are found in mammals, which correspond to the three subclasses of mammals (see Chapter 34). Monotremes or prototherians, such as the platypus, are the only mammals that lay fertilized eggs. In marsupials or metatherians such as the kangaroo, the young are born while still extremely undeveloped. They then crawl up the mother's abdomen to her pouch, where they attach to a nipple to suckle and obtain nourishment. They mature within the pouch. Compared to marsupials, humans and other eutherian mammals retain their young within the uterus for a longer period of time, and nourish them via transfer of nutrients and gases through a structure called the **placenta**.

During pregnancy, many physiological changes occur in both the embryo and the mother. The first event of pregnancy in eutherian (placental) mammals is **implantation**, when the blastocyst embeds within the uterine endometrium, which occurs in humans within 1–2 weeks, typically around 8–10 days after fertilization. Initially, the implanted blastocyst receives nutrients directly from the endometrial glands. However, shortly after implantation, newly developing embryonic tissues merge with the endometrium to form the placenta (Figure 51.11), which remains in place and grows larger as the embryo matures into a **fetus**. (In humans, an embryo is called a fetus after the eighth week of gestation.) The placenta, therefore, has a maternal portion and a fetal portion.

The placenta is rich in blood vessels from both the mother and the fetus. The maternal and fetal sets of vessels lie in close proximity. The fetal portion of the placenta, called the chorion, contains convoluted structures called chorionic villi that provide a large surface area containing capillaries for exchange of



(a) Location of the placenta in the uterus **(b) Detailed view of the placenta**

Figure 51.11 **The structure of the placenta.** In all mammals, the placenta is composed of both fetal and maternal tissues. **(a)** Overview of placental structure in the human. **(b)** Enlarged view of the placenta showing the relationship between fetal and maternal structures. Note that in humans, blood in the fetal and maternal circulations does not mix.

Concept check: *Note that the umbilical arteries are shown in blue to signify that they carry deoxygenated blood, and the umbilical vein is shown in red to signify it carries oxygenated blood. Normally, arteries carry oxygenated blood, and veins carry deoxygenated blood, except in the pulmonary circulation (see Chapter 48). Why is the circulation through the placenta like that of the lungs?*

nutrients, gases, and other solutes. Nutrients and oxygen from the mother are carried through maternal arteries, where her blood pools in large areas of the fetal placenta surrounding the fetal capillaries. Solutes diffuse from the maternal blood into fetal capillaries, and from there flow into the umbilical vein, a portion of the fetal circulation. In turn, carbon dioxide and other waste products from the fetus are carried through the umbilical artery to the placenta, where they diffuse into the mother's circulation, from which they can be excreted. Because of this placental organization, the blood of the mother and the fetus do not mix together.

Prenatal development in humans is generally divided into three trimesters, each of which lasts about 3 months (Figure 51.12). During the first 2 months of pregnancy, the organs of

(a) First-trimester human embryo (6 weeks) **(b) Second-trimester human fetus (16 weeks)** **(c) Early third-trimester human fetus (24 weeks)**

Figure 51.12 Prenatal development in humans.

the embryo develop. At the end of the first trimester, the rudiments of the organs are present, and the developing fetus is about an inch long. The second trimester is an extremely rapid phase of growth. During the third trimester, the lungs of the fetus mature so that they are ready to function as gas-exchange organs.

Genomes & Proteomes Connection

The Evolution of the Globin Gene Family Has Been Important for Internal Gestation in Mammals

As discussed in Chapter 21, genes can become duplicated to create gene families. Gene families have been important in the evolution of complex traits because the various members of a gene family can enable the expression of complex, specialized forms and functions.

An interesting example is the globin gene family in animals. Globin genes encode polypeptides that are subunits of proteins that function in oxygen binding. Hemoglobin, which is made in erythrocytes, carries oxygen throughout the body in all vertebrates and many invertebrates, delivering oxygen to all of the body's cells. In humans, the globin gene family is composed of several homologous genes that were originally derived from a single ancestral globin gene (refer back to Figure 21.8).

All of the globin polypeptides are subunits of proteins that play a role in oxygen binding, but the various family members tend to have specialized functions. For example, certain globin genes are expressed only during particular stages of embryonic development. This has particular importance in placental mammals, because the oxygen demands of a growing embryo and fetus are quite different from the demands of its mother. These different demands are met by the differential expression of hemoglobin genes during prenatal development.

The hemoglobin protein of adult mammals is composed of four globin polypeptides—two encoded by the α-globin gene and two encoded by the β-globin gene. Altogether, five globin genes, designated α, β, γ, ε, and ζ, encode the major subunits that are found in hemoglobin proteins at different developmental stages. During embryonic development, the ε-globin and ζ-globin genes are turned on, resulting in embryonic hemoglobin with a very high affinity for oxygen (Table 51.1). At the fetal stage, these genes are turned off, and the α-globin and γ-globin genes are turned on, producing fetal hemoglobin with slightly less (but still high) affinity for oxygen. Finally, just before birth, expression of the γ-globin gene decreases, and the β-globin gene is turned on, resulting in adult hemoglobin, which has a lower affinity for oxygen than either the embryonic or fetal forms. The higher affinities of embryonic and fetal hemoglobins enable the embryo and fetus to remove oxygen from the mother's bloodstream and use that oxygen to meet their own metabolic demands. Therefore, the expression of different globin genes at particular stages of development enables placental mammals to develop in the uterus without either breathing on their own or being continually exposed to atmospheric oxygen (as occurs for vertebrate embryos that develop externally within eggs).

Table 51.1 Globin Gene Expression During Mammalian Development

Stage of development	Globin genes expressed	Hemoglobin composition	Oxygen affinity (P_{50})*
Embryo	ε-globin and ζ-globin	Two ε-globin and two ζ-globin subunits	5–13.5 mmHg
Fetus	γ-globin and α-globin	Two γ-globin and two α-globin subunits	19.5 mmHg
Birth to adult	β-globin and α-globin	Two β-globin and two α-globin subunits	26.5 mmHg

*P_{50} values represent the partial pressure of oxygen required to half-saturate hemoglobin (see Chapter 48): A lower P_{50} indicates a higher affinity of hemoglobin for oxygen. The value for embryos is an estimate based on in vitro experiments. All values are for human hemoglobins.

Birth Is Dependent on Hormones That Elicit a Positive Feedback Loop

Birth—also called **parturition**—is initiated by the actions of several hormones and other factors secreted by the mother and the placenta (Figure 51.13). In humans and many other mammals, the placenta begins to secrete large amounts of estrogens such as estradiol into the maternal circulation toward the end of the third trimester of pregnancy. Estrogens have at least two major effects on uterine tissue at this time. First, they promote gap junction formation between uterine smooth muscle cells, which enables coordinated uterine contractions. Second, estrogens enhance uterine sensitivity to oxytocin.

Recall from Chapter 50 that oxytocin is a posterior pituitary gland hormone that stimulates contraction of uterine muscle. The high level of estradiol in the mother's blood near the end of pregnancy stimulates the production of oxytocin receptors within the cells of the smooth muscle layer of the uterus, making the uterus more sensitive to oxytocin. At the same time, the fetus usually positions itself with its head above the uterine cervix in preparation for birth. The pressure of the fetus's head pressing on the cervix stretches the smooth muscle of the uterus and cervix. This stretch is detected by neurons in these structures. Signals from the stretch-sensitive neurons are sent to the mother's hypothalamus, triggering the release of still more oxytocin from the posterior pituitary gland.

Binding of oxytocin to its receptors initiates the strong uterine muscle contractions that are the hallmark of **labor**. In addition to its direct action on uterine muscle, oxytocin stimulates uterine secretion of prostaglandins that act with oxytocin to increase the strength of the muscle contractions. The stronger contractions elicit more oxytocin release from the mother's

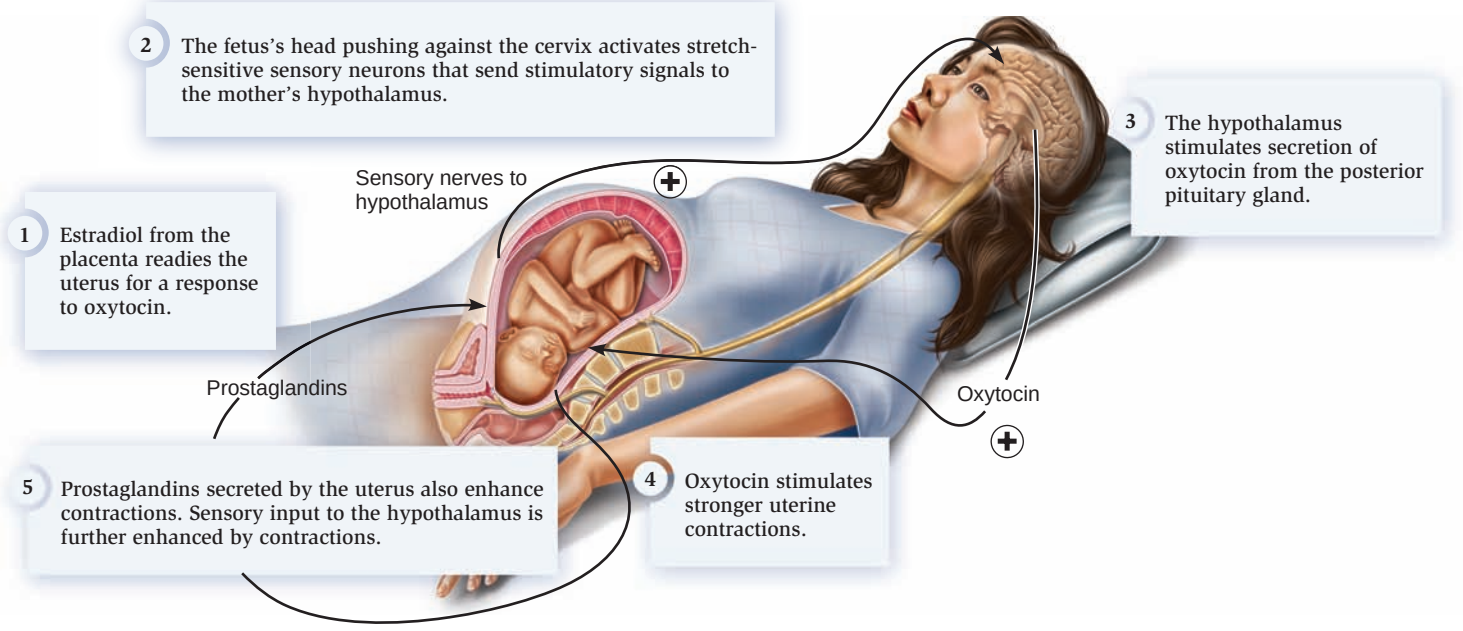


Figure 51.13 **Hormonal control of parturition.** Birth relies on maternal hormones that act on the uterus, and neural signals from the uterus. In response to sensory neural input arising from the push of the fetus on the cervix, the maternal posterior pituitary gland releases oxytocin, which stimulates uterine smooth muscle contractions. The secretion of prostaglandins by the uterus also increases the strength of the contractions. Sensory receptors in the uterus detect the more forceful contractions and signal the mother's posterior pituitary gland to secrete more oxytocin, thus completing a positive feedback loop that further strengthens the contractions.

pituitary, which causes yet stronger contractions, setting up a positive feedback loop that continues until the baby is born.

Labor occurs in three stages (Figure 51.14). The initial stage induces dilation and thinning of the cervix to allow passage of the fetus out of the uterus. As the uterine contractions get stronger and more frequent toward the end of labor, the fetus is pushed, usually headfirst, through the cervix and the vagina and out into the world; this is the second stage of labor. In the third and final stage, the contractions continue for a short while. Blood vessels within the placenta and umbilical cord contract and block further blood flow, making the newborn independent from the mother. The placenta detaches from the uterine wall and is delivered a few minutes after the birth of the baby.

In mammals, the young are nurtured for a period after birth by milk produced within the mother's mammary glands and secreted via the nipples. The monotremes, in which the young of some species use their pliable bills to attach to the breast of the mother and draw milk directly through the skin, are an exception. The production of milk is called **lactation**. During pregnancy, an elevated blood progesterone level suppresses the secretion of the anterior pituitary hormone prolactin, which is required for milk production. In humans, lactation begins shortly after birth in response to a declining blood concentration of progesterone previously provided by the placenta. Whereas the formation of milk is dependent on prolactin, the actual release of milk from the breast is dependent on activation of smooth muscle cells surrounding secretory ducts in the breast. These cells are stimulated to contract by the presence of oxytocin. Oxytocin, therefore, plays a key role in two major processes, birth and nourishment of the young.

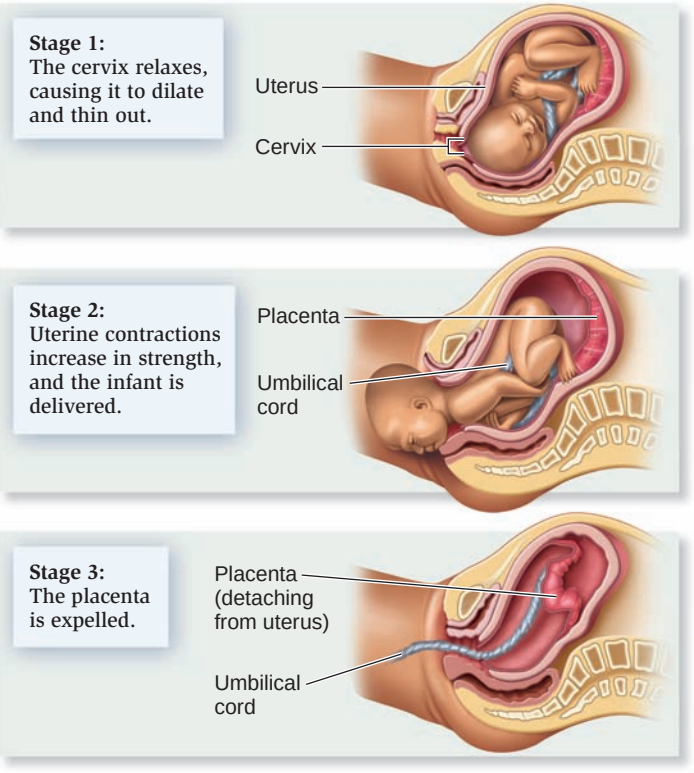

Figure 51.14 **The three stages of labor.**

Concept check: *Many female mammals consume the placenta after giving birth. What is the benefit of this?*

51.5 Timing of Reproduction with Favorable Times of Year

A species' survival depends on successful production of offspring, and the likelihood that those offspring will survive to adulthood and reproduce is influenced to a large degree by the environment into which they are born. For that reason, reproductive cycles often occur at times of the year when the likelihood of reproductive success is greatest—when the young will have sufficient nutrients to sustain them during their period of rapid growth. In general, animals that live under more uniformly favorable conditions—stable temperatures, ample rainfall, and abundant food—have less dramatic cycles of reproductive activity. Many tropical species, for example, reproduce several times each year. By contrast, many temperate zone animals have seasonal reproductive cycles that reflect large fluctuations in environmental conditions. For example, insects such as the mayfly live as underwater larvae for a year before emerging into the adult (reproductively active) stage, but the emergence occurs only during the favorable summer months.

Animals synchronize the production of offspring with favorable environmental conditions by several means. In **sperm storage**, females store and nourish sperm in their reproductive tract for long periods of time, as long as 2 years in honeybees and 4 years in some turtles. Certain insectivorous bats such as *Myotis lucifugus* use a different strategy. These bats mate in the fall, but the ovarian cycle in females is halted before ovulation, and sperm are stored and nourished in the female's uterus over the winter. Upon arousal from hibernation in the spring, the female ovulates one or more oocytes, which are fertilized by the stored sperm. This type of reproductive cycle, called **delayed ovulation**, ensures that such bats mate when they are in prime condition and that young are born when temperatures and food supplies are optimal.

Other animals have **delayed implantation**, in which a fertilized egg reaches the uterus but does not implant until environmental conditions are more favorable for the newly produced young. This type of reproduction is common among carnivores, notably the mustelids (weasels) and some bears.

Finally, many animals (cats, some hamsters, sheep, and many birds) have seasonal periods of mating followed immediately by implantation and pregnancy. Such seasonal breeding results from neuroendocrine changes in the hypothalamus in response to changes in the length of daylight. In some seasonal breeders with short gestation periods, such as hamsters, these neuroendocrine changes occur when day length increases in spring. The young are born in the late spring or in summer when conditions are favorable. Other seasonal breeders with long gestation times—sheep, for example—reproduce in response to shorter day length. Ewes are impregnated by rams in the fall, as the days grow shorter, and they carry the pregnancy through the winter. Lambs are born in the spring, providing a relatively long growth period before onset of the next winter. If sheep were to mate in summer, lambs would be born in late fall or winter, when conditions are much less favorable.

Unlike the examples just described, humans neither have a seasonal breeding cycle nor alter the timing of implantation or ovulation. Moreover, sperm can survive in a woman's reproductive tract for only a short time—2 or 3 days. Human reproduction, therefore, is far less responsive to environmental changes, day length, or other factors. However, human reproductive success can be seriously curtailed by sickness and other factors, as we see next.

51.6 Impact on Public Health

Human reproduction can be affected by many factors, some voluntary and some not. Approximately 5–10% of U.S. adults are not fertile; that is, they cannot reproduce. In men and women alike, fertility can be compromised by a variety of factors. In this section, we discuss some of the common causes of **infertility**—the inability of a man to produce sufficient numbers or quality of sperm to impregnate a woman, or the inability of a woman to become pregnant or maintain a pregnancy. We then conclude by examining the methods in use today to prevent pregnancy in fertile women.

Infertility May Result from Disease, Developmental Disorders, Inadequate Nutrition, and Stress

As many as 75% of infertility cases have some identifiable cause, and among the more prominent causes is disease. Primary among the diseases that affect fertility are sexually transmitted diseases (STDs). For example, some STDs may cause blockage in the ducts of the testes, preventing normal sperm transport.

Developmental disorders are conditions that are either present at birth or arise during childhood and adolescence. In some developmental disorders that affect fertility, inherited mutations of genes that code for enzymes involved in the biosynthesis of reproductive hormones cause abnormal expression of those genes. The result is either too much or too little of one or more of these hormones, notably estradiol or testosterone. Other developmental disorders that compromise fertility include malformations of the cervix or oviducts.

Adequate nutrition is required for normal growth and development of all parts of the body, including the reproductive system. Because the reproductive system is not essential for an individual's survival, it often becomes inactive when nutrients are chronically scarce, such as during starvation. In this way, precious stores of energy in the body are preserved for vital functions, such as the operation of the brain and heart.

Nutrition can also affect reproduction before adulthood. Undernourished children may enter puberty several years later than normal. The brains of mammals contain a center that monitors the body's fat stores. One of the triggers that initiate puberty in girls may be a signal—such as the hormone leptin—from adipose tissue to the brain. Very low fat stores in undernourished girls signal the brain that the body does not contain sufficient fuel to support the energetic demands of pregnancy; consequently, puberty is delayed.

Starvation or poor nutrition is considered a type of stress, defined as any real or perceived threat to an animal's homeostasis. Physical and psychological stress can and do affect fertility in humans. In the short term, stress can produce hormonal changes that are adaptive in meeting a crisis. However, long-term stress is damaging to many aspects of health, including reproductive health. Many nonessential functions—including the maintenance of menstrual cycles in women—are suppressed by chronic stress. The reproductive consequences of stress, including starvation, appear to be much greater in females than in males, perhaps because only females bear the energetic cost of pregnancy. Interestingly, the human body responds to long-term strenuous exercise in a way that is similar to its response to long-term stress. This is why many young ballerinas and gymnasts experience delayed puberty and why in female marathon runners, menstrual cycles may be abnormal or absent.

When the causes of infertility cannot be determined, a variety of factors come under suspicion. Among these possible causes are ingestion of toxins (for example, certain heavy metals such as cadmium), tobacco smoking, marijuana use, injuries to the gonads, and aging. Recall that as women age, they experience a loss of fertility, an event called menopause. Although reproductive function declines with age in men, they do not experience complete cessation of gamete production even at very advanced ages.

Among several currently available treatments for increasing the likelihood of pregnancy in infertile couples are hormone therapy for the woman to increase egg production and a collection of procedures known as assisted reproductive technologies (ART). In the most common ART procedure, called in vitro fertilization, sperm and eggs collected from a man and a woman are placed together in culture dishes. Once the sperm have fertilized the eggs, and the resulting zygotes have undergone several cell divisions, one or more embryos are inserted into a woman's uterus in the hope that one will implant. When this procedure was first used in 1978, the children born as a result came to be known as "test-tube babies." Since then, over 200,000 children have been born using this technology, which is typically effective about 30–35% of the time.

We turn now to a discussion of the other side of fertility issues—namely, the ways in which pregnancy is prevented.

Contraception Usually Prevents Pregnancy

The voluntary use of procedures to suppress fertility is commonly termed birth control. The use of such procedures to prevent fertilization or the implantation of a fertilized egg is termed **contraception**. By contrast, procedures or circumstances that cause the death of an embryo or fetus after implantation produce an **abortion**. Abortions can occur either spontaneously—usually when the embryo is in some way defective—or they can be induced by substances or surgical procedures. A substance that induces an abortion is called an abortifacient.

Methods of contraception can be either permanent or temporary. The permanent forms of contraception surgically prevent the transport of gametes through the reproductive tract (Figure 51.15a). **Vasectomy** is a surgical procedure in men that severs the vas deferens, thereby preventing the release of sperm at ejaculation (however, semen is still released). In women, **tubal ligation** involves the cutting and sealing of the oviducts. This procedure prevents the movement of the egg from the oviduct into the uterus. These procedures are considered permanent, because it is difficult—sometimes impossible—to reverse the surgery.

Temporary methods of preventing fertilization can be barrier methods, which prevent sperm from reaching an egg (Figure 51.15b). Barrier methods include **vaginal diaphragms**, which are placed in the upper part of the vagina just prior to intercourse and block movement of sperm to the cervix, and **condoms**, which are sheathlike membranes worn over the penis that collect the ejaculate. In addition to their contraceptive function, condoms significantly reduce the risk of STDs such as HIV infection, syphilis, gonorrhea, chlamydia, and herpes. Other types of contraception do not reduce this risk.

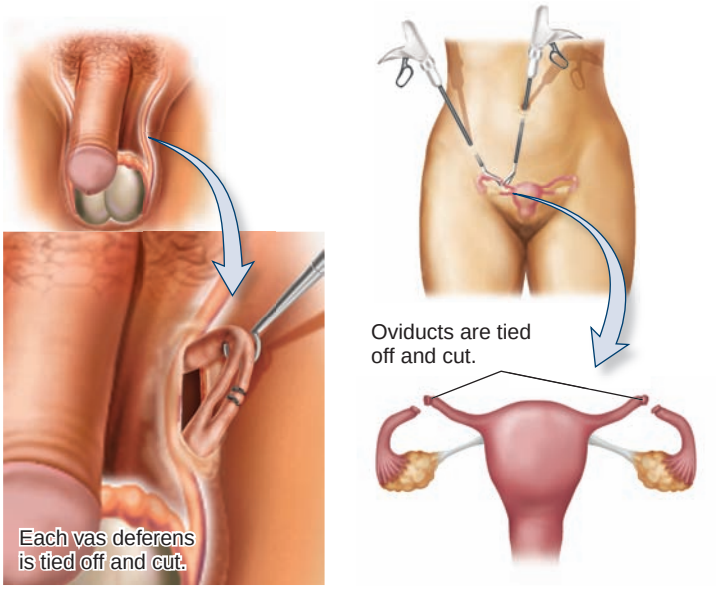
Another temporary form of contraception involves synthetic hormones. Oral contraceptives (birth control pills) are synthetic forms of estradiol and progesterone, taken by mouth, that prevent ovulation in women by inhibiting pituitary LH and FSH release. The hormones in these pills also affect the composition of cervical mucus such that sperm cannot easily pass through it into the uterus. In addition to the oral route, hormones can be administered by injections and skin patches.

Although no chemical contraceptive agents are widely used by males, a recent experimental formulation of testosterone and progesterone given by injection has proven effective in suppressing sperm production in men. In another approach, American researcher Michael O'Rand and colleagues demonstrated in 2004 that long-term administration of antibodies against a protein expressed specifically in the testis and epididymis of male primates completely suppressed fertility in 100% of the monkeys tested. Whether or not this novel approach to controlling fertility will be effective in humans remains to be determined.

A final temporary method of contraception involves placement in the uterus of an **intrauterine device** (**IUD**), a small object that interferes with the endometrial preparation required for acceptance of the blastocyst. Unlike the other forms of contraception described here, an IUD works after fertilization—by preventing implantation (although some IUDs also inhibit sperm movement and survival in the uterus). Although not as widely used as other contraceptives in the U.S., IUDs are the most commonly used means of contraception by women worldwide because of their effectiveness and simplicity of use.

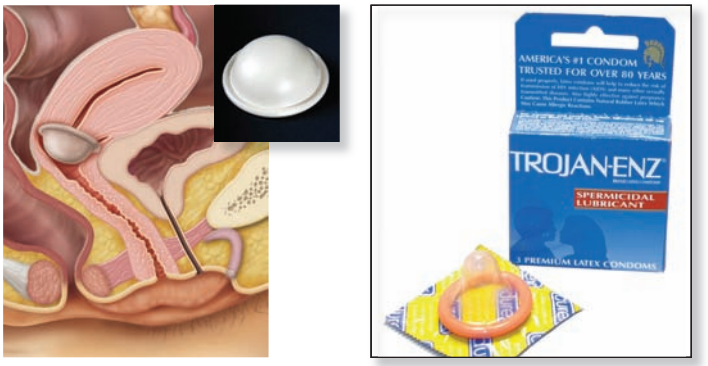
In addition to the contraceptive methods used before or during intercourse, within 72 hours after intercourse, women can take a variety of drugs that typically interfere with ovulation or implantation. Approaches include a high dose of estrogen, or two large doses (12 hours apart) of a combined estrogen-progestin oral contraceptive. However, the drug RU486 (mifepristone) is more effective and produces fewer side effects; this drug antagonizes progesterone's effects on the endometrium, causing it to erode. RU486 can also be used as an abortifacient if pregnancy has occurred.

Used prior to the advent of modern contraception, and still in use today by individuals who prefer not to use contraceptives,



Vasectomy (<1.0%)
(a) Permanent methods

Tubal ligation (<1.0%)



Diaphragm (5–20%)

Condoms (male) (2–15%)

Oral contraceptive (1–2%)
(b) Temporary methods

Intrauterine device (IUD) (1–2%)

Figure 51.15 **Examples of contraceptive methods.** These methods may be used by men or women to **(a)** permanently or **(b)** temporarily prevent pregnancy. The estimated first year failure rates for each method are given in parentheses (collected from data published by the U.S. Food and Drug Administration and other organizations). A failure rate of 10% means that 10 of every 100 women using that method of contraception will become pregnant in the first year of use. The large range for use of condoms and diaphragms is due to improper use of these devices by many people. Female condoms are also available and have a failure rate of approximately 20%.

is the rhythm method, which involves abstaining from sexual intercourse near the time of ovulation. Its main drawback is the difficulty in precisely pinpointing the time of ovulation, even using laboratory techniques. One problem with predicting the time of ovulation is that several of the detectable changes characteristic of the midpoint of the ovarian cycle—including a small rise in body temperature and changes in the cellular characteristics of the vaginal epithelium—occur only after ovulation. This problem, plus the fact that ovulation can occur any time between days 5 and 15 of the 28-day cycle, explains why the rhythm method has a relatively high failure rate.

Summary of Key Concepts

51.1 Asexual and Sexual Reproduction

- Asexual reproduction occurs when offspring are produced from a single parent, without the fusion of genetic material from two parents. Budding occurs when part of the parent organism pinches off to form a complete new individual. Some animals reproduce by the regeneration of a complete organism from small body fragments. Parthenogenesis is the development of offspring from an unfertilized egg. (Figure 51.1)
- Sexual reproduction is the production of a new individual by the joining of two haploid gametes: a sperm from the father and an egg from the mother. The union of a sperm and an egg—fertilization—produces a diploid zygote, which develops into an embryo.
- Sexual reproduction was shown by Paland and Lynch to be more effective in eliminating deleterious mutations from a population of *Daphnia* than asexual reproduction. (Figure 51.2)

51.2 Gametogenesis and Fertilization

- Male and female gametes are formed within the gonads—the testes in males and the ovaries in females.
- Gametogenesis—the formation of gametes—begins with diploid primordial cells called germ cells. In spermatogenesis, one spermatogonium becomes a primary spermatocyte. This gives rise by meiosis to two haploid secondary spermatocytes, which yield four spermatids that mature into four sperm cells. In oogenesis, one oogonium becomes a primary oocyte. This produces by meiosis a haploid secondary oocyte that can yield a fertilized egg. (Figure 51.3)
- At the tip of a sperm's head is a special structure called the acrosome, which contains proteolytic enzymes that help break down the outer layers of the secondary oocyte.
- Within the ovaries, each oocyte undergoes growth and development within a structure called a follicle before it leaves the ovary in a process called ovulation.
- In external fertilization, sperm and eggs are released into an aquatic environment where they unite and avoid desiccation. (Figure 51.4)
- Terrestrial animals use internal fertilization, in which sperm are deposited within the reproductive tract of the female during the act called copulation.
- External accessory sex organs, such as the penis, physically join the male and female during copulation so that sperm can be deposited directly into the female's reproductive tract.

- In hermaphroditism, individuals can fertilize their own eggs with their own sperm, but in most hermaphroditic species, individuals exchange sperm with another individual.
- When an embryo develops within the mother and the mother gives birth to live young, the process is called viviparity. Development of an embryo that occurs primarily outside the mother, sometimes within a protective shell, is called oviparity. In ovoviviparity, eggs covered with a thin shell are produced and hatch inside the mother's body, but the offspring receive no nourishment from the mother.

51.3 Mammalian Reproductive Structure and Function

- Sperm produced within each testis move out of the seminiferous tubules and into the epididymis, which leads into the vas deferens, a muscular tube leading to the ejaculatory duct. The urethra conducts semen, a mixture containing fluid and sperm, during ejaculation. The fluid components of semen are produced in the seminal vesicles, the bulbourethral glands, and the prostate gland. (Figures 51.5, 51.6, 51.7)
- The female genitalia are composed of large outer folds called the labia majora, plus smaller, inner folds called the labia minora. At the anterior part of the labia minora is the clitoris, which is erectile tissue. In mammals, the external opening of the reproductive tract leads to the vagina, a tubular structure into which sperm are deposited. Sperm then move through a fibrous structure called the cervix, which forms the opening to the conical-shaped uterus. Tubes called oviducts extend between the uterus and each of two ovaries. In the ovary, primary oocytes develop into secondary oocytes (the ovarian cycle). Sperm typically fertilize secondary oocytes in the oviduct. The fertilized egg undergoes several cell divisions to become a blastocyst, a ball of cells that enters the uterus, where it will develop into an embryo. (Figures 51.8, 51.9)
- In females, changes in hormone secretion produce the ovarian cycle and also control the uterine cycle or menstrual cycle. The latter name refers to menstruation, a period of bleeding at the beginning of the uterine cycle. (Figure 51.10)
- Following the release of a secondary oocyte during ovulation, cells in the empty follicle proliferate and develop into a structure called the corpus luteum, which degenerates if fertilization does not occur. If fertilization does occur, the blastocyst develops a surrounding layer of cells that secrete an LH-like hormone, called chorionic gonadotropin (CG), which maintains the corpus luteum.
- The event during which a woman stops having ovarian cycles is called menopause.

51.4 Pregnancy and Birth in Mammals

- The time during which a developing embryo and fetus grow within the uterus of the mother is termed pregnancy, or gestation. Humans and other eutherian mammals retain and nourish their young within the uterus via transfer of nutrients and gases through a structure called the placenta. (Figure 51.11)
- The first event of pregnancy is implantation, when the blastocyst imbeds within the uterine endometrium. Shortly after implantation, newly developing embryonic tissues merge with the endometrium to form the placenta, which remains in place and grows larger as the embryo matures into a fetus. There are three trimesters to human pregnancy. (Figure 51.12)
- The evolution of the globin gene family contributed to the ability of placental mammals to develop inside the mother's uterus. (Table 51.1)
- Birth, or parturition, is initiated by the actions of hormones produced by the placenta and by the mother's endocrine system. The hormone oxytocin stimulates the strong uterine muscle contractions that are the hallmark of the three-stage process called labor. (Figures 51.13, 51.14)
- In mammals, the young are nurtured for a period after birth by milk produced in the process called lactation.

51.5 Timing of Reproduction with Favorable Times of Year

- Animals synchronize the production of offspring with favorable environmental conditions by several means. In sperm storage, females store and nourish sperm in their reproductive tract for long periods of time. In delayed ovulation, the ovarian cycle in females is halted before ovulation, and sperm are stored and nourished in the female's uterus until a more favorable time for birth of the young. In delayed implantation, a fertilized egg reaches the uterus but does not implant until later, when environmental conditions are more favorable for the newly produced young. In addition, seasonal mating is practiced by many species.

51.6 Impact on Public Health

- Infertility is the inability of a man to produce sufficient numbers or quality of sperm to impregnate a woman, or the inability of a woman to become pregnant or maintain a pregnancy. A primary cause is STDs.
- The use of procedures to prevent fertilization or implantation of a fertilized egg is termed contraception. Procedures or circumstances that cause the death of an embryo or fetus after implantation produce an abortion.
- Vasectomy is a form of contraception in which transport of gametes through the male reproductive tract is prevented by surgically severing the vas deferens. Tubal ligation involves cutting and sealing of the oviducts. Intrauterine devices (IUDs) prevent implantation of a blastocyst. (Figure 51.15)
- Two types of barrier contraceptives are vaginal diaphragms, which are placed in the upper part of the vagina just prior to intercourse and block movement of sperm to the cervix, and condoms, which are sheathlike membranes worn over the penis that collect the ejaculate. Oral contraceptives are used to prevent ovulation.

Assess and Discuss

Test Yourself

1. The development of offspring from unfertilized eggs is
   a. budding.
   b. cloning.
   c. fragmentation.
   d. parthenogenesis.
   e. implantation.

2. Which is considered an advantage of sexual reproduction?
   a. necessity to locate a mate
   b. increased energy expenditure in producing gametes that may not be used in reproduction
   c. increased genetic variation
   d. decreased genetic variation
   e. both a and b
3. Spermatogonia
   a. are germ cells.
   b. are diploid cells.
   c. are male gametes.
   d. have flagella.
   e. a and b only
4. Compared to external fertilization, in internal fertilization,
   a. male gametes have a higher chance to come into close proximity to female gametes.
   b. gametes are less protected against predation or other harmful environmental factors.
   c. there is a decreased likelihood of desiccation of gametes.
   d. gametes come into contact only outside the mother's reproductive tract.
   e. b and c only
5. Which of the following is an example of ovoviviparity?
   a. Honeybees lay soft eggs within the hive.
   b. Sharks hatch from shell-covered fertilized eggs within the female's body.
   c. Birds hatch from shell-covered fertilized eggs laid within a nest.
   d. Fetal mammals obtain nourishment from the mother through a placenta.
   e. Amphibian eggs are released into the water column, where they may be fertilized.
6. The fructose in semen is secreted by
   a. the epididymis.
   b. the seminiferous tubules.
   c. the seminal vesicles.
   d. the prostate gland.
   e. the bulbourethral glands.
7. A major function of FSH is to
   a. stimulate the development of the gonads during early development.
   b. stimulate spermatogenesis in males and oocyte maturation in females.
   c. increase the secretion of testosterone by the testes.
   d. regulate the secretion of the bulbourethral glands.
   e. inhibit the activity of Sertoli cells in the testes.
8. During the human ovarian cycle, ovulation is stimulated by
   a. a decrease in FSH secretion.
   b. an increase in progesterone secretion.
   c. an increase in LH secretion.
   d. the presence of semen in the vagina.
   e. a decrease in estradiol level in the bloodstream.
9. During the secretory phase of the menstrual cycle, endometrial glands secrete
   a. hormones that increase the likelihood of pregnancy.
   b. nutritive substances that sustain an embryo during the first two weeks of development.
   c. hormones that prevent ovulation.
   d. waste products into the lumen of the uterus.
   e. both a and c.
10. During the _____ stage of labor in mammals, the placenta is expelled from the uterus.
    a. first
    b. second
    c. third
    d. It is not expelled; the placenta is reabsorbed.

Conceptual Questions

1. Distinguish between viviparity, ovoparity, and ovoviviparity, and give examples of animals for each type. Which type characterizes humans? What is an advantage of viviparity?
2. What are some of the costs associated with sexual reproduction? What outweighs those costs and accounts for the observation that most animals reproduce sexually?
3. How does the hypothalamus influence vertebrate reproduction?

Collaborative Questions

1. Define asexual reproduction and give three examples.
2. Compare and contrast internal fertilization and external fertilization.

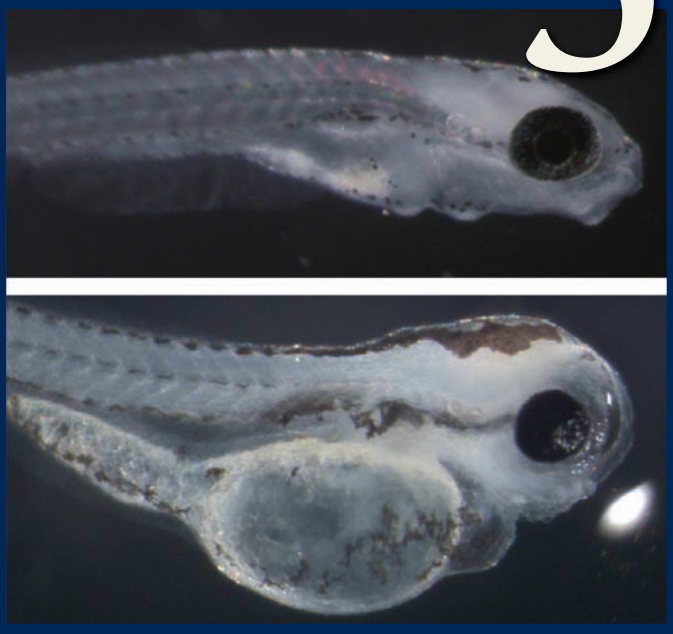
Chapter Outline



How embryonic development can go wrong—a normal zebrafish embryo (top) and one exposed to ethanol (bottom).

During the late 1950s and early 1960s in Europe, a drug called thalidomide was developed for use as an anticonvulsive treatment for epilepsy; it was also prescribed as an antihistamine for allergies. Although further testing revealed no beneficial effects on these conditions, it was noted that thalidomide seemed to calm nausea and help people sleep. In 1961, thalidomide was the most widely used sleeping medication in Europe, where it was also prescribed to combat morning sickness (nausea) in pregnant women.

Soon afterward, however, physicians in Europe and Australia noticed that babies born to mothers who had taken thalidomide sometimes had severely malformed limbs, with hands and feet often emanating directly from the body. It became clear that certain cells in human embryos, such as those that give rise to arms and legs, are selectively and adversely affected by this toxic compound. Ultimately, thousands of babies worldwide were deformed due to thalidomide. The drug was quickly eliminated from pharmaceutical markets, and the U.S. was largely spared from its effects due to prompt legislative action. Such tragedies underscore the importance of continued research into the mechanisms that regulate the normal development of an embryo. Environmentally or drug-induced developmental abnormalities occur throughout the animal kingdom. The chapter-opening photo, for example, shows the effect of ethanol on development of a zebrafish embryo. (An **embryo** is an early stage of a multicellular organism during which the organization of the organism is largely formed.) Such models are helping researchers understand the effects of alcohol consumption and other environmental factors on human embryo development.

In Chapter 51, we learned how animals reproduce. Chapter 19 covered how the sequential actions of genes provide a program for the development of an organism from a fertilized egg to an adult, discussing both animals and plants. In this chapter, we will learn about the cellular and molecular processes that lead to the formation of an animal embryo. We will first briefly review some basic principles of animal development from Chapter 19. Then we will consider the five general events of embryonic development. Next, we will examine the cellular and molecular mechanisms that control development. We conclude with an overview of how abnormal development impacts the human condition.

52.1 Principles of Animal Development

The biological information that controls embryonic development resides in both the organism's genetic material—its DNA—and in the cytoplasm of the egg. A fertilized egg (that is, a **zygote**) first becomes transformed into a cluster of cells without specialized functions, and ultimately into a complex organism containing organs with specific and evolutionarily conserved functions. In biology, the **morphology** of an organism refers to its organization and structure. **Morphogenesis** is the process that creates morphology. These events occur during a period of time known as an animal's development. The process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts is called **embryonic development**. Development is often accompanied

by growth, but they are different processes. Growth produces more or larger cells, whereas development produces organisms with a defined set of characteristics. Let's begin by reviewing some of the fundamental processes that underlie this development, first introduced in Chapter 19.

As animals develop, cells arrange themselves in coordinated ways that lead to the establishment of a **body plan** or **pattern**. The final, adult body pattern is organized along three axes: the **dorsoventral axis**, the **anteroposterior axis**, and the **right-left axis** (refer back to Figure 19.2a). Along these axes are often separate sections, or body segments, each containing specific body parts such as a wing or leg.

To establish the correct body plan, each cell in a developing animal must "know" where it is within the body, where it should move to, whether or not it should divide (or die), and what types of functions it will ultimately perform. This is possible because each cell receives positional information from its neighboring cells. This information is provided by cellular secretions into the extracellular fluid and by cell membrane proteins that interact with proteins on the membranes of other cells.

In addition to being stimulated to divide or to die (by apoptosis), positional information may cause the migration of a cell or group of cells from one region of the embryo to another (refer back to Figure 19.3). It may also cause **cellular differentiation**—the process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes. (In the thalidomide cases we discussed in the introduction, for example, cells that should have differentiated into those capable of developing into limbs were destroyed or damaged.) Now let's look at the general events that occur during embryonic development.

52.2 General Events of Embryonic Development

Even though the adult forms of animals vary immensely in size and morphology, embryonic development follows a similar pattern in most animals. As described in Chapter 32, most modern animals are triploblasts; that is, they develop from embryos with three germ cell layers. Such triploblasts include vertebrates, arthropods, echinoderms, and mollusks. Development in these animals can be categorized into five general events: fertilization, cleavage, gastrulation, neurulation, and organogenesis (Figure 52.1). In this section, we will examine the key aspects of each of the five general events of animal development. However, it should be noted that many species also go through an event called metamorphosis, which is a transition from a feeding larval form to an adult (refer back to Figure 33.28). Metamorphosis occurs after organogenesis and facilitates the rapid growth of young organisms into mature ones. Examples of metamorphosis include the transformation of a caterpillar into a butterfly and that of a tadpole into a frog.

Event 1: Fertilization Involves a Union Between Sperm and Egg to Create a Zygote-Stage Embryo

In all species of triploblasts, the events in **fertilization** are quite similar. The description that follows summarizes some of the hallmark events following external fertilization in sea urchins, a well-studied model organism.

In sea urchins, as in many animals, the sperm must penetrate a jellylike layer consisting of glycoproteins and

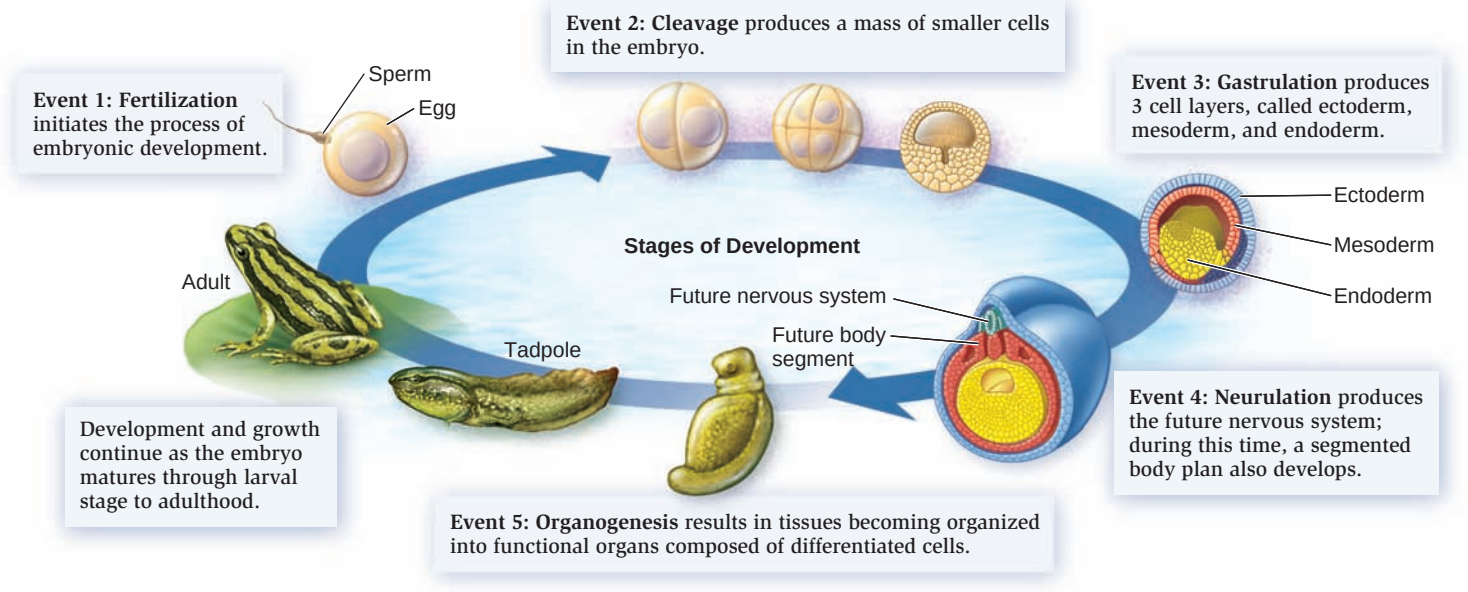


Figure 52.1 **Overview of events of embryonic development.** This figure shows the general events that all vertebrate embryos go through, using a frog as an example.

Concept check: *What is the final process called by which a tadpole develops into an adult frog, and is this unique to frogs?*

polysaccharides before contacting the plasma membrane of the egg. The sperm is able to do this because of the **acrosomal reaction**, in which proteases and other hydrolytic enzymes are released from the acrosome in the tip of its head onto the jelly coat of the egg (Figure 52.2a). These enzymes dissolve a localized region of the jelly coat, allowing the sperm head to bind to proteins in the egg's plasma membrane. Binding is followed by fusion of the sperm head membrane with the egg membrane, and shortly thereafter by penetration of the sperm head with its nucleus into the egg.

Additional sperm are prevented from fusing with the egg because the fusion of sperm and egg depolarizes the egg. This depolarization blocks other sperm from binding to egg membrane proteins and is known as the **fast block to polyspermy**. Without this block, a single egg could receive chromosomes from two or more sperm, resulting in zygotes that fail to develop normally or at all. Polyspermy does occur in some animals, notably urodeles (newts and salamanders), but in such cases, the nucleus from only one sperm fuses with the nucleus of the egg; the remaining nuclei are degraded inside the egg.

The acrosomal reaction is followed by the **cortical reaction** (Figure 52.2b). Normally, the cytosolic calcium concentration in eggs, as in most cells, is kept low by several mechanisms, including one in which Ca^{2+} is transported by an ATP-dependent pump out of the cytosol and into the endoplasmic reticulum. When the sperm binds to the egg, inositol trisphosphate (IP_3) (refer back to Figure 9.16) is released from the region of the plasma membrane nearest to the sperm entry point. IP_3 then binds to nearby sites on the endoplasmic reticulum and opens Ca^{2+} channels. Within 10 seconds after a sperm cell binds to an egg, Ca^{2+} is released from the lumen of the endoplasmic reticulum and into the cytosol. This signal is propagated across

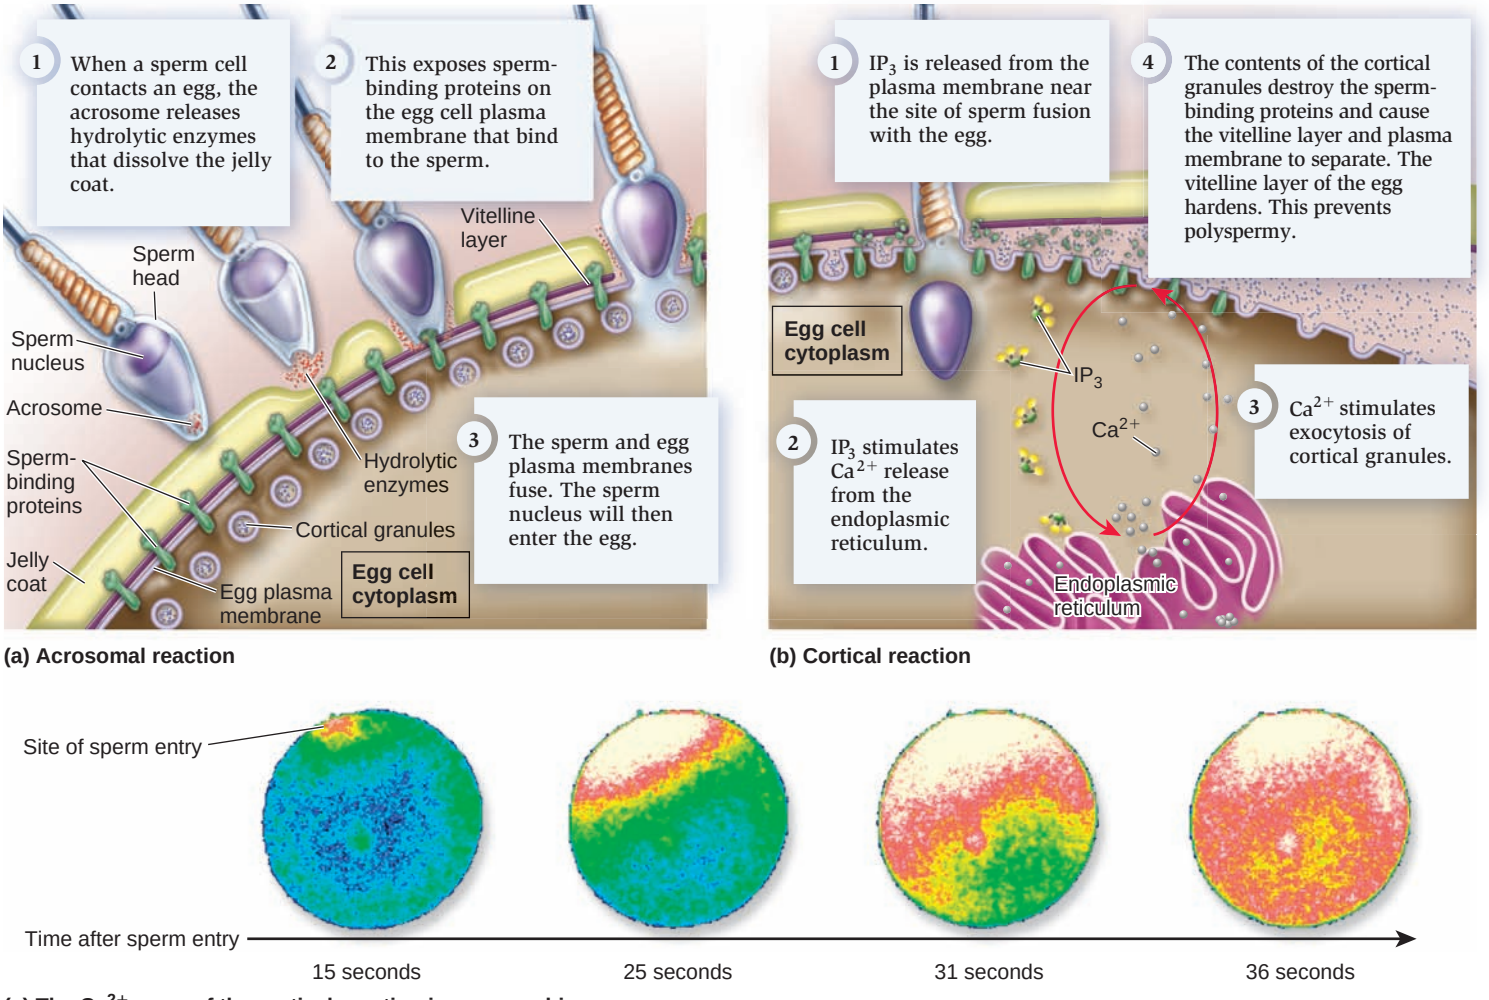

Figure 52.2 **Fertilization of an egg by a sperm.** **(a)** Acrosomal reaction. The contact of a sperm with an egg initiates a series of events that permits the head of the sperm to bind to the plasma membrane of the egg. This depolarizes the egg and blocks other sperm from entering; this is known as the fast block to polyspermy. **(b)** Cortical reaction. Sperm fusion leads to an increased level of cytosolic Ca^{2+} that ultimately causes the vitelline layer of the egg to harden, creating the slow block to polyspermy. **(c)** Calcium wave in a sea urchin egg. The increase in cytosolic Ca^{2+} begins near the site of sperm entry and propagates throughout the egg. Green and blue represent regions of low cytosolic Ca^{2+}; yellow and red represent regions of high cytosolic Ca^{2+}.

the entire endoplasmic reticulum, resulting in the transmission of a **calcium wave** across the egg over a period of about 30 seconds. This calcium wave can be visualized by injecting the cytosol of an unfertilized egg with a calcium-sensitive fluorescent dye that becomes highly fluorescent when Ca^{2+} is released from the endoplasmic reticulum (Figure 52.2c).

The release of Ca^{2+} in the cortical reaction has several important effects. First, membrane-bound vesicles in the egg's cytosol, called cortical granules, release enzymes and other substances that inactivate the sperm-binding proteins on the plasma membrane. In addition, the outer coating of the egg cell, known as the vitelline layer in sea urchins, or the zona pellucida in vertebrates, becomes hardened and begins to separate from the plasma membrane. These events create another barrier to more sperm fusing with the egg, a process called the **slow block to polyspermy**. Additionally, the burst of cytosolic Ca^{2+} both leads to the activation of molecular signaling pathways that initiate the first cell cycle and triggers an increase in protein synthesis and metabolism within the egg cell.

Shortly afterwards, the nucleus of the sperm fuses with the nucleus of the egg, creating a diploid zygote. The first cell division of the zygote occurs approximately 90 minutes after fertilization in sea urchins and amphibians, but it can take up to 24 hours in mammals.

Event 2: Cell Divisions Without Cell Growth Create a Cleavage-Stage Embryo

The initial cell cycles of embryos are unique because they involve repeated cell divisions without cell growth. The process by which these cell cycles occur is called **cleavage**. The embryonic cells repeatedly split in two, resulting in several generations of daughter cells that are roughly half the size of the cells that gave rise to them. These early cell cycles that lack cell growth are characterized as "biphasic," because they alternate only between the mitotic (M) phase and DNA synthesis (S) phase of the cell cycle—neither the G_1 nor G_2 phase occurs (see Chapter 9 for a discussion of the cell cycle).

In most species in which development occurs outside the mother, where eggs can be eaten by predators, cell division during cleavage represents some of the fastest cell cycles found in nature. The cell cycle during cleavage in amphibians, for example, requires only 20 minutes. During each 20-minute cell cycle, complete genome replication, mitosis, and duplication of the nuclear envelope are followed by cytokinesis. In eutherian (placental) mammals, however, in which development occurs within the protective environment of the mother's body, biphasic cell divisions during cleavage are relatively slow, requiring about 12 hours to complete.

The two half-size daughter cells produced by each cell division during cleavage are known as **blastomeres**. Individual blastomeres are bound together, and the outer single-cell layer of blastomeres forms a sheet of epithelial cells that separates the embryo from its environment. After formation of the outer epithelial layer, the embryos of many animals take up water and form a cavity called a **blastocoel**. The embryo at this stage is called a **blastula**. The blastocoel provides a space into which cells will migrate to form the digestive tract and other structures of the embryo, as described later in Event 3.

Incomplete Cleavage: Birds and Fishes Among triploblasts, cleavage-stage embryos can vary dramatically in size and appearance. This variation is in part related to whether or not the egg contains yolk and, if so, the location and amount of yolk that was deposited in the egg. Yolk is a nutrient-rich food store that will be used by the developing embryo. The eggs of birds, some fishes, and some other vertebrates have large amounts of yolk. In the eggs of these species, yolk is most concentrated toward one end—or pole—of the egg, called the **vegetal pole**. Much less yolk, and much more cytoplasm, is concentrated near the opposite pole, called the **animal pole** (Figure 52.3). These poles form the apices of the vegetal and animal hemispheres, which determine in part the future anteroposterior (head-tail) and dorsoventral (back-front or top-bottom, depending on the species) axes of the embryo.

In some but not all species that exhibit animal and vegetal poles, cleavage of the zygote is called incomplete because only the region of the zygote and embryo containing the animal hemisphere undergoes cell division. This process is also called **meroblastic cleavage** (Figure 52.4). Instead of forming a ball of cells (a blastula), in this type of cleavage, a flattened disc of blastomeres known as a **blastoderm** develops on top of the yolk mass.

Complete Cleavage: Amphibians and Mammals In animals whose eggs have smaller amounts of yolk, cleavage during the first cell division is complete and bisects the entire zygote into two equal-sized blastomeres. Such **holoblastic cleavage** occurs in amphibians and mammals (Figure 52.4). In amphibians, cleavage-stage embryos form a blastula, as previously noted. In mammals, however, cleavage-stage embryos undergo a process called compaction, in which the amount of physical contact between cells is maximized. At this stage, the embryo in these species is called a **morula**. The resulting blastomeres in mammals then proceed to form a **blastocyst**, the mammalian counterpart of a blastula.

Cleavage and Implantation in Mammals In mammals, the events of fertilization and cleavage occur in the oviduct

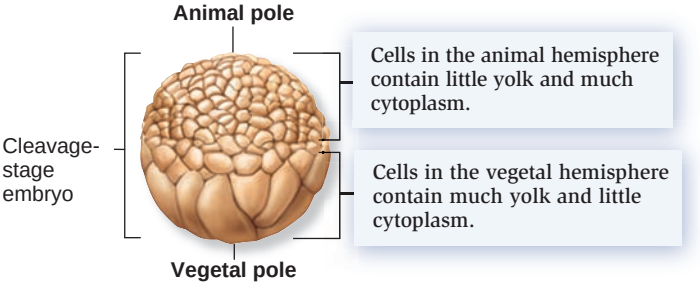

Figure 52.3 **Polarity in an amphibian cleavage-stage embryo.** Cells of the animal hemisphere contain little yolk and much cytoplasm. Cells of the vegetal hemisphere contain much yolk and little cytoplasm.

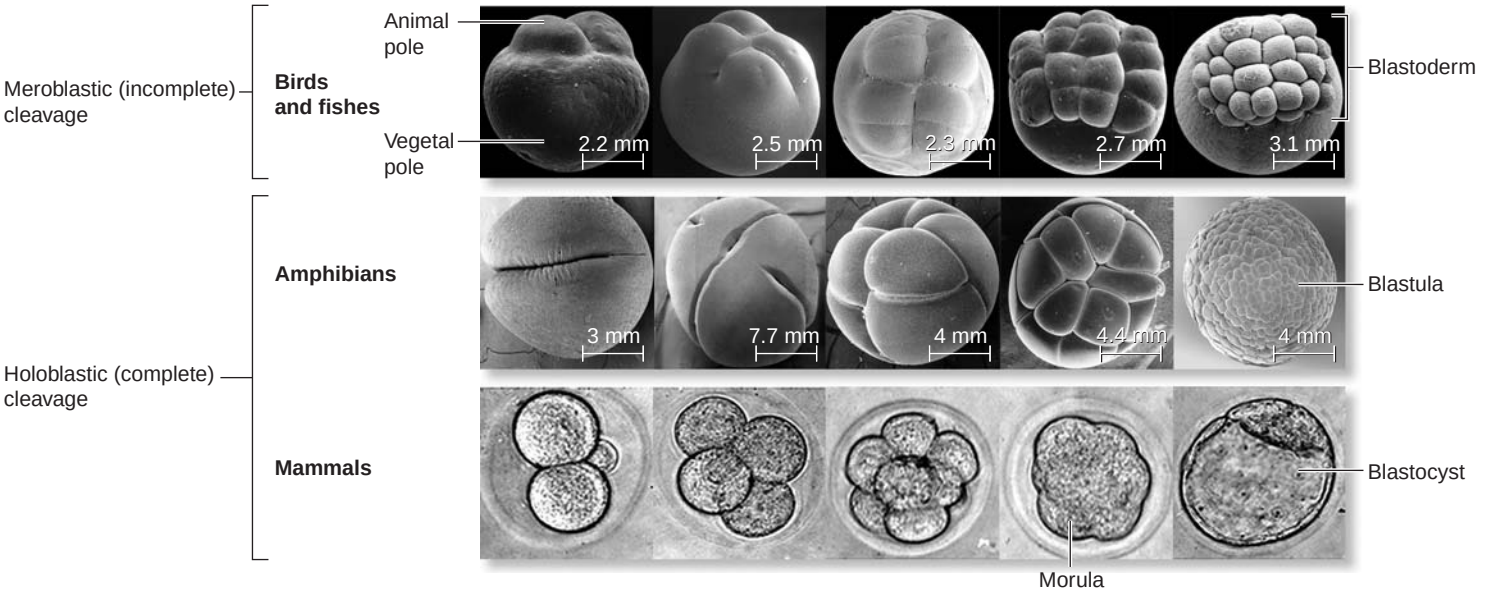

Figure 52.4 **Meroblastic and holoblastic cleavage.** As seen in these electron micrographs, early embryos of birds and many fishes undergo incomplete (meroblastic) cleavage, whereas most amphibian and mammalian embryos undergo complete (holoblastic) cleavage. The amount of yolk in the egg (not visible in these images) contributes to many of these morphological differences observed in various species. Source (top and middle row): © Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited.

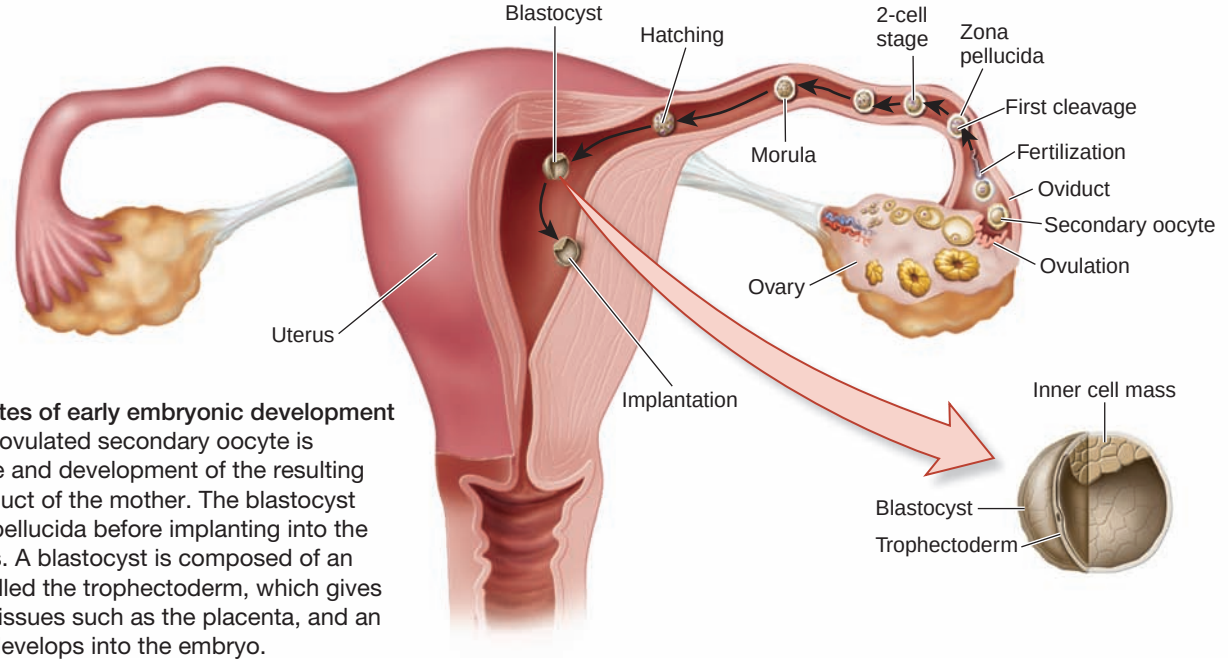

Figure 52.5 **The sites of early embryonic development in mammals.** After an ovulated secondary oocyte is fertilized, initial cleavage and development of the resulting zygote occur in the oviduct of the mother. The blastocyst hatches from the zona pellucida before implanting into the inner lining of the uterus. A blastocyst is composed of an outer epithelial layer, called the trophectoderm, which gives rise to extraembryonic tissues such as the placenta, and an inner cell mass, which develops into the embryo.

Concept check: *Fertilization is internal in mammals. Is this true of all vertebrates? (You may need to refer back to Chapter 51.)*

(Figure 52.5). The blastocyst has a different morphological appearance than the blastula or blastoderm embryos in non-mammalian species, and no animal-vegetal polarity that is analogous to that of other chordates exists. The blastocyst consists of an outer epithelial layer called the trophectoderm, which gives rise to the placenta, and an inner layer called the inner cell mass, which develops into the embryo. After the blastocyst forms, the embryo hatches from the zona pellucida, a layer of glycoproteins that surrounds the secondary oocyte and is retained up to this time. The embryo then becomes embedded in the endometrial wall of the mother's uterus, a process known as implantation (Figure 52.5; also see Chapter 51). This entire process takes 4 days in mice and about 8–10 days in humans.

Toward the end of cleavage, cell cycles become less synchronous, and the embryo begins to express its own genes. The embryo's shift from existing exclusively on maternal factors to developing in response to products derived from its own genome begins 6–24 hours after fertilization in vertebrates. This is followed by the next general event of development, called gastrulation.

Event 3: Gastrulation Establishes the Three Germ Layers in the Embryo

Following cleavage is **gastrulation**, one of the most dramatic events of embryonic development in animals because of the major cell movements that occur. During gastrulation, the hollow ball of cells that makes up a blastula or blastocyst is developed into a highly organized structure called a **gastrula** (refer back to Figure 32.3). In the gastrula-stage embryo, the three germ layers—**ectoderm**, **mesoderm**, and **endoderm**—become clearly established. These distinct germ layers are partially differentiated tissues that are easily recognized by their appearance under a light microscope. The layers occupy discrete regions of the embryo, with an outer ectoderm, a middle mesoderm, and an inner endoderm layer. Each type of germ layer eventually gives rise to different structures. The organization that emerges during gastrulation is most evident by the clear establishment of the digestive tube and body axes. Gastrulation is the first time when both the anteroposterior and dorsoventral body axes are clearly evident in the embryo.

Scientists have established the ultimate fate of the three germ layers with an experimental procedure called **fate mapping**. In this technique, a single cell or a small population of cells within an embryo is specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development (Figure 52.6).

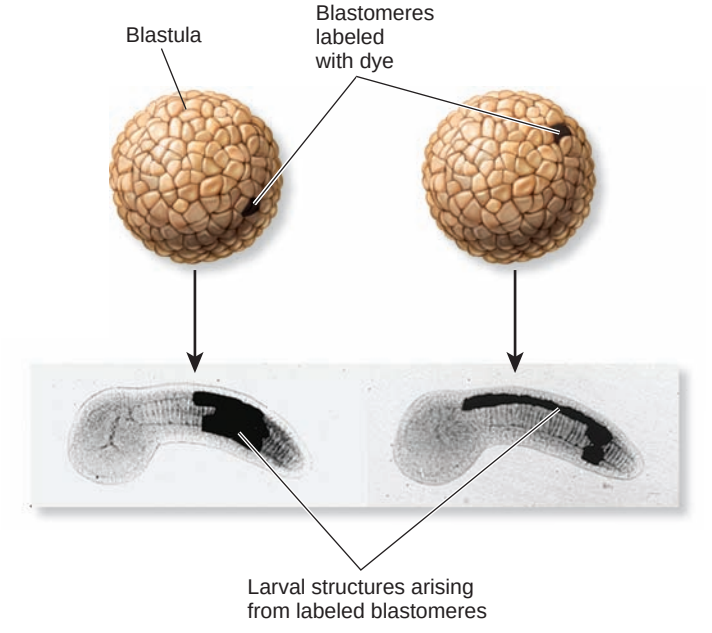

Figure 52.6 **Fate mapping during embryonic development.** In fate mapping, an individual embryonic cell (a blastomere) is labeled with a dye. The fate of that cell can then be followed, showing that different cells in the embryo (in this case, a urochordate blastula) form different structures in the tadpole-like larva, as shown by the dark regions.

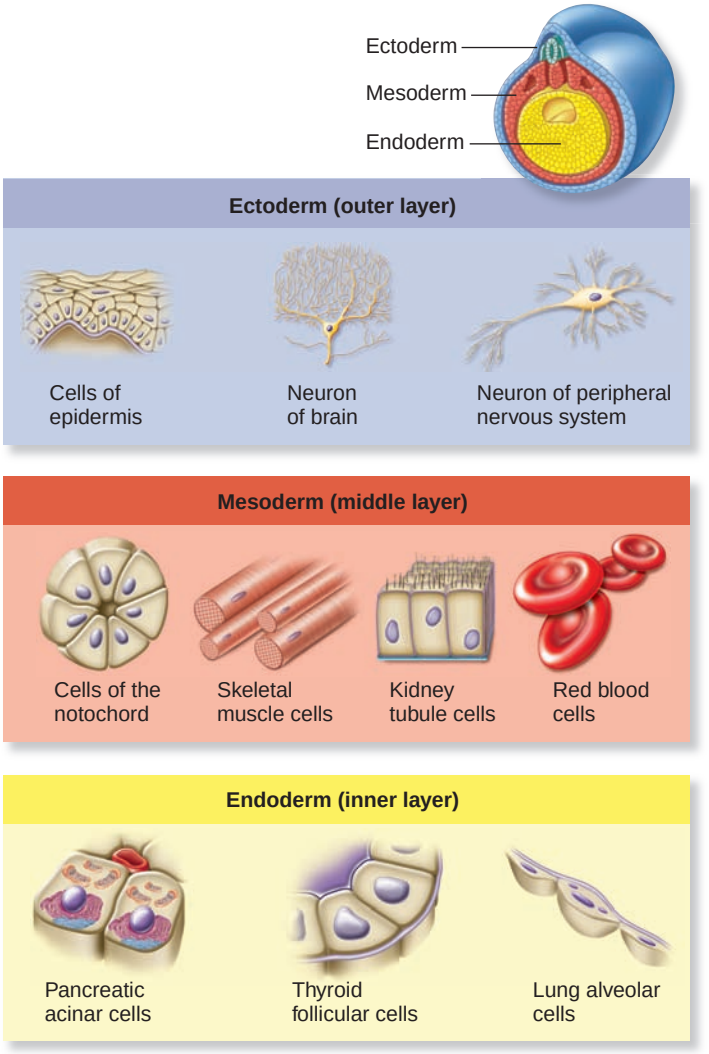

Figure 52.7 **Examples of cell types derived from ectoderm, mesoderm, and endoderm.**

Use of this technique in a variety of vertebrates has shown that the ectoderm in the gastrula forms the epidermis and nervous system in the later embryo (Figure 52.7). The mesoderm gives rise to muscles, kidneys, blood, heart, limbs, connective tissues, and the notochord, which is a key feature of all chordates, described later in this section of the chapter. The endoderm becomes the epithelial lining of the pancreas, thyroid, lungs, gut, liver, and urinary bladder.

Gastrulation occurs in all vertebrates. Many of the genes responsible for specifying gastrulation processes are conserved from fishes to humans. Although the developmental steps vary among vertebrate species, gastrulation usually is initiated by changes in a small number of cells within an external epithelial cell layer. This leads to a morphologically distinct structure that clearly defines the anteroposterior axis of the animal.

Some of our most detailed descriptions of the events in gastrulation come from the study of frog embryos. Three features of amphibians make them ideal for analyzing embryonic development using nongenetic mechanisms. First, fertilization and embryonic development occur outside the mother, making it easy to observe and manipulate embryos as they develop. Second, eggs are abundant—adult females carry thousands of eggs and can be induced to lay them by injecting a specific hormone—and are easily fertilized, usually by simply placing a male in an aquarium with an ovulating female. Third, amphibian embryos develop rapidly. In frogs, for example, development from fertilized egg to tadpole formation takes only about 35 hours. The major events in gastrulation as described in amphibians are depicted in Figure 52.8 and described next.

Invagination and Involution: Formation of Germ Layers and Archenteron Prior to gastrulation, the blastula is enclosed in a simple, spherical epithelial cell layer. Gastrulation begins when a band of tissue extending perpendicularly to the animal-vegetal axis at the widest part of the embryo **invaginates** (pinches in), pushing cells from the outside of the embryo to the inside (Figure 52.8, step 1). This process creates a small opening called the **blastopore**, which defines the anteroposterior axis of the animal. Invagination begins when a few epithelial cells located at the vegetal hemisphere of the blastula—called bottle cells—undergo a drastic change in their morphology, causing them to elongate toward their basal end and forcing the cells toward the interior of the embryo. The initiating site of invagination becomes what is called the dorsal lip of the blastopore. This change in morphology of only a few key cells in the embryo initiates the gastrulation process in amphibians.

Once the bottle cells change their shape and push into the interior of the embryo, other cell movements occur, and together these orchestrated movements establish the mesoderm and endoderm of the organism, including its future digestive tract. Just before invagination begins near the "equator" or midline of the embryo, cells of the animal hemisphere spread out and move downward. The bottle cells then form and move in at the blastopore. Animal hemisphere cells continue to migrate downward. When they arrive at the blastopore, they too enter the opening and subsequently migrate upward along the roof of the blastocoel, toward the animal pole of the embryo. This folding back of sheets of surface cells into the interior of the embryo is called **involution** (Figure 52.8, step 2). Both endodermal and mesodermal cells involute from the blastopore toward the opposite end of the embryo. After involution, dorsal mesodermal cells migrate toward the animal pole by crawling along the roof of the blastocoel, with endoderm following closely behind.

As the opening from the blastopore extends into the embryo, a new cylindrically shaped cavity called the **archenteron** displaces the existing blastocoel (Figure 52.8, steps 2 and 3). The archenteron will become the organism's digestive tract. The blastopore opening remains sealed with a yolk-rich piece of tissue called the yolk plug until later in development.

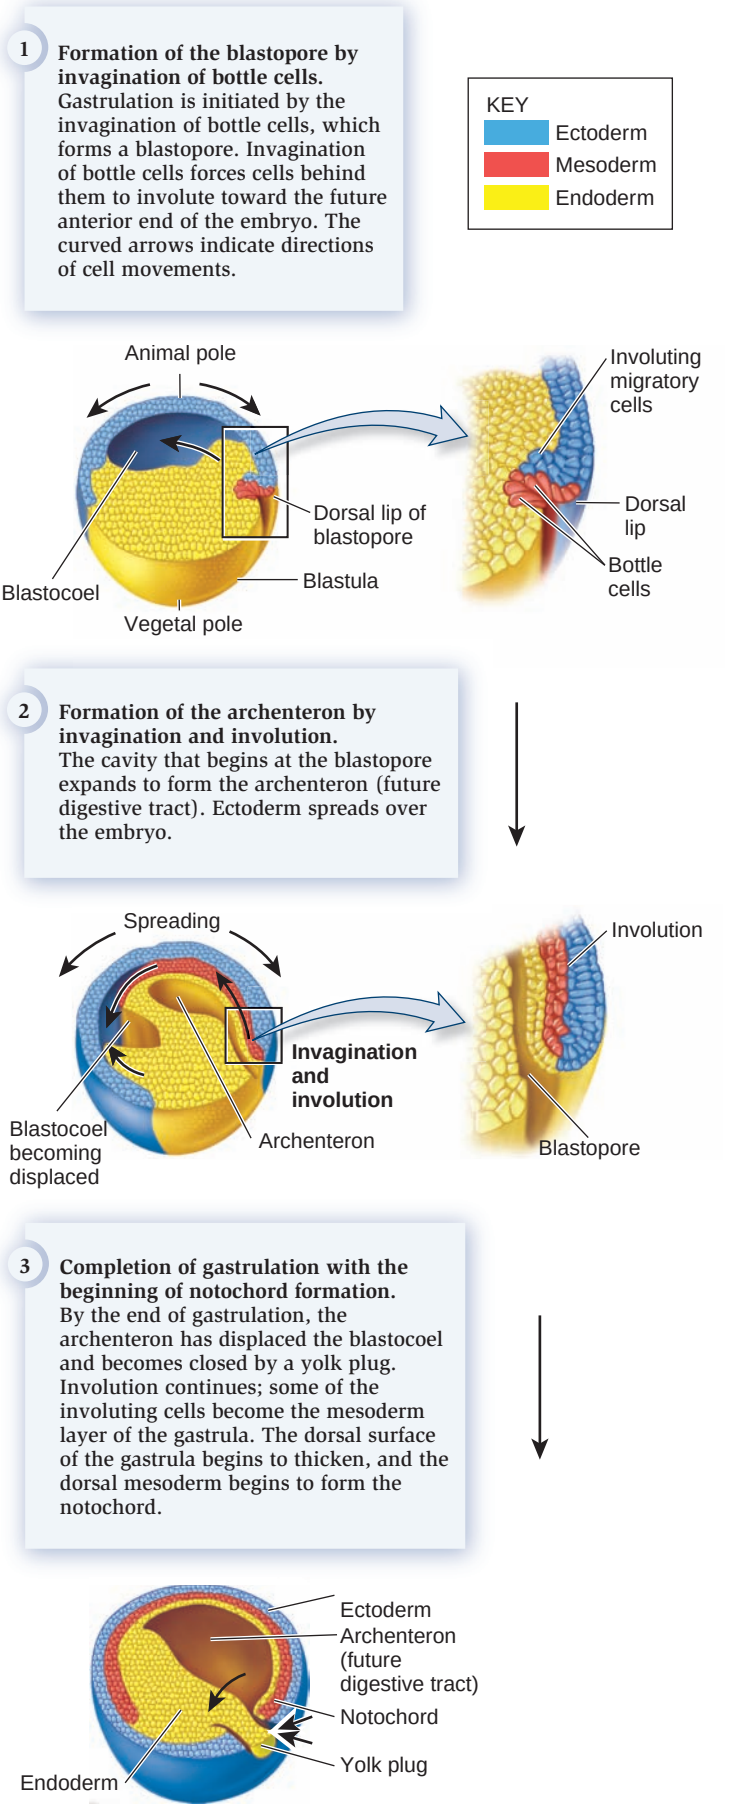

Figure 52.8 The events of gastrulation in amphibians.

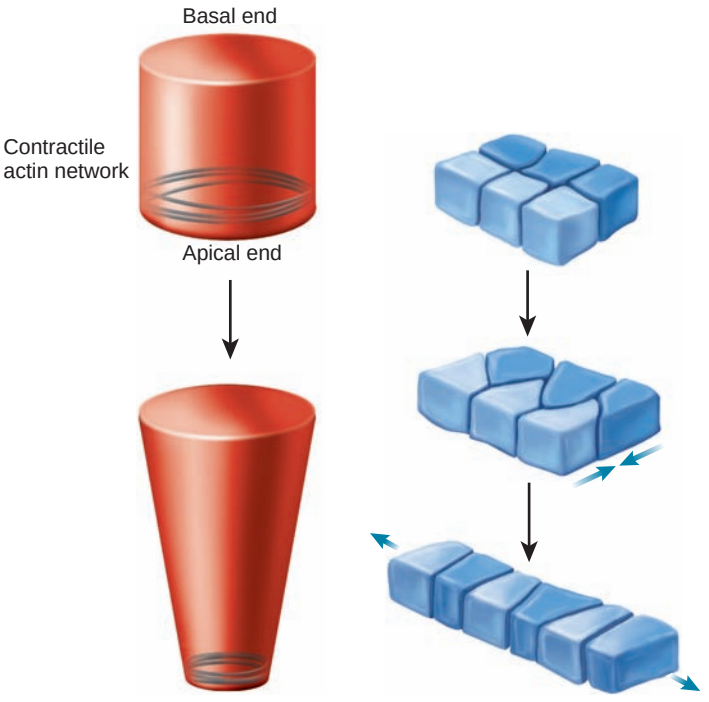

Figure 52.9 Two mechanisms that affect cell shape and movement.

In chordates and echinoderms, the opening formed by the blastopore ultimately becomes the anus of the organism (refer back to Figure 32.5). Meanwhile, during involution, surface cells spread from the animal hemisphere to surround the entire vegetal hemisphere to become the future ectoderm. The result of these cellular rearrangements is an embryo with three distinct germ layers.

Mechanisms for Changes in Cell Shape and Position How do cells change shape and position during the process of embryonic development? Several processes are at work. For example, bottle cells initiate gastrulation through a process called **apical constriction** (Figure 52.9a). As discussed in Chapter 10, epithelial cells may have a ring of actin filaments that underlie anchoring junctions between neighboring cells (refer back to Figure 10.18). In apical constriction, the actin rings connected to the adherens junctions constrict, elongating the cells.

The spreading of ectoderm in the animal hemisphere toward the vegetal hemisphere is mediated by a cellular process called **convergent extension**. During this process, two rows of cells merge to form a single elongated layer (Figure 52.9b). Convergent extension produces the movement of sheets of cells.

Notochord Formation A distinguishing anatomical feature that begins forming at the end of gastrulation in all chordates is the **notochord**—a mesodermal structure that provides rigidity along the anteroposterior axis in the dorsal side of the gastrula (Figure 52.8, step 3). The presence of a notochord defines the phylum Chordates, which also includes the urochordates. Interestingly, urochordates such as the tunicates form a tadpole-like larva but develop into adults that lack vertebrae. The similarities between urochordate and vertebrate larva—including the formation of a notochord—have led many to believe that urochordates may be quite similar to the ancestor species of current-day vertebrates. The notochord persists in the trunk and tail of fishes and amphibians; in birds and mammals, the notochord disappears by the time vertebrae have formed.

In the amphibian embryo, after formation of the archenteron, the dorsal surface of the gastrula begins to thicken, and the dorsal mesoderm forms the notochord. The notochord elongates through convergent extension. By the time the notochord has formed, the dorsal ectoderm overlying the notochord begins to thicken, which initiates the next general event in development, called neurulation. Before we discuss that event, however, we consider another important event that occurs during gastrulation: the establishment of germ cells.

Primordial Germ Cells During gastrulation, a specialized group of cells arise called **primordial germ cells** (**PGCs**). The PGCs often arise independently of the three germ layers in the embryo. This cell lineage has two primary functions: (1) to protect and propagate the genetic content of the species and (2) to undergo meiosis and differentiate into gametes—sperm or eggs—in the adult organism. PGCs are stem cells that can divide through mitosis to make copies of themselves. Some of the resulting daughter cells can later undergo meiosis and differentiate into gametes.

The eggs and resulting embryos of some species contain certain cytoplasmic determinants—called the **germ plasm** (Figure 52.10a)—that help define and specify the PGCs in the gastrula stage. In amphibian eggs, for example, the germ plasm occupies a small region of cytoplasm around the vegetal pole and contains a specific subset of maternal mRNAs. These cytoplasmic determinants are inherited by a subpopulation of blastomeres during cleavage. At the beginning of gastrulation, blastomeres that inherit these cytoplasmic determinants differentiate into PGCs. At a later stage of development, the PGCs migrate to primordial gonads that eventually will form testes

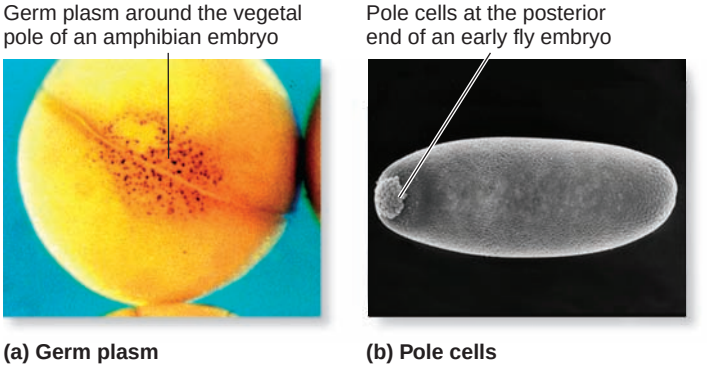

Figure 52.10 Germ plasm and primordial germ cells (PGCs) during gastrulation. **(a)** Germ plasm in an amphibian embryo visualized by labeling an mRNA that is specifically expressed in PGCs. **(b)** In fly embryos, the PGCs are called pole cells.

or ovaries. In flies, by contrast, PGCs are the first cells to form at the posterior end of the embryo and are called pole cells (Figure 52.10b).

In mammals, neither germ plasm nor pole cells have been identified. Instead, a few mesoderm-like cells begin to express PGC-specific genes early during gastrulation. These cells migrate along the hindgut during gastrulation and, as in amphibians, eventually intermix with gonad primordial cells later in development. Thus, the establishment of PGCs occurs during the earliest phases of animal development and signifies the broad importance of this cell lineage for the propagation of species.

Event 4: Neurulation Involves Formation of the Central Nervous System and Segmentation of the Body

By studying development in several different vertebrate species, researchers are beginning to understand some of the fundamental steps in the formation of the central nervous system (CNS)—the brain and spinal cord—in vertebrates. The multistep embryological process responsible for initiating CNS formation is called **neurulation** (Figure 52.11). Neurulation occurs just after gastrulation and involves the formation of the **neural tube** from ectoderm located dorsal to the notochord. All neurons and their supporting cells in the CNS originate from neural precursor cells derived from the neural tube. During neurulation, the embryo also develops segmented structures. Next, we discuss the processes of neurulation and body segmentation.

Neural Tube Formation Neurulation in vertebrates occurs in four major steps, as shown in Figure 52.11. In the first step, ectoderm overlaying the notochord thickens by the elongation of cells in the dorsal region to form the neural plate, with adjacent regions that will eventually form a structure called the neural crest (discussed shortly) and the epidermis. The neural plate then elongates by convergent extension, resulting in the formation of a single, dorsal elongated epithelial cell layer that is aligned with the animal's anteroposterior axis.

Next, the neural plate forms the neural tube through a series of apical constrictions (steps 2 and 3, Figure 52.11). In the second step, a column of cells along the midline of the neural plate—the medial hinge point—undergoes apical constriction. This initiates the folding phase of neurulation and leads to the formation of the neural groove. After folding, in the third step, bilateral columns of cells in the dorsal lateral hinge points then undergo apical constriction, leading

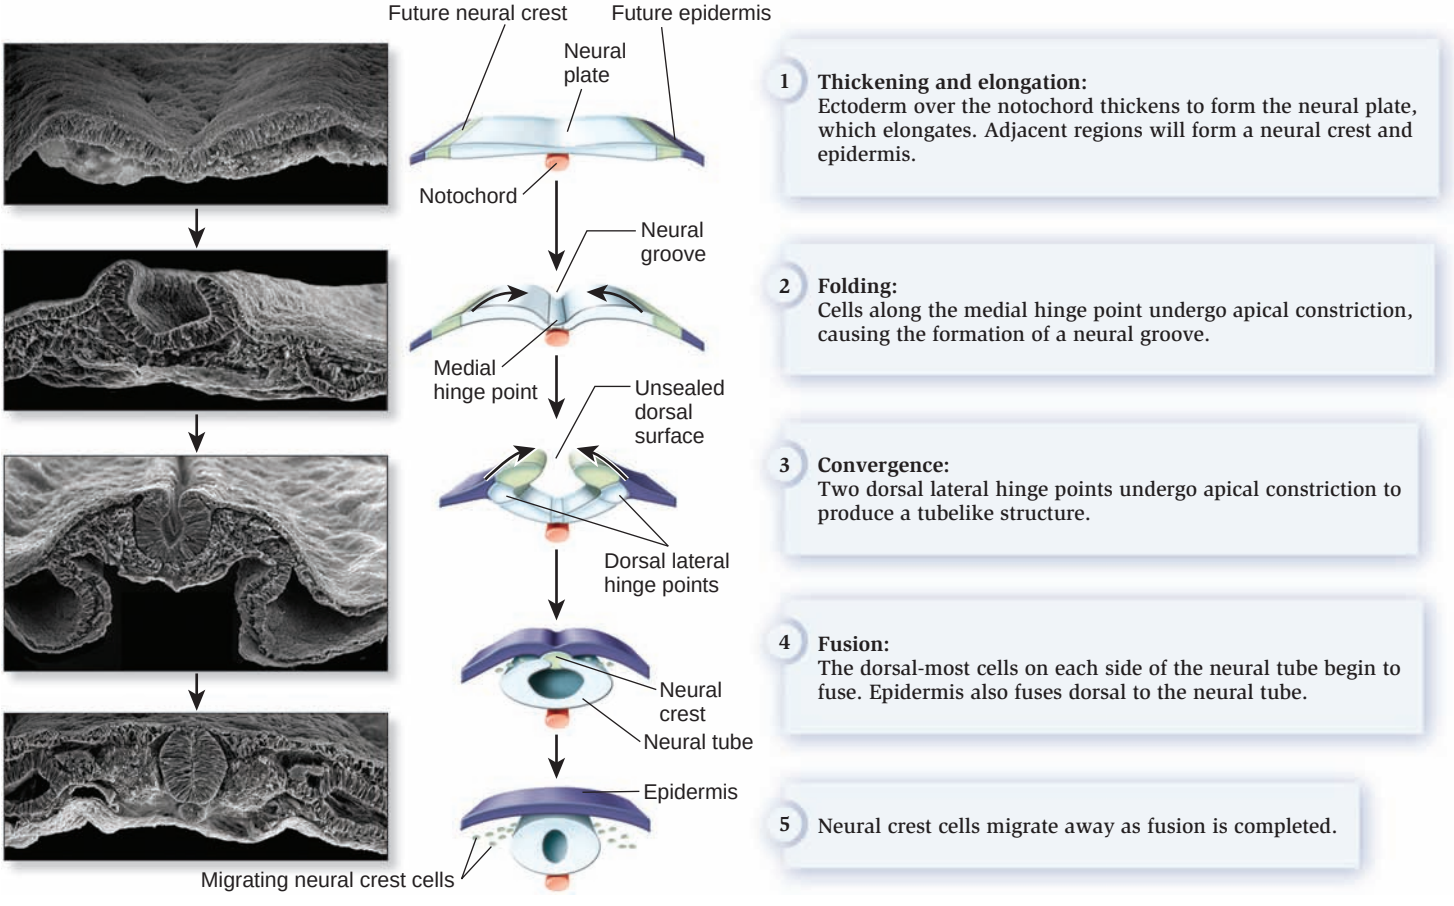

Figure 52.11 **Neurulation and the beginning of neural crest formation in vertebrates.** The four major steps of neurulation include thickening and elongation; folding, which creates the neural groove; convergence, in which the neural tube begins to take shape; and fusion, in which the neural tube is completed. In a later event, cells migrate away from the neural tube to form several other structures, including the neural crest.

to convergence of the two sides of the neural groove and generation of a tubelike structure that is not yet sealed on the dorsal side.

In the fourth step of neurulation, called fusion, the dorsalmost cells on either side of the neural tube are released from adjacent ectoderm and fuse with each other, culminating in the closure of the neural tube. At the same time, ectoderm on either side of the neural tube moves toward the centerline, then up and over the neural tube, where it fuses and forms the dorsal epidermis of the embryo. At this time, the next step in the process involves the neural crest cells.

Neural Crest Formation Another important cell lineage that arises during neurulation is the **neural crest**, which is unique to vertebrates. It consists of cells that originate from the ectoderm overlaying the dorsal side of the newly formed neural tube and that migrate to other regions of the embryo (Figure 52.11, step 5). Once these cells reach their final destination in the embryo, they differentiate into a variety of cell types different from those that arise from the rest of the ectoderm. All neurons and supporting cells of the peripheral nervous system in vertebrates are derived from neural crest cells. In addition, the neural crest gives rise to skeletal and cartilaginous structures in the head and face, melanocytes (specialized cells that provide pigmentation to the skin of vertebrates), the medulla (the inner region) of the adrenal glands, and connective tissue in numerous organs, notably the heart.

Segmentation and the Formation of Somites As embryos develop, distinct tissues acquire recognizable shapes and patterns, and the body often becomes segmented along the anteroposterior axis of the embryo. **Segmentation** allows individual body segments to have more specialized functions. In some animal taxa, such as insects, body segments are found in the adult animal. In vertebrates, the segmentation process helps define repeated structures such as vertebrae and ribs, which form later during development. Segmentation of the body plan along the anteroposterior axis becomes apparent during neurulation.

During neurulation, the mesoderm becomes segmented from the anterior end first, giving rise to blocklike structures of mesoderm called **somites** (Figure 52.12). The segmentation of somitic mesoderm continues toward the posterior end of the animal and into the tail, as can be seen in Figure 52.12b. The number of somite pairs that forms can vary considerably among species (50 in chicks, 65 in mice, and 500 in some snakes). Because the rate of embryonic development within a given species often varies with temperature and other environmental factors, stages of embryo development are often standardized according to the number of somites that have formed.

Somites arise from a group of loosely packed mesodermal cell aggregates that condense into epithelial somites, which consist of a hollow ball or vesicle enclosed by an epithelial layer. The scanning electron micrograph in Figure 52.12a shows a dorsal view of a chick embryo undergoing somite formation. These epithelial somites are located toward the anterior end,

(b) Segmentation in an early chick embryo as seen with a light microscope

Figure 52.12 Segmentation of mesoderm into somites during neurulation. **(a)** This scanning electron micrograph shows early events in the segmentation process: the formation of epithelial somites toward the anterior end of a chick embryo. **(b)** Light-microscopic image of a chick embryo, showing body segments along the anteroposterior axis.

and unsegmented mesoderm can be seen extending toward the posterior end. The epithelial somites are transient structures, and the cells within them soon transform into two morphologically distinct structures that eventually form ribs/skeletal muscle and vertebrae, respectively.

Event 5: Organogenesis Is the Process of Organ Formation

As described in Chapter 40, organs are specialized structures that consist of arrangements of two or more tissue types. Most organs, such as the kidney, contain all four tissue types: nervous, muscle, epithelial, and connective tissue (see Chapters 10 and 40). The developmental event in which cells and tissues form organs is called **organogenesis**. Each germ layer gives rise to particular types of cells found within different organs (see Figure 52.7).

Many organs begin to form during or just after neurulation. However, these organs become functional at different times during development. For example, the lungs of mammals do not acquire the ability to function until shortly before birth. By contrast, the heart is the first functional organ to form in the vertebrate embryo. It begins to beat and pump blood before all the embryo's somites have formed (by 2.5 days after fertilization in chicks, 9 days in mice, and about 22 days in humans).

As we saw in Chapter 40, the development of different organs in animals is controlled by genes in the embryo, notably the *Hox* genes. *Hox* genes are important for establishing structures along the anteroposterior axis. Many of the genes controlling the processes of gastrulation, neurulation, and organogenesis encode secreted proteins or growth factors that induce cells in their local vicinity to differentiate along a specific developmental pathway. For example, the notochord produces many signaling proteins that help establish tissue patterns in the embryo. Proteins produced within it induce segment-specific expression of the *Hox* genes in subsequent stages of development. Next, we will see how such growth factors can be studied during embryonic development.

52.3 Control of Cell Differentiation and Morphogenesis During Animal Development

Thus far, we have examined the five general events of embryonic development. In this section, we will turn our attention to certain molecular mechanisms that are crucial for cell differentiation and morphogenesis.

Positional Information Is Conveyed Internally and Externally to Each Cell

The process of embryonic development requires that cells divide, move to specific sites, and acquire distinct functional properties (that is, differentiate). As we discussed, cells receive positional information that determines how they differentiate. There are two primary mechanisms of conveying such positional information. The first mechanism is an internal one, which involves the unequal acquisition by daughter cells of various cytoplasmic factors during cell division, a process known as **autonomous specification**. The second is a variety of external cell-to-cell signaling mechanisms, a process called **conditional specification**. These two mechanisms provide embryonic cells with a continuously changing internal and external environment, in which cells ultimately fulfill their unique spatial and functional fates. This differentiation process involves alterations of gene expression in which specific cells express a unique set of genes required for a particular function.

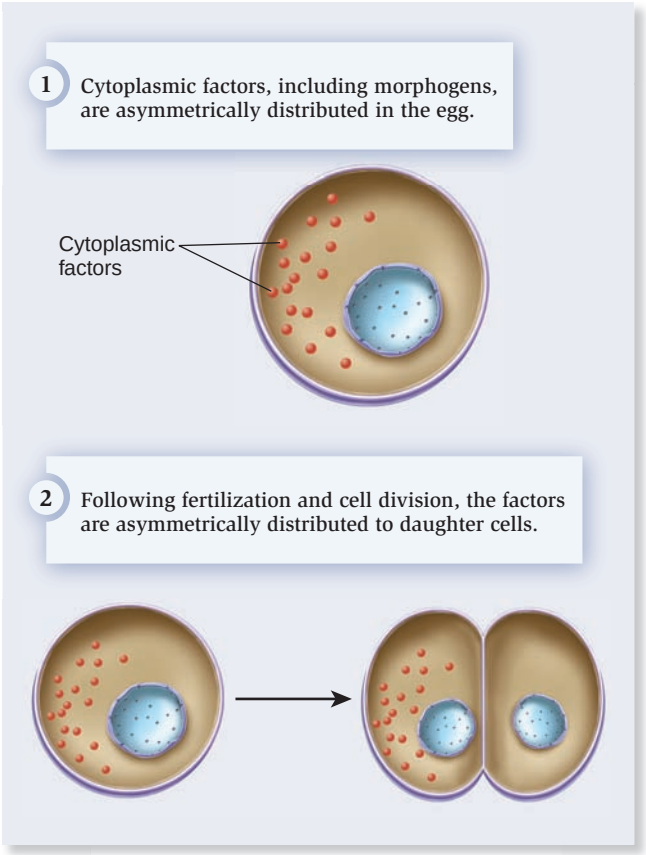
There are two main molecular mechanisms that mediate these forms of internal and external communication: morphogens and cell-to-cell contacts (refer back to Figure 19.5). **Morphogens** are molecules that impart positional information and promote developmental changes at the cellular level. Morphogens are the cytoplasmic factors involved in autonomous specification. They can also be used in conditional specification as cell-to-cell signals.

The concentration of a morphogen determines its activity. For example, some morphogens are only effective above a certain threshold concentration. Others may direct cells along different developmental pathways at different concentrations.

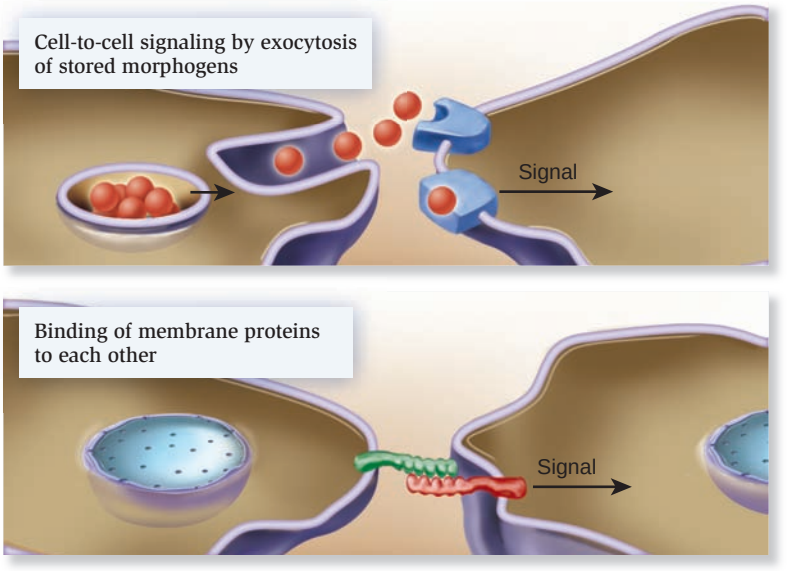
The concentrations of morphogens may vary within or between cells in an embryo. Some morphogenic gradients may be established in the cytoplasm of the oocyte. This is a form of autonomous specification (Figure 52.13a). In this process, the morphogen gradient results in daughter cells that have unequal amounts of the morphogen in their cytoplasm. The presence or lack of the morphogen at a threshold concentration will then determine how the cell differentiates. Second, a morphogenic gradient can be established in the embryo by secretion into extracellular fluids. This is a type of conditional specification (Figure 52.13b). For example, one or more cells may secrete a morphogen into the surrounding extracellular fluid at a specific stage of development. After secretion, the morphogen contacts neighboring cells, generating an intracellular signal such as a second messenger. This signal may influence the developmental fate of those cells. This process, whereby one or more cells governs the developmental fate of neighboring cells, is known as **induction**.

In contrast to morphogen secretion, the mechanism of direct cell-to-cell contacts used in conditional specification involves proteins that are present in the cell membrane and that can interact with other proteins in the cell membranes of other cells. This interaction generates intracellular signals. Specific cell-to-cell contacts play a major role in determining the final positioning of individual cells within different regions of an embryo.

Throughout development, mechanisms of autonomous and conditional specification function together so that distinct cells respond appropriately. We will focus in the rest of this section



(a) Autonomous specification



(b) Conditional specification

Figure 52.13 **Mechanisms that convey positional information during embryonic development.** **(a)** In autonomous specification, cell fate is determined through the unequal segregation of subcellular components during mitosis. **(b)** In conditional specification, cells respond to signals generated by neighboring embryonic cells or to membrane-bound proteins.

on how these mechanisms lead cells to differentiate into each of the numerous diverse cell types with unique functions in the developing organism. Such differentiation involves changes in both gene expression and subcellular organization. Identifying the precise autonomous and conditional signals that specify each cell lineage in the embryo is one of the biggest challenges facing developmental biologists in the 21st century. Let's look at some examples of these mechanisms now.

Autonomous Specification: Asymmetric Distribution of Intracellular Morphogens in the Oocyte

An example of autonomous specification can be found during the cleavage events of embryonic development. During early cleavage, cell cycles can be extremely rapid, such that little or no gene transcription occurs during early cleavage. Consequently, nearly all cellular division and differentiation processes during cleavage are regulated by cytoplasmic factors that resided in the oocyte prior to fertilization. Subcellular components that were synthesized prior to fertilization are called maternal factors. These factors include many mRNAs and morphogens that are stockpiled in the maturing oocyte during oogenesis to facilitate cleavage in the absence of transcription.

Conditional Specification: Concentration Gradients of Extracellular Morphogens Control Cell Differentiation in Vertebrate Embryos

Conditional specification often involves cellular induction, the process by which a cell or group of cells induces a response in a neighboring group of cells in the embryo. The idea of cellular induction during embryonic development arose from experiments in which cells isolated from one part of an amphibian embryo were analyzed in the presence or absence of cells isolated from a different region of the embryo.

An example of cellular induction was observed in experiments performed by Dutch developmental biologist Pieter Nieuwkoop during the 1950s. Nieuwkoop isolated cells from a region near either the animal pole or the vegetal pole of late blastula stage (that is, during cleavage) amphibian embryos. When cells from around the animal pole, a region called the animal cap, were cultured in an appropriate growth medium, they formed undifferentiated spherical structures composed primarily of ectodermal cells. When cells isolated from around the vegetal pole were cultured, undifferentiated clumps of endodermal cells resulted. However, when animal and vegetal cells were cultured together, Nieuwkoop observed the formation of

mesodermal derivatives from the animal pole cells. This suggested that factors released by cells of the vegetal hemisphere could induce differentiation of animal hemisphere cells. This type of experiment, called an **animal cap assay**, has been used extensively to identify morphogens secreted by embryonic cells that induce cells in the animal hemisphere to differentiate into mesoderm. Nieuwkoop went on to show that different vegetal cells isolated from various positions along the dorsoventral axis induced specific types of mesoderm.

One family of proteins—named transforming growth factor betas (TGF-βs)—soon emerged as important morphogens involved in the induction of mesoderm. By purifying these proteins and then adding them to a culture medium containing animal caps, researchers demonstrated that TGF-β proteins have mesoderm-inducing activity. In the absence of TGF-βs, animal caps grow in culture to form clumps of ectodermal tissue that resemble skin cells. However, when purified TGF-βs are added to these cells, they differentiate into mesoderm. TGF-β proteins bind to a specific receptor molecule expressed on the surface of animal cap cells, inducing them to differentiate into mesoderm.

A key question was whether different TGF-β proteins specify different types of mesodermal cells, or whether a single protein at different concentrations can specify all types of mesodermal cells. The morphogenic activity of one TGF-β protein—activin—in an animal cap assay is shown in Figure 52.14. At low concentrations, activin induces the ectoderm to differentiate into mesodermal, bloodlike cells. However, at incrementally higher concentrations, muscle cells, notochord, and fully differentiated heart cells are produced. These results show that certain TGF-β proteins exert different effects depending on their concentrations.

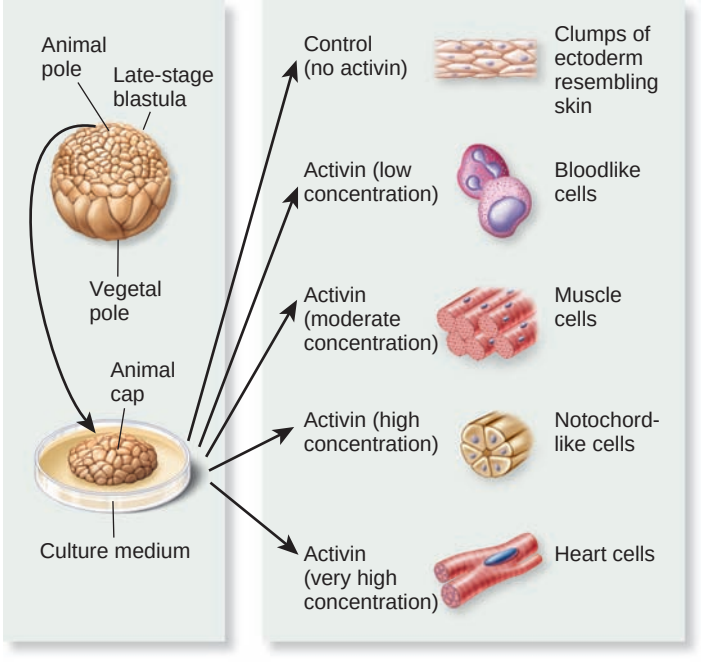


Figure 52.14 **Use of an animal cap assay to demonstrate morphogen activity in conditional specification.** Activin, a member of the TGF-β protein family, functions as a morphogen in an animal cap assay by inducing different types of mesoderm at different concentrations. In the absence of activin, no mesodermal derivatives develop, and the animal caps form cells resembling skin cells. Low concentrations of activin induce the formation of mesodermal derivatives resembling blood cells, whereas moderate concentrations produce muscle cells, and higher concentrations produce such mesodermal derivatives as notochord and heart cells.

Concept check: *How might it be possible for a single molecule to exert different effects on cells at different concentrations?*

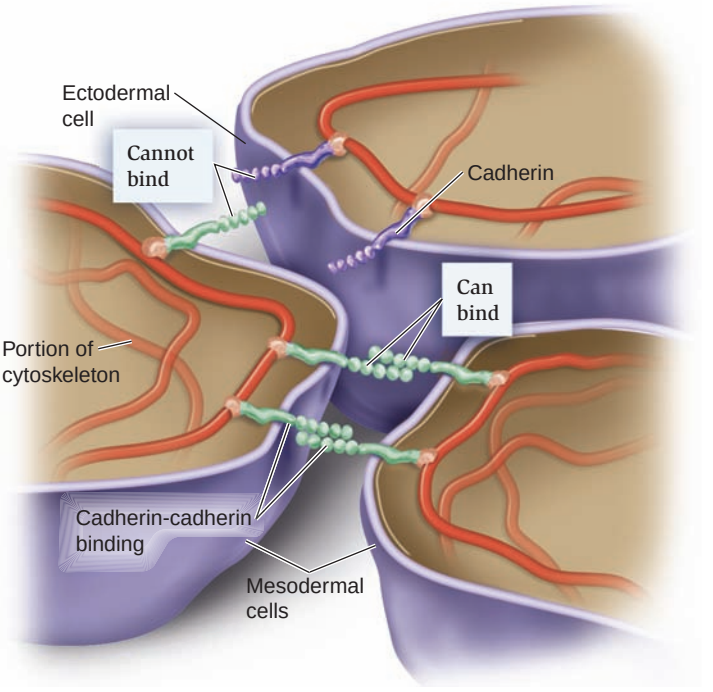

Figure 52.15 **Role of cadherins in cell-to-cell contact.** Developing cells express one type of cadherin. Similar cadherins bind with each other to promote cell-to-cell contacts. Cells expressing dissimilar cadherins cannot bind and thus do not form associations.

Cell-to-Cell Contact Involves Binding of Membrane Proteins

During the major cell movements of embryonic development, how do cells receive information about where they are supposed to be? One way is that the different classes of cells are held together by cell-to-cell contact. Cells within ectoderm, mesoderm, and endoderm express different genes that encode distinct cadherin proteins, which are cell adhesion molecules (described in Chapter 10). Only cadherins of the same type can bind to one another (Figure 52.15). As a result, for example, mesodermal cells tend to adhere to each other but not to endodermal or ectodermal cells.

This property of cells within distinct germ layers is best illustrated by cell dissociation and mixing experiments. When the cells of a gastrula are completely dissociated and then mixed with each other and allowed to reassociate, a fairly well-organized ball of cells forms. When the ectoderm, mesoderm, and endoderm cells within this ball are identified biochemically, the cells are observed to sort themselves out. The cells usually bind only to cells of the same type, and mesodermal cells tend

to reside between the ectodermal and endodermal cells. This experiment indicates that cells within each germ layer can find each other and self-associate via cell-to-cell interactions.

Genomes & Proteomes Connection

Groups of Embryonic Cells Can Produce Specific Body Structures Even When Transplanted into Different Animals

One of the early ideas to emerge from the study of developmental biology was the concept of the morphogenetic field, a group of embryonic cells that ultimately produce a specific body structure. Long before genes and their encoded proteins were identified, embryologists discovered that particular groups of embryonic cells in amphibians have a striking characteristic: They form complete body structures when transplanted to another site in the embryo. This has been observed for cells that form the eyes, limbs, and heart in vertebrates and the eyes, antennae, legs, and wings in insects. In insects, these morphogenetic fields are called imaginal discs.

One of the first morphogenetic fields postulated in vertebrates was the limb field. Between 1910 and 1930, two important observations were made concerning the limb field. First, removing this group of cells from either side of an early developing embryo led to an embryo that lacked a limb at the corresponding position. Second, transplanting a limb field to a new location within pre-limb embryos led to the development of an additional limb at the new location. Interestingly, fate-mapping studies showed that certain cells within the field give rise to specific regions of the limb. These types of experiments suggested that cells within morphogenetic fields were uniquely specified to become particular embryonic structures before any physical evidence for the structure itself could be observed in the embryo.

In the 1920s, the German zoologists Hans Spemann and Hilde Mangold discovered an extremely important field with amazing properties in an early gastrula. This region of the gastrula is now known as **Spemann's organizer**. Their experiments involved dissecting a small piece of tissue from the dorsal lip of the blastopore in an early gastrula of a newt, and transplanting it to the opposite side of another gastrula (Figure 52.16). The result was the formation of a second notochord and neural tube during gastrulation and neurulation in the host embryo, and ultimately the formation of an entirely new body axis—the resulting embryo developed two bodies!

In their experiments, the researchers used two very closely related species of newts. *Triton taeniatus*, which is pigmented, served as the tissue donor, and *Triton cristatus*, which is nonpigmented, served as the host embryo. By transplanting a pigmented Spemann's organizer from the donor embryo into a nonpigmented host embryo, Spemann and Mangold could visually track the origin of the newly developed tissue. The results showed that the secondary notochord and neural tube were composed in large part of host (nonpigmented) cells, with some pigmented cells remaining from the transplanted tissue. This indicated that the transplanted tissue—which they named the "organizer"—had induced cells in the host to differentiate into neural tissue on the transplanted side of the embryo. More recent work has shown that the organizer secretes morphogens—unknown at the time of Spemann's experiments—responsible for inducing the formation of a new embryonic axis. In 1935, Spemann was acknowledged for his important discovery of cellular induction by receiving the first Nobel Prize for studies in developmental biology.

In the past two decades, scientists have identified several genes expressed specifically in Spemann's organizer. Strikingly, many of these genes, which were first discovered in amphibians, are conserved in all vertebrates. These organizer-specific genes are expressed in very small regions of early gastrula embryos, allowing researchers to identify the equivalent of Spemann's

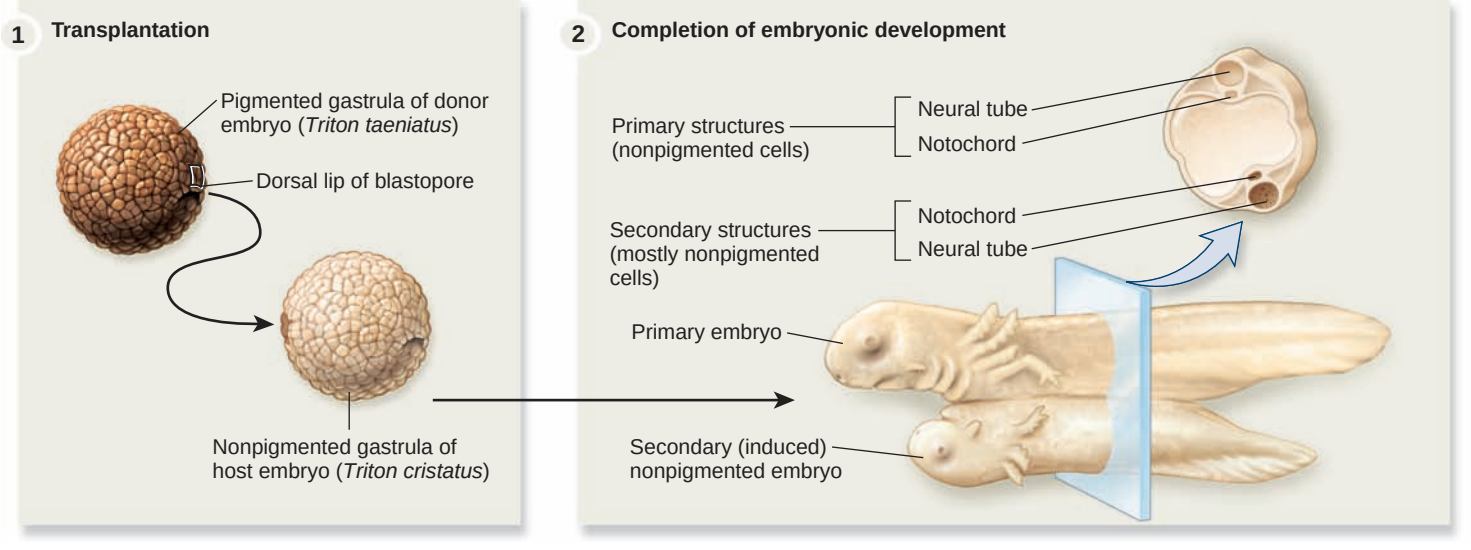

Figure 52.16 **Experiment on newt embryos that led to the discovery of Spemann's organizer.** Note that the secondary body axis formed by the transplanted organizer is composed of host (nonpigmented) tissue, indicating that the organizer (donor) tissue induced the host tissue to differentiate.

organizer in these other species. The names given the organizer in different species vary. In chicks, it is called Hensen's node, whereas in mice, it is simply referred to as the node.

With advances in molecular genetics during the 1960s and 1970s, molecular biologists began to re-examine the concept of a morphogenetic field. An important goal of this new generation of molecular biologists was to identify the specific genes transcribed within Spemann's organizer that give this region the ability to form an entirely new body structure. They thought that identifying these genes would provide key insights into the genetic control systems that govern embryonic patterning during gastrulation in vertebrates. However, identifying unknown genes and their protein products was a daunting challenge. Eventually, in 1992, the first secreted morphogen expressed specifically in the organizer was isolated, as we see next.

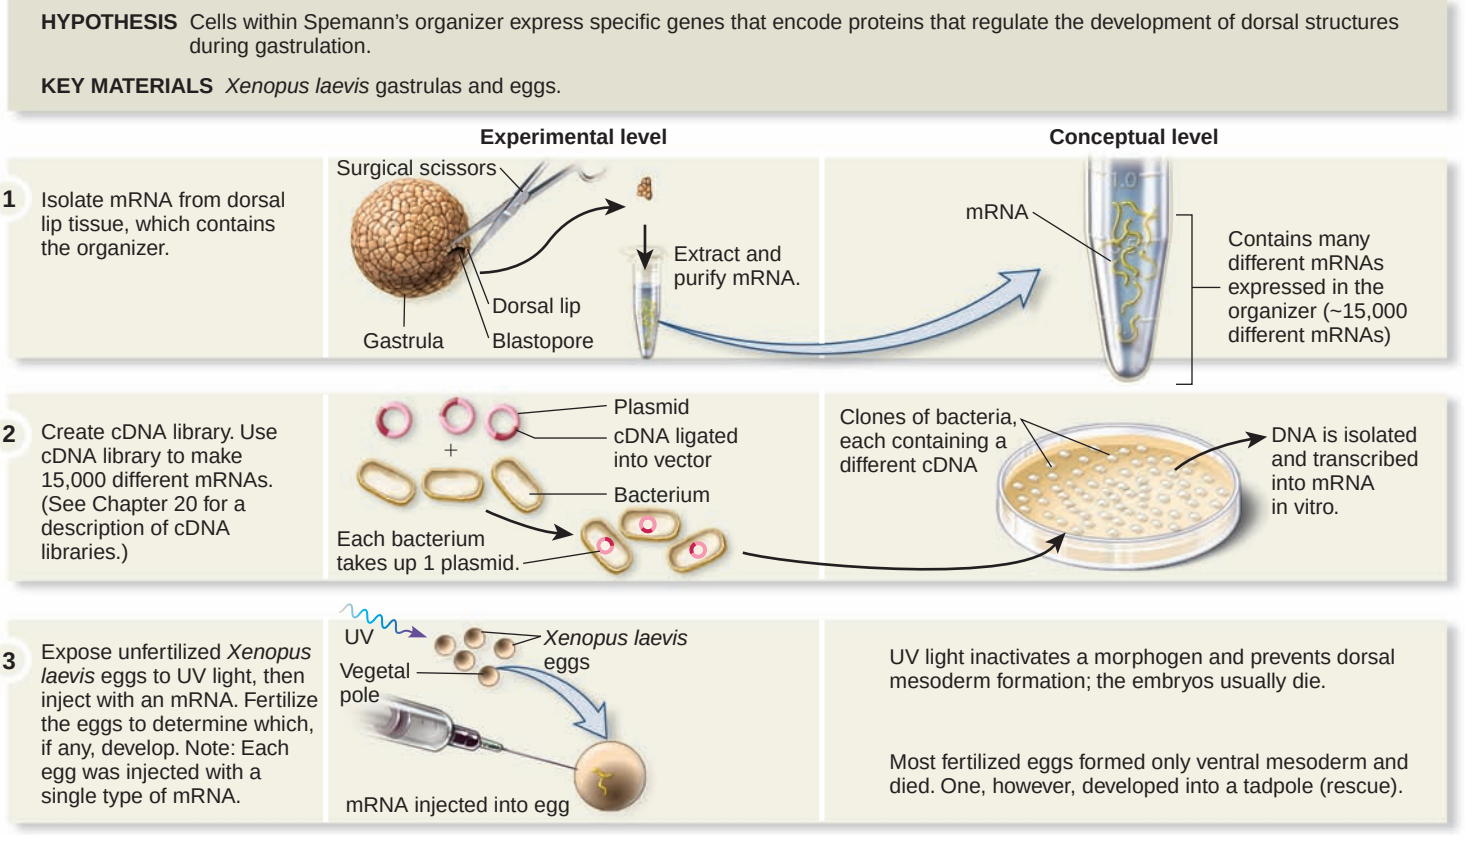
Feature Investigation

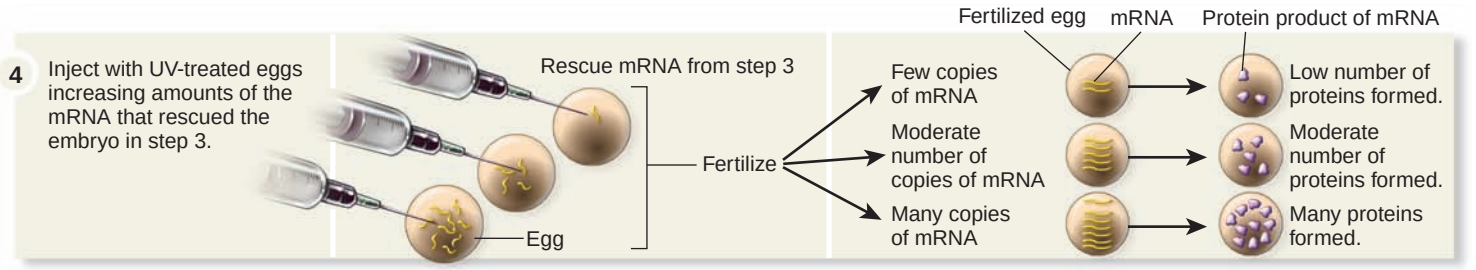
Richard Harland and Coworkers Identified Genes Expressed Specifically in the Organizer

In the early 1990s, Richard Harland and his colleagues hypothesized that morphogens expressed in the organizer should promote the formation of dorsal structures such as those found in the head of embryos. To search for genes that promote the formation of dorsal structures and that are expressed in the organizer during gastrulation, Harland's group took advantage of a key property of unfertilized eggs of the frog *Xenopus laevis*. When these eggs are exposed to UV light at their vegetal hemisphere, they fail to form tadpoles after the eggs are fertilized. However, embryos derived from UV-treated eggs do form primitive mesoderm, but only ventral mesoderm forms. Dorsal mesoderm, which normally gives rise to the notochord and somites, does not form in UV-treated eggs, and the resulting "ventralized" embryos soon die. The embryos appear to be lacking one or more morphogens needed for proper dorsal development.

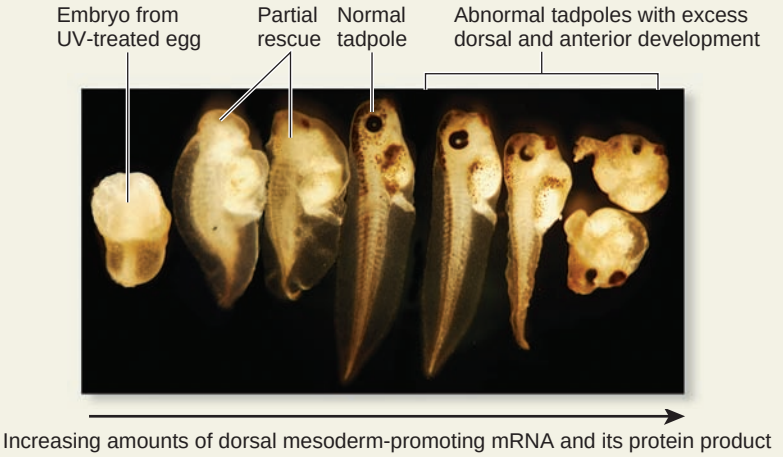
To identify genes in the organizer that encode morphogens that promote the formation of structures such as the notochord, Harland and colleagues used a strategy called expression cloning, as shown in Figure 52.17. First, after dissecting a frog embryo, they isolated and purified mRNA from dorsal-lip tissue containing the organizer. Second, they constructed a cDNA library (see Chapter 20) from the purified mRNA. This resulted

Figure 52.17 Harland and colleagues discovered the morphogen noggin using expression cloning.





5 THE DATA



6 CONCLUSION Cells in Spemann's organizer secrete a morphogen—termed noggin—that directs normal dorsal development in *Xenopus laevis* embryos.

7 SOURCE Smith, W.C., and Harland, R.M. 1992. Expression cloning of noggin, a new dorsalizing factor localized to the Spemann organizer in *Xenopus* embryos. *Cell* 70:829–840.

in approximately 15,000 different cDNAs, each of which corresponded to a single gene that had been expressed in the organizer. Their next task was to transcribe each of these cDNAs back into mRNA in vitro. In a third step, the researchers injected these different mRNAs into thousands of unfertilized UV-treated eggs, which they then fertilized. Each egg was injected with a single type of mRNA. Their idea was that any mRNA that produced a protein with dorsal mesoderm-promoting activity might "rescue" the embryos and result in free-swimming tadpoles.

Using this procedure, the researchers identified one mRNA whose protein product rescued the embryo (step 3). They then injected increasing amounts of this mRNA into UV-treated eggs, fertilized the eggs, and examined the morphology of the resultant tadpoles. They discovered that the protein product from this mRNA acted as a morphogen because it induced different embryonic structures at different concentrations. At low concentrations, it partially rescued the embryos. At moderate concentrations, it resulted in the formation of normal embryos. However, at very high concentrations, the embryos developed too much dorsal mesoderm and not enough ventral mesoderm. These abnormal embryos developed large heads and extremely small trunks. Further studies identified the gene that coded for this mRNA and verified that it was transcribed in Spemann's organizer. They named the gene *noggin* (from a slang term for brain or head), because it caused embryos to develop large heads when present in abnormally high levels (see right side of the data).

Later work revealed that noggin protein promotes dorsal development by inhibiting ventral development. Noggin protein inhibits at least two other morphogens that are known to induce ventral, but not dorsal, mesoderm. These studies showed that antagonistically acting proteins expressed and secreted from certain cells in the organizer can specify precise structures in a concentration-dependent fashion. Further work in mice revealed that *noggin* is expressed in the node of mammals. Specific deletion of the *noggin* gene in mice leads to defects in dorsal structures. This indicates that *noggin* plays a fundamental role during gastrulation in mammals as well as amphibians.

The discovery of *noggin* and its mechanism of action revealed that the normal development of embryos requires a balance between stimulatory and inhibitory factors. The inhibition of developmental processes—such as the suppression of ventral mesoderm by *noggin*—appears to be a normal part of the mechanism by which development of an organism occurs.

Experimental Questions

1. Why were scientists interested in identifying genes expressed exclusively in Spemann's organizer?
2. What hypothesis did Harland and colleagues test?
3. How did the scientists identify possible genes that are important for the development of dorsal structures, and how did they test the gene products to determine their activity?

52.4 Impact on Public Health

Given the complexity and precision of the five general developmental events we have described in this chapter, it may not be surprising that on occasion these processes fail to occur properly. When this happens in humans, its impact can be devastating. Many health problems in humans are caused by genetic or environmental factors that disrupt embryonic development. As we have seen, the early development of an embryo is among the most complex processes found in nature. Because embryonic development is affected by genetic as well as environmental factors, a number of diseases and disorders in humans stem from problems that arise during this process.

An example of a condition involving defective embryonic development is spina bifida, caused by the failure of the neural tube to close at either the anterior or posterior end during neurulation. Signs and symptoms of spina bifida, which occurs in about 7 of every 10,000 births in the U.S., vary depending on the degree to which the neural tube fails to close. In minor forms, gaps may occur between a few vertebrae at the bottom of the back, and impairment of motor or sensory function may not be apparent at birth. However, neurological deterioration often becomes evident during childhood or adulthood. Surgical procedures soon after birth can improve the long-term quality of life for patients with spina bifida, but prevention of this condition—by increasing the amount of folic acid the embryo gets during pregnancy—is much more effective. Up to 75% of spina bifida cases may be prevented if women in the first trimester of pregnancy increase their dietary intake of folic acid, a common B vitamin needed during the rapid growth that occurs during embryonic development.

Whereas spina bifida appears to be related to deficient folic acid levels during neurulation, other embryonic defects are caused by foreign chemicals introduced during pregnancy. Given the deleterious effects of certain chemical compounds on specific phases of embryonic development in humans, it is not surprising that ingested or inhaled compounds such as tobacco, alcohol, and other drugs can also have severe and devastating consequences on a developing fetus. Indeed, the leading overall cause of mental retardation worldwide is fetal alcohol syndrome (FAS), which occurs in babies whose mothers drink excessive amounts of alcohol during pregnancy. In addition to cognitive disorders, children born with FAS also show malformed facial features and joints and altered overall growth characteristics (also seen in other vertebrate embryos exposed experimentally to ethanol; see the chapter-opening photo). These morphological features are likely caused by the generally detrimental effects that ethanol has on cell division. The cognitive deficits are thought to result from the death of developing CNS neurons, which are particularly susceptible to the toxic effects of ethanol.

Unlike the previous conditions, which are caused by environmental conditions surrounding the embryo, other embryonic defects are caused by genetic defects. The most common genetic disorder affecting humans is Down syndrome (formerly called Down's syndrome), which arises from an egg containing two copies of chromosome 21. The effects in an embryo that ultimately acquires three copies of chromosome 21—two from the egg and one from the sperm—are complex, such that multiple physical and neurological disorders are associated with this syndrome.

Finally, cleft lip or palate (or both combined) are relatively common (roughly 1:1,000 births in the U.S.) developmental disorders that appear to share both a genetic and an environmental basis. During early development in humans, the tissues of the lip and palate exist as two structures that merge around weeks 5–7 of embryonic development. In cleft lip, the tissues of the upper lip fail to fuse, whereas in cleft palate, those of the palate fail to fuse; in some cases, these two deformities occur together. In the latter case, the result is a gap or groove that extends from the mouth into the nasal cavity. Cleft lip/palate is a disfiguring condition that leads to speech impediments, difficulty eating and drinking (for example, an affected infant cannot readily produce the suction needed to drink from a bottle or nipple), and repeated infections. The only treatment for cleft lip/palate is surgical repair of the affected tissues, which is often quite successful but which usually entails numerous surgical procedures over several years (Figure 52.18). Despite intensive research, the causes of cleft lip/palate are still uncertain. However, certain environmental agents have been linked with an increased risk of cleft lip/palate, notably maternal ingestion of alcohol, lead, cocaine, certain antiseizure drugs, or possibly vitamin deficiencies during pregnancy. Recently, researchers have identified several genes in which loss-of-function mutations affect the way in which the palate develops, contributing to a cleft.

The World Health Organization has compiled the number of birth defects around the world by geographic region in order

Figure 52.18 Child with cleft lip/palate before and at two different ages after surgeries.

to assess the extent of the impact of developmental disorders on public health. The resulting document, entitled *The World Atlas of Birth Defects*, indicates that regional differences in the incidences of a given birth defect can be dramatic. For example, the rate of spina bifida varies from 1 in every 10,000 births in France to about 15–30 in every 10,000 births in Mexico and Ireland. The occurrence of Down syndrome, by contrast, varies from about 7 cases per 10,000 births in Cuba to 22 per 10,000 births in Chile. Together, 27 different birth defects affect 2–3% of all babies born in the world today, an astonishing number when one considers the world's population of roughly 6.5 billion, with annual worldwide births of nearly 150 million.

Summary of Key Concepts

52.1 Principles of Animal Development

- The process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts is called embryonic development.
- The process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes, is called cellular differentiation.
- Four responses to positional information are cell division, cell migration, cell differentiation, and apoptosis.

52.2 General Events of Embryonic Development

- Development in many animals, including vertebrates, involves five general events: fertilization, cleavage, gastrulation, neurulation, and organogenesis. (Figure 52.1)
- Major events in fertilization include the acrosomal reaction and the cortical reaction. During the acrosomal reaction, the binding of a sperm with the egg membrane triggers a series of events producing the fast block to polyspermy, which prevents other sperm from binding to the egg. During the cortical reaction, events produce a calcium wave that leads to additional barriers to more sperm, a process called the slow block to polyspermy. (Figure 52.2)
- During cleavage, which involves cell divisions without cell growth, the daughter cells are called blastomeres. When the embryo forms an outer epithelial layer and an inner cavity, it is called a blastula. The mammalian counterpart of a blastula is called a blastocyst.
- Cleavage-stage embryos in triploblast organisms have animal and vegetal hemispheres. The hemispheres determine in part the future anteroposterior and dorsoventral axes of the embryo. (Figure 52.3)
- Incomplete or meroblastic cleavage occurs in birds, some fishes, and some other vertebrates whose eggs contain large amounts of yolk. Complete or holoblastic cleavage occurs in amphibians and mammals, whose eggs have smaller amounts of yolk. In mammals, cleavage occurs in the oviduct and the embryo implants in the uterine wall. (Figures 52.4, 52.5)
- In fate mapping, a small population of embryonic cells is specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development. (Figure 52.6)
- During gastrulation, the hollow ball of cells that makes up the blastula or blastocyst is converted into a highly organized structure in which the three germ layers—endoderm, mesoderm, and ectoderm—and the primordial germ cells are established. Each germ layer gives rise to specific structures. An embryo that is undergoing gastrulation is called a gastrula. (Figure 52.7)
- Gastrulation begins when a band of tissue invaginates (pinches in), creating a small opening called the blastopore. During gastrulation, the embryo forms a cavity called the archenteron, which will become the organism's digestive tract. (Figure 52.8)
- During gastrulation, two cellular processes are crucial to development: apical constriction, in which a reduction in the diameter of the actin rings connected to the adherens junctions causes the cells to elongate toward their basal end, and convergent extension, in which two rows of cells merge to form a single elongated layer. (Figure 52.9)
- A distinguishing anatomical feature that forms at the end of gastrulation in all chordates is the notochord.
- During gastrulation, primordial germ cells (PGCs) become established. Amphibian eggs contain certain cytoplasmic determinants, called the germ plasm, that help define and specify the PGCs in the gastrula stage. In flies, PGCs are the first cells to form at the posterior end of the embryo and are called pole cells. (Figure 52.10)
- Neurulation is the multistep embryological process responsible for initiating CNS formation. Neurulation occurs just after gastrulation and involves the formation of the neural tube from ectoderm located dorsal to the notochord. (Figure 52.11)
- Another important cell lineage that arises during neurulation is the neural crest, which gives rise to all neurons and supporting cells of the peripheral nervous system in vertebrates.
- During neurulation, the mesoderm becomes segmented from the anterior end first, giving rise to blocklike structures of mesoderm called somites. (Figure 52.12)
- The developmental event during which cells and tissues form organs is called organogenesis.

52.3 Control of Cell Differentiation and Morphogenesis During Animal Development

- Two mechanisms convey positional information during embryonic development: autonomous specification, which involves internal factors, and conditional specification, which involves external signals. (Figure 52.13)
- Morphogens and cell-to-cell contacts are the molecular mechanisms behind autonomous and conditional specification.
- Morphogens can elicit different cellular responses at distinct concentrations in an embryo.
- Autonomous specification involves the asymmetric distribution of intracellular morphogens and other factors in the oocyte.
- A type of experiment called an animal cap assay has been used extensively to identify morphogens secreted by embryonic cells that induce cells in the animal hemisphere to differentiate into mesoderm. This is a type of conditional specification. (Figure 52.14)
- In another type of cell-to-cell interactions, cells use membrane proteins called cadherins to bind to other like cells, ensuring

that the cells will move together during development. (Figure 52.15)

- An extremely important region in the early gastrula is known as Spemann's organizer. The organizer secretes morphogens responsible for inducing the formation of a new embryonic axis. (Figure 52.16)
- Richard Harland and coworkers discovered the *noggin* gene in frog embryos and demonstrated that it acted to promote dorsal development by inhibiting ventral development. (Figure 52.17)

52.4 Impact on Public Health

- An important example of a condition involving defective embryonic development is spina bifida, caused by the failure of the neural tube to close completely during neurulation.
- The leading overall cause of mental retardation worldwide is fetal alcohol syndrome (FAS), which occurs in babies whose mothers drink excessive amounts of alcohol during pregnancy.
- In Down syndrome, the most common genetic disorder affecting humans, the embryo has three copies of chromosome 21. The effects are complex and include multiple physical and neurological disorders.
- Cleft lip or palate is a developmental disorder that occurs in 1:1,000 births in the U.S.; it has both genetic and environmental causes. (Figure 52.18)

Assess and Discuss

Test Yourself

1. The acrosomal and cortical reactions occur during which event of development?
   a. fertilization
   b. cleavage
   c. gastrulation
   d. neurulation
   e. organogenesis
2. Cadherins are
   a. adhesion protein molecules that attach cells to extracellular material.
   b. genes necessary for proper germ layer formation.
   c. adhesion protein molecules that allow cells of a given germ layer to adhere to each other.
   d. germ layers.
   e. proteins that provide structural support to the cytoplasm of cells.
3. Cell differentiation that results from cell-to-cell signaling is
   a. autonomous specification.
   b. conditional specification.
   c. communicative specification.
   d. gastrulation.
   e. embryogenesis.
4. The three germ layers of triploblasts are established during
   a. fertilization.
   b. cleavage.
   c. blastula formation.
   d. gastrulation.
   e. neurulation.
5. The limbs of vertebrates are formed from
   a. the endoderm.
   b. the mesoderm.
   c. the ectoderm.
   d. all of the above.
6. In vertebrates, the digestive tract forms from
   a. the blastopore.
   b. the dorsal lip.
   c. the archenteron.
   d. the mesoderm.
   e. both a and d.
7. The cells that give rise to gametes
   a. are derived from the mesoderm.
   b. often arise independently from the three germ layers.
   c. originate directly from the tissue that will develop into the gonads.
   d. are some of the last cells of the embryo to differentiate.
   e. are formed the same way in all animals.
8. Cells of the neural crest
   a. give rise to the central nervous system.
   b. originate from the ectoderm.
   c. migrate to different areas of the body and differentiate into a variety of cells, including neurons of the peripheral nervous system.
   d. all of the above
   e. b and c only
9. Which is true of Spemann's organizer?
   a. It is unique to amphibian embryos.
   b. It arises early in cleavage-stage embryos.
   c. It secretes morphogens, including the protein called noggin.
   d. It is found in the dorsal lip region of early gastrula-stage embryos.
   e. c and d are both correct.
10. Morphogens
    a. are proteins that stimulate responses in the cells of an embryo.
    b. are important signaling proteins in the process of embryonic development.
    c. can elicit different cell responses at different concentrations.
    d. contribute to autonomous specification.
    e. all of the above

Conceptual Questions

1. Distinguish between embryonic development, growth, and differentiation.
2. During organogenesis in vertebrates, some organs develop and become functional sooner than others. Why is it important, for example, that the heart of a terrestrial vertebrate develop sooner than its lungs?
3. Distinguish between autonomous and conditional specification.

Collaborative Questions

1. Discuss the process of gastrulation.
2. Discuss the process of neurulation.

Chapter Outline

Immune Systems

53

In an immune system response, a macrophage engulfs numerous bacteria (false-color SEM).

All animals must defend themselves against environmental factors that threaten their survival, including predation, intraspecific fighting, accidents, and hazardous substances. In addition, animals must contend with various threats within their internal environment, including the invasion of potentially harmful microorganisms such as bacteria, the presence of foreign molecules such as the products of microorganisms, and the presence of abnormal cells such as cancerous cells.

The ability of an animal to ward off these internal threats—an animal's **immunity**, or immune defenses—is the subject of this chapter. The cells and organs within an animal's body that contribute to immune defenses collectively constitute an animal's **immune system**. The study of immunity is called immunology. Immunologists examine the processes by which the immune system protects an animal from foreign matter, whether living or nonliving. In these processes, the body's immune defenses recognize the body's own molecules as "self" and attack anything that is foreign, or "nonself."

Immune defenses are often divided into two types: innate and acquired. In **innate immunity**, the body's defenses are present at birth and act against foreign materials in much the same way regardless of the specific identity of the invading material. Thus, the innate immunity of animals is also known as "nonspecific immunity." Innate immunity includes the body's external barriers (skin and mucous membranes), plus a set of cellular and chemical defenses that oppose substances that breach those barriers. An example of an innate immune response is seen in the chapter-opening photo, in which a cell known as a macrophage is engulfing several bacteria. All animals have innate immune defenses. In contrast, **acquired immunity** develops only after the body is exposed to foreign substances. This type of immunity is characterized by the ability of certain cells of the immune system to recognize a foreign substance and initiate a response that targets that substance specifically. For this reason, acquired immunity is also known as "specific immunity." Another feature distinguishing acquired immunity is that repeated exposure to a foreign substance elicits greater and greater defense responses, unlike the situation for nonspecific immunity, where each exposure to the foreign material elicits the same defense responses. Thus, acquired immunity is also known by a third name, "adaptive immunity." Specific immune defenses have been identified in all vertebrates except for the jawless fishes, but they have not been unequivocally identified in invertebrates.

We begin the chapter with a brief overview of the different microorganisms that cause disease in animals. We then consider the mechanisms that provide animals with innate and acquired defenses against harmful microorganisms. We conclude with a discussion of the public health implications of some selected immunity-related conditions in humans.

53.1 Types of Pathogens

As just noted, the body's immune defenses must protect against a variety of foreign materials, but most important among them are disease-causing microorganisms, or **pathogens**. Pathogens exist in nearly every possible ecological niche on Earth. Both terrestrial and aquatic animals, including invertebrates and vertebrates, encounter each of the three major types of pathogens: certain bacteria, viruses, and eukaryotic parasites. A fourth type of infectious agent—proteins called prions—were considered in Chapter 18 and will not be discussed here.

As discussed in Chapter 27, bacteria are single-celled prokaryotic organisms that lack a true nucleus. Bacteria can either damage tissues at open wound sites or release toxins that enter the bloodstream and disrupt functions in other parts of the

body. Bacteria are responsible for many diseases and infections, including typhoid fever, strep throat, skin infections, middle ear infections, and food poisoning. The major ways in which bacteria gain entry into an animal's body are through direct bodily contact, open wounds, inhalation through the respiratory tract, and ingestion via fecal contamination of food or water. The latter situation may arise because many infectious bacteria enter the intestines and are excreted in feces, which may be deposited near food or water sources used by some animals.

Viruses are nucleic acids enclosed within a protein coat (see Chapter 18). Unlike bacteria, viruses lack the metabolic machinery to synthesize the proteins they require to replicate themselves. Instead, they must infect a host cell and use its biochemical and genetic machinery, including nucleotides and energy sources, to make more viruses. The viral nucleic acid directs the host cell to synthesize the proteins required for viral replication. After entering a cell, some viruses, such as the common cold virus, multiply rapidly, kill the cell, and then infect other cells. Other viruses can lie dormant within host cells before suddenly undergoing rapid replication, which causes cell damage or death. Finally, certain viruses can transform their host cells into cancerous cells. Viruses are responsible for a great variety of illnesses, including some sexually transmitted diseases (refer back to Figure 18.2). Like bacterial infections, viral infections can spread rapidly among animals and can be lethal. Viruses typically enter the body through the respiratory tract or through open wounds.

Eukaryotic parasites—whether protists, fungi, or multicellular organisms such as worms—damage a host by using the host's nutrients for their own growth and reproduction or by secreting toxic chemicals. In humans, parasites account for an enormous number of cases of disease annually. For example, several hundred million people are infected each year with one of the mosquito-borne protists of the genus *Plasmodium* that causes malaria. Parasitic infections may enter a host through the bite of an infected insect, as in malaria; by ingestion of food or water containing parasitic organisms, such as roundworms; or in some cases, by penetrating the skin, as with blood flukes. What are the first defenses that such pathogens encounter?

53.2 Innate Immunity

Innate (nonspecific) immune defenses protect against foreign cells or substances without having to recognize the invaders' specific identities. This type of defense mechanism is called innate because animals inherit the ability to perform these protective functions and because this type of immunity does not require prior exposure to invaders. Instead of distinguishing among foreign materials, nonspecific defenses recognize some general, conserved property marking the invader as foreign, such as particular classes of carbohydrates or lipids present in the cell walls of many different kinds of microbes.

In this section, we will consider the innate immune defenses. These include defenses at the body surfaces, the actions of phagocytic cells, the response to injury known as inflammation, and various proteins secreted by cells of the immune system that facilitate the destruction of pathogens.

The Body Surface Is an Initial Line of Defense

An animal's initial defenses against pathogens are the barriers provided by surfaces exposed to the external environment. Very few microorganisms can penetrate the intact skin or body surface of most animals, particularly the tough, thick, or scaly skin characteristic of many vertebrates or the rigid exoskeleton of many arthropods. In addition, glands in the body surfaces of both invertebrates and vertebrates secrete a variety of antimicrobial molecules, including mild acids and enzymes such as lysozyme that destroy bacterial cell walls.

The mucus secreted by cells in the mucous membranes lining the respiratory and upper gastrointestinal tracts of vertebrates also contains antimicrobial molecules. More importantly, mucus is sticky—microbes that become stuck in it are prevented from penetrating the mucous membrane barrier. They are either swept up by cilia into the pharynx and then swallowed, or they are engulfed by cells that are present in both tracts. Pathogens ingested with food are often destroyed by the acidic environment of an animal's midgut.

If a pathogen is able to penetrate a barrier and gain entry into an animal's internal tissues and fluids, other nonspecific defense mechanisms are activated. These mechanisms are mediated by several types of cells that reside in the body fluids and tissues, as described next.

Phagocytic Cells Provide Innate Defense Against Pathogens That Enter the Body

Several different types of cells in vertebrates play key roles in innate immunity (Figure 53.1). Many of these cells are **phagocytes**—cells capable of **phagocytosis**. Phagocytosis is a type of endocytosis in which the cell engulfs particulate matter, which usually is then destroyed by proteases or oxidizing compounds such as hydrogen peroxide. Phagocytes are found in the body fluids, such as hemolymph and blood, and also within various tissues and organs. Phagocytes are present in all classes of animals and are among the most fundamental and ancestral forms of immune defenses.

In vertebrates, most phagocytes belong to the type of blood cells called white blood cells, or **leukocytes** (Figure 53.1). All leukocytes are derived from a common type of stem cell (see Chapter 19), which in mammals and birds is found in the bone marrow. These stem cells give rise to several types of leukocytes and other cells that have specialized functions. The leukocytes involved in innate immunity include neutrophils, eosinophils, monocytes, macrophages, basophils, and natural killer cells.

Neutrophils are phagocytes and the most abundant leukocytes. They are found in blood and enter tissues during inflammation. After neutrophils engulf bacteria by phagocytosis, the bacteria are destroyed within endocytotic vacuoles by proteases, oxidizing compounds, and antibacterial proteins called defensins. The production and release of neutrophils from bone

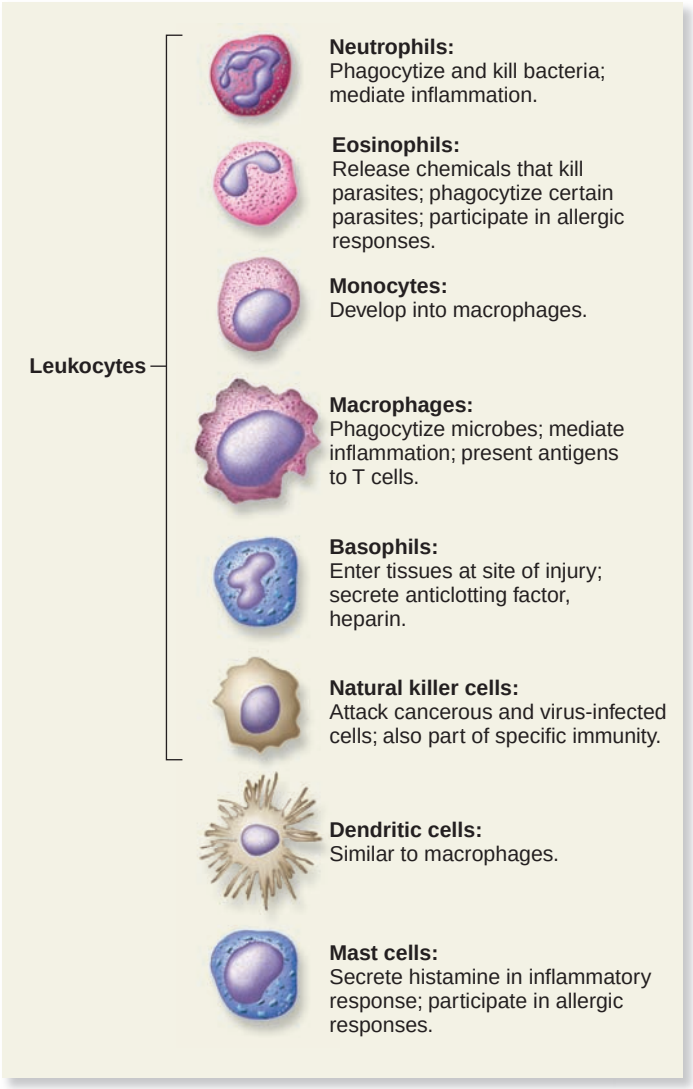

Figure 53.1 **Cells involved in nonspecific immunity in vertebrates.** Note that six of these types of cells are leukocytes.

marrow is greatly stimulated during the course of an infection. **Eosinophils** are found in the blood, and mucosal surfaces lining the gastrointestinal, respiratory, and urinary tracts, where they fight off parasitic invasions. In some cases, eosinophils act by releasing toxic chemicals that kill parasites, and in other cases by phagocytosis. **Monocytes** are phagocytes that circulate in the blood for a short time, after which they migrate into tissues and organs and develop into **macrophages**. Macrophages are strategically located where they will encounter invaders, including epithelia in contact with the external environment, such as skin and the linings of respiratory and digestive tracts. Macrophages are large phagocytes capable of engulfing viruses and bacteria, as shown in the chapter-opening photo.

In contrast to these other leukocytes, **basophils** are secretory cells. They secrete an anticlotting factor called heparin at the site of an infection, which helps the circulation flush out the infected site. Basophils also secrete histamine, which attracts infection-fighting cells and proteins to the site.

Natural killer (**NK**) **cells** are another kind of leukocyte called lymphocytes, of which there are several types. We will learn more about the other types of lymphocytes later, because they play the major role in acquired immunity. NK cells, however, participate in both innate and acquired immunity. These cells are part of the body's innate defenses because they recognize general features on the surface of cancerous cells or any virus-infected cells. NK cells arise in the bone marrow, but their life history remains unclear. They act by releasing chemicals into the vicinity of cancerous or virus-infected cells, thereby killing those cells.

In addition to leukocytes, two other types of cells derived from bone marrow stem cells play important roles in nonspecific immunity. **Dendritic cells** are scattered throughout most tissues, where they perform various macrophage-like functions. **Mast cells** are found throughout connective tissues, particularly beneath the epithelial surfaces of the body. Mast cells secrete many locally acting molecules, including histamine. Histamine and other substances are involved in inflammation, an important component of the nonspecific defense mechanism to which we now turn.

Inflammation Is an Innate Response to Infection or Injury

Inflammation is an innate local response to infection or injury. The functions of inflammation are to destroy or inactivate foreign invaders, to clear the infected region of dead cells and other debris, and to set the stage for tissue repair. The key cellular components of this process are phagocytes, primarily neutrophils, macrophages, and dendritic cells, as well as mast cells.

The events of inflammation are induced and regulated by chemical mediators. These include a family of proteins called **cytokines** that function in both innate and acquired immune defenses. Cytokines provide a chemical communication network that synchronizes the components of the immune response. Most cytokines are secreted by more than one type of immune system cell and also by nonimmune cells such as endothelial cells and fibroblasts.

The sequence of local events in a typical inflammatory response to a bacterial infection is summarized in Figure 53.2. A tissue injury such as that caused by the splinter shown here begins the inflammation process, which causes the familiar signs and symptoms of local redness, swelling, heat, and pain.

Substances secreted into the extracellular fluid from mast cells, injured tissue cells, and neutrophils contribute to the inflammatory response. For example, histamine from mast cells and nitric oxide from endothelial cells (Figure 53.2, step 1) cause dilation of the small blood vessels in the infected and damaged area, and the vessels become leaky (step 2).

These vascular changes provide two benefits. First, the increased blood flow to the inflamed area, which accounts for the redness and heat, increases the delivery of beneficial proteins and leukocytes and increases local metabolism to facilitate healing. Second, the increased vascular permeability ensures that the plasma proteins that participate in inflammation can gain entry to the interstitial fluid. The swelling in an inflamed area also results from this increased leakiness of blood vessels.

Once neutrophils and other leukocytes arrive at the site of the injury, they begin the process of phagocytizing and

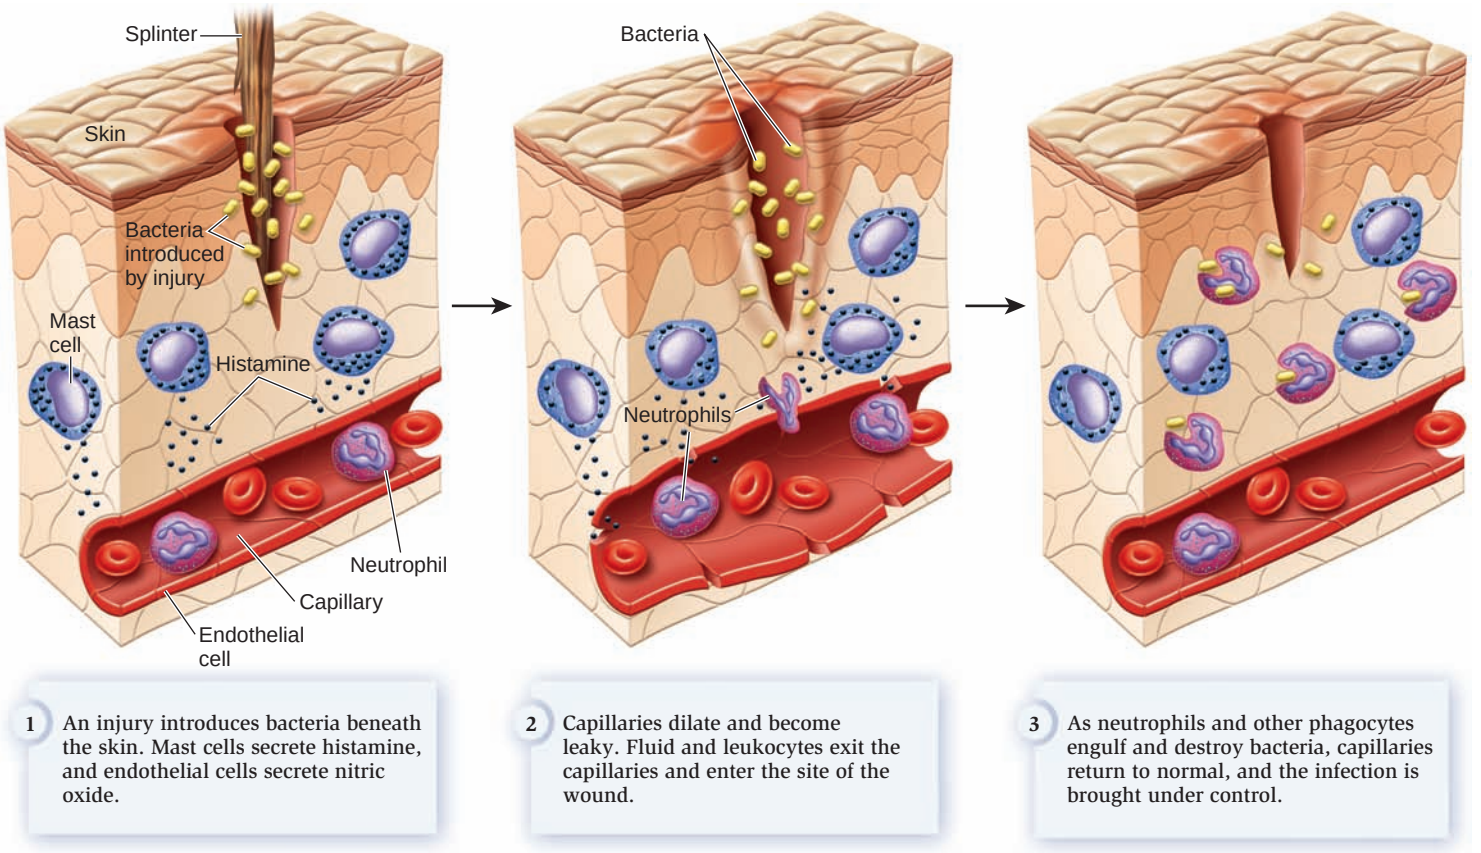

Figure 53.2 **The events in inflammation.** Shown are the initial stages of inflammation in response to a penetrating wound that introduces bacteria beneath the skin.

Concept check: *Inflammation is often associated with swelling of the inflamed area. Could this swelling have an adaptive value?*

destroying invading microbes (Figure 53.2, step 3). The initial step in phagocytosis involves the interaction of phagocyte surface receptors with certain carbohydrates or lipids in the microbial cell walls. Subsequently, the neutrophils and other phagocytes also release antimicrobial substances into the extracellular fluid that can destroy microbes even before phagocytosis occurs. Other secreted substances such as nitric oxide function as inflammatory mediators. The result is positive feedback: Once phagocytes enter the area and encounter microbes, they release inflammatory mediators that bring even more phagocytes into the area.

Inflammation sets the stage for tissue repair. Nearby connective tissue cells called fibroblasts divide rapidly and secrete large quantities of collagen, the major component of extracellular matrices, and nearby blood vessel cells proliferate to restore blood supply. Ultimately, tissue repair may be imperfect, leaving a scar largely composed of fibroblasts, collagen, and other proteins.

Inflammation—indeed any stage of an illness—may be accompanied by **fever**, an increase in an animal's body temperature that results from an infection. This is distinguished from hyperthermia, an increase in body temperature resulting from any number of causes, such as overexertion. In humans, a temperature greater than 38°C (100.4°F) is considered to be a fever (normal is about 37°C [98.6°F]). The precise mechanisms by which a fever arises are not completely understood. It is clear, however, that in mammals, cytokines released into the circulation by activated macrophages act within the hypothalamus to raise the body's set point for temperature. The result is a decrease in heat dissipation and an increase in heat generation. In ancient times, a fever was considered beneficial in helping fight off an infection, and this may indeed be true. While a sustained high fever requires medical attention because of the damaging effects of high temperature on membrane function, enzyme activity, and other processes (see Chapter 46), a low or moderate increase in temperature appears to stimulate leukocyte activity and proliferation and provides a less hospitable environment for at least some types of pathogens.

Antimicrobial Proteins Include Interferons and Complement Proteins

In addition to phagocytes and the inflammatory response, there are at least two other types of innate defenses against invading pathogens used by the body. These defenses allow for extracellular killing of microbes without prior exposure to those microbes. The first is used against viruses. **Interferons** are proteins that generally inhibit viral replication inside host cells. In response to viral infection, most cell types produce interferons and secrete them into the extracellular fluid. When the interferons bind to plasma membrane receptors on the secreting cell and on other cells, each cell synthesizes a variety of proteins

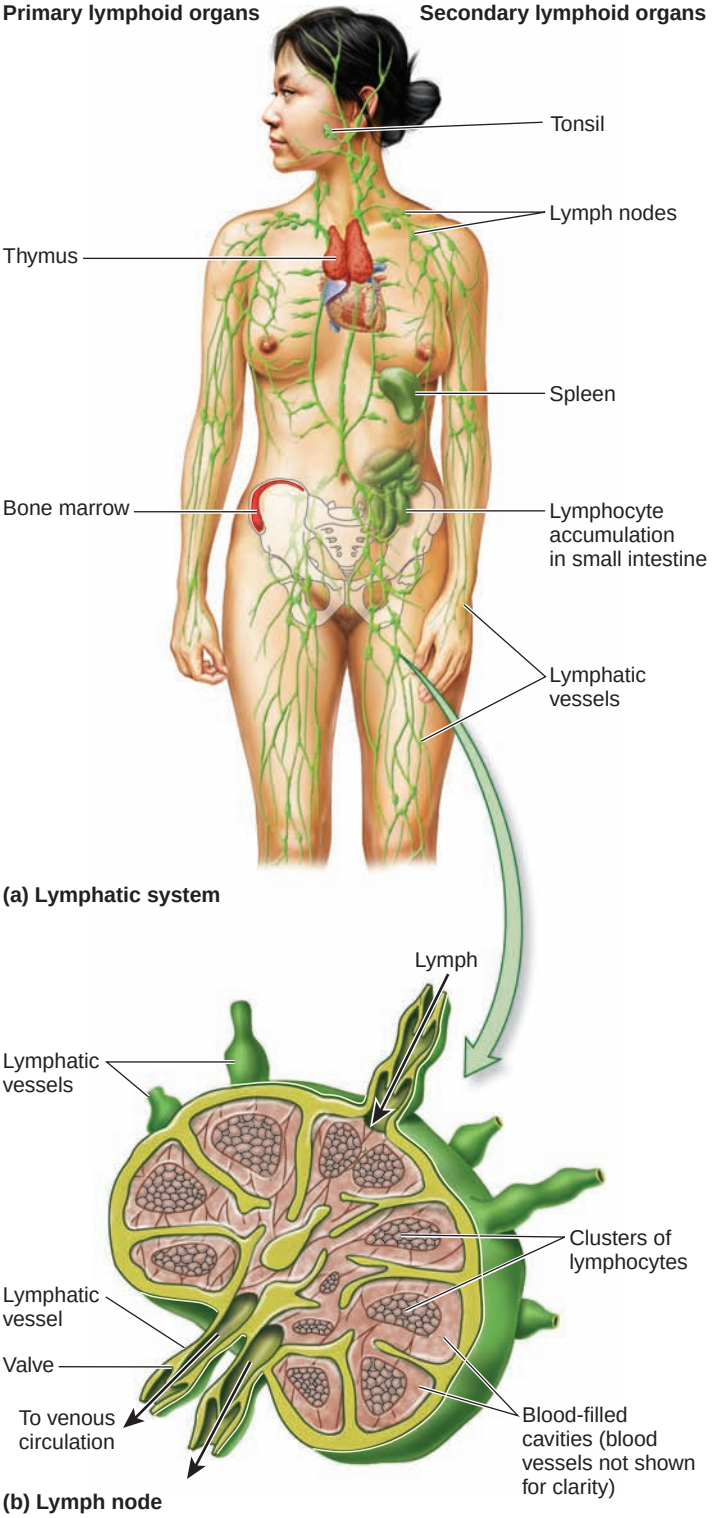

Figure 53.3 **The lymphatic system in humans.** **(a)** The major components of the human lymphatic system. Primary lymphoid organs are shown in red, and secondary lymphoid organs are shown in green. In adult humans, the primary lymphoid organs in bone are found in the sternum, ribs, parts of the skull, small regions of the femur and humerus, and, as shown here, the hip bones. **(b)** The structure of a lymph node. Lymph nodes occur along the course of lymphatic vessels, which drain interstitial fluid from tissues and return it to the venous circulation. Within a lymph node, lymph percolates through open cavities containing clusters of lymphocytes.

Concept check: *From where does lymph arise?*

that interfere with the ability of the viruses to replicate. Interferons are not specific. Many kinds of viruses induce interferon synthesis, and the same interferons, in turn, can inhibit the multiplication of many different kinds of viruses.

The second type of nonspecific defense is provided by the family of plasma proteins known as **complement**. Inactive complement proteins normally circulate in the blood at all times. When they contact the surface of microbes, a cascade of events results in the activation of complement proteins. Among their many actions, including those in specific immunity, complement proteins stimulate the release of histamine from mast cells, thereby increasing permeability of local blood vessels, as described earlier. Five of the active proteins generated in the complement cascade form a multiunit protein called the **membrane attack complex** (**MAC**), which, by embedding itself in the microbial plasma membrane, creates porelike channels. Water and salts enter the microbe through the channels, and the microbe bursts. We turn now to the type of immunity that is distinguished by an ability to recognize great numbers of specific foreign molecules.

53.3 Acquired Immunity

In acquired, or specific immune defense mechanisms, cells of the immune system first encounter and later recognize a specific foreign cell or protein to be attacked, as opposed to recognizing some general feature of pathogens. Any molecule that can trigger a specific immune response is called an **antigen**. An antigen is any molecule that the host does not recognize as self. Most antigens are either proteins or very large polysaccharides. Antigens include the protein coats of viruses, bacterial surface proteins, specific macromolecules on pollens and other allergens, cancerous cells, transplanted cells, and toxins.

This type of immunity is found in all classes of vertebrates except jawless fishes and was once thought to be absent in invertebrates. Recently, however, scientists who study the evolution of immune systems have uncovered several interesting features of invertebrate immune function that suggest some invertebrates have a limited ability to adapt immune activity to a specific invader. Despite this intriguing finding, however, we will consider acquired immune responses in the context in which they are best understood, the jawed vertebrates.

The Immune System Consists of Lymphoid Organs, Tissues, and Cells

The cells of the immune system that are responsible for acquired immunity are a type of leukocyte called **lymphocytes**. Like all leukocytes, lymphocytes circulate in the blood, but most of them reside in a group of organs and tissues that constitute the **lymphatic system** (Figure 53.3a). The system is composed primarily of a network of lymphatic vessels. These vessels drain the fluid known as lymph, which filters out of capillaries into the interstitial spaces. The lymph is eventually returned to the circulatory system. Various lymphoid organs and tissues are

located throughout the lymphatic system. They are grouped into primary and secondary lymphoid organs.

The primary lymphoid organs are the structures in which lymphocytes differentiate into mature immune cells. These are the bone marrow in birds and mammals and the thymus gland in all vertebrates. In animals without extensive bone marrow, specialized regions of other organs such as the kidney and liver serve as primary lymphoid organs.

The primary lymphoid organs supply mature lymphocytes to secondary lymphoid tissues and organs, where the lymphocytes multiply and function. These include the lymph nodes of mammals (Figure 53.3b), the spleen (found in all jawed vertebrates and the largest secondary lymphoid structure), the tonsils (small, rounded lymphoid organs in the pharyngeal region of mammals), and scattered lymphocyte accumulations in the linings of the intestinal, respiratory, genital, and urinary tracts. With some exceptions (for example, adult humans, in which the thymus gland is no longer very active), destruction of or damage to a primary lymphoid organ results in a severe inability to fight off infections. The loss of any of the secondary lymphoid organs, while not as serious, nevertheless raises the risk of local or systemic infections throughout an animal's life. For example, in humans, the spleen must occasionally be surgically removed due to injury or disease. Such individuals must be monitored carefully for the rest of their lives because of their increased vulnerability to infection.

After leaving the bone marrow or thymus gland, lymphocytes circulate between the secondary lymphoid organs, blood, lymph, and all the tissues of the body. Lymphocytes from all the secondary lymphoid structures continually leave those structures and are carried to the bloodstream. Simultaneously, some circulating lymphocytes leave venules all over the body to enter the interstitial fluid. From there, they reenter lymphatic vessels and are carried back to secondary lymphoid organs. This constant recirculation of lymphocytes increases the likelihood that any given lymphocyte will encounter an antigen it is specifically programmed to recognize.

Lymphocytes Provide Specific Immunity Against Antigens in Humoral and Cell-Mediated Immunity

There are different kinds of lymphocytes that participate in coordinated specific immune system responses (Figure 53.4). In addition to NK cells described earlier, the two major types of lymphocytes are **B cells** and **T cells**. B cells were first observed to mature in an avian organ called the bursa of Fabricius—thus the name B cells. In mammals, B cells mature within bone marrow. Some B cells differentiate further into **plasma cells**, which synthesize and secrete antibodies, proteins that bind to and help destroy foreign molecules, as described later. T cells are so named because they mature within the thymus gland.

T cells may directly kill infected, mutated, or transplanted cells. T cells include two distinct types of lymphocytes: cytotoxic T cells and helper T cells. **Cytotoxic T cells** travel to the location of their targets, bind to these targets by recognizing an antigen, and directly kill those targets via secreted chemicals. In addition, responses mediated by cytotoxic T cells are directed against body cells that have become cancerous or infected by pathogens. Natural killer cells also destroy such cells by secreting toxic chemicals.

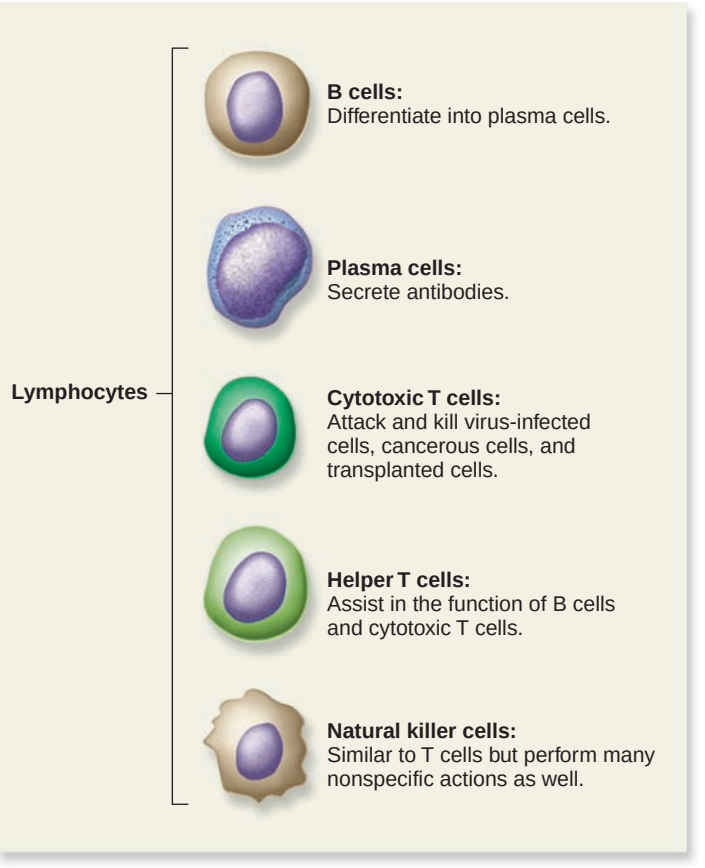

Figure 53.4 **Cells involved in acquired immunity in vertebrates.** Some important functions of each type of lymphocyte are included. The shape and color conventions shown in this figure will be used throughout this chapter.

As their name implies, **helper T cells** do not themselves function as "attack" cells. Instead, they assist in the activation and function of B cells and cytotoxic T cells. With only a few exceptions, B cells and cytotoxic T cells cannot function adequately unless they are stimulated by cytokines secreted from helper T cells.

Lymphocytes carry out their role by recognizing antigens such as those found on viruses, bacteria, and the surface of cancerous cells. The ability of lymphocytes to distinguish one antigen from another plays a central role in acquired immunity. Immunologists recognize two types of acquired immunity. In **humoral immunity**, plasma cells secrete antibodies that bind to antigens. In **cell-mediated immunity**, cytotoxic T cells directly encounter and destroy infected body cells, cancerous cells, or transplanted cells.

Acquired Immune Responses Occur in Three Stages

Thus far, we have considered the types of lymphocytes involved in an acquired immune response and how they circulate through the body. An acquired immune response can usually be divided into three stages (Figure 53.5): recognition of antigen, activation

of lymphocytes, and attack against antigen. In the first stage, lymphocytes encounter and recognize an antigen. In the second stage, lymphocytes are activated and then proliferate and differentiate to produce effector cells and memory cells. **Effector cells** are plasma cells and cytotoxic T cells, which carry out the attack response; **memory cells** remain poised to recognize the antigen if it returns in the future. In the third stage, an attack is launched against the recognized antigen by effector cells and/or their secretions. Let's look at each of these stages more closely.

Stage 1: Recognition of Antigen During its development, each lymphocyte synthesizes a type of membrane receptor that can bind to a specific antigen. If subsequently the lymphocyte encounters that antigen, the antigen becomes bound to the receptor. This specific binding is the meaning of the word "recognize" in immunology. Antigens that bind to a lymphocyte receptor are said to be recognized by the lymphocyte. The ability of lymphocytes to distinguish one antigen from another, therefore, is determined by the nature of their plasma membrane receptors. Each lymphocyte is specific for just one type of antigen.

Stage 2: Activation of Lymphocytes The binding of an antigen to a receptor on a lymphocyte activates that lymphocyte. Upon activation, the lymphocyte undergoes multiple cycles of cell division. The result is the formation of many identical plasma cells called clones that express the same receptor as the receptor that first recognized the antigen. The chemical nature of the antigen determines which individual lymphocytes will be activated to form clones. This process requires the function of helper T cells, which divide when activated and then secrete the cytokines that promote cell division. Some of the cloned lymphocytes become plasma cells, and others function as memory cells.

In a typical person, the size of the lymphocyte population is staggering. Over 100 million different lymphocytes, each with the ability to recognize a unique antigen, are found in a person's immune system. This vast population explains why our bodies are able to recognize so many different antigens as foreign and eventually destroy them.

Stage 3: Attack Against Antigen The effector plasma cells and cytotoxic T cells attack all antigens of the kind that initiated the immune response. Plasma cells carry out a humoral

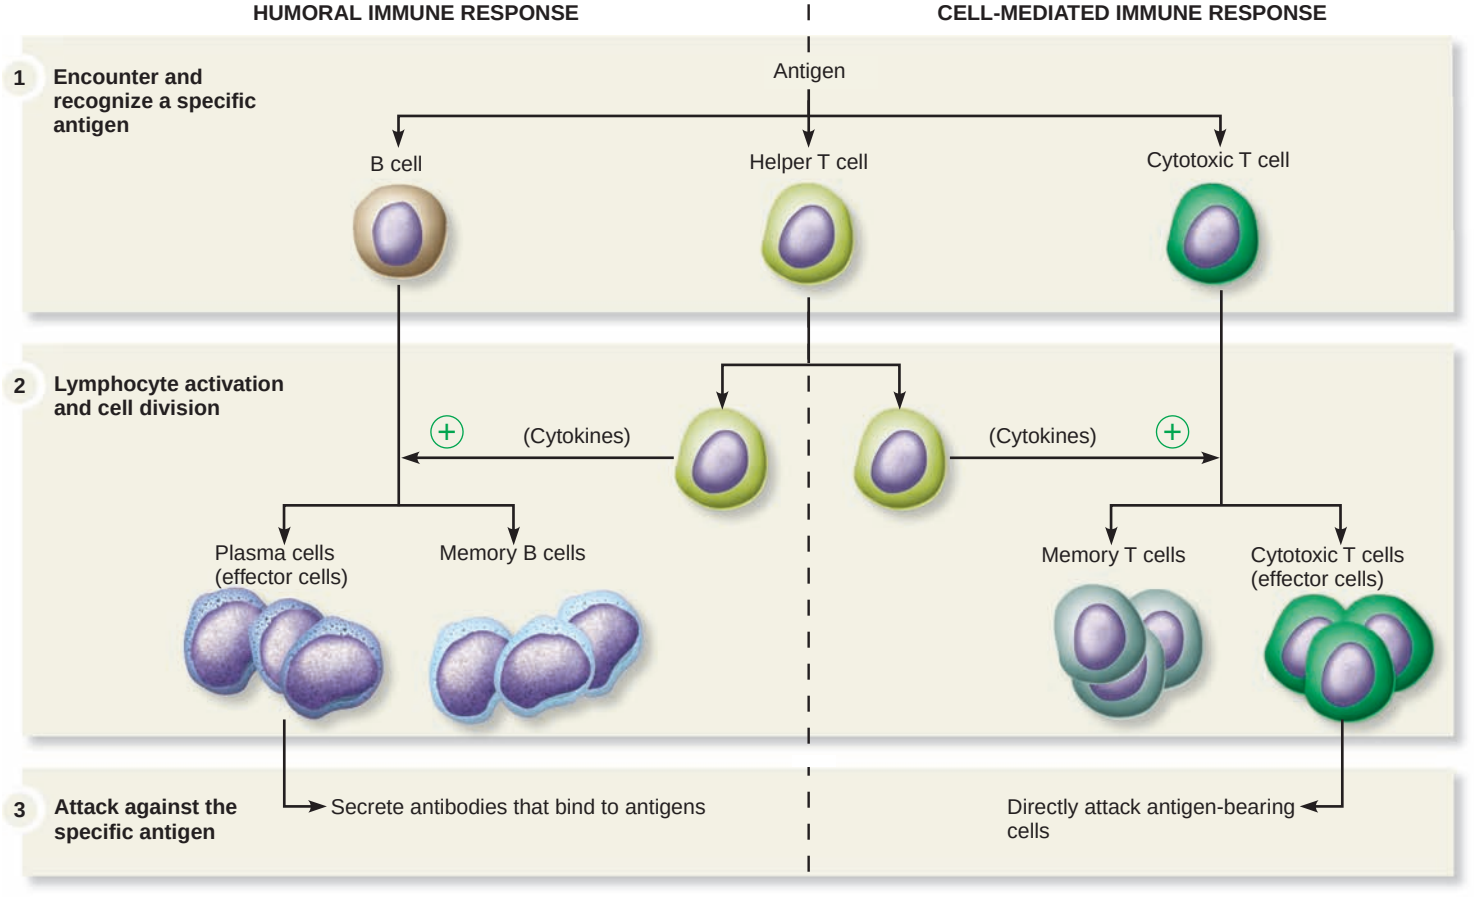

Figure 53.5 **The three stages of a specific (acquired) immune response.** All three cell types in step 1 recognize the same antigen. Helper T cells secrete cytokines that activate B cells and cytotoxic T cells, as indicated by the + symbols. Both B cells and T cells undergo cell division to form clones when activated, and in both cases, a portion of the cells are set aside as memory cells to fight off a future infection of the same type.

response by secreting antibodies into the blood. These antibodies then recruit and guide other molecules and cells that perform the actual attack. Activated cytotoxic T cells, by contrast, carry out cell-mediated immunity. They directly attack and kill the cells bearing the antigens.

Once the attack is successfully completed, the great majority of B cells, plasma cells, and cytotoxic T cells that participated in it die by apoptosis. The timely death of these effector cells prevents the immune defense from becoming excessive and possibly destroying the body's own tissues. However, memory cells persist even after the immune response has been successfully completed, so they can recognize and fight off any future infection with the same type of antigen. Let's look at each of these three stages in more detail, first for humoral immunity and then cell-mediated immunity.

In Humoral Immunity, B Cells Produce Immunoglobulins That Serve as Receptors or Antibodies

In stage 1 of humoral immunity (Figure 53.5), as mentioned, B cells recognize antigens with the help of B-cell receptors. When B cells are activated, they proliferate and differentiate into plasma cells, which secrete **antibodies**. These are proteins that travel all over the body to reach antigens identical to those that stimulated their production. In the extracellular body fluids, antibodies combine with these antigens and guide an attack that eliminates the antigens or the cells bearing them, a process we will discuss in more detail later. Such antibody-mediated responses are also called humoral immune responses, the adjective "humoral" denoting communication by way of soluble chemical messengers (the old word "humors" was once used to refer to bodily fluids). Antibody-mediated responses are the major defense against bacteria, viruses, and other microbes in the extracellular fluid, and against toxin molecules.

B-cell receptors and antibodies share many structural and functional similarities (Figure 53.6). They are both members of a family of proteins called **immunoglobulins** (Ig). However, there are some differences between them. B-cell receptors have a transmembrane domain that anchors them in the plasma membrane of the B cell. These immunoglobulins function as receptors for antigens (Figure 53.6a). Antibodies are soluble proteins that are secreted from plasma cells (Figure 53.6b).

B-Cell Receptors Prior to their activation, B cells express B-cell receptors that recognize specific antigens (Figure 53.6a). Interestingly, B-cell receptors and the antibodies made by plasma cells are encoded by the same genes. In plasma cells, the pre-mRNA is alternatively spliced, a phenomenon described in Chapter 13, so the transmembrane domain is not present in the protein. For this reason, the B-cell receptor in a particular B cell and secreted antibodies from the resulting plasma cells recognize the exact same antigen.

Immunoglobulin Structure Each immunoglobulin molecule is composed of four interlinked polypeptides: two long **heavy chains** and two short **light chains** (Figure 53.6b). A hinge region that provides the molecule with flexibility separates the light chains and upper parts of the heavy chains from the lower parts of the heavy chains. A key feature of immunoglobulins is their **variable region**, which gets its name because it varies among different B cells. The variable region is the site that specifically recognizes a particular antigen.

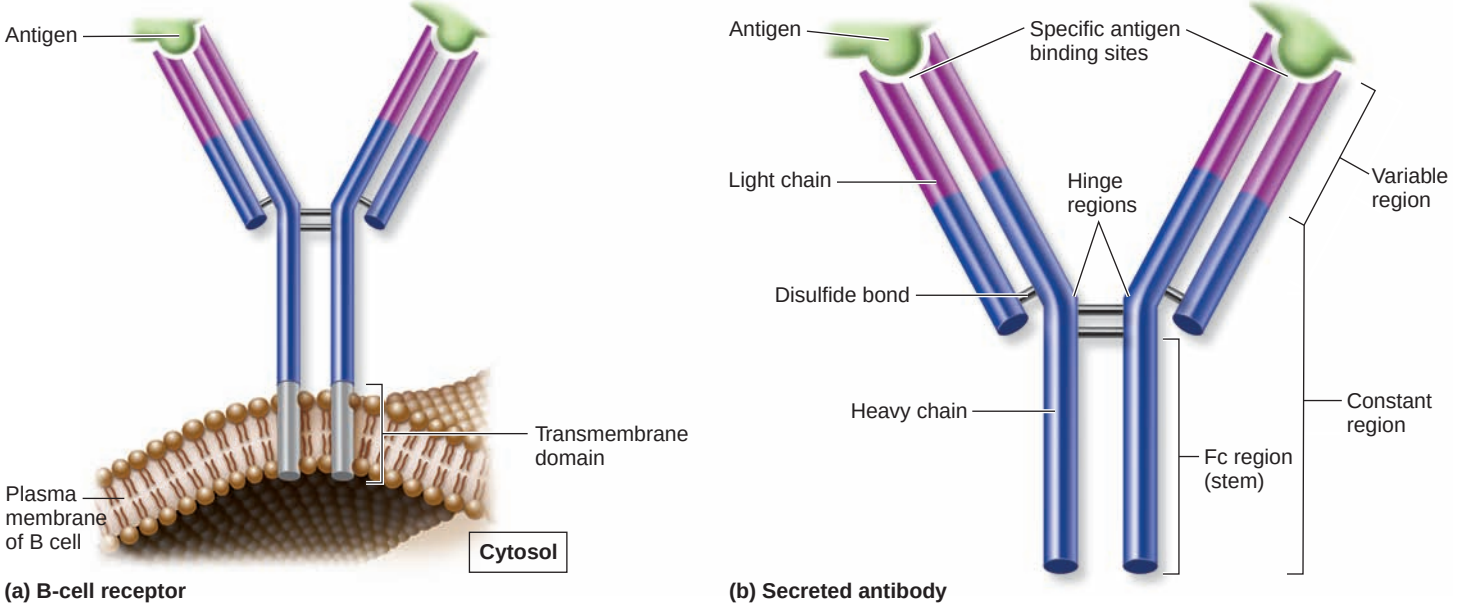

Figure 53.6 Immunoglobulins. (a) B-cell receptor and (b) secreted antibody. Immunoglobulins are composed of two heavy chains and two light chains. Disulfide bonds hold the chains together. Within each immunoglobulin class, the constant regions, including the Fc regions (stems), have identical amino acid sequences. In contrast, the antigen-binding sites formed by the light- and heavy-chain variable regions have unique amino acid sequences and give each antibody its specificity for a particular antigen.

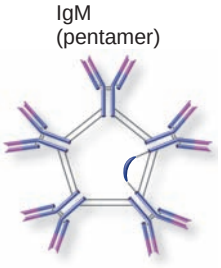
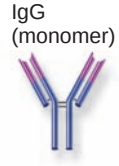
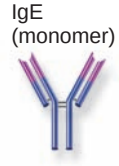


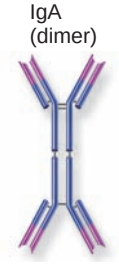
Mammals have five classes of immunoglobulins, designated IgM, IgG, IgE, IgA, and IgD. All vertebrates have IgM molecules. These pentamers (made of five Ig molecules connected by disulfide bridges and other linkages) are the first Ig class produced after antigen exposure, but their blood concentration declines afterward. Some vertebrates have only some of the other classes and also express unique immunoglobulins not found in mammals. By contrast, invertebrates lack immunoglobulins. However, they have proteins containing regions called Ig-domains (or Ig-folds) with sequences that are similar to those of immunoglobulins. These proteins may be ancestral to immunoglobulins and in some cases have been shown to carry out immune activities.



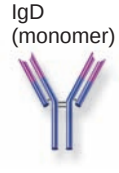
The most abundant immunoglobulins in mammals are IgM and IgG. IgG, commonly called gamma globulin, is the most abundant Ig class in terms of blood concentration. Together these two immunoglobulin classes provide the bulk of specific immunity against bacteria and viruses in the extracellular fluid.



IgE antibodies are monomers that participate in defenses against multicellular eukaryotic parasites and also mediate allergic responses. Although present in blood at low concentrations, they also exist in mast cell membranes. When mast cell IgE molecules bind antigen, the mast cell secretes its histamine into the extracellular fluid, causing vasodilation and contributing to the allergic response. In people who are particularly sensitive to allergens, this response is easily demonstrated by a pinprick injection of an antigen, such as proteins associated with hay fever, into a small region under the skin. The resultant local inflammation and reddening of the skin are mediated in large part by IgE molecules.



IgA antibodies exist as dimers and are secreted by plasma cells in the linings of the gastrointestinal, respiratory, and genitourinary tracts and in tear ducts and salivary glands. They act locally in the linings of these structures or on their surfaces, as they are present in their secretions. For example, IgA molecules secreted into saliva help keep animals' mouths relatively free of pathogens. IgA molecules are also secreted by the mammary glands of mammals shortly after birth and therefore are the major antibodies in milk.



The functions of IgD are still unclear. However, IgD molecules are present both in blood and on the surface of B cells, and they are known to bind antigen on B cells, thus possibly contributing to B-cell activation.

The two heavy chains of an immunoglobulin have a stem called the Fc region (Figure 53.6b), which contains two or three domains depending on the class of immunoglobulin. The amino acid sequences of the Fc domains are identical for all immunoglobulins of a given class and are therefore known as **constant regions**.

Part of each heavy and light chain contains a constant region. In addition, as mentioned, they contain a variable region that serves as the antigen-binding site. In contrast to the constant regions of the heavy and light chains, the amino acid sequences of the variable regions vary widely from immunoglobulin to immunoglobulin in a given Ig class. The enormous number of variable sequences results in countless unique structures of immunoglobulins within each class. Thus, each of the five classes of antibodies contains up to millions of unique immunoglobulins, each capable of combining with only one specific antigen or, in some cases, with several antigens whose structures are very similar. The genetic basis for this remarkable array of immunoglobulins was first identified in the 1970s, as we see next.

Genomes & Proteomes Connection

Recombination and Hypermutation Produce an Enormous Number of Different Immunoglobulin Proteins

The human genome contains about 200 genes that encode immunoglobulins. This raises an intriguing question. How can the body produce millions of different immunoglobulin proteins if there are only 200 immunoglobulin genes? The answer is that the 200 genes undergo a unique process involving gene rearrangements. This phenomenon was discovered by Susumu Tonegawa and others in the 1970s.

Along the length of a typical immunoglobulin gene are numerous gene segments that code for a piece of the final immunoglobulin protein (Figure 53.7). In light chains, these gene segments are of three types, called variable, joining, and constant segments. A total of about 300 variable (V) segments code for the N-terminal region of the antigen-binding site. These are next to four joining (J) segments and a single constant (C) segment. Each segment along the length of the gene is associated with recognition sequences that bind two enzymes, called RAG-1 and RAG-2 (for recombination-activating gene). These enzymes, which are expressed only in developing lymphocytes, cut randomly at the end of a V segment and at the beginning of a J segment. The intervening region is lost, and then other enzymes paste the V and J segments together. The result is a new, permanent immunoglobulin gene for that B cell. Because any V segment can be linked with any J segment, the number of possible final genes among different B cells is huge. Additionally, heavy chains have multiple segments that are spliced together in this way, except that they have yet another segment (designated D) and more V segments, yielding an even greater number of possible heavy-chain genes. Because any heavy chain can combine with any light chain in a given B cell, the number of possible combinations of immunoglobulins is immense.

The number of possible immunoglobulins is increased even further in two more important ways within B cells. First, the joining process of the V, D, and J segments is not always

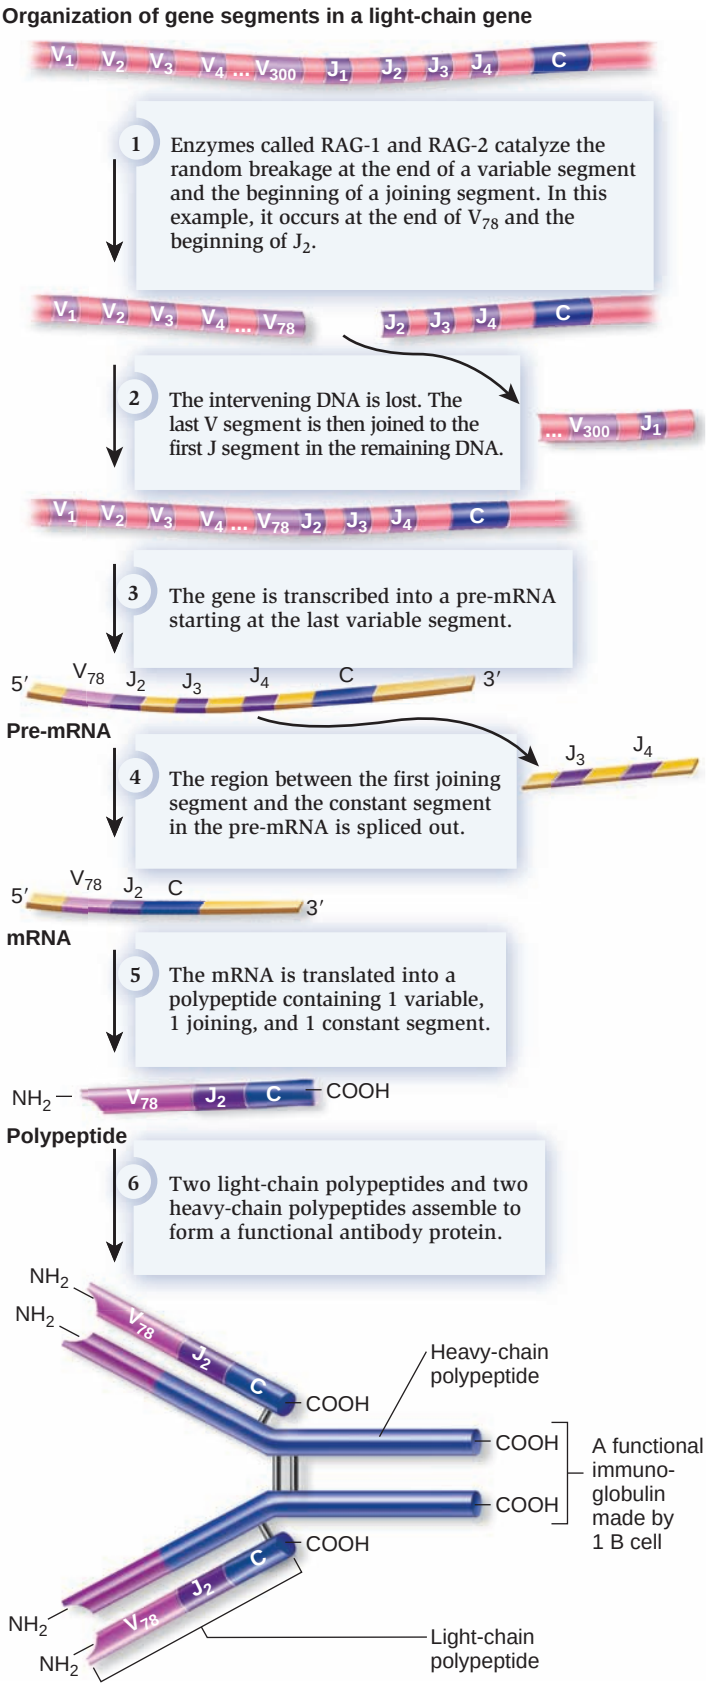


Figure 53.7 **The mechanism of immunoglobulin diversity.** Events similar to those depicted here also occur in the heavy chains.

precise. Occasionally, a few nucleotides may be lost at a joining end, resulting in a different amino acid sequence in the immunoglobulin protein. Second, in a subset of activated B cells, the DNA coding for the variable antigen-binding sites of immunoglobulins undergoes a process known as **hypermutation**, which primarily produces point mutations. During this process, cytosines are deaminated into uracils. After DNA replication, this leads to numerous C to T mutations. In addition, the presence of numerous uracils within the DNA recruits lesion-replicating DNA polymerases (see Chapter 11). These DNA polymerases are error prone, which leads to several additional types of mutations. The result is a hypervariable region of the light and heavy chains of all immunoglobulins. Hypermutation in lymphocytes appears to arise from lymphocyte-specific expression of a novel enzyme capable of deaminating cytosine.

The three processes of gene recombination, imprecise joining of gene segments, and hypermutation cause each lymphocyte within an individual's body to produce a unique type of immunoglobulin. The immune system can produce an incredibly diverse array of antibodies capable of recognizing many different antigens because the body makes hundreds of millions of different lymphocytes. Nearly any foreign antigen that is taken into the body will be recognized by some lymphocytes in this large population.

Activated B Cells Produce Plasma Cells Whose Antibodies Attack Pathogens

In stages 2 and 3 of the humoral immune response, B cells are activated and divide into plasma and memory cells. The plasma cells then secrete antibodies that attack the antigen detected (see Figure 53.5). In this section, we will take a closer look at these processes.

Clonal Selection B cells are activated by a specific antigen, with the aid of a helper T cell (a process which we will discuss later). When an antigen-stimulated lymphocyte divides and replicates itself, the progeny of this lymphocyte—all of which express the same receptor—are clones. The process by which these clones are formed is called **clonal selection** (Figure 53.8). This term emphasizes that lymphocyte proliferation is selected by exposure to an antigen.

Antibody Attack via Opsonization The antibodies secreted from the plasma cells circulate through the lymphatic system and the bloodstream. Eventually, the antibodies combine with the antigen that initiated the immune response. These antibodies then direct the attack against the pathogen to which they are now bound. Thus, immunoglobulins play two distinct roles in humoral immune responses. First, during antigen recognition, immunoglobulins (B-cell receptors) on the surface of B cells bind to antigen brought to them. Second, immunoglobulins (antibodies) secreted by the resulting plasma cells bind to pathogens bearing the same antigens, marking them as the targets to be attacked.

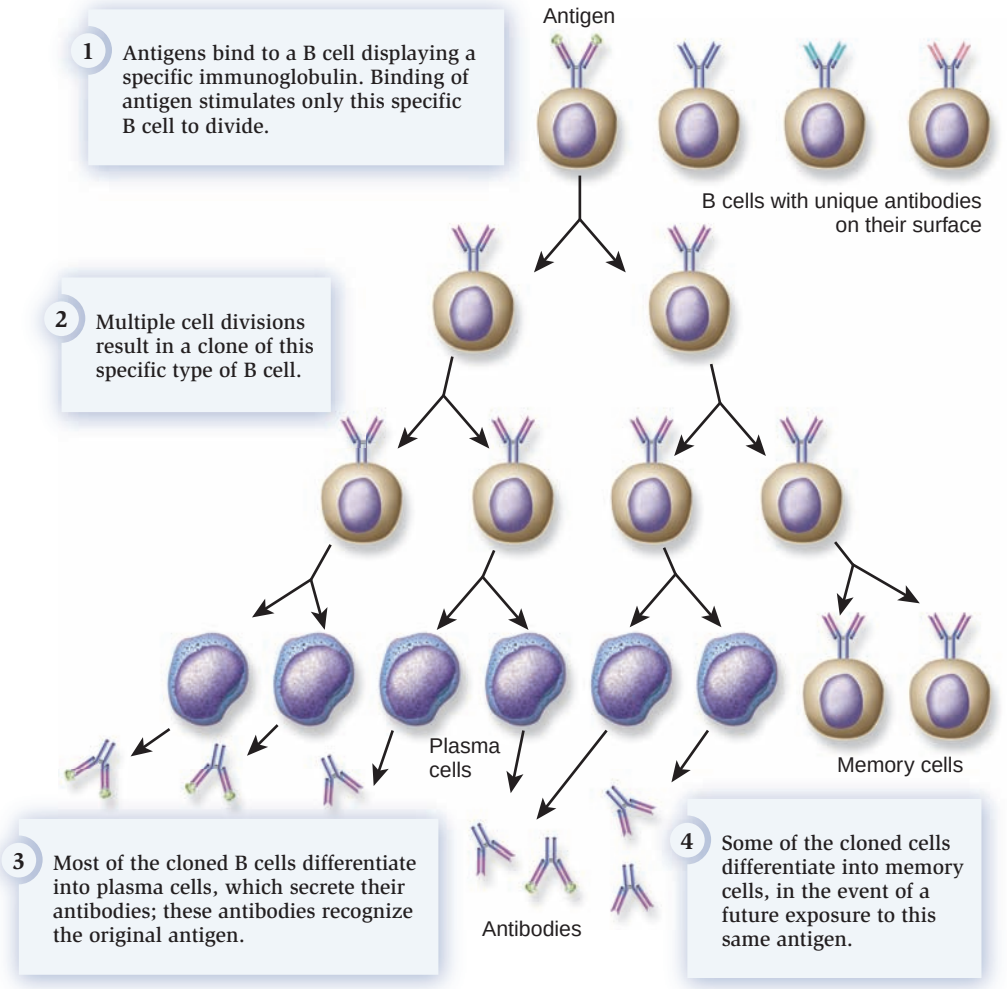

Figure 53.8 Clonal selection. In this example, a B cell with a specific surface immunoglobulin recognizes an antigen and is stimulated to divide into a clone of identical cells.

Instead of directly killing the pathogens, antibodies bound to antigen on the pathogen surface inactivate the pathogens in various ways. Antibodies may physically link the pathogens to phagocytes (neutrophils and macrophages), complement proteins, or NK cells. This linkage—called **opsonization**—triggers the attack mechanism and ensures that only the pathogens, and not nearby body cells, are killed.

In a second mechanism, antibodies directed against toxins produced by bacterial pathogens in the extracellular fluid bind to the toxins, thereby preventing them from harming susceptible body cells. The antibody-antigen complexes that are formed are then destroyed by phagocytes.

In a similar way, antibodies produced against certain viral surface proteins bind to the viruses in the extracellular fluid, preventing them from attaching to the plasma membranes of potential host cells. As with bacterial toxins, the antibody-virus complexes that are formed are subsequently phagocytized.

In Cell-Mediated Immunity, T Cells Recognize Antigens Complexed with Self Proteins

We now turn to stages 1 and 2 of cell-mediated immunity, in which T cells recognize and are activated by antigen (see Figure 53.5). T-cell receptors for antigens have specific regions that differ from one T cell to another. As shown in Figure 53.9a, they are composed of two polypeptides, each with a variable and constant region, along with a transmembrane domain. The variable regions recognize an antigen. As in B-cell development, multiple DNA rearrangements occur during T-cell maturation, leading to millions of distinct types of T cells, each with a receptor of unique specificity. For T cells, this maturation occurs as they develop in the thymus.

In addition to their general structural differences, B-cell and T-cell receptors differ in a much more important way. T-cell receptors cannot combine with antigen unless the antigen is first complexed with certain of the body's own plasma membrane proteins. The T-cell receptor then recognizes and interacts with the entire self protein–antigen complex.

The plasma membrane self proteins that must be complexed with the antigen in order for T-cell recognition to occur are encoded by a gene family known as the **major histocompatibility complex** (**MHC**), and thus the proteins are called MHC proteins. Other than identical twins, no two individuals have the same sets of MHC genes, so no two individuals have the same MHC proteins on the plasma membranes of their cells. MHC proteins are cellular "identity tags" that serve as genetic markers of self.

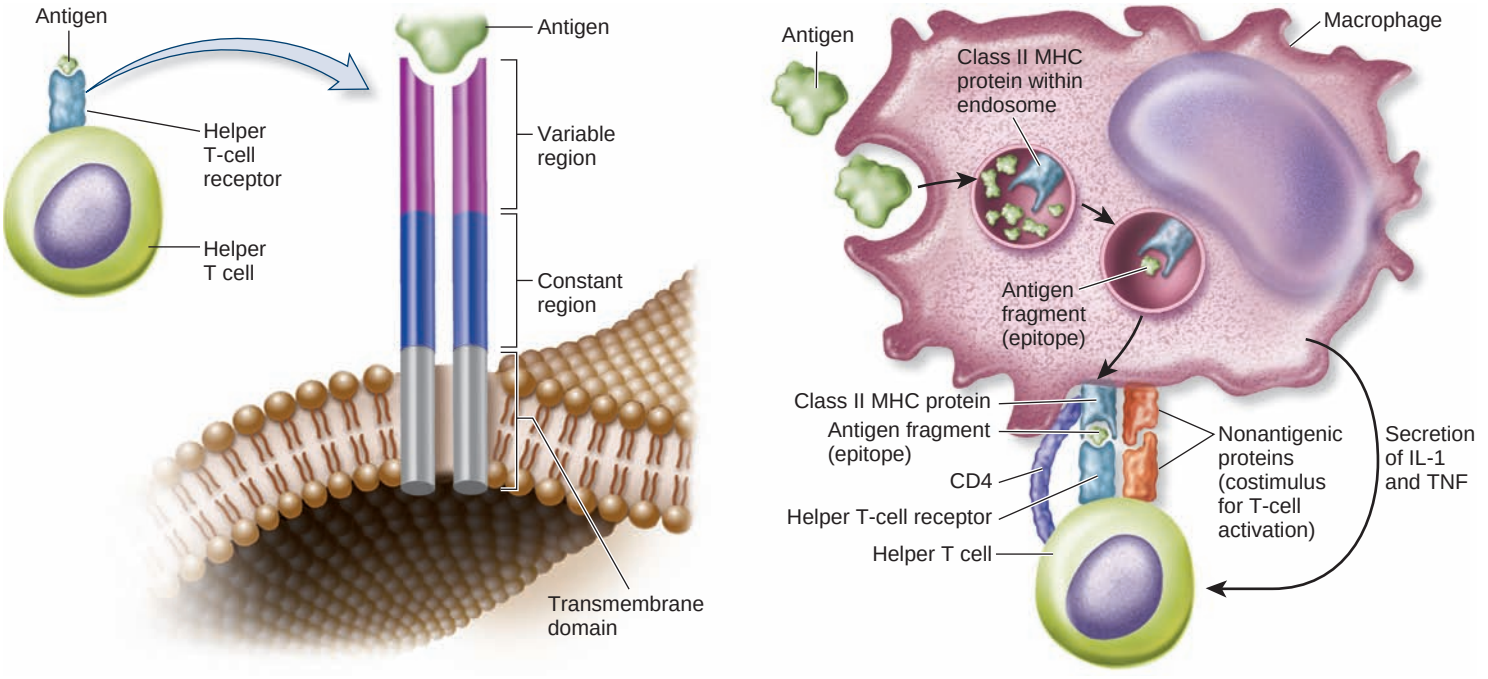

Figure 53.9 **The T-cell receptor and antigen presentation.** **(a)** Structure of a T-cell receptor. **(b)** Antigen presentation. In the initial events in helper T-cell activation, antigen fragments are complexed with a class II MHC protein within an antigen-presenting cell such as a macrophage. The complex is then displayed on the cell surface and binds to a helper T-cell receptor. Also required for T-cell activation are the binding of nonantigenic proteins between the APC and the attached helper T cell, and the actions of the cytokines IL-1 and TNF.

Two major classes of MHC proteins are known. Class I MHC proteins are found on the surface of all human body cells except erythrocytes. Class II MHC proteins are found primarily on the surface of macrophages, B cells, and dendritic cells.

The two different types of T cells have different MHC requirements. Cytotoxic T cells require antigen to be associated with class I MHC proteins, whereas helper T cells require class II MHC proteins. One reason for this difference stems from the presence of different proteins on their surfaces; helper T cells can be identified by a unique membrane protein called CD4, and cytotoxic T cells are identified by a membrane protein known as CD8. CD4 binds to class II MHC proteins, whereas CD8 binds to class I MHC proteins.

How do antigens, which are foreign, end up complexed with MHC proteins on the surface of the body's own cells? The answer involves the mechanism known as antigen presentation, described next.

Antigen Presentation to Helper T Cells As previously noted, helper T cells can bind antigen only when the antigen appears on the plasma membrane of a host cell complexed with the cell's class II MHC proteins. Cells bearing these complexes, therefore, function as **antigen-presenting cells** (**APCs**). Because only macrophages, B cells, and dendritic cells express class II MHC proteins, only these cells can function as APCs for helper T cells.

Let's consider the function of macrophages as APCs for helper T cells (Figure 53.9b). After a microbe or noncellular antigen has been phagocytized by a macrophage in a nonspecific response, antigens, such as proteins, are partially broken down into smaller peptide fragments by the macrophage's proteolytic enzymes within intracellular vesicles called endosomes. The resulting digested fragments then bind in the endosome to class II MHC proteins synthesized by the macrophage. Each fragment-MHC complex is then transported to the cell surface, where it is displayed in the plasma membrane. A specific helper T-cell receptor then binds this entire complex on the cell surface of the macrophage. The CD4 protein helps link the two cells. What is complexed to MHC proteins and presented to the helper T cells is not the intact antigen but instead a peptide fragment of the antigen—called an antigenic determinant, or **epitope**. Even so, it is customary to call this antigen presentation rather than epitope presentation.

B cells process antigen and present it to helper T cells in essentially the same way as macrophages do. The ability of B cells to present antigen to helper T cells is a second function of B cells in response to antigenic stimulation, in addition to their differentiation into antibody-secreting plasma cells.

The binding between the helper T-cell receptor and antigen bound to class II MHC proteins on an APC is the essential antigen-specific event in helper T-cell activation. However, by itself this specific binding will not result in T-cell activation. In addition, interactions occur between nonantigenic proteins on the surfaces of the attached helper T cell and the APC. These interactions provide a necessary costimulus for T-cell activation (Figure 53.9b).

Finally, the antigenic binding of the APC to the T cell plus the costimulus induce the APC to secrete large amounts of two

cytokines—interleukin 1 (IL-1) and tumor necrosis factor (TNF). These molecules also stimulate the attached helper T cell.

Thus, the APC participates in the activation of a helper T cell in three ways: (1) antigen presentation, (2) provision of a costimulus, and (3) secretion of cytokines. As discussed, activated helper T cells then secrete cytokines that stimulate B cells and cytotoxic T cells.

Helper T Cells and B-Cell Activation Now we can go back to B cells and understand how they are activated by the actions of helper T cells. This process begins when a helper T cell specific for a particular antigen binds to a complex of that antigen and a class II MHC protein on an APC, activating the helper T cell. Along with other signals, this binding induces the activated helper T cell to divide. Some of the resulting activated helper T cells then bind to B cells that display the same antigen on their surfaces. This binding, along with additional cytokines, stimulates the B cell to go through the process of clonal selection. Thus, helper T cells are so named because their secretions help activate B cells that have bound antigen, in addition to their participation in activation of cytotoxic T cells and antigen presentation, our next subject.

Antigen Presentation to Cytotoxic T Cells Unlike helper T cells, cytotoxic T cells require class I MHC proteins for activation. Class I MHC proteins are synthesized by all nucleated cells. This distinction helps explain the major function of cytotoxic T cells—destruction of any of the body's own altered cells that have become cancerous or infected with viruses. The crucial point is that the antigens that complex with class I MHC proteins typically arise within body cells. They are endogenous antigens, synthesized by a body cell.

How do such antigens arise? In viral infections, once a virus has entered a host cell, the viral nucleic acid instructs the host cell to manufacture viral proteins, which are foreign to the cell. In cancerous cells, one or more of the cell's genes have become altered by chemicals, radiation, or other factors. The altered genes, called oncogenes, code for proteins that are not normally found in the body. Such abnormal proteins act as antigens.

In both virus-infected and cancerous cells, cytosolic enzymes hydrolyze some of the endogenously produced antigenic proteins into peptide fragments, which are transported into the endoplasmic reticulum. There the fragments are complexed with the host cell's class I MHC proteins and then shuttled by exocytosis to the plasma membrane, where a cytotoxic T cell specific for the antigen/MHC protein complex can bind to it. Once binding occurs, cytotoxic T cells release chemicals that kill the infected or cancerous cell, as discussed next.

Activated Cytotoxic T Cells Kill Infected or Cancerous Cells

The previous sections described how immune responses provide long-term defenses against bacteria, viruses, and individual foreign molecules that enter the body's extracellular fluid. We now examine how the body's own cells that have become infected by viruses or transformed into cancerous cells are destroyed by stage 3 cell-mediated immune responses (see Figure 53.5).

What is the value of destroying virus-infected host cells? First, such destruction prevents cells from making more viruses. Second, for cells that already are making mature viruses, it results in the release of the viruses into the extracellular fluid, where they can be neutralized by circulating antibody.

Role of Cytotoxic T Cells A typical cytotoxic T-cell response triggered by viral infection of a vertebrate's body cells is summarized in Figure 53.10. The response triggered by a cancerous cell would be similar. In this discussion, we go back to stages 1 and 2 of the cell-mediated response to see how they lead up to the antigen attack in stage 3. A virus-infected cell produces foreign proteins, viral antigens that are processed and presented on the plasma membrane of the cell complexed with class I MHC proteins. Cytotoxic T cells specific for the particular antigen bind to the complex (Figure 53.10, step 1). As with B cells, binding to antigen alone does not cause activation of the cytotoxic T cell. Cytokines from nearby activated helper T cells are also required.

Macrophages phagocytize extracellular viruses (or, in the case of cancer, antigens released from the surface of cancerous cells) and then process and present antigen, in association with class II MHC proteins, to the helper T cells (step 2). In addition, the macrophages provide a costimulus and also secrete IL-1 and TNF. The activated helper T cell releases IL-2 and other cytokines, which stimulate proliferation of the helper T cell.

IL-2 and other cytokines also act on the cytotoxic T cell bound to the surface of the virus-infected or cancerous cell, stimulating this attack cell to proliferate. Why is proliferation important if a cytotoxic T cell has already located and bound to its target? The answer is that there is rarely just one virus-infected or cancerous cell. By expanding the population of cytotoxic T cells capable of recognizing the particular antigen, the likelihood is greater that the other virus-infected or cancerous cells will be encountered by an appropriate cytotoxic T cell.

The cytotoxic T cells specific for that virus then find and bind to other virus-infected cells (step 3). The cytotoxic T cell releases the contents of its secretory vesicles directly into the extracellular space between itself and the target cell to which it is bound (thereby ensuring that other nearby host cells will not be killed). These vesicles contain proteases, and a protein called perforin, which is similar in structure to the proteins of the complement system's membrane attack complex. Perforin is believed to insert into the target cell's membrane and form channels ("perforations") through the membrane (step 4). In this manner, it causes the attacked cell to take in the proteases secreted by the cytotoxic T cell, which is believed to induce apoptosis. The pores also cause the attached cell to take in water and burst. The cytotoxic T cell is not harmed by this process and can then continue to kill other virus-infected cells (step 5). Target cell killing by activated cytotoxic T cells occurs by several mechanisms, but this is one of the most important.

This shows that the body can eliminate viruses in two ways: through the humoral actions of antibodies in body fluids

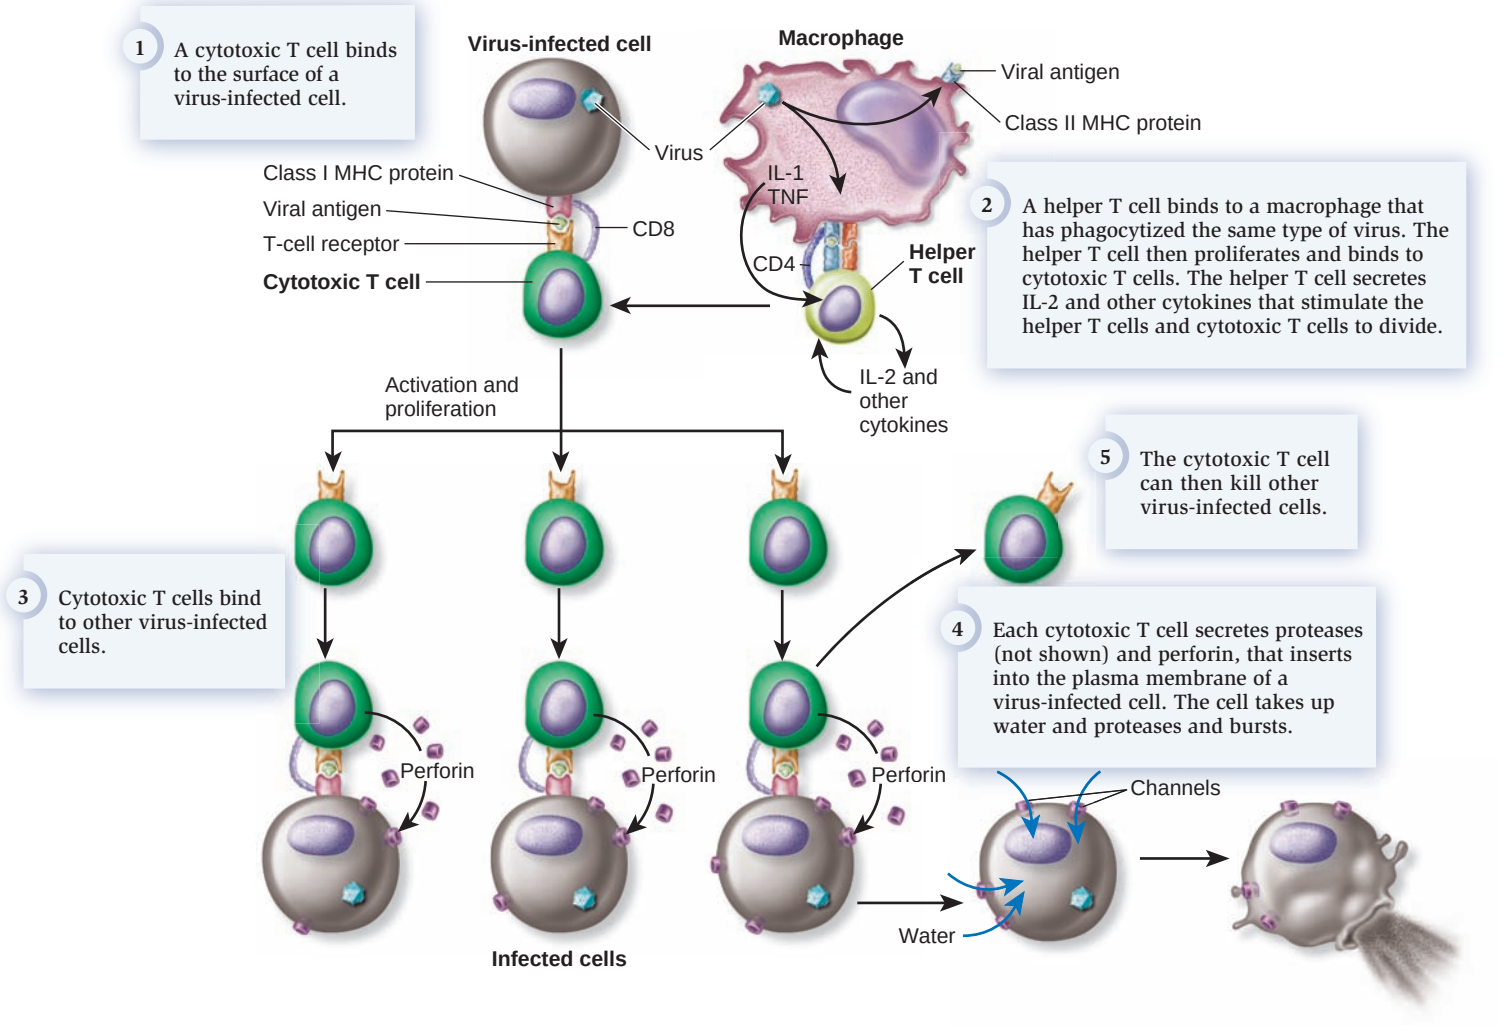

Figure 53.10 **Summary of events in the killing of virus-infected cells by cytotoxic T cells.** The sequence is similar for cancerous cells attacked by a cytotoxic T cell.

and through the cell-mediated killing of virus-infected cells by cytotoxic T cells. Although cytotoxic T cells play an important role in the attack against such cells, they are not the only ones.

Role of Natural Killer (NK) Cells NK cells also destroy virus-infected and cancerous cells by secreting toxic chemicals. As mentioned earlier, NK cells can recognize general features on the surface of such cells and participate in innate immunity. In addition, in a cell-mediated immune response, NK cells can be linked to such target cells by antibodies and then can destroy them by release of toxic molecules.

Summary: Example of an Acquired Immune Response

Let's bring together our discussion of the humoral immune system by looking in detail at one example. One classic humoral immune response results in the destruction of bacteria. The sequence of events, which is quite similar to the humoral response to a virus in the extracellular fluid, is summarized in Figure 53.11. For this example, we consider the response in mammals, in which lymph nodes are present. Many features of the response, however, are similar in other vertebrates.

This process starts the same way as for nonspecific responses, with the bacteria penetrating one of the body's linings through an injury and entering the interstitial fluid (Figure 53.11, step 1). The bacteria then move with lymph into the lymphatic system and are carried to lymph nodes (step 2). Within the lymph node, a macrophage and a B cell recognize one of the bacteria as a foreign substance and bind to it.

As we have discussed, the process of B-cell activation usually requires the activation of helper T cells. The helper T cell binds to a complex of processed antigen and class II MHC protein on an APC (step 3). In this case, the APC is a macrophage that has phagocytized the bacterium, hydrolyzed its proteins into peptide fragments, complexed the fragments with class II MHC proteins, and displayed the complexes on its surface. Once a helper T cell specific for the complex binds to it, the helper

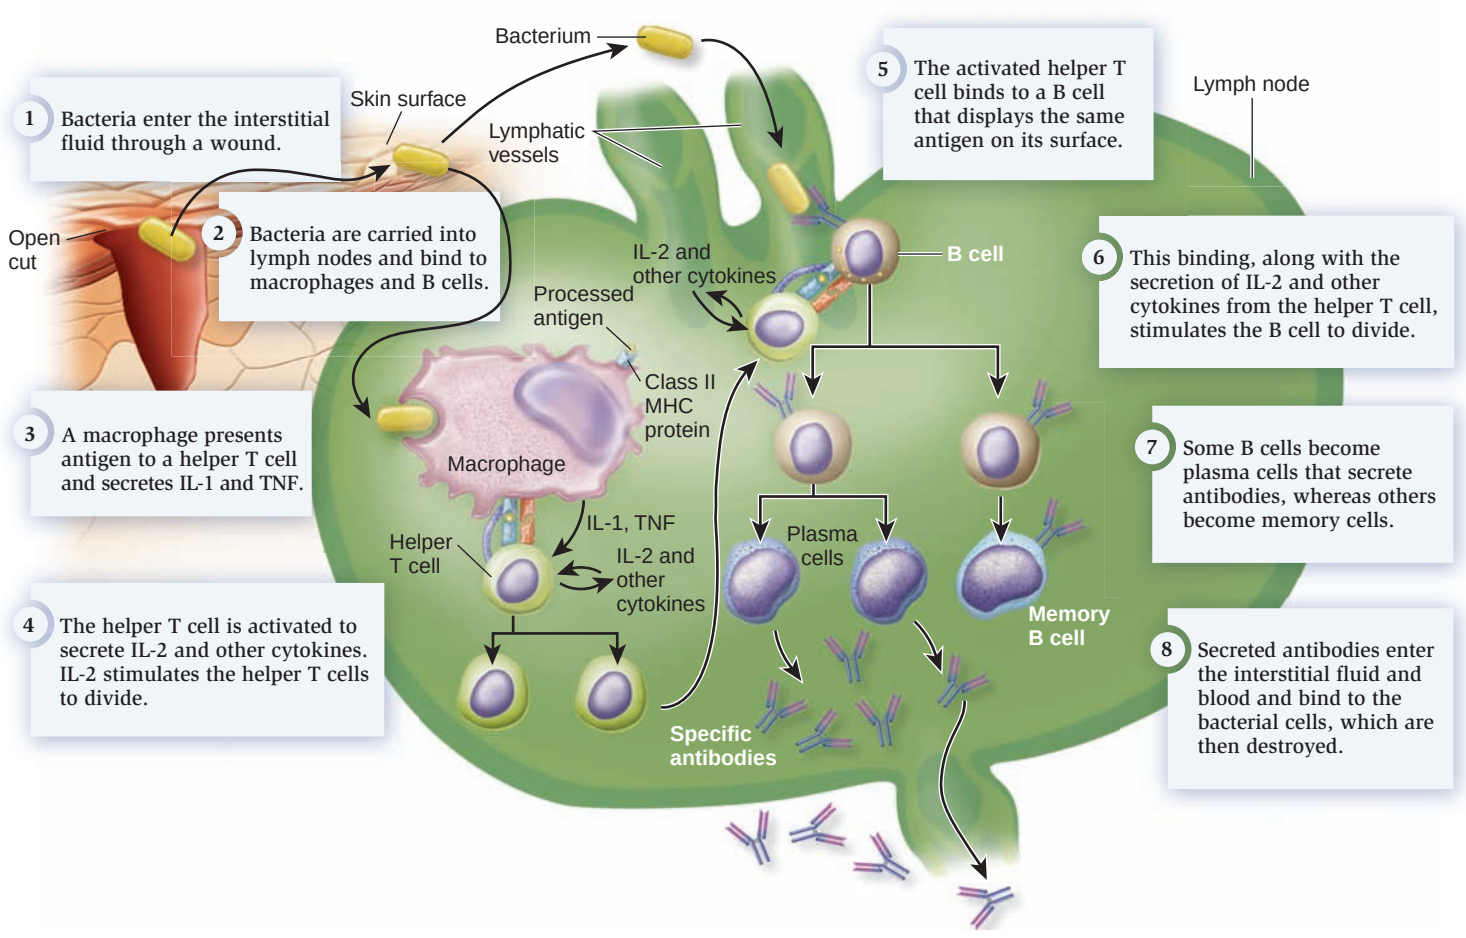

Figure 53.11 **Summary of events in a typical humoral immune response.** Most of the events depicted occur within a lymph node.

T cell becomes activated. The macrophage helps this process in two other ways: It provides a costimulus, and it secretes the cytokines IL-1 and TNF.

IL-1 and TNF stimulate the helper T cell to secrete another cytokine, IL-2. IL-2 stimulates the activated helper T cell to divide. This leads eventually to the formation of a clone of activated helper T cells (step 4), which bind to B cells and also secrete IL-2 and other cytokines (step 5). Certain of these cytokines provide the additional signals that are usually required to activate nearby antigen-bound B cells to proliferate (step 6). These cells differentiate into memory cells, which help ward off possible future attacks by the same antigen, and plasma cells, which then secrete specific antibodies (step 7). The antibodies enter the bloodstream and bind to bacterial cells, which are then destroyed (step 8).

B Cells and T Cells That Recognize Self Molecules Must Be Killed or Inhibited

As we have seen, the lymphocytes responsible for the specific immune response in vertebrates are very capable killers of pathogens—so capable, in fact, that it raises a question: Why don't these cells attack and kill normal self cells? In other words, how does the body distinguish between self and nonself components and develop what is called **immune tolerance**, or tolerance of your own antigens?

Recall that the huge diversity of lymphocyte receptors is ultimately the result of multiple random DNA cutting/recombination processes. It is virtually certain, therefore, that every animal possessing specific immune defenses would have clones of lymphocytes with receptors that could bind to that individual's own proteins. The continued existence and functioning of such lymphocytes would be disastrous, because such binding would launch an immune attack against all body cells expressing these proteins.

At least two mechanisms explain why individuals normally lack active lymphocytes that respond to self components. First, during early development in vertebrates, T cells are exposed to a wide mix of self proteins in the thymus. Those T cells with receptors capable of binding self proteins are destroyed by apoptosis in a process termed **clonal deletion**. The second process, termed **clonal inactivation**, occurs outside the thymus and causes potentially self-reacting T cells to become nonresponsive. B cells undergo similar processes. The mechanisms by which these two events occur are still under investigation.

Occasionally, however, these mechanisms fail, and the body's immune cells attack the body's own cells. When this happens in humans, it produces **autoimmune disease**. Autoimmune diseases are conditions in which the body's normal state of immune tolerance somehow breaks down, with the result that both humoral and cell-mediated attacks are directed against the body's own cells and tissues. A growing number of human diseases are being recognized as autoimmune in origin. Examples are multiple sclerosis, in which myelin around neurons is attacked; myasthenia gravis, in which the receptors for acetylcholine on skeletal muscle cells are the targets; rheumatoid arthritis, in which joints are damaged; systemic lupus erythematosus, in which numerous organs are damaged; and type 1 diabetes mellitus, in which the insulin-producing cells of the pancreas are destroyed. Treatments for autoimmune disease range from treating the symptoms (for example, administering insulin to individuals with diabetes) to suppressing the immune system with drugs.

Immunological Memory Is an Important Feature of Acquired Immunity

As we have learned, the specific or acquired immune response to a given antigen depends on whether or not the body has previously been exposed to that antigen. Consider, for example, the humoral immune response. In mammals, antibody production in response to the first contact with an antigen occurs slowly, over a few weeks. This response to an initial antigen exposure is termed a **primary immune response** (Figure 53.12). Any subsequent infection by the same pathogen elicits an immediate and heightened production of additional specific antibodies against that particular antigen, a reaction termed a **secondary immune response**.

In the case of humoral immunity, this secondary response occurs more quickly, is stronger, and lasts longer because memory B cells that were produced in response to the initial antigen exposure are quickly stimulated to multiply and differentiate into thousands of plasma cells. These cells then produce large amounts of specific antibodies. The immune system's ability to produce this secondary response is called **immunological memory**.

Immunological memory explains why we and other animals are able to fight off many illnesses to which we have been previously exposed, such as many common childhood diseases. The acquired response to exposure to any type of antigen is known as **active immunity**. Active immunity not only results from natural exposure to antigens, but it is also the basis for the artificial exposures to antigen that occur in vaccinations. In **vaccinations**, small quantities of living, dead, or altered microbes, small quantities of toxins, or harmless antigenic molecules derived from a microorganism or its toxin are injected into the body, resulting in a primary immune response, including the production of memory cells. Subsequent natural exposure to the immunizing antigen results in a rapid, effective response that can prevent or reduce the severity of disease.

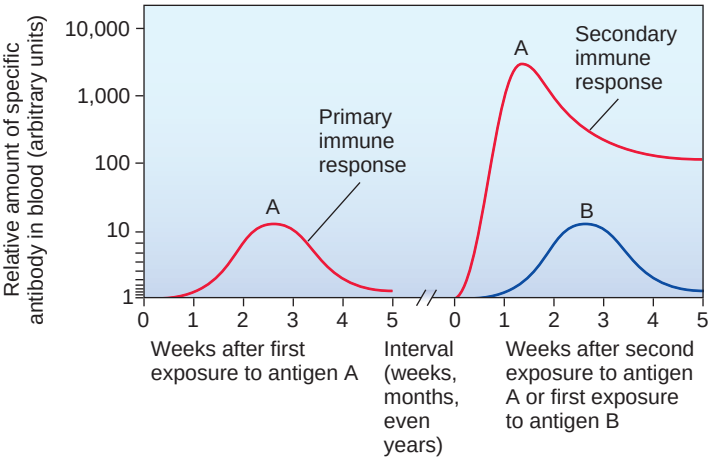

Figure 53.12 **Primary and secondary immune responses.** In a primary response, as shown on the left of this graph, an initial exposure to an antigen produces modest levels of specific antibody over a period of weeks. In a secondary response, subsequent exposure to the same antigen results in greater antibody production that occurs more rapidly and lasts longer than a primary response. (Note that the scale of the y-axis on the graph is logarithmic.) The secondary response is specific for that antigen. Exposure at that time to another antigen for the first time produces the usual primary response.

Concept check: What is the advantage of a secondary immune response?

In contrast to active immunity, another type of acquired immunity, called **passive immunity**, confers protection against disease through the direct transfer of antibodies from one individual to another. Passive immunity can occur naturally, as when IgG molecules cross the mammalian placenta to protect a fetus from various pathogens, or when a newborn mammal receives antibodies from breast milk. It can also occur artificially, as when a human patient is given an injection of IgG molecules shortly after exposure to hepatitis viruses. Recent advances in the creation of highly specific and pure antibodies, called **monoclonal antibodies** because they are derived from a single clone of cells prepared in a laboratory, have paved the way for the use of passive immunity to combat certain types of cancer. Because antibodies are proteins with a limited life span, the protection afforded by the transfer of antibodies in passive immunity is relatively short-lived, usually lasting only a few weeks or months.

Immunizations are very important in preventing disease among humans and domesticated animals. This is especially important when humans or other animals live in dense populations. A good example is seen in certain invertebrates such as social insects, which live in populations with enormous numbers of individuals in confined areas. Do such populations have any naturally occurring protection against widespread disease that could otherwise ravage an entire colony of animals? This question has been explored recently by biologists studying social insects such as ants and termites, as described next.

Feature Investigation

Traniello and Colleagues Demonstrated That Social Insects May Develop "Social Immunity"

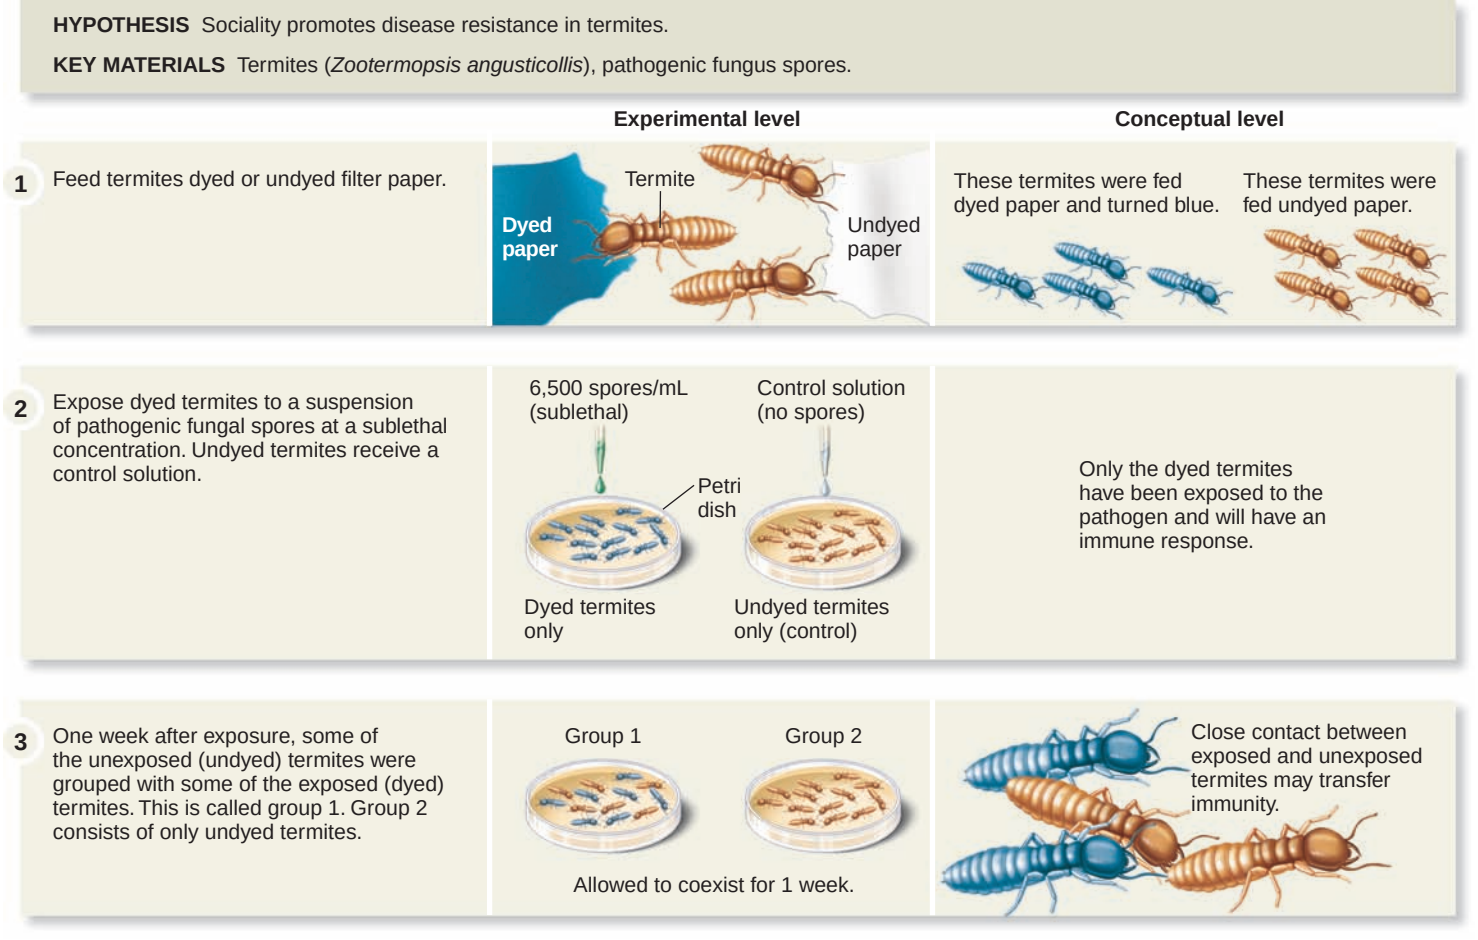
Biologists have questioned how highly social animals living in dense colonies protect themselves from disease transmission. Such social animals include wood-eating termites that exist in very large numbers in complex nests. Termites may encounter a range of pathogens because they nest in moist, decaying wood, which provides a favorable environment for bacteria, fungi, and other parasites. A single infected termite could rapidly spread disease from insect to insect in a densely populated colony, but rarely are entire colonies wiped out by infection. In part, this occurs because termites kill microbes by producing antimicrobial secretions that are used to line their nests. In addition, behavioral adaptations, such as grooming to remove pathogens from nest mates' cuticles and the removal of sick or dead animals from the nest, help reduce disease transmission.

Another possible mechanism of protection from disease, called "social immunity," involves the transfer of infection resistance from immunized to susceptible nest mates. This phenomenon was recently identified by James Traniello and coworkers while studying the termite *Zootermopsis angusticollis*. The researchers discovered that these termites were able to survive a pathogen challenge better when they are living in a group than when they are isolated as individuals. This indicates that an individual's immunity is enhanced when they are surrounded by nest mates.

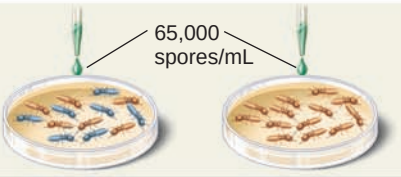
To determine how this may occur, Traniello and his colleagues tested the susceptibility of the termites to parasitic fungi (Figure 53.13). They divided the animals into two groups. To distinguish the groups from each other, one group was fed paper that contained a dye that marked the animals with a visible color. The investigators then exposed this group of dyed termites to a sublethal dose of fungal spores to immunize them

Figure 53.13 Traniello and colleagues demonstrated that social insects may develop "social immunity."

Concept check: What other animals besides social insects live in extremely dense colonies and require protection against devastating illnesses sweeping through the entire population?



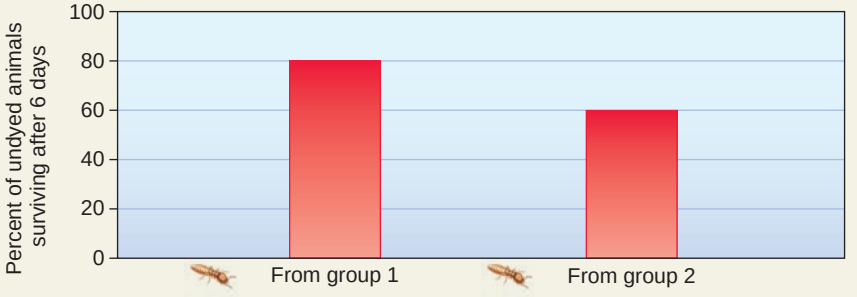
4 Expose group 1 and group 2 to a potentially lethal concentration of fungal spores. Measure the percentage of undyed termites that survive after 6 days.



If immunity is transferred, a higher percentage of undyed animals in group 1 should survive exposure to the spores.

5 THE DATA

Results from step 4:



6 CONCLUSION Immunity against deadly pathogens can be transferred from exposed termites to unexposed termites.

7 SOURCE Traniello, J.F., Rosengaus, R.B., and Savoie, K. 2002. The development of immunity in a social insect: evidence for the group facilitation of disease resistance. *Proceedings of the National Academy of Sciences USA* 99:6838–6842.

against the fungus. The other (undyed) group was exposed only to a control solution. One week following exposure to spores or control solutions, half of the control group of animals was combined into a single nest with the immunized animals, while the other half of the control group remained in a separate nest.

One week later, the animals in each group were exposed to a potentially lethal dose of fungal spores, and their survival was recorded after 6 days. Undyed termites that had not experienced an initial exposure to spores but had later nested with animals that were exposed and thus immunized had a significantly higher survival rate following exposure to the lethal dose of spores compared to animals that did not nest with immunized animals. Thus, the investigators concluded that social contact between nonimmunized and immunized animals resulted in a transfer of immunity to the more-susceptible members of the group.

The mechanism of social immunization is not known but could be related to either the oral exchange of secretions or contact with inactivated spores remaining on the bodies of immunized animals. Whatever the mechanism may prove to be, the consequence is striking: The close physical contact that is characteristic of social insect behavior helps propagate colonywide immunization against potentially deadly pathogens. Moreover, it is not unique to *Zootermopsis angusticollis*. Researchers in Denmark have recently demonstrated a similar phenomenon in the garden ant *Lasius neglectus*.

Experimental Questions

1. What features of termite physiology and/or behavior reduce the chance that an infection will spread throughout the colony?
2. What hypothesis was tested by Traniello and colleagues?
3. How did the researchers test this hypothesis, and what were the results of the study?

53.4 Impact on Public Health

In this section, we will consider a few ways in which the functioning of a person's immune system is affected by lifestyle, medical interventions, allergies, and destruction of immune cells. Collectively, the effects of these problems have an almost immeasurable impact on society in terms of worker productivity, health-care resources, and the economy.

Lifestyle Has an Important Influence on Immunity

Protein-calorie malnutrition is the single greatest contributor to decreased resistance to infection worldwide. When inadequate amino acids are available to synthesize essential proteins, immune function is impaired. Deficits of specific nonprotein nutrients can also lower resistance to infection.

Both stress and state of mind can affect resistance to infection and to cancer. The immune system can alter neural and endocrine function, and, in turn, neural and endocrine activity modifies immune function. Lymphoid tissue is connected to nerves, and immune cells have receptors for many neurotransmitters and hormones. Conversely, immune cells release cytokines that have important effects on the brain and endocrine system. Moreover, lymphocytes secrete several hormones that are also produced by endocrine glands. The multiple "mind-body" interactions that affect disease resistance are the subject of a field called psychoneuroimmunology.

Of the hormones associated with stress, the adrenal hormone cortisol has received the most attention due to its powerful suppressive activity on inflammation and specific immunity. Among other things, cortisol inhibits production of inflammatory mediators, reduces capillary permeability in injured areas, and suppresses the growth and activity of certain types of leukocytes. In this way, it acts as a sort of brake on the immune system. During chronic stress or when cortisol is used to treat certain illnesses for long periods of time, it may cause immunosuppression. This is a key link between stress and health. Chronic stress may lead to high cortisol levels that, by suppressing the body's immune responses, lowers resistance to infection.

Another feature of a person's lifestyle that appears to affect immune function is exercise. The influence of physical exercise on the body's resistance to infection and cancer has been debated for decades. Present evidence indicates that the intensity, duration, regularity, and psychological stress of the exercise all have important influences, both negative and positive, on a variety of immune functions, such as the numbers of circulating NK cells. Despite these complexities, most experts currently consider moderate exercise and physical conditioning to have net beneficial effects on the immune system and on disease resistance. A 2005 study suggested that exercise may be particularly beneficial in warding off the onset of breast cancer, one of the most common types of cancer in women.

Organ Transplants and Blood Transfusions Are Medical Procedures That Can Cause Serious Immune Reactions

Both organ transplants and blood transfusions have saved numerous lives. However, both also carry the possibility of provoking immune reactions that can threaten the life of the recipient. Since the mid-20th century, organ transplants from a healthy or recently deceased donor to a recipient have become widespread. The United Network for Organ Sharing reports that approximately 27,000 organs are transplanted in the U.S. each year, with kidney (16,000), liver (6,000), heart (2,000), and lung (1,200) accounting for most of the transplants. The major obstacle to successful transplantation of tissues and organs is a reaction called graft rejection, in which the immune system recognizes the transplants (also called grafts) as foreign and attacks them as it would any other foreign cells. Although B cells and macrophages play some role in graft rejection, cytotoxic T cells and helper T cells are mainly responsible. To minimize this possibility, patients are given drugs that suppress immune function.

Except for grafts from identical twins, the class I MHC proteins on graft cells differ from those on the recipient's cells, as do the class II MHC proteins present on macrophages in the graft cells. Consequently, the recipient's T cells recognize the MHC proteins in the graft as foreign, and cytotoxic T cells (with the aid of helper T cells) destroy the graft cells.

Blood transfusion reactions, in which erythrocytes are destroyed after the transfusion, are a special example of tissue rejection in that antibodies rather than cytotoxic T cells are the major factor in rejection. Although erythrocytes lack MHC proteins, they have plasma membrane components that can function as antigens when transfused into another person's blood. Of the more than 400 erythrocyte antigens, the ABO system (see Chapter 16) of carbohydrates is the most important for transfusion reactions.

The four possible blood types—A, B, AB, and O—are genetically determined. Individuals with type A blood have erythrocytes bearing the A antigen. Those whose erythrocytes have the B antigen are type B, those that produce both antigens are type AB, and those that produce neither antigen are considered type O. Genes cannot code for the carbohydrates that function as antigens; instead, the genes code for the particular enzymes that catalyze the attachment of the carbohydrates onto cell surface proteins. Additionally, the plasma of type A individuals contains anti-B antibodies. Type B individuals have anti-A antibodies, AB individuals have neither antibody, and type O individuals have both. Scientists do not yet understand how these antibodies occur without prior exposure to the appropriate antigen.

What would happen if a person with type A blood were given type B blood (something that would not be done in actual practice)? There are two incompatibilities. The recipient's anti-B antibodies would bind to the transfused erythrocytes, and the anti-A antibodies in the transfused plasma would attack the recipient's erythrocytes. Therefore, a type A person cannot receive blood containing B antigens but can receive blood of type A.

By similar logic, type B individuals can receive blood of type B without an immune response occuring. Because AB individuals have neither anti-A nor anti-B antibodies, they can receive blood of any type and are considered "universal recipients." By contrast, type O individuals, who have both anti-A and anti-B antibodies, can receive only type O blood. Because type O blood has neither A nor B antigens, however, it can be transfused into individuals of all types without being destroyed by the recipient's immune system, and thus type O people are considered "universal donors." Nonetheless, type O blood is not an ideal match for a person with type A, B, or AB blood. Although the transfused (type O) blood is safe from immune attack, the recipient's blood may still be affected by the anti-A and anti-B antibodies in type O blood.

Allergies Affect the Quality of Life of Millions of People

An allergy (also known as hypersensitivity) is a condition in which immune responses to environmental antigens cause inflammation and damage to body cells. Antigens that induce allergic reactions are called allergens. Common examples of allergens include ragweed pollen and animal dander. Most allergens themselves are relatively or completely harmless. It is the immune responses to them that cause the damage. In essence, then, allergy is immunity gone awry, for the response is of inappropriate strength and duration for the stimulus. In the U.S. alone, as many as 40 million people (about 13% of the population) suffer from allergies.

For any allergy to develop, a genetically predisposed person must first be exposed to the allergen—a process called sensitization. Subsequent exposures elicit the damaging immune responses we recognize as an allergy.

Hypersensitivities can be broadly classified according to the speed of the reaction. Allergies that take up to several days to develop are considered delayed hypersensitivities. The skin rash that appears after contact with poison ivy is an example. More common are reactions considered immediate hypersensitivities, which can develop in minutes or up to a few hours. These allergies are also called IgE-mediated hypersensitivities because they involve IgE antibodies.

In immediate hypersensitivity, sensitization to the allergen leads to the production of specific antibodies and a clone of memory B cells. In individuals who are genetically susceptible to allergies, antigens that elicit immediate hypersensitivity reactions stimulate the production of IgE antibodies. Upon their release from plasma cells, these IgE molecules circulate throughout the body and become attached to mast cells in connective tissue. When the same antigen subsequently enters the body at some future time and binds with IgE that is bound to mast cells, the mast cell is stimulated to secrete many inflammatory mediators, including histamine, that then initiate an inflammatory response.

The signs and symptoms of IgE-mediated hypersensitivity reflect both the effects of inflammatory mediators and the body site in which the antigen–IgE–mast cell binding occurs. When, for example, a previously sensitized person inhales ragweed pollen, the antigen combines with IgE on mast cells in the airways. The mast cells release their contents, which induce increased mucous secretion, increased blood flow, swelling of the epithelial lining, and contraction of the smooth muscle surrounding airways. These effects produce the congestion, runny nose, sneezing, and difficulty in breathing characteristic of hay fever. Antihistamines are drugs taken by people to block the action of histamine that is released during allergic responses. These drugs prevent histamine from binding to its receptor protein on its target cells, thereby preventing or relieving some of the symptoms of allergy.

Acquired Immune Deficiency Syndrome (AIDS) Is a Growing Pandemic

Acquired immune deficiency syndrome (**AIDS**) is caused by the **human immunodeficiency virus** (**HIV**), which incapacitates the immune response by preferentially infecting helper T cells. HIV is a retrovirus; such viruses have a nucleic acid core of RNA rather than DNA. Once inside a helper T cell, HIV uses the enzyme reverse transcriptase to transcribe the virus's RNA into DNA, which is then integrated into the T cell's chromosomes. Viral replication within the T cell results in the death of the cell.

HIV infects helper T cells because the CD4 protein in their plasma membranes acts as a receptor for an HIV capsid protein. However, binding to CD4 is not sufficient to enable HIV to enter the helper T cell. Another T-cell surface protein, which normally acts as a receptor for certain cytokines, must serve as a coreceptor. Interestingly, individuals possessing a mutation in this cytokine receptor are highly resistant to HIV infection, so much research is now focused on the possible therapeutic use of chemicals that can bind to and block this coreceptor.

HIV not only directly kills helper T cells, but it also indirectly causes additional helper T-cell death by inducing cytotoxic T cells to kill HIV-infected helper T cells. In addition, by still poorly understood mechanisms, HIV causes the death of many uninfected helper T cells by apoptosis. Without adequate numbers of helper T cells, neither B cells nor cytotoxic T cells can function normally. Both humoral and cell-mediated immunity are compromised. Many individuals with AIDS die from infections and cancers that ordinarily would be readily handled by a fully functional immune system.

AIDS, first described in 1981, has since reached pandemic proportions. About 40 million people worldwide are infected with HIV, and an estimated 15,000 new infections occur each day. The major routes of HIV transmission are (1) unprotected sexual intercourse with an infected partner; (2) transfer of contaminated blood or blood products between individuals, such as during a blood transfusion or the sharing of needles among intravenous drug users; (3) transfer from an infected mother to her child across the placenta or during delivery; or (4) transfer via breast milk during nursing.

The great majority of individuals now infected with HIV show no signs of AIDS. Their infections are diagnosed by the presence of anti-HIV antibodies or HIV RNA in the blood. However, if left untreated, HIV infection commonly develops into AIDS in about 10 years. During the first 5 years, killed helper T cells are typically replaced by new cells, so T-cell levels remain normal, and the individual remains asymptomatic. Over the next 5 years, T-cell levels begin to decline, until at some point, AIDS reveals itself in the form of opportunistic viral, bacterial, and fungal infections. Certain unusual cancers, such as Kaposi's sarcoma, also occur with high frequency. In untreated individuals, death usually occurs within 2 years after the onset of AIDS symptoms.

Treatment for HIV-infected individuals has two components: one directed against the virus itself to delay progression of the disease, and one to prevent or treat the opportunistic infections and cancers that ultimately cause death. One current antiviral approach involves administering a "cocktail" of four drugs, known as HAART (highly active antiretroviral therapy). Two of the drugs inhibit the action of reverse transcriptase in converting viral RNA into DNA within the host cell, a third drug inhibits an HIV enzyme required for assembling new viruses, and a recently developed fourth class of drugs called fusion inhibitors prevents the virus from entering T cells. These treatments have been demonstrated to be effective in slowing the rate at which infection with HIV leads to AIDS. Unfortunately, however, the HAART regimen is associated with numerous side effects, including nausea, vomiting, diarrhea, metabolic disturbances resulting in part from insulin resistance, and liver damage. Much research is under way to find better treatments and ultimately to cure this scourge.

Summary of Key Concepts

- An animal's cells and organs that collectively contribute to its immune defenses, or immunity, constitute the animal's immune system.
- In innate (nonspecific) immunity, the body's defenses are present at birth and act against foreign materials in much the same way regardless of the specific identity of the invading material. Acquired (specific) immunity develops only after the body is exposed to foreign substances and targets those foreign substances specifically.

53.1 Types of Pathogens

- Pathogens are of three major types: bacteria, viruses, and eukaryotic parasites.

53.2 Innate Immunity

- An important innate defense is composed of phagocytes—cells capable of phagocytosis. In vertebrates, most phagocytes belong to the blood cells called leukocytes. The leukocytes involved in innate immunity include neutrophils, eosinophils, monocytes, macrophages, basophils, and natural killer (NK) cells. (Figure 53.1)
- Two other types of cells play important roles in innate immunity: dendritic cells and mast cells.
- Inflammation is an innate local response to infection or injury characterized by local redness, swelling, heat, and pain. The events of inflammation are induced and regulated by chemical mediators called cytokines. (Figure 53.2)
- Antimicrobial proteins include interferons, which inhibit viral replication, and complement proteins, which kill microbes without prior phagocytosis. Activation of the complement proteins results in the formation of a membrane attack complex (MAC), which creates water channels in the microbial plasma membrane and causes the microbe to swell and burst.

53.3 Acquired Immunity

- A foreign molecule that the host does not recognize as self and that triggers an acquired immune response is an antigen.
- Leukocytes called lymphocytes are responsible for acquired immune responses. Although lymphocytes circulate in the blood, most of them reside in a group of organs and tissues that constitute the lymphatic system. (Figure 53.3)
- Lymphocytes responsible for acquired immunity are B and T cells. B cells differentiate into antibody-producing cells called plasma cells. T cells include cytotoxic T cells, which directly kill target cells, and helper T cells, which assist in the activation and function of B cells and cytotoxic T cells. (Figure 53.4)
- Immunologists recognize two types of acquired immunity. In humoral immunity, plasma cells secrete antibodies that bind to antigens. In cell-mediated immunity, cytotoxic T cells directly attack and destroy abnormal body cells.
- Acquired immune responses occur in three stages. The first stage is recognition of antigen; the second is activation of lymphocytes; and the third is attack against antigen. When a lymphocyte is stimulated by an antigen, it divides and produces clones of itself, all of which express the same receptor. After activation, some of the cloned lymphocytes function as effector cells, which carry out the attack response; other cells function as memory cells, which remain poised to recognize the antigen if it returns in the future. (Figure 53.5)
- In humoral immunity, B cells recognize antigens with B-cell receptors. When B cells are activated, they proliferate and differentiate into plasma cells, which secrete antibodies.
- Both B-cell receptors and antibodies belong to a family of proteins called immunoglobulins. Immunoglobulins have two heavy chains and two light chains. The lower halves of the heavy chains contain constant regions, which are identical for all immunoglobulins of a given Ig class. At the other end of the Ig molecule, the two chains form a variable region that serves as the antigen binding site. (Figures 53.6, 53.7)
- The process known as hypermutation, which primarily involves numerous C to T point mutations, is crucial to enabling plasma cells to produce a diverse array of antibodies capable of recognizing many different antigens.
- B cells that are activated by an antigen differentiate into plasma cells by a process called clonal selection. (Figure 53.8)
- Antibodies combine with the antigen that activated the B cell and guide an attack that eliminates the antigen or the cells bearing it.
- In cell-mediated immunity, T cells can recognize antigens only when they are complexed with self proteins.
- Major histocompatibility complex (MHC) proteins are cellular "identity tags" that serve as genetic markers of self. Class I MHC proteins are found on the surface of all human body cells except erythrocytes. Class II MHC proteins are found only on the surface of macrophages, B cells, and dendritic cells.
- Antigen-presenting cells (APCs) are cells bearing fragments of antigen, called antigenic determinants or epitopes, complexed with the cell's MHC proteins.
- The binding between a helper T-cell receptor and an antigen bound to class II MHC proteins on an APC is essential to helper T-cell activation. Once activated, helper T cells can help to activate both B cells and cytotoxic T cells. (Figure 53.9)
- Cell-mediated immune responses are mediated by cytotoxic T cells, which directly kill virus-infected and cancerous cells via secreted chemicals. Humoral immune responses are mediated by B cells and plasma cells. In both types of responses, helper T cells are required. (Figures 53.10, 53.11)
- The process by which the body distinguishes between self and nonself components is called immune tolerance. Individuals normally lack active lymphocytes that respond to self components because of two mechanisms. T cells with receptors capable of binding self proteins are destroyed by apoptosis in a process termed clonal deletion. Clonal inactivation causes potentially self-reacting lymphocytes to become nonresponsive.
- When the body's immune cells attack the body's own cells, the result is autoimmune disease.
- Upon initial exposure to an antigen, the body produces a primary immune response. Any subsequent exposure to the same antigen elicits an immediate and heightened

response termed a secondary immune response. The immune system's ability to produce this secondary response is called immunological memory. (Figure 53.12)

- The acquired response to exposure to any type of antigen is known as active immunity. The artificial exposures to antigen that occur in vaccinations and immunizations also induce active immunity. In contrast, passive immunity confers protection against disease through the direct transfer of antibodies from one individual to another. Monoclonal antibodies may pave the way for the use of passive immunity to combat certain types of cancer.
- Some animals, such as social insects, can confer immunity on each other through social contact, called "social immunity." (Figure 53.13)

53.4 Impact on Public Health

- Factors that affect the body's defense mechanisms include lifestyle; organ transplants and blood transfusions; allergies; and AIDS, caused by the human immunodeficiency virus (HIV). AIDS reduces the body's immunity by killing helper T cells.

Assess and Discuss

Test Yourself

1. Which of the following is not an example of a barrier defense in animals?
   a. skin
   b. secretions from skin glands
   c. exoskeleton
   d. mucus
   e. antibodies
2. The leukocytes that are found in mucosal surfaces and that play a role in defending the body against parasitic infections are
   a. neutrophils.
   b. eosinophils.
   c. basophils.
   d. monocytes.
   e. NK cells.
3. The vascular changes of inflammation
   a. lead to an increase in bacterial cells at the injury site.
   b. decrease the number of leukocytes at the injury site.
   c. allow plasma proteins to move easily from the bloodstream to the injury site.
   d. increase the number of antibodies at the injury site.
   e. activate lymphocytes.
4. Which is correct regarding acquired immunity?
   a. Acquired immunity only requires the presence of helper T cells to function properly.
   b. Acquired immunity does not require exposure to a foreign substance.
   c. Acquired immunity is triggered by contact with a particular antigen.
   d. Acquired immunity includes inflammation.
   e. All of the above are correct.
5. Memory B cells are
   a. cloned lymphocytes that are active in subsequent infections.
   b. cloned lymphocytes that are active during a primary infection.
   c. NK cells that recognize cancer cells and destroy them.
   d. cells that produce antibodies.
   e. macrophages that have recognized self antigens.
6. The immunoglobulin that is passed from mother to fetus across the placenta is
   a. IgA.
   b. IgD.
   c. IgE.
   d. IgG.
   e. IgM.
7. The region of an antibody that is the antigen binding site is
   a. the constant region.
   b. the variable region.
   c. the heavy chain.
   d. the light chain.
   e. the hinge region.
8. A major difference between the activation of B cells and T cells is that
   a. T cells must interact with antigens bound to plasma membranes.
   b. B cells interact only with free antigens.
   c. B cells are not regulated by helper T cells.
   d. T cells produce antibodies.
   e. none of the above
9. Cells that process foreign proteins and complex them with their MHC proteins are called
   a. cytotoxic T cells.
   b. plasma cells.
   c. NK cells.
   d. antigen presenting cells.
   e. helper T cells.
10. HIV causes immune deficiency because the virus
    a. destroys all the cytotoxic T cells.
    b. preferentially destroys helper T cells that regulate the immune system.
    c. directly inactivates plasma cells.
    d. causes mutations that lead to autoimmune diseases.
    e. does all of the above.

Conceptual Questions

1. Distinguish between innate immunity and acquired immunity.
2. Explain the function of cytotoxic T cells.
3. Describe the basic structure of an immunoglobulin.

Collaborative Questions

1. Discuss three types of pathogens that affect the health of animals.
2. Describe the functions of helper T cells.

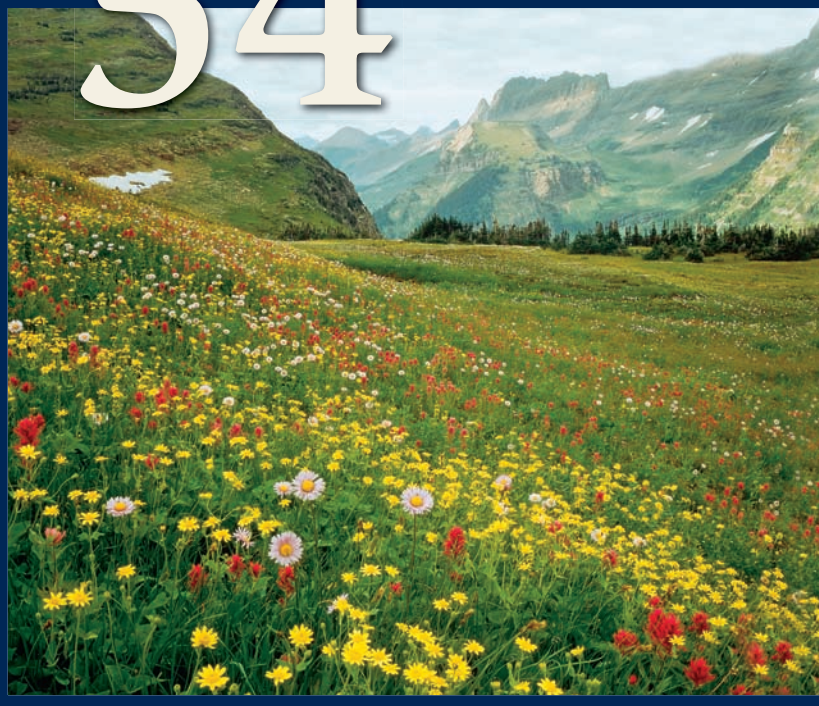
Chapter Outline

An Introduction to Ecology and Biomes

54



What controls the densities of these flowering plants at Glacier National Park, Montana? Is it temperature or rainfall? Or is it the availability of pollinators, herbivory by insects or vertebrates, or competition with other plant species for resources? Ecology seeks to answer questions such as these.

In 2006, a study led by J. Alan Pounds of the Monteverde Cloud Forest Preserve in Costa Rica reported that fully two-thirds of the 110 species of harlequin frogs in mountainous areas of Central and South America had become extinct over the previous 20 years. The researchers noted that populations of other species, such as the Panamanian golden frog (*Atelopus zeteki*), had been greatly reduced (Figure 54.1). The question was why. The culprit was identified as a disease-causing fungus, *Batrachochytrium dendrobatidis*, but Pounds's study implicated global warming—a gradual increase in the average temperature of the Earth's atmosphere—as the agent causing outbreaks of the fungus. One effect of global warming is to increase the cloud cover, which reduces daytime temperatures and raises nighttime temperatures. Researchers believe that this combination has created favorable conditions for the spread of *B. dendrobatidis* and other diseases, which thrive in cooler daytime temperatures. Pounds, the team's lead researcher and an ecologist, was quoted as saying, "Disease is the bullet killing frogs, but climate change is pulling the trigger."

Ecology is the study of interactions among organisms and between organisms and their environments. Interactions among organisms are called **biotic** interactions, and those between organisms and their nonliving environment are termed **abiotic** interactions. These interactions, in turn, govern the numbers of species in an area and their population densities. In this first chapter of the ecology unit, we will introduce you to the four broad areas of ecology: organismal, population, community, and ecosystems ecology. Next, we will explore how ecologists approach and conduct their work. We will then turn our focus to abiotic interactions and examine the effects of factors such as temperature, water, light, pH, and salt concentrations on the distributions of organisms. We conclude with a consideration of climate and its large influence on biomes, the major types of habitats where organisms are found.

In other chapters in this unit, we'll also learn how plants compete with one another, how herbivores affect plant abundance, and how natural enemies impact prey populations. We'll examine the effects of humans on the environment, including pollution, global warming, and the introduction of exotic species of plants and animals.

Figure 54.1 **Diminishing and disappearing populations.** Population sizes of the Panamanian golden frog (*Atelopus zeteki*) have diminished greatly over the past 20 years, and populations of many other species of harlequin frogs have disappeared entirely. Ecologists are investigating the reasons for this decline.

Ecologists are among the best-equipped scientists to study these phenomena. Before 1960, the field of ecology was dominated by taxonomy, natural history, and speculation about observed patterns. An ecologist's tools of the trade might have included sweep nets, quadrats (small, measured plots of land used to sample living things), and specimen jars. Since that time, an explosion in the number of ecological studies has occurred, and ecologists have become active in investigating environmental change on local, regional, and global scales. Ecologists have embraced experimentation and adapted concepts and methods derived from agriculture, physiology, biochemistry, genetics, physics, chemistry, and mathematics. Their tools have kept pace with technological innovations. Now an ecologist's equipment is just as likely to include portable computers, satellite-generated images, and chemical autoanalyzers.

Ecological studies have important implications in the real world, as will be amply illustrated by examples discussed throughout the unit. However, there is a distinction between ecology and **environmental science**, the application of ecology to real-world problems. To use an analogy: Ecology is to environmental science as physics is to engineering. Both physics and ecology provide the theoretical framework on which to pursue more applied studies. Engineers rely on the principles of physics to build bridges. Environmental scientists rely on the principles of ecology to solve environmental problems.

54.1 The Scale of Ecology

Ecology ranges in scale from the study of an individual organism through the study of populations to the study of communities and ecosystems (Figure 54.2). In this section, we introduce each of the broad areas of organismal, population, community, and ecosystem ecology and provide an investigation that helps illuminate the field of population ecology.

Organismal Ecology Investigates How Adaptations and Choices by Individuals Affect Their Reproduction and Survival

Organismal ecology can be divided into two subdisciplines. The first, **physiological ecology**, investigates how organisms are physiologically adapted to their environment and how the environment impacts the distribution of species. Much of this chapter discusses physiological ecology. The second area, **behavioral ecology**, focuses on how the behavior of an individual organism contributes to its survival and reproductive success, which, in turn, eventually affects the population density of the species.

Population Ecology Describes How Populations Grow and Interact with Other Species

Population ecology focuses on groups of interbreeding individuals, called populations. A primary goal is to understand the factors that affect a population's growth and determine its size and density. Although the attention of a population ecologist may be aimed at studying the population of a particular species, the relative abundance of that species is often influenced by its interactions with other species. Thus, population ecology includes the study of **species interactions**, such as predation, competition, and parasitism. Knowing what factors impact populations can help us lessen species endangerment, stop extinctions, and control invasive species.

(d) Nutrient flow in an African grassland community

Figure 54.2 **The scale of ecology.** **(a)** Organismal ecology. What is the temperature tolerance of this zebra? **(b)** Population ecology. What factors influence the growth of zebra populations in Africa? **(c)** Community ecology. What factors influence the number of species in African grassland communities? **(d)** Ecosystems ecology. How do water, energy, and nutrients flow among plants, zebras, and other herbivores and carnivores in African grassland communities?

Feature Investigation

Callaway and Aschehoug's Experiments Showed That the Secretion of Chemicals Gives Invasive Plants a Competitive Edge Over Native Species

One important topic in the area of population ecology concerns **introduced** or **exotic species**, species moved from a native location to another location, usually by humans. Such species sometimes spread so aggressively that they crowd out native organisms, in which case they are considered **invasive species**. Of the 300 most invasive plants in the U.S., over half were brought in for gardening, horticulture, or landscaping purposes. Invasive species have traditionally been thought to succeed because they have escaped their natural enemies, primarily insects that remained in the country of origin and were not transported to the new locale. One way of controlling these species, therefore, has been to import the plant's natural enemies. This is known as **biological control**. However, new research on the population ecology of diffuse knapweed (*Centaurea diffusa*), an invasive Eurasian plant that has established itself in many areas of North America, suggests a different reason for their success.

Researchers Ragan Callaway and Erik Aschehoug hypothesized that the roots of this particular species secrete powerful toxins, called **allelochemicals,** that kill the roots of other species, allowing *Centaurea* to proliferate. To test their hypothesis, Callaway and Aschehoug collected seeds of three native Montana grasses, *Koeleria cristata*, *Festuca idahoensis*, and *Agropyron spicata*, and grew each of them with or without the exotic *Centaurea* species (Figure 54.3). As hypothesized, *Centaurea* depressed the biomass of the native grasses. When the experiments were repeated with grasses native to Eurasia, *Koeleria*

Figure 54.3 Experimental evidence of the effect of allelochemicals on plant production.

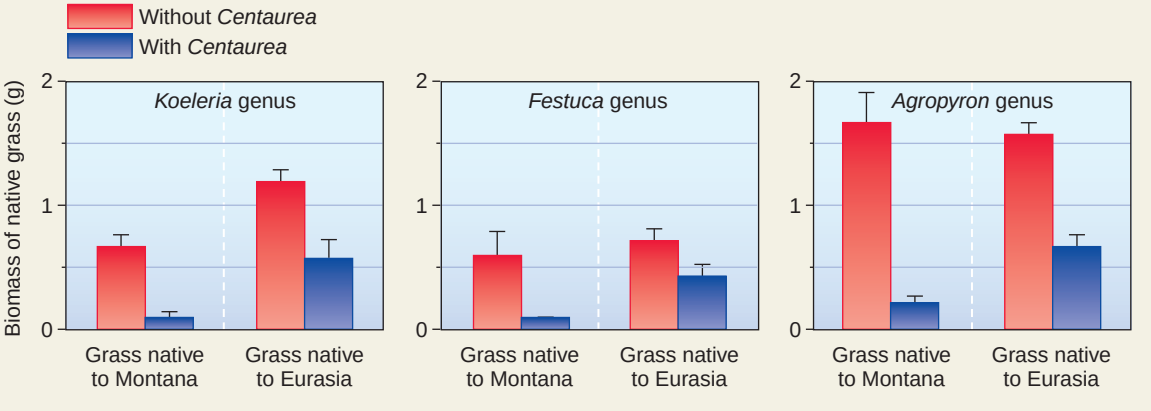
HYPOTHESIS Exotic plants from Eurasia outcompete native Montana grasses by secreting allelochemicals from their roots.

STARTING LOCATION *Centaurea diffusa,* a Eurasian plant, is invading Montana grasslands because it outcompetes 3 native grasses: *Koeleria cristata*, *Festuca idahoensis,* and *Agropyron spicata*.

	Experimental level	Conceptual level
1 Collect seeds of native Montana grasses and plant with and without seeds of invasive *C. diffusa* from Eurasia. Three months after sowing seeds, the plants are harvested, dried, and weighed.		*C. diffusa* significantly reduces biomass of native Montana grasses.
2 Collect seeds of grasses from Eurasia of the same three genera as the Montana grasses and plant with and without *C. diffusa*. Three months after sowing seeds, the plants are harvested, dried, and weighed.		*C. diffusa* doesn't depress the biomass of grasses native to Eurasia as much.

3 **THE DATA***

*The biomass is that of the genus noted at the top of each graph.



4 **CONCLUSION** *Centaurea diffusa,* a Eurasian grass, is invasive in the U.S. because it secretes allelochemicals, which inhibit the growth of native plants.

5 **SOURCE** Callaway, R.M., and Aschehoug, E.T. 2000. Invasive plants versus their old and new neighbors. *Science* 290:521–523.

laerssenii, *Festuca ovina*, and *Agropyron cristatum*, the growth of each species was inhibited, but to a significantly lesser degree than the growth of the Montana species.

In other experiments not described in Figure 54.3, Callaway and Aschehoug added activated carbon to the soil, which absorbs the chemical excreted by the *Centaurea* roots. With activated carbon added, the Montana grass species increased in biomass compared to the previous experiments. The researchers concluded that *C. diffusa* outcompetes Montana grasses by secreting an allelochemical and that Eurasian grasses are not as susceptible to the chemical's effect because they coevolved with it. If the reason for the success of invasive plants can be attributed to the chemicals they secrete, this calls into question the effectiveness of biological control of invasive plants by importation of their natural enemies. This study on the population biology of an invasive plant has changed the way we think about why such species succeed and could affect the way we attempt to control them in the future.

Experimental Questions

1. Prior to Callaway and Aschehoug's study, what was the prevailing hypothesis of why invasive species succeed in new environments?
2. Briefly describe the evidence collected to support the allelochemical hypothesis.
3. What was the function of the activated carbon used in a subsequent test of the hypothesis?

Community Ecology Focuses on What Factors Influence the Number of Species in a Given Area

We've just seen how a population of an invasive plant may produce allelochemicals that give it a growth advantage over populations of other species. On a larger scale, **community ecology** studies how populations of species interact and form functional communities. In a forest, there are many populations of trees, herbs, shrubs, grasses, the herbivores that eat them, and the carnivores that prey on the herbivores. Community ecology focuses on why certain areas have high numbers of species (that is, are species rich), while other areas have low numbers of species (that is, are species poor).

Although ecologists are interested in species richness for its own sake, a link also exists between species richness and community function. Ecologists generally believe that species-rich communities perform better than species-poor communities. It has also been proposed that more species make a community more stable, that is, more resistant to disturbances such as introduced species. Community ecology also considers how species composition and community structure change over time and, in particular, after a disturbance, a process called succession.

Ecosystem Ecology Describes the Passage of Energy and Nutrients Through Communities

An **ecosystem** is an interacting system of a community of organisms and the physical environment in which they live. **Ecosystem ecology** deals with the flow of energy and cycling of chemical elements among organisms within a community and between organisms and the environment. Following this flow of energy and chemicals necessitates an understanding of feeding relationships between species, called food chains. In food chains, each level is called a trophic level, and many food chains interconnect to form complex food webs.

As we learned in Chapter 6, the second law of thermodynamics states that in every energy transformation, free energy is reduced because heat energy is lost in the process, and the entropy of the system increases. There is, therefore, a unidirectional flow of energy through an ecosystem, with energy dissipated at every step. An ecosystem needs a recurring input of energy from an external source—in most cases, the sun—to sustain itself. In contrast, chemicals such as nitrogen do not dissipate and constantly cycle between abiotic and biotic components of the environment, often becoming more concentrated in organisms in higher trophic levels.

54.2 Ecological Methods Focus on Observation and Experimentation

How do ecologists go about studying their subject? In this section, we will examine the value of different ecological methods such as observation and experimentation. Let's suppose you are employed by the United Nations' Food and Agricultural Organization (FAO), which operates internationally out of Rome, Italy. As an ecologist, you are charged with finding out what causes outbreaks of locusts, a type of grasshopper whose population periodically erupts in Africa and other parts of the world, destroying crops and causing food shortages.

First of all, you might draw up a possible web of interaction between the factors that could affect locust population size

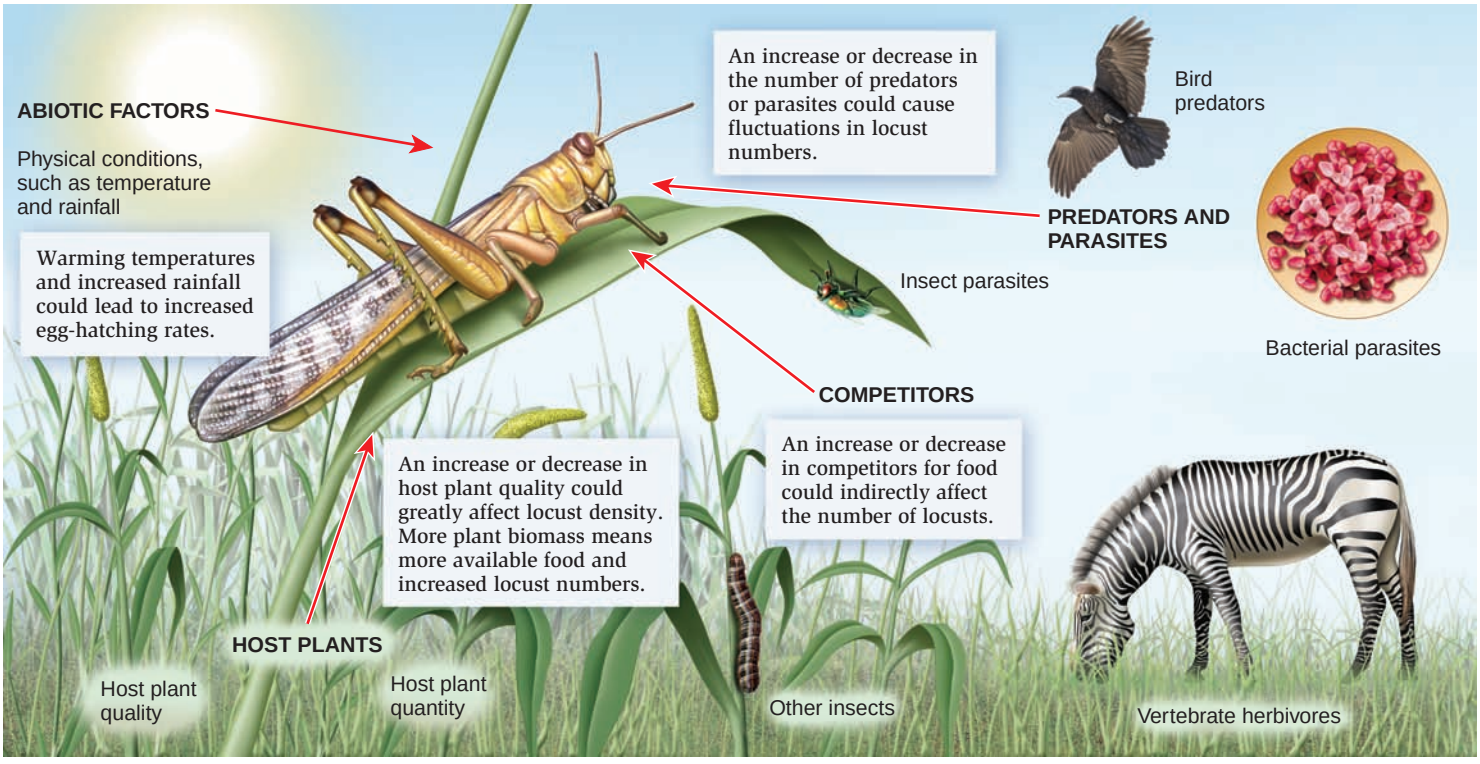


Figure 54.4 Interaction web of factors that might influence locust population size.

(Figure 54.4). These interactions are many and varied, and they include

- abiotic factors, such as temperature, rainfall, wind, and soil pH;
- natural enemies, including bird predators, insect parasites, and bacterial parasites;
- competitors, including other insects and larger vertebrate grazers;
- host plants, including increases or decreases in either the quality or quantity of the plants.

With such a vast array of factors to be investigated, where is the best place to start? As discussed in Chapter 1, hypothesis testing involves a five-stage process: (1) observations, (2) hypothesis formation, (3) experimentation, (4) data analysis, and (5) acceptance or rejection of the hypothesis. In our study of locusts, we begin by careful observation of the organism in its native environment. We can analyze the fluctuations of locusts and determine if the populations vary with fluctuations in the other phenomena, such as levels of parasitism, numbers of predators, or food supply. Imagine we found that locust numbers are affected by bird predation levels and that an inverse relationship exists between predation levels and locust numbers. As predation levels increase, locust numbers decrease. If we plotted this relationship graphically, the resulting graph would look like that depicted in Figure 54.5a. This result would give us some confidence that predation levels determined locust numbers, and this would be our hypothesis. In fact, we would have so much confidence that we could create a statistically determined "line of best fit" to represent a summary of the relationship between these two variables, which is shown in the graph.

However, if the points were not highly clustered, as in Figure 54.5b, we would have little confidence that predation affects locust density. Many statistical tests are used to determine whether or not two variables are significantly correlated. In the studies in this unit, unless otherwise stated, most graphs like Figure 54.5a imply that a meaningful relationship exists between the two variables. We call this type of relationship a significant **correlation**. In this graph, locust density shows a negative linear relationship with predation; therefore, we say that locust density is negatively correlated with predation.

We have to be cautious when forming conclusions based on correlations. For example, large numbers of locusts could be associated with large, dense plants. We might conclude from this that food availability controls locust density. However, an alternative conclusion would be that large plants provide locusts refuge from bird predators, which cannot attack them in the dense interior. While it would appear that biomass affects locust density by providing abundant food, in actuality, predation would still be the most important factor affecting locust density. Thus, correlation does not always mean causation. For this reason, after conducting observations, ecologists usually turn to experiments to test their hypotheses.

In our example, an experiment might involve removing predators from an area inhabited by locusts. If predators are having a significant effect, then removing them should cause

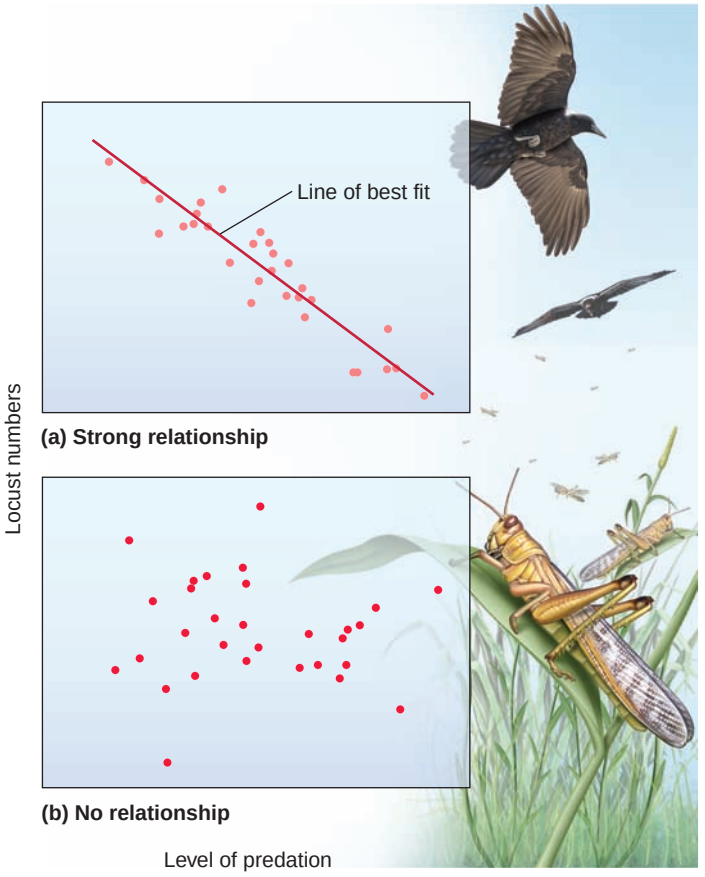

Figure 54.5 **How locust numbers might be correlated with predation.** In this case, higher locust numbers are found in nature where predation levels are lowest. We can draw a line of best fit **(a)** to represent this relationship. In **(b)**, the relationship between locust numbers and predation levels might be so weak that we would not have much confidence in a linear relationship between the variables.

Concept check: *What would it mean if the line of best fit sloped in the opposite direction?*

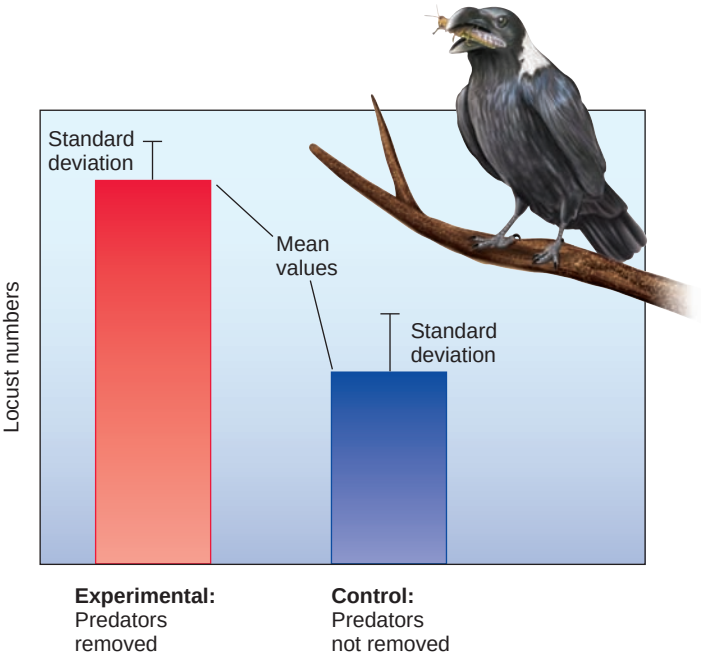

Figure 54.6 **Graphic display of hypothetical results of a predator removal experiment.** The two bars represent the average number of locusts where predators are removed (experimental group) and where predators are not removed (control group). The vertical lines (the standard deviations or standard errors) give an indication of how tightly the individual results are clustered around the mean. The shorter the lines, the tighter the cluster, and the more confidence we have in the result.

an increase in locust numbers. We would have two groups: a group of locusts with predators removed (the experimental group) and a group of locusts with predators still present (the control group), with equal numbers of locusts in both groups at the start of the experiment. Any differences in locust population density would be due solely to differences in predation. Reduced predation might be achieved by putting a cage made of chicken wire over and around bushes containing locusts, so that birds are denied access. Experiments often have a defined time frame, and in our example, we could look at locust survivorship over the course of one generation of locust and predator.

Performing the experiments several times is called **replication**. We might replicate the experiment 5 times, 10 times, or even more. We would add up the total number of surviving locusts from each replicate and calculate the mean, which is the sum divided by the number of values. In the experimental group, let's suppose that the numbers of surviving locusts in each replicate are 5, 4, 7, 8, 12, 15, 13, 6, 8, and 10; the mean number surviving would be 8.8. In the control group, which still allows predator access, the numbers surviving might be 2, 4, 7, 5, 3, 6, 11, 4, 1, and 3, with a mean of 4.6. Without predators, the mean number of surviving locusts would therefore be almost double the average number surviving with predators. Our data analysis would give us confidence that predators were indeed the cause of our changes in locust numbers. The results of such experiments can be illustrated graphically by a bar graph (Figure 54.6). Ecologists can use a variety of tests to see if the differences between the control data and the experimental data are statistically significant, which means that the differences are not likely to have occurred as a result of random chance. We won't look at the mechanics of these tests, but in this unit, when experimental and control data are presented as differing, these are considered to be statistically significant differences unless stated otherwise.

By the way, it turns out that predation is not the primary factor that controls locust populations. The results we have been discussing were hypothetical. Weather, in particular, rain, is the most important feature governing locust population size. Moist soil allows eggs to hatch and provides water for germinating plants, allowing a ready source of food for the hatchling locusts. In fact, physical or abiotic factors such as amount of moisture usually have powerful effects in most ecological systems. In the next part of the chapter, we turn our attention to an examination of the effects of the physical environment on the distribution patterns of organisms.

54.3 The Environment's Impact on the Distribution of Organisms

Both the distribution patterns of organisms and their abundance are limited by physical features of the environment such as temperature, wind, availability of water and light, salinity, and pH (Table 54.1). In this section, we will examine these features of the environment.

Temperature Has an Important Effect on the Distribution of Plants and Animals

Temperature is perhaps the most important factor in the distribution of organisms because of its effect on biological processes and because of the inability of most organisms to regulate their body temperature precisely. For example, the organisms that form coral reefs secrete a calcium carbonate shell. Shell formation and coral deposition are accelerated at high temperatures but are suppressed in cold water. Coral reefs are therefore abundant only in warm water, and a close correspondence is observed between the 20°C isotherm for the average daily temperature during the coldest month of the year and the limits of the distribution of coral reefs (Figure 54.7). An isotherm is a line on a map connecting points of equal temperature. Coral reefs are located between the two 20°C isotherm lines that are formed above and below the equator.

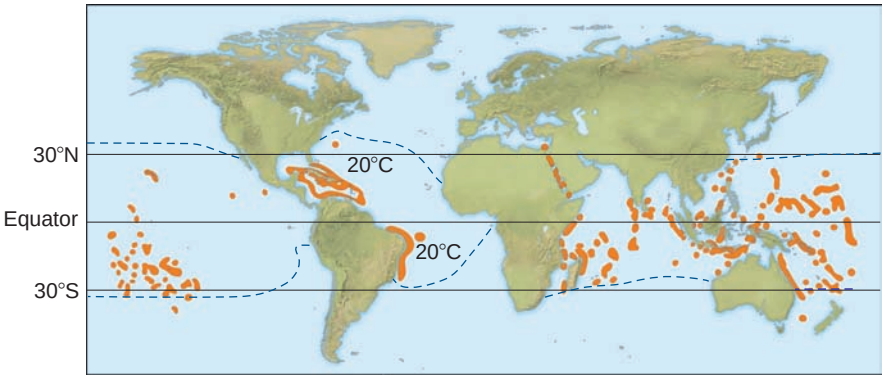
Frost is probably the single most important factor limiting the geographic distribution of tropical and subtropical plants. In plants, cold temperature can be lethal because cells may rupture if the water they contain freezes. In the Sonoran Desert in Arizona, saguaro cacti can easily withstand frost for one night as long as temperatures rise above freezing the following day, but they are killed when temperatures remain below freezing for more than 36 hours. This means that the cactus's distribution is limited to places where the temperature does not remain below freezing for more than one night (Figure 54.8).

Table 54.1 Selected Abiotic Factors and Their Effects on Organisms

Factor	Effect
Temperature	Low temperatures freeze many plants; high temperatures denature proteins. Some plants require fire for germination.
Wind	Wind amplifies effects of cool temperatures (wind chill) and water loss; creates pounding waves.
Water	Insufficient water limits plant growth and animal abundance; excess water drowns plants and other organisms.
Light	Insufficient light limits plant growth, particularly in aquatic environments.
Salinity	High salinity generally reduces plant growth in terrestrial habitats; affects osmosis in marine and freshwater environments.
pH	Variations in pH affect decomposition and nutrient availability in terrestrial systems; directly influences mortality in both aquatic and terrestrial habitats.

The geographic range limits of endothermic animals are also affected by temperature. For example, the eastern phoebe (*Sayornis phoebe*), a small bird, has a northern winter range that coincides with an average minimum January temperature of above 4°C. Such limits are probably related to the energy demands associated with cold temperatures. Cold temperatures mean higher metabolic costs, which are, in turn, dependent on high feeding rates. Below 4°C, the eastern phoebe cannot feed fast enough or, more likely, find enough food to keep warm.

High temperatures are also limiting for many plants and animals because relatively few species can survive internal temperatures more than a few degrees above their metabolic optimum. We have discussed how corals are sensitive to low temperatures; however, they are sensitive to high temperatures



(a) Worldwide distribution of coral reefs

(b) A coral reef

Figure 54.7 **Locations of coral reefs.** **(a)** Coral reef formation is limited to waters bounded by the 20°C isotherm (dashed line), a line where the average daily temperature is 20°C during the coldest month of the year. **(b)** Coral reef from the Pacific Ocean.

Concept check: *Why are coral reefs limited to warm water?*

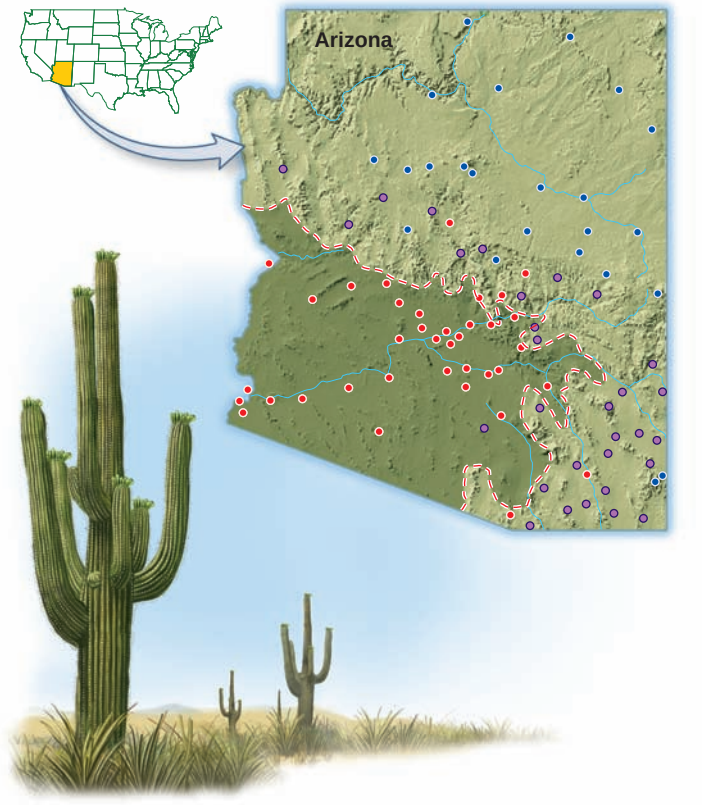


Figure 54.8 **Saguaro cacti in freeze-free zones.** A close correspondence is seen between the range of the saguaro cactus (dark green area) and the area in which temperatures do not drop below freezing (0°C).

Figure 54.9 **Coral bleaching.** Mantanani Island, Malaysia.

Figure 54.10 **Giant sequoia.** A park ranger uses a drip torch to ignite a fire at Sequoia National Park in California. Periodic, controlled human-made fires mimic the sporadic wildfires that normally burn natural areas. Such fires are vital to the health of giant sequoia populations, because they serve to open the pine cones and release the seeds.

Concept check: *Why are some fires very destructive to natural systems?*

as well. When temperatures are too high, the symbiotic algae that live within coral die and are expelled, causing a phenomenon known as coral bleaching. Once bleaching occurs, the coral tissue loses its color and turns a pale white (Figure 54.9). El Niño is a weather phenomenon characterized by a major increase in the water temperature of the equatorial Pacific Ocean. In the winter of 1982–1983, an influx of warm water from the eastern Pacific raised temperatures just 2–3°C for 6 months, which was enough to kill many of the reef-building corals on the coast of Panama. By May 1983, just a few individuals of one species, *Millepora intricata*, were alive. Scientists are concerned that future climate changes may increase the frequency of coral bleaching.

The ultimate high temperatures that many terrestrial organisms face are brought about by fire. However, some species depend on frequent low-intensity fires for their reproductive success. The longleaf pine (*Pinus palustris*) of the southeast U.S. produces serotinous cones, which remain sealed by pine resin until the heat of a fire melts them open and releases the seeds. In the west, giant sequoia trees are similarly dependent on periodic low-intensity fires for germination of their seeds. Such fires both enhance the release of seeds and clear out competing vegetation at the base of the tree so that seeds can germinate and grow (Figure 54.10). Fire-suppression practices that attempt to protect forests from fires can actually have undesirable results by preventing the regeneration of fire-dependent

species. Furthermore, fire prevention can result in an accumulation of vegetation beneath the canopy (the understory) that may later fuel hotter and more damaging fires.

Keep in mind that it is not average temperatures that usually limit the range of species but rather the frequency of occasional extremes, such as freezes for the saguaro cacti. Farmers know this only too well. The frequency and strength of periodic freezes limit the northern distribution of oranges in Florida and the southern distribution of coffee in Brazil, not average temperatures for the coldest months. Experimentally moving organisms outside their normal range and monitoring survivorship is a useful way to establish what factors control the natural limits of species. Of course, such movements must be done in a carefully controlled manner to ensure that there is no risk of species becoming invasive in their new habitats. Again, physical extremes, such as fires or severe freezes, may be apparent only in isolated years, so ecologists often have to wait many years to determine whether extremes are limiting the distribution and abundance of plants and animals in the field.

Despite the obvious relationships between species distributions and temperature, we need to be cautious about solely relating the two. The temperatures measured for constructing isotherm maps such as that in Figure 54.7a are not always the temperatures that the organisms experience. For example, in nature, an organism may choose to lie in the sun or hide in the shade, both of which affect the temperatures it experiences. Such local variations of the climate within a given area, or **microclimate**, can be important for a particular species. In the spring, temperate forests turn green from the ground upwards. Herbaceous species leaf out first, followed by shrubs, small trees, and large trees, because the air is warmer closer to the ground. Dark-colored surfaces such as soil absorb more light and produce more heat, which also helps to warm the ground cover first.

Because so many species are limited in their distribution patterns by global temperatures, ecologists are concerned that if global temperatures rise, as they are predicted to, many species will be driven to extinction or that their geographic ranges will shrink and the location of centers of agriculture and forestry will be altered. The increase in the average temperature of Earth's atmosphere and oceans is called global warming, and it is caused by a process known as the greenhouse effect.

The Greenhouse Effect The Earth is warmed by the **greenhouse effect**. In a greenhouse, sunlight penetrates the glass and raises temperatures, with the glass acting to trap the resultant heat inside. Similarly, solar radiation in the form of short-wave energy passes through the atmosphere to heat the surface of the Earth. At night, this energy is radiated from the Earth's warmed surface back into the atmosphere, but in the form of long-wave infrared radiation. Instead of letting it escape back into space, however, atmospheric gases absorb much of this infrared energy and radiate it back to the Earth's surface, causing its temperature to rise further (Figure 54.11). The greenhouse effect is a naturally occurring process that is responsible for keeping the earth warm enough to sustain life. Without some type of greenhouse effect, global temperatures would be much lower than they are, perhaps averaging only −17°C compared to the existing average of +15°C.

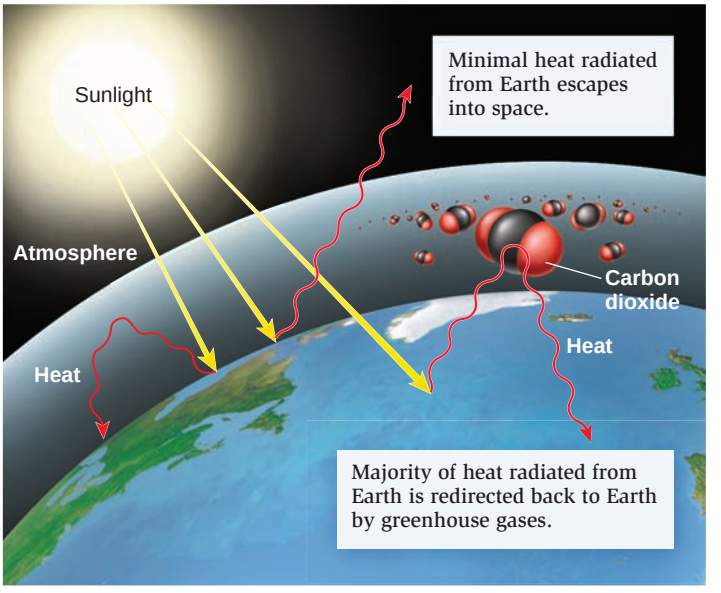

Figure 54.11 **The greenhouse effect.** Solar radiation, in the form of short-wave energy, passes through the atmosphere to heat the Earth's surface. Long-wave infrared energy is radiated back into the atmosphere. Much infrared energy is absorbed by atmospheric gasses, including carbon dioxide molecules, and reflected back to Earth, causing global temperatures to rise.

The greenhouse effect is caused by a group of atmospheric gases that together make up less than 1% of the total volume of the atmosphere. These gases—primarily water vapor, carbon dioxide, methane, nitrous oxide, and chlorofluorocarbons—are referred to as greenhouse gases (Table 54.2).

Global Warming Ecologists are concerned that human activities are increasing the greenhouse effect and causing **global warming**, a gradual elevation of the Earth's surface temperature. According to the Intergovernmental Panel on Climate Change 2007 report, warming of the climate is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising average global sea level. Most greenhouse gases have increased in atmospheric concentration since industrial times. Of those increasing, the most important is carbon dioxide (CO_2). As Table 54.2 shows, although CO_2 has a lower global warming potential per unit of gas (relative absorption) than any of the other major greenhouse gases, its concentration in the atmosphere is much higher. Annual emissions of CO_2 have increased by about 80% between 1970 and 2004.

To predict the effect of global warming, most scientists focus on a future point, about 2100, when the concentration of atmospheric CO_2 will have doubled—that is, increased to about 700 ppm compared with the late-20th-century level of 350 ppm. Scientists estimate that at that time, average global temperatures will be somewhere in the range of 1–6°C (about 2–10°F) warmer than present and will increase an additional 0.5°C each decade. This increase in heat might not seem like

Table 54.2 Selected Greenhouse Gases and Their Contribution to Global Warming*

	Carbon dioxide (CO_2)	Methane (CH_4)	Nitrous oxide (N_2O)	Chlorofluorocarbons (CFCs)
Relative absorption per ppm of increase**	1	21	310	10,000
Atmospheric concentration ppm†	385	1.75	0.315	0.0005
Contribution to global warming	73%	7%	19%	1%
Percent from natural sources; type of source	20–30%; volcanoes	70–90%; swamps, gas from termites and ruminants	90–100%; soils	0%
Major human-made sources	Fossil fuel use, deforestation	Rice paddies, landfills, biomass burning, coal and gas exploitation	Cultivated soil, fossil-fuel use, automobiles, industry	Previously manufactured products (for example, aerosol propellants) but now banned in the U.S. and the E.U.

*Water vapor is not included in this table.
**Relative absorption is the warming potential per unit of gas.
†ppm = parts per million

much, but it is comparable to the warming that ended the last ice age. Future consequences would include a further contraction of snow cover and a decrease in sea ice extent, heat waves and drought in dry areas, heavier precipitation in moister areas, and an increase in tropical cyclone intensity.

Assuming this scenario of gradual global warming is accurate, we need to consider what the consequences might be for plant and animal life. At the beginning of the chapter, we saw how global warming is believed to be contributing to the decline and extinction of some amphibian species. Although many species can adapt to slight changes in their environment, the anticipated changes in global climate are expected to occur too rapidly to be compensated for by normal evolutionary processes such as natural selection. Plant species cannot simply disperse and move north or south into the newly created climatic regions that will be suitable for them. Many tree species take hundreds, even thousands, of years for seed dispersal. Paleobotanist Margaret Davis predicted that in the event of a CO_2 doubling, the sugar maple (*Acer saccharum*), which is presently distributed throughout the midwestern and northeastern U.S. and southeastern Canada, would die back in all areas except in northern Maine, northern New Brunswick, and southern Quebec (Figure 54.12). Of course, this contraction in the tree's distribution could be offset by the creation of new favorable habitats in central Quebec. However, most scientists believe that the climatic zones would shift toward the poles faster than trees could migrate via seed dispersal; therefore, extinctions would occur. Interestingly, scientists are beginning to be able to genetically modify organisms to change their temperature tolerances, as described next.

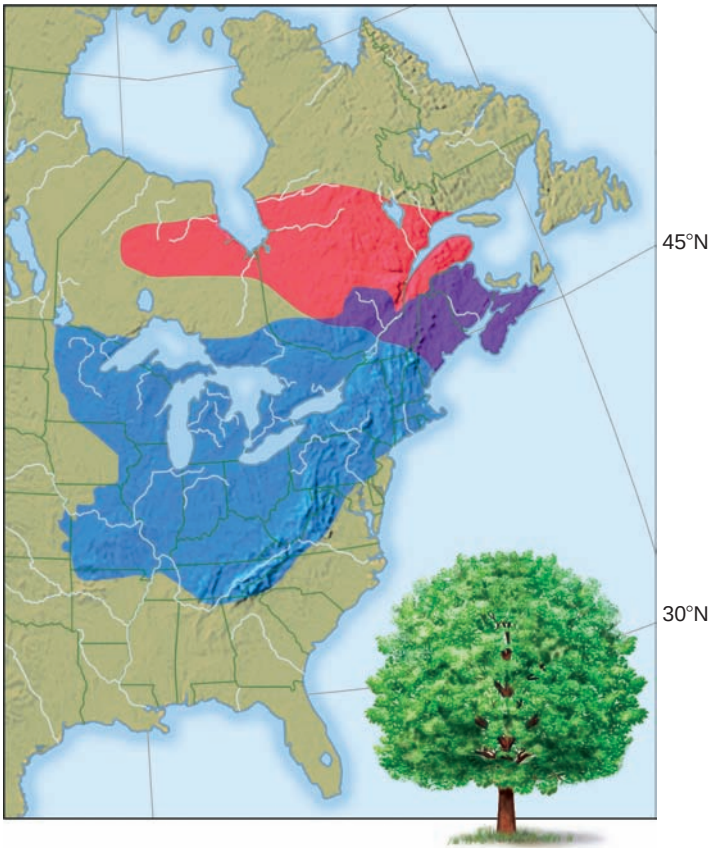

Figure 54.12 Possible changes in the range of sugar maples due to global warming. The present geographic range of the sugar maple (blue shading) and its potential range under doubled CO_2 levels (red shading) in North America. Purple shading indicates the region of overlap, which is the only area where the sugar maple would be found before it spread into its new potential range.

Genomes & Proteomes Connection

Temperature Tolerance May Be Manipulated by Genetic Engineering

Below-freezing temperatures can be very damaging to plant tissue, either killing the plant or greatly reducing its productivity. Frost injury causes losses to agriculture of more than $1 billion annually in the U.S. Frost has been considered an unavoidable result of subfreezing temperatures, but genetic engineering is beginning to change this view.

Between 0°C and −40°C, pure water will be a liquid unless provided with an ice nucleus or template on which an ice

crystal can be built. Researchers discovered that some bacteria commonly found on leaf surfaces act as ice nuclei, triggering the formation of ice crystals and eventually causing frost damage. The genes that confer ice nucleation have been identified, isolated, and deactivated in an engineered strain of the bacteria *Pseudomonas syringae*. When this strain is allowed to colonize strawberries, frost damage is greatly reduced, and plants can withstand an additional 5°C drop in temperature before frost forms. The promise of this technique for increasing agricultural yields and altering normal plant-distribution patterns is staggering.

At the other end of the temperature spectrum, heat shock proteins (HSPs) help organisms cope with the stress of high temperatures. At high temperatures, proteins may denature, that is, either unfold or bind to other proteins to form misfolded protein aggregations. HSPs act as molecular chaperones, proteins that help in the proper folding of other proteins, to prevent these types of events from taking place. HSPs normally constitute only about 2% of the cell's soluble protein content, but this can increase to 20% when a cell is stressed, whether by heat, cold, drought, or other condition. The genes that encode HSPs are extremely common and are found in the genomes of all organisms, from bacteria to plants and animals.

In the tropics, high temperatures can substantially decrease the growth rates and productivity of many crop species. There is now substantial interest in identifying crop strains with naturally high HSP levels for use in crop-breeding programs. Given the projected continuation of global warming, such research seems particularly timely.

Wind Can Amplify the Effects of Temperature

Wind is created by temperature gradients. As air heats up, it becomes less dense and rises. As hot air rises, cooler air rushes in to take its place. For example, hot air rising in the tropics is replaced by cooler air flowing in from more temperate regions, thereby creating northerly or southerly winds.

Wind affects living organisms in a variety of ways. It increases the rate of heat loss by convection, the transfer of heat by the movement of air next to the body (the wind chill factor). Wind also contributes to water loss in organisms by increasing the rate of evaporation in animals and transpiration in plants. For example, the tree line in alpine areas is often determined by a combination of low temperatures and high winds, an environmental condition in which transpiration exceeds water uptake.

Winds can also intensify oceanic wave action, with resulting effects for aquatic organisms. On the ocean's rocky shore, seaweeds survive heavy surf by a combination of holdfasts and flexible structures. The animals of this zone have powerful organic glues and muscular feet to hold them in place (Figure 54.13).

(a) Brown alga with a holdfast

(b) A mussel with byssal threads

Figure 54.13 **Animals and plants of the intertidal zone adhering to their rocky surface.** **(a)** The brown alga (*Laminaria digitata*) has a holdfast that enables it to cling to the rock surface. **(b)** The mussel (*Mytilus edulis*) attaches to the surface of a rock by proteinaceous threads (byssal threads) that extend from the animal's muscular foot.

The Availability of Water Has Important Effects on the Abundance of Organisms

Water has an important effect on the distribution of organisms. Cytoplasm is 85–90% water, and without moisture, there can be no life. As noted in Chapter 2, water performs crucial functions in all living organisms. It acts as a solvent for chemical reactions, takes part in hydrolysis and dehydration reactions, is the means by which animals eliminate wastes, and is used for support in plants and in some invertebrates as part of a hydrostatic skeleton.

The distribution patterns of many plants are limited by available water. Some plants, such as the water tupelo tree (*Nyssa aquatica*) in the southeast U.S., do best when completely flooded and are thus found predominantly in swamps. In contrast, coastal plants that grow on sand dunes experience very little fresh water. Their roots penetrate deep into the sand to extract moisture. In cold climates, water can be present but locked up as permafrost and, therefore, unavailable—this is termed frost drought. Alpine trees can be affected by frost drought. The trees stop growing at a point on the mountainside where they cannot take up enough moisture to offset transpiration losses. This point, known as the timberline, is readily apparent on many mountainsides. Not surprisingly, the density of many plants is limited by the availability of water. For example, a significant correlation is observed between rainfall and creosote bush density in the Mojave Desert.

Animals face problems of water balance, too, and their distribution and population density can be strongly affected by

water availability. Because most animals depend ultimately on plants as food, their distribution is intrinsically linked to those of their food sources. Such a phenomenon regulates the number of buffalo (*Syncerus caffer*) in the Serengeti area of Africa. In this area, grass productivity is related to the amount of rainfall in the previous month. Buffalo density is governed by grass availability, so a significant correlation is found between buffalo density and rainfall (Figure 54.14). The only exception occurs in the vicinity of Lake Manyara, where groundwater promotes plant growth.

The importance of water in limiting animal population density was underscored by an extraordinary event caused by El Niño. As we noted in Chapter 23, seed abundance on some Galápagos Islands is strongly linked to rainfall. During the 1982–1983 rainy season, rainfall on Isla Genovesa in the Galápagos Islands increased from its normal 100–150 mm to 2,400 mm. Plants responded with prodigious growth, and certain finches (*Geospiza* spp.) bred up to eight times rather than their normal maximum of three, probably because of increased abundance of fruits and seeds. The population densities of finches were exceptionally high by the end of the breeding season.

Light Can Be a Limiting Resource for Plants and Algae

Because light is necessary for photosynthesis, it can be a limiting resource for plants. However, what may be sufficient light to support the growth of one plant species may be insufficient for another. Many plant species grow best in shady conditions, such as eastern hemlock (*Tsuga canadensis*). Its saplings grow in the understory below the forest canopy, reaching maximal photosynthesis at one-quarter of full sunlight. Other plants, such as sugarcane (*Saccharum officinarum*) or the desert shrub *Larrea*, continue to increase their photosynthetic rate as light intensity increases.

In aquatic environments, light may be an even more limiting factor because water absorbs light, preventing photosynthesis at depths greater than 100 m. Most aquatic plants and algae are limited to a fairly narrow zone close to the surface, where light is sufficient to allow photosynthesis to occur. This zone is known as the **photic zone**. In marine environments, seaweeds at greater depths have wider thalli (leaflike light-gathering structures) than those nearer the surface, because wide thalli can collect more light. In addition, in aquatic environments, plant color changes with depth. At the surface, plants and algae appear green, as they are in terrestrial conditions, because they absorb red and blue light, but not green. At greater depths, red light is mostly absorbed by water, leaving predominantly blue-green light. Red algae occur in deeper water because they possess pigments that enable them to utilize blue-green light efficiently (Figure 54.15).

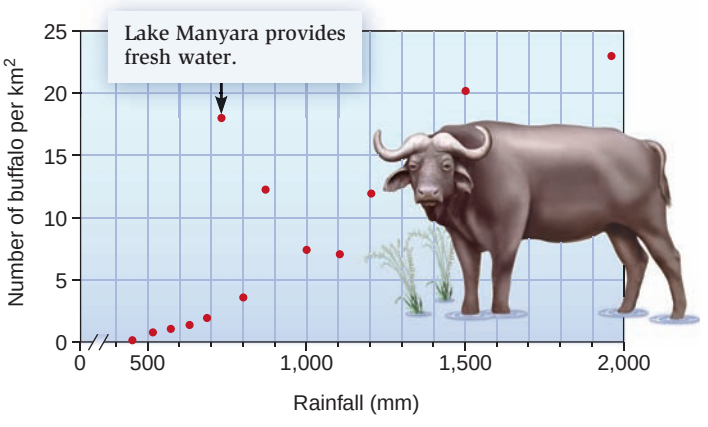

Figure 54.14 **The relationship between the amount of rainfall and the density of buffalo.** In the Serengeti area of Africa, buffalo density is very much dependent on grass availability, which itself is dependent on annual rainfall. The main exception is where there is permanent water, such as Lake Manyara, where greater water availability leads to greater grass growth and buffalo densities.

(a) Green algae at the ocean surface

(b) Red algae at a greater depth

Figure 54.15 **Algae growing at different ocean depths.** **(a)** In the eastern Pacific Ocean, off the coast of California, these giant kelp floating at the ocean surface are green, just like terrestrial plants. **(b)** In contrast, at 75-m depth, in the McGrail Bank off of the Gulf of Mexico, most seaweeds are pink and red because the pigments can absorb the blue-green light that reaches such depths.

The Concentration of Salts in Soil or Water Can Be Critical

Salt concentrations vary widely in aquatic environments and have a great impact on osmotic balance in animals. Oceans contain considerably more dissolved minerals than rivers because oceans continually receive the nutrient-rich waters of rivers, and the sun evaporates pure water from ocean surfaces, making concentrations of minerals such as salts even higher.

The phenomenon of osmosis influences how living organisms cope with different environments. Freshwater fishes cannot live in salt water, and saltwater fishes cannot live in fresh water. Each employs different mechanisms to maintain an osmotic balance with their environment. Freshwater fishes are hyperosmotic (having a higher concentration of ions) to their environment and tend to gain water by osmosis as it diffuses through the thin tissue of the gills and mouth. To counter this, the fish continually eliminate water in the urine. However, to avoid losing all dissolved ions, many ions are reabsorbed into the bloodstream at the kidneys. Many marine fishes are hypoosmotic (having a lower concentration of ions) to their environment and tend to lose water as seawater passes over the mouth and gills. They drink water to compensate for this loss, but the water contains a higher concentration of salt, which must then be excreted at the gills and kidneys (refer back to Chapter 49).

Salt in the soil also affects the growth of plants. In arid terrestrial regions, salt accumulates in soil where water settles and then evaporates. This can also be of great significance in agriculture, where continued watering in arid environments, together with the addition of salt-based fertilizers, greatly increases salt concentration in soil and reduces crop yields. A few terrestrial plants are adapted to live in saline soil along seacoasts. Here the vegetation consists largely of **halophytes**, species that can tolerate higher salt concentrations in their cell sap than regular plants. Species such as mangroves and *Spartina* grasses have salt glands that excrete salt to the surface of the leaves, where it forms tiny white salt crystals (Figure 54.16).

Figure 54.16 **Plant adaptations for salty conditions.** Special salt glands in the leaves of *Spartina* exude salt, enabling this grass to exist in saline intertidal conditions.

The pH of Soil or Water Can Limit the Distribution of Organisms

As discussed in Chapter 2, the pH of water can be acidic, alkaline, or neutral. Variation in pH can have a major impact on the distribution of organisms. Normal rainwater has a pH of about 5.6, which is slightly acidic because the absorption of atmospheric CO_2 and SO_2 into rain droplets forms carbonic and sulfuric acids. However, most plants grow best at a soil water pH of about 6.5, a value at which soil nutrients are most readily available to plants. Only a few genera, such as rhododendrons (*Rhododendron*) and azaleas (*Azalea*), can live in soils with a pH of 4.0 or less. Furthermore, at a pH of 5.2 or less, nitrifying bacteria do not function properly, which prevents organic matter from decomposing. In general, alkaline soils containing chalk and limestone have a higher pH and sustain a much richer flora (and associated fauna) than do acidic soils (Figure 54.17).

Generally, the number of fishes and other species also decreases in acidic waters. The optimal pH for most freshwater fishes and bottom-dwelling invertebrates is between 6.0 and 9.0. Acidity in lakes increases the amount of toxic metals, such as mercury, aluminum, and lead, which can leach into the water from surrounding soil and rock. Both too much mercury and too much aluminum can interfere with gill function, causing fishes to suffocate. In the U.S. northeast, acid rain has caused high mercury levels, and some states have advised that children and pregnant women should not eat freshwater fishes.

(a) Rich flora on alkaline soil **(b) Sparse flora on acidic soil**

Figure 54.17 **Species-rich floras of chalk grassland compared to species-poor floras of acid soils.** **(a)** At Mount Caburn, in the lime-rich chalk hills of Sussex County, England, there is a much greater variety of plant and animal species than at **(b)** a heathland site in England. Heathlands are a product of thousands of years of human clearance of natural forest areas and are characterized by acidic, nutrient-poor soils.

Concept check: *Why do acidic soils support fewer species of plants and animals than lime-rich soils?*

The susceptibility of both aquatic and terrestrial organisms to changes in pH explains why ecologists are so concerned about **acid rain**, precipitation with a pH of less than 5.6. Acid rain results from the burning of fossil fuels such as coal, oil, and natural gas, which releases sulfur dioxide and nitrogen oxide into the atmosphere. These react with oxygen in the air to form sulfuric acid and nitric acid, which falls to the Earth's surface in rain or snow. When this precipitation falls on rivers and especially lakes, it can turn them more acidic, and they lose their ability to sustain fishes and other aquatic life. For example, lake trout disappear from lakes in Ontario and the eastern U.S. when the pH dips below about 5.2. Although this low pH does not affect survival of the adult fish, it affects the survival of juveniles.

Acid rain is important in terrestrial systems, too. For example, acid rain can directly affect forests by killing leaves or pine needles, as has happened on some of the higher mountaintops in the Great Smoky Mountains. It can also greatly lower soil pH, which can result in a loss of essential nutrients such as calcium and nitrogen. Low soil calcium results in calcium deficiencies in plants, in the snails that consume the plants, and in the birds that eat the snails, ultimately causing weak eggshells that break before hatching. Decreased soil pH also kills certain soil microorganisms, preventing decomposition and recycling of nitrogen in the soil. Decreases in soil calcium and nitrogen weaken trees and other plants and may make them more susceptible to insect attack.

Acid rain is a common problem in the northeastern U.S. and Scandinavia, where sulfur-rich air drifts over from the Midwest and the industrial areas of Britain, respectively, causing the deposition of highly acidic rain (look ahead to Figure 59.23). The problem was particularly acute during the 1960s and 1970s, but decreased manufacturing and the use of low-sulfur coal and the introduction of sulfur-absorbing scrubbers on the smokestacks of coal-burning power plants have somewhat reduced the problem in recent years. Acid rain is clearly a problem with a wide-ranging impact on ecological systems.

54.4 Climate and Its Relationship to Biological Communities

Temperature, wind, precipitation, and light are components of **climate**, the prevailing weather pattern in a given region. As we have seen, the distribution and abundance of organisms are influenced by these factors. Therefore, to understand the patterns of abundance of life on Earth, ecologists need to study the global climate. In this section, we examine global climate patterns, focusing on how temperature variation drives atmospheric circulation and how features such as elevation and landmass can alter these patterns. We will see how climate largely determines the occurrence of different **biomes**, the major community types on Earth such as tropical forests and hot deserts.

Atmospheric Circulation Is Driven by Global Temperature Differentials

Substantial differences in temperature occur over the Earth, mainly due to latitudinal variations in the incoming solar radiation. In higher latitudes, such as northern Canada and Russia, the sun's rays hit the Earth obliquely and are spread out over more of the planet's surface than they are in equatorial areas (Figure 54.18). More heat is also lost in the atmosphere of higher latitudes because the sun's rays travel a greater distance through the atmosphere, allowing more heat to be dissipated by cloud cover. The result is that 40% less solar energy strikes polar latitudes than equatorial areas. Generally, temperatures increase as the amount of solar radiation increases (Figure 54.19). However, at the tropics, both cloudiness and rain reduce average temperature, so temperatures do not continue to increase toward the equator.

Global patterns of atmospheric circulation and precipitation are influenced by solar energy. In 1735, English meteorologist George Hadley made the initial contribution to a model of general atmospheric circulation. In his model, high temperatures at the equator cause the surface equatorial air to heat up and rise vertically into the atmosphere. As the warm air rises away from its source of heat, it cools and becomes less buoyant, but the cool air does not sink back to the surface because of the warm air behind it. Instead, the rising air spreads north and south away from the equator, eventually returning to the surface at the poles. From there it flows back toward the equator to close the circulation loop. Hadley suggested that on a nonrotating Earth, this air movement would take the form of one large convection cell in each hemisphere.

When the effect of the Earth's rotation is added, however, the surface flow is deflected to the right in the Northern

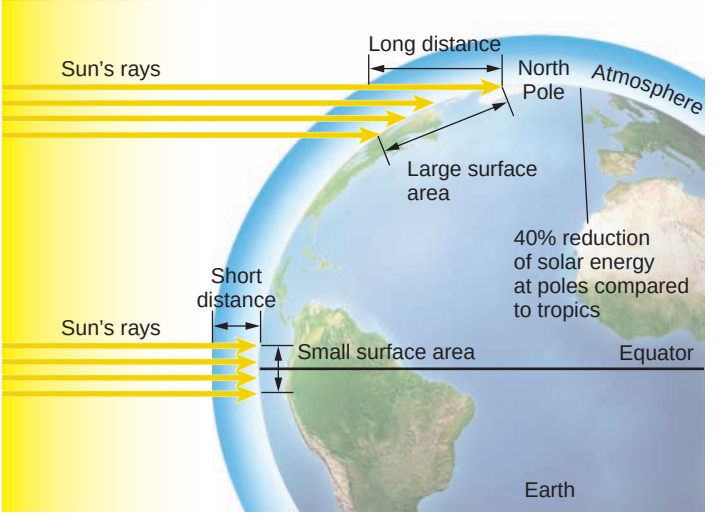

Figure 54.18 The intensity of solar radiation at different latitudes. In polar areas, the sun's rays strike the Earth at an oblique angle and deliver less energy than at tropical locations. In tropical areas, the energy is concentrated over a smaller surface and travels a shorter distance through the atmosphere.

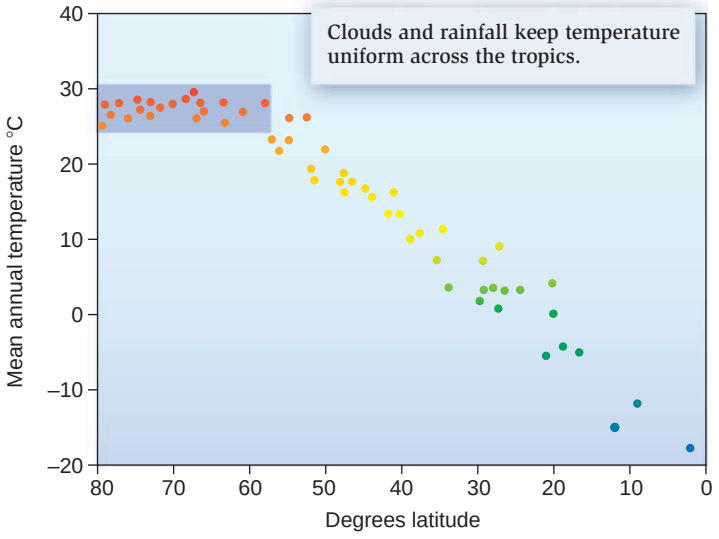

Figure 54.19 **Variation of the Earth's temperature.** The temperatures shown in this figure were measured at moderately moist continental locations of low elevation.

Concept check: *Why is there a wide band of similar temperatures at the tropics?*

Hemisphere and to the left in the Southern Hemisphere. This consequence is known as the **Coriolis effect**. Hadley's one-cell circulation has since been modified to account for the Coriolis effect and other newer data. In the 1920s, a three-cell circulation in each hemisphere was proposed to fit the Earth's heat balance (Figure 54.20). The contribution of George Hadley is still recognized, in that the cell nearest the equator is called the **Hadley cell**. In the Hadley cell, the warm air rising near the equator forms towers of cumulus clouds that provide rainfall, which, in turn, maintains the lush vegetation of the equatorial rain forests. As the upper flow in this cell moves toward the poles, it begins to subside, or fall back to Earth, at about 30° north and south of the equator. These **subsidence zones** are areas of high pressure and are the sites of the world's tropical deserts, because the subsiding air is relatively dry, having released all of its moisture over the equator. Winds are generally weak and variable near the center of this zone of descending air. Subsidence zones have popularly been called the horse latitudes. The name is said to have been coined by Spanish sailors crossing the Atlantic, whose ships were sometimes rendered motionless in these waters and who reportedly were forced to throw horses overboard as they could no longer water or feed them.

From the center of the subsidence zones, the surface flow splits into the westerlies, which flow toward the poles, and the equatorial flow, which is deflected by the Coriolis effect and forms trade winds. In the Northern Hemisphere, the trades are from the northeast, the direction from which they provided the sail power to explore the New World; in the Southern Hemisphere, the trades are from the southeast. The trade winds from both hemispheres meet near the equator in a region called the intertropical convergence zone (ITCZ), also known as the doldrums. Here the light winds and humid conditions provide the monotonous weather that may be the basis for the expression "in the doldrums."

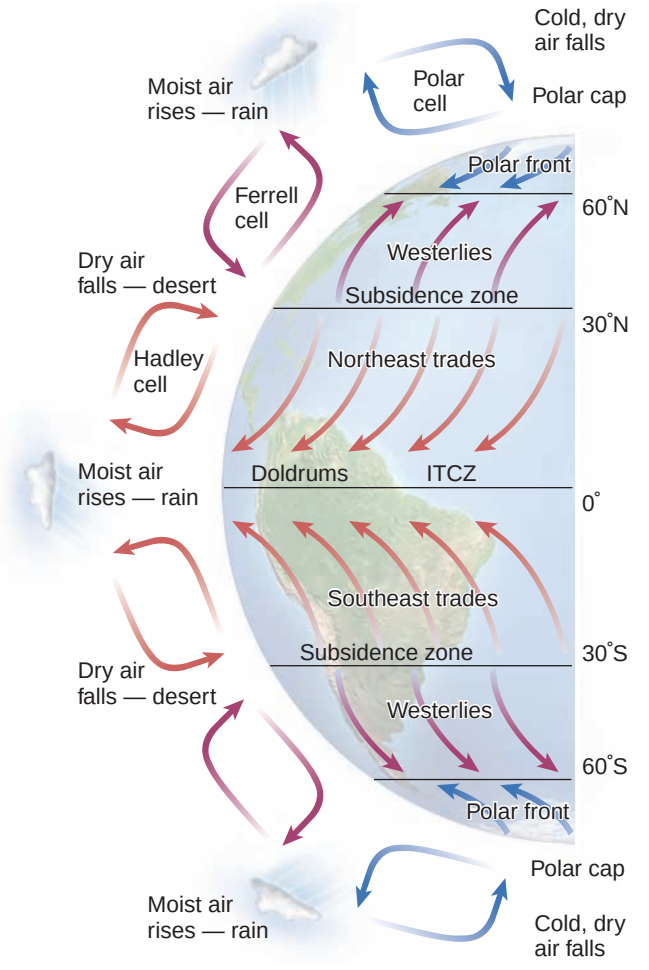

Figure 54.20 **Three-cell pattern of atmospheric circulation.** Three-cell model of the atmospheric circulation on a uniform, rotating Earth heated at the equator and cooled at the poles.

In the three-cell model, the circulation between 30° and 60° latitude, called the **Ferrell cell**, is opposite that of the Hadley cell. The net surface flow is poleward, and because of the Coriolis effect, the winds have a strong westerly (flowing from west to east) component. These prevailing westerlies were known to Benjamin Franklin, perhaps the first American weather forecaster, who noted that storms migrated eastward across the colonies. The final circulation cell is known as the **polar cell**. At the poles, the air has cooled and descends, but it has little moisture left, explaining why many high-latitude regions are actually desert-like in condition.

The three-cell model provides a good understanding of global circulation but is still oversimplified. The Hadley and polar cells are strong, but the Ferrell cell is much weaker, with passing high and low pressure systems, depending on the seasons. The sun does not remain constantly over the equator but moves annually between 23.5°N and 23.5°S and back again, creating seasonal changes. There is also differential heating between land and water. These effects modify the position of the three cells of circulation (Figure 54.21). In fact, the secondary

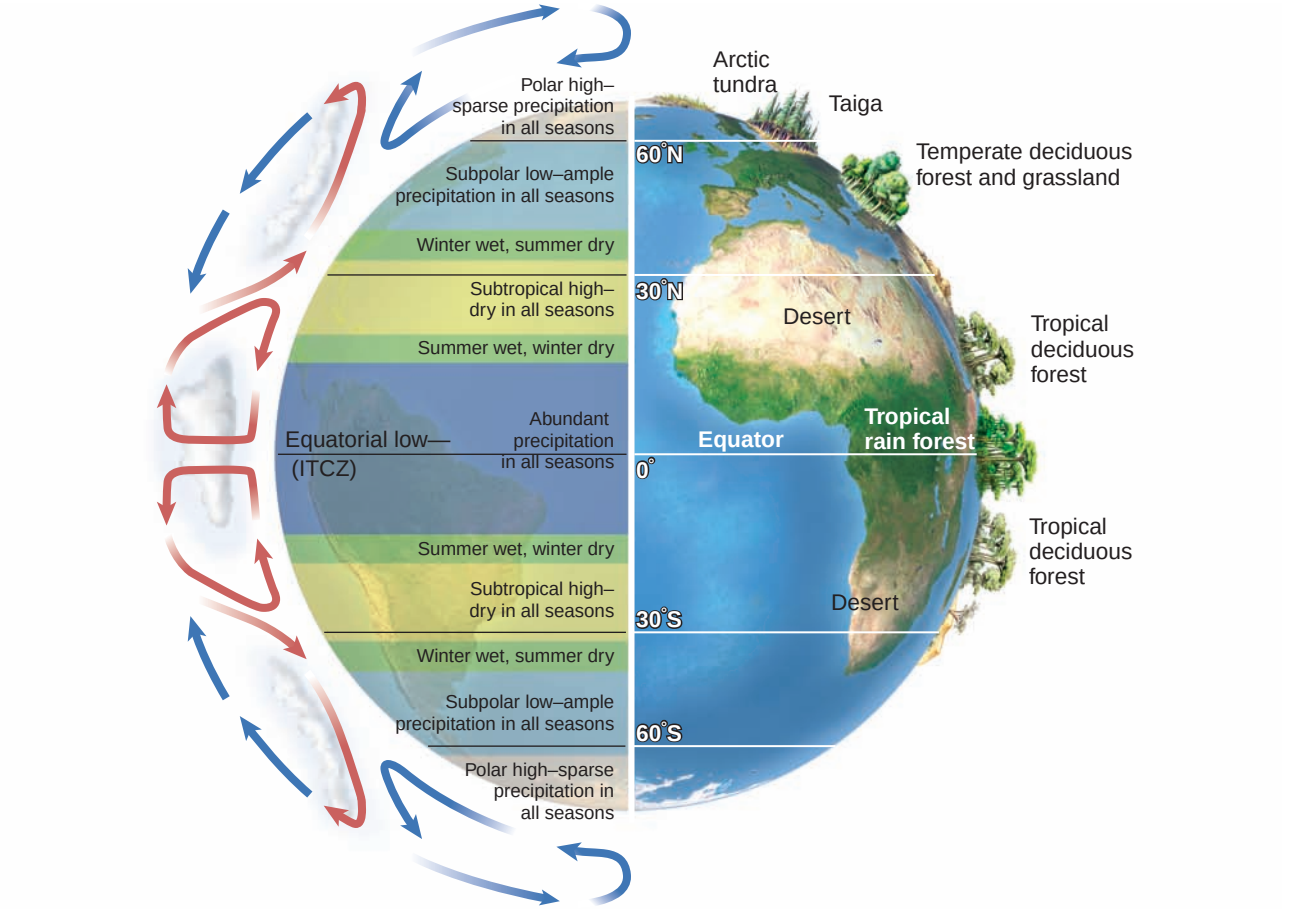

Figure 54.21 **Global circulation based on a modified three-cell model.** Tropical forests exist mainly in a band around the equator, where it is hot and rainy. At around 30° north and south, the air is hot and dry, and deserts exist. A secondary zone of precipitation exists at around 45° to 55° north and south, where temperate forests are located. The polar regions are generally cold and dry.

zones of high precipitation can come anywhere from about 35° to 65°, with between 45° and 55° being most common.

The distributions of the major biomes are largely determined by temperature differences and the wind patterns they generate. Hot, tropical forest blankets the tropics, where rainfall is high. At about 30° latitude, the air cools and descends, but it is without moisture, so the hot deserts occur around that latitude. The middle cell of the circulation model shows us that at about 35° to 65° latitude, the air has warmed and gained moisture, so it ascends, dropping rainfall over the wet, temperate forests of the Pacific Northwest and Western Europe in the Northern Hemisphere and New Zealand and Chile in the Southern Hemisphere.

Elevation and Other Features of a Landmass Can Also Affect Climate

Thus far, we have considered how global temperatures and wind patterns affect climate. The geographic features of a landmass can also have an important impact. For example, the elevation of a region greatly influences its temperature range. On mountains, temperatures decrease with increasing elevation. This decrease is a result of a process known as **adiabatic cooling**, in which increasing elevation leads to a decrease in air pressure. When air is blown across the Earth's surface and up over mountains, it expands because of the reduced pressure. As it expands, it cools at a rate of about 10°C for every 1,000 m in elevation, as long as no water vapor or cloud formation occurs. (Adiabatic cooling is also the principle behind the function of a refrigerator, in which refrigerant gas cools as it expands coming out of the compressor.) A vertical ascent of 600 m produces a temperature change roughly equivalent to that brought about by an increase in latitude of 1,000 km. This explains why mountaintop vegetation, even in tropical areas, can have the characteristics of a colder biome.

Mountains can also influence patterns of precipitation. For example, when warm, moist air encounters the windward side of a mountain, it flows upward and cools, releasing precipitation in the form of rain or snow. On the side of the mountain sheltered from the wind (the leeward side), drier air descends, producing what is called a **rain shadow**, an area where precipitation is noticeably less (Figure 54.22a). In this way, the western side of the Cascade Range in Washington State receives more than 500 cm of annual precipitation, whereas the eastern side receives only 50 cm.

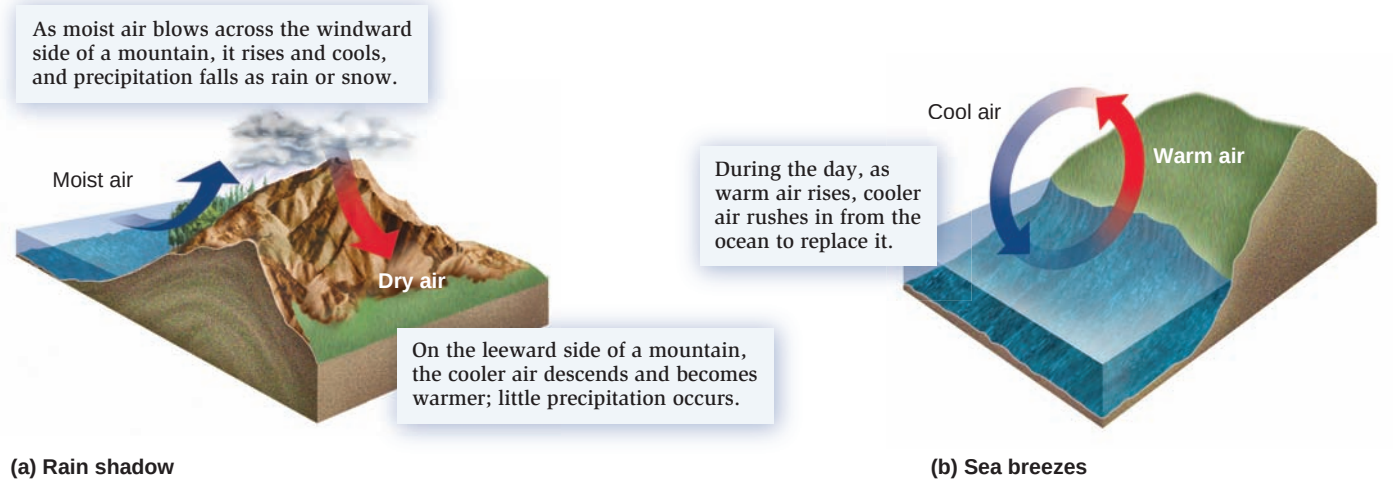

Figure 54.22 The influence of elevation and proximity to water on climate.

The proximity of a landmass to a large body of water can affect climate because land heats and cools more quickly than the sea does. The specific heat of the land is much lower than that of the water, allowing the land to warm more quickly during the day. The warmed air rises and cooler air flows in to replace it. This pattern creates the familiar onshore sea breezes in coastal areas (Figure 54.22b). At night, the land cools quicker than the sea, and so the pattern is reversed, creating offshore breezes. The sea, therefore, has a moderating effect on the temperatures of coastal regions and especially islands. The climates of coastal regions may differ markedly from those of their climatic zones. Many never experience frost, and fog is often evident. Thus, along coastal areas, different vegetation patterns may occur compared to those in areas farther inland. In fact, some areas of the U.S. would be deserts were it not for the warm water of the sea and the moisture-laden clouds that form above them.

Together with the rotation of the Earth, winds also create ocean currents. The major ocean currents act as "pinwheels" between continents, running clockwise in the ocean basins of the Northern Hemisphere and counterclockwise in those of the Southern Hemisphere (Figure 54.23). The Gulf Stream, equivalent in flow to 50 times the world's major rivers combined, brings warm water from the Caribbean and the U.S. coasts across to Europe, the climate of which is correspondingly moderated. The Humboldt Current brings cool conditions almost to the equator along the western coast of South America.

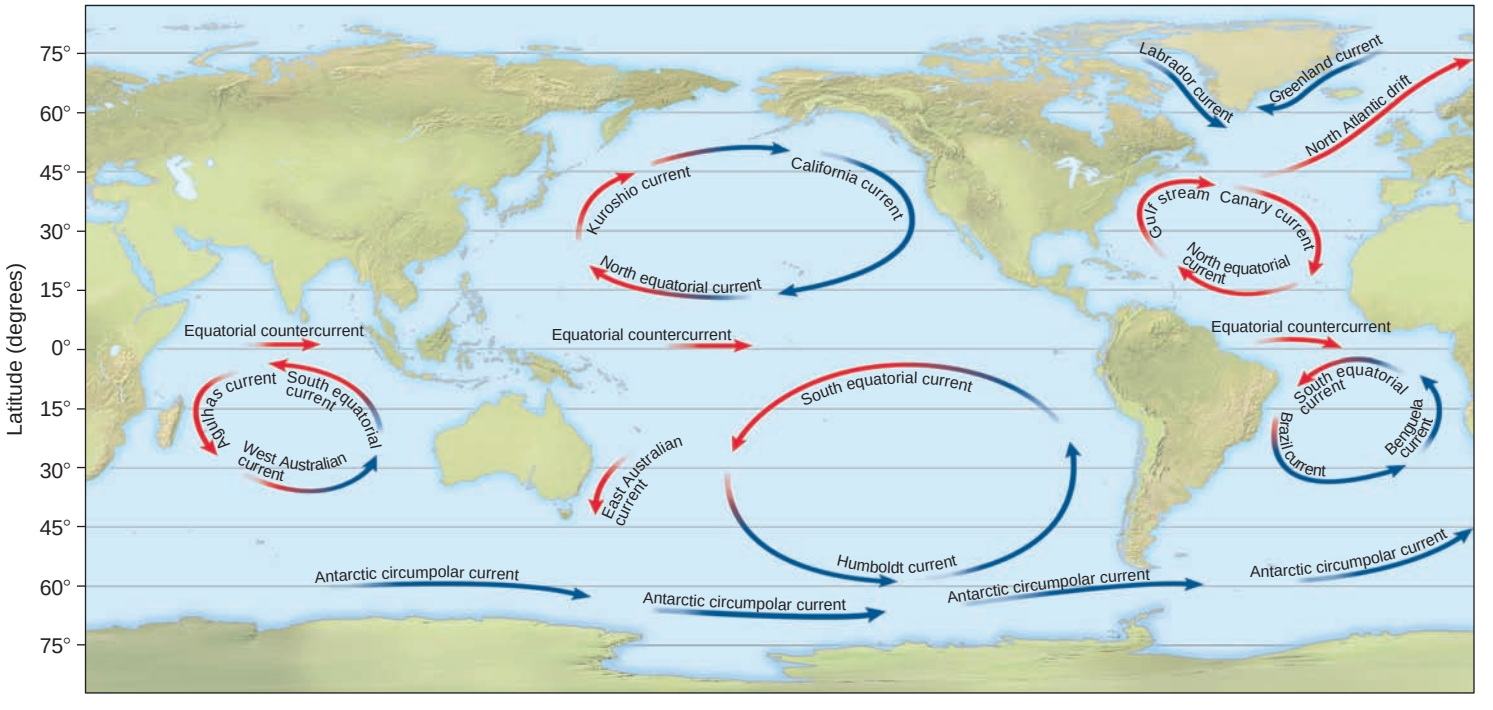

Figure 54.23 **Ocean currents of the world.** The red arrows represent warm water; the blue arrows, cold water.

54.5 Biome Types Are Determined by Climate Patterns and Other Physical Variables

Differences in climate on Earth help to define its different terrestrial biomes. Many types of classification schemes are used for mapping the geographic extent of terrestrial biomes, but one of the most useful was developed by the American ecologist Robert Whittaker, who classified biomes according to the physical factors of average annual precipitation and temperature (Figure 54.24). In this scheme, we recognize 10 terrestrial biomes (Figure 54.25). Aquatic biomes are generally differentiated by water salinity or current strength. In this section, we explore the main characteristics of Earth's major terrestrial and aquatic biomes.

In this chapter we have discussed how the physical environment profoundly influences the distribution and abundance of life on Earth. In subsequent chapters, we will explore the impact of other factors on the distribution of plants and animals. On a smaller scale, the presence of predators, parasites, or competitors can also control where organisms are found. Part of an organism's fundamental niche may be occupied by a competitively superior species. We will examine the influences of such factors in Chapter 57. For animals, social interactions with other members of the same species, such as fights over territory or mates, can also have an effect on population distributions. To discuss these issues, Chapter 55 examines animal behavior.

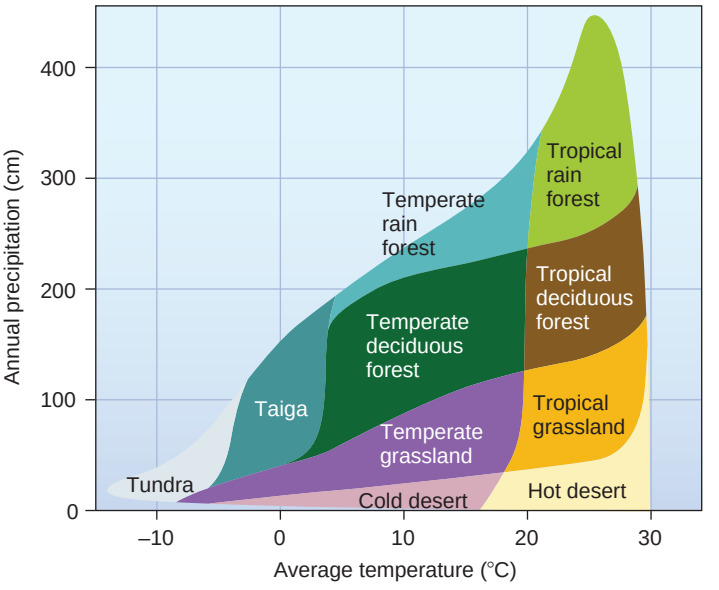

Figure 54.24 **The relationship between the world's terrestrial biome types and temperature and precipitation patterns.**

Concept check: *What other factors may influence biome types?*

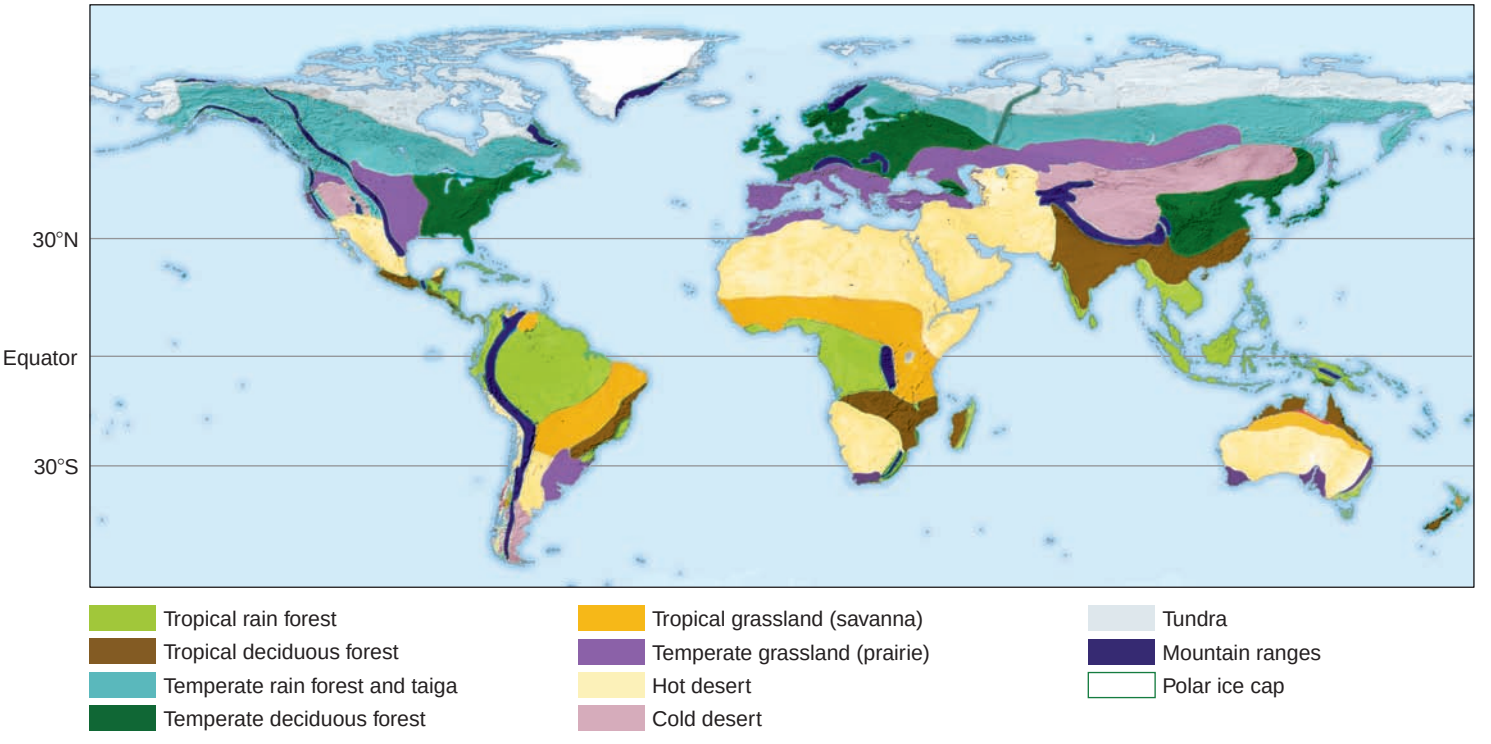

Figure 54.25 **Geographic location of terrestrial biomes.** The distribution patterns of taiga and temperate rain forest are combined because of their similarity in tree species and because temperate rain forest is actually limited to a very small area.

Terrestrial Biomes

Figure 54.26a–j illustrates the 10 terrestrial biomes and identifies their main characteristics.

Although these broad terrestrial biomes are a useful way of defining the main types of communities on Earth, ecologists acknowledge that not all communities fit neatly into one of these 10 major biome types. Also, one biome type often grades into another, as seen on mountain ranges (Figure 54.26k). Soil conditions can also influence biome type. In California, serpentine soils, which are dry and nutrient-poor, support only sparse vegetation. In the eastern U.S., most of New Jersey's coastal plain, called the Pine Barrens, consists of sandy, nutrient-poor soil that cannot support the surrounding deciduous forest and instead contains grasses and low shrubs growing among open stands of pygmy pitch pine and oak trees.

Tropical Rain Forest

Figure 54.26a

Tropical rain forest in Fiji

Physical Environment: Rainfall exceeds 230 cm per year, and the temperature is hot year round, averaging 25–29°C. Soils are often shallow and nutrient-poor.

Location: This biome is found in equatorial regions. Tropical forests cover much of northern South America, Central America, western and central Africa, Southeast Asia, and various islands in the Indian and Pacific oceans.

Plant Life: The numbers of plant species found in tropical forests can be staggering, often reaching as many as 100 tree species per square kilometer. Leaves often narrow to "drip-tips" at the apex so that rainwater drains quickly. Many trees have large buttresses that help support their shallow root systems. Little light penetrates the **canopy**, the uppermost layer of tree foliage, and the ground cover is often sparse. Vines and epiphytes, plants that live perched on trees and are not rooted in the ground, are common.

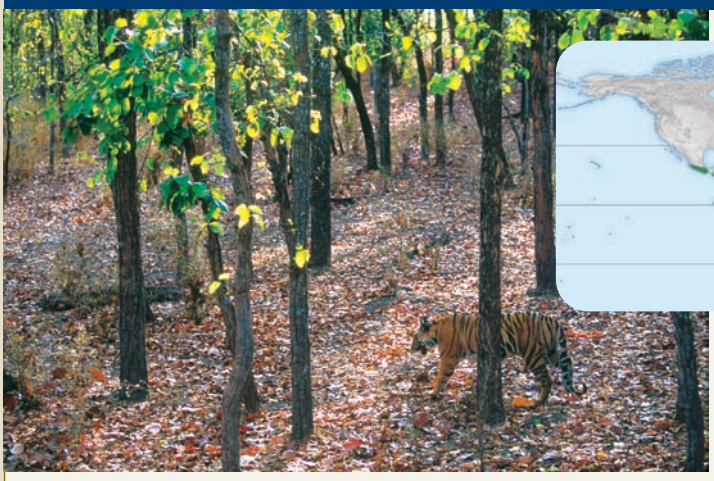
Animal Life: Animal life in the tropical rain forests is diverse; insects, reptiles, amphibians, and mammals are well represented. Large mammals, however, are not common. Because many of the plant species are widely scattered in tropical forests, it is risky for plants to rely on wind for pollination or to disperse their seed. This means that animals are important in pollinating flowers and dispersing fruits and seeds. Mimicry and bright protective coloration, warning of bad taste or the existence of toxins, are common.

Effects of Humans: Humans are impacting tropical forests greatly by logging and by clearing the land for agriculture. Many South American tropical forests are cleared to create grasslands for cattle.

Terrestrial Biomes (continued)

Tropical Deciduous Forest

Figure 54.26b



Tropical deciduous forest in Bandhavgarh National Park, India

Physical Environment: Rainfall is substantial, at around 130–280 cm a year, and temperatures are hot year round, averaging 25–39°C. This biome experiences a distinct dry season that is often 2 to 3 months or longer. Soil water shortages can occur in the dry season.

Location: This biome exists in equatorial regions where rainfall is more seasonal than in tropical rain forests. Much of India consists of tropical deciduous forest, containing teak trees. Brazil, Thailand, and Mexico also contain tropical deciduous forest. At the wet edges of this biome, it may grade into tropical rain forests; at the dry end, it may grade into tropical grasslands or savannas.

Plant Life: Because of the biome's distinct dry season, many of the trees in tropical deciduous forests shed their leaves, just as they do in temperate forests, and an understory of herbs and grasses may grow during this time. Indeed, because the canopy is often more open than in the tropical rain forest and more sunlight reaches the ground, a denser closed forest—what we might think of as a "tropical jungle"—exists at the forest floor. Where the dry season is 6 to 7 months long, tropical deciduous forests may contain shorter, thorny plants such as acacia trees, and the forest is referred to as a tropical thorn forest.

Animal Life: The diversity of animal life is high, and species such as monkeys, antelopes, wild pigs, and tigers are present. However, as with plant diversity, animal diversity is less than that of tropical rain forests. Tropical thorn forests may contain more browsing mammals; hence, the development of plant thorns as a defense.

Effects of Humans: The soil of tropical deciduous forests is more fertile than that of tropical rain forests. Land is increasingly being logged and cleared for agriculture and a growing human population.

Temperate Rain Forest

Figure 54.26c

Hoh Rain Forest in Olympic National Park, Washington

Physical Environment: There is abundant rainfall, usually exceeding 200 cm a year. The condensation of water from dense coastal fogs augments the normal rainfall. Temperatures seldom drop below freezing in the winter, and summer temperatures rarely exceed 27°C.

Location: The area of this biome type is small, consisting of a thin strip along the northwest coast of North America from northern California through Washington State, British Columbia, and into southeast Alaska (where it is called tongass). It also exists in southwestern South America along the Chilean coast. Indeed, it is found only in coastal locales because of the moderating influence of the ocean on air temperature.

Plant Life: The dominant vegetation type, especially in North America, consists of large evergreen trees such as western hemlock, Douglas fir, and Sitka spruce. The high moisture content allows epiphytes to thrive. Cool temperatures slow the activity of decomposers, so the litter layer is thick and spongy.

Animal Life: In North America, the temperate rain forest is rich in species such as mule deer, elk, squirrels, and numerous birds such as jays and nuthatches. Because of the abundant moisture and moderate temperatures, reptiles and amphibians are also common.

Effects of Humans: This biome is a prolific producer of wood and supplies much timber; logging threatens the survival of the forest in some areas.

Temperate Deciduous Forest

Figure 54.26d

Temperate deciduous forest in Minnesota

Physical Environment: Annual rainfall is generally between 75 and 200 cm. Temperatures fall below freezing each winter but not usually below −12°C.

Location: Large tracts of temperate deciduous forest are evident in the eastern U.S., eastern Asia, and western Europe. In the Southern Hemisphere, eucalyptus forests occur in Australia, and stands of southern beech are found in southern South America, New Zealand, and Australia.

Plant Life: Species diversity is much lower in temperate deciduous forests than in the tropical forests, with about only 3 to 4 tree species per square kilometer, and several tree genera may be dominant in a given locality—for example, oaks, hickories, and maples are usually dominant in the eastern U.S. Commonly, leaves are shed in the fall and reappear in the spring. Many herbaceous plants flower in spring before the trees leaf out and block the light. Even in the summer, though, the forest is not as dense as in tropical forests, so there is abundant ground cover.

Animal Life: Animals are adapted to the vagaries of the climate; many mammals hibernate during the cold months, birds migrate, and insects enter diapause, a condition of dormancy passed usually as a pupa. Reptiles, which are dependent on solar radiation for heat, are relatively uncommon. Mammals include squirrels, wolves, bobcats, foxes, bears, and mountain lions.

Effects of Humans: Logging has eliminated much of the temperate deciduous forest from populated portions of Europe and North America. Because the annual leaf drop promotes high soil nutrient levels, soils are rich and easily converted to agriculture. Much of the human population lives in the temperate deciduous forest, and both agriculture and development are the threats to the biome.

Temperate Coniferous Forest (Taiga)

Figure 54.26e

Temperate coniferous forest in Canada

Physical Environment: Precipitation is generally between 30 and 70 cm and often occurs in the form of snow. Temperatures are very cold, often below freezing for long periods of time.

Location: The biome of coniferous forests, known commonly by its Russian name, taiga, lies north of the temperate-zone forests and grasslands. Vast tracts of taiga exist in North America and Russia, and mountain taiga exists on mountainous areas. In the Southern Hemisphere, little land area occurs at latitudes at which one would expect extensive taiga to exist.

Plant Life: Most of the trees are evergreens or conifers with tough needles, hence its similarity to temperate rain forest. In this biome, spruces, firs, and pines generally dominate, and the number of tree species is relatively low. Many of the conifers have conical shapes to reduce bough breakage from heavy loads of snow. As in tropical forests, the understory is sparse because the dense year-round canopies prevent sunlight from penetrating. Soils are poor because the fallen needles decay so slowly in the cold temperatures that a layer of needles builds up and acidifies the soil, reducing the numbers of understory species.

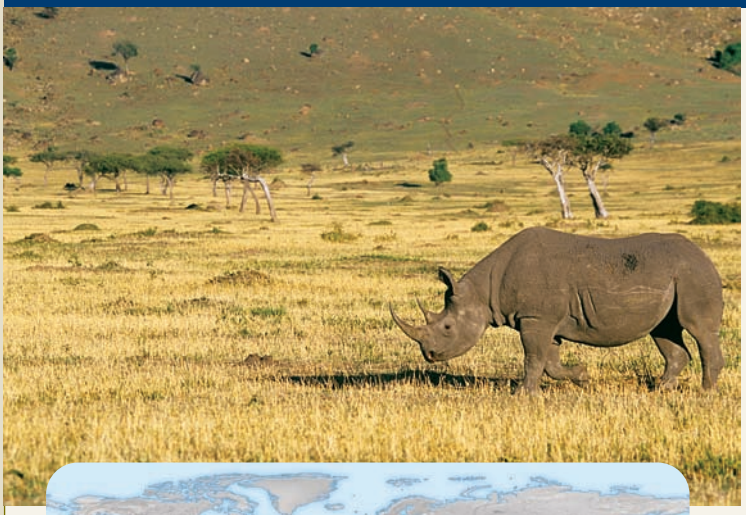
Animal Life: Reptiles and amphibians are rare because of the low temperatures. Insects are strongly periodic but may often reach outbreak proportions in times of warm temperatures. Mammals that inhabit this biome, such as bears, lynxes, moose, beavers, and squirrels, are heavily furred.

Effects of Humans: Humans have not extensively settled these areas, but they have been quite heavily logged. Exploration and development of oil and natural gas reserves are also a threat.

Terrestrial Biomes (continued)

Tropical Grassland (Savanna)

Figure 54.26f



Tropical grassland of the Masai Mara Game Reserve in Kenya

Physical Environment: This biome includes hot, tropical areas, with a low or seasonal rainfall between 50 and 130 cm per year. There is often an extensive dry season. Temperatures average 24–29°C.

Location: Extensive savannas occur in Africa, South America, and northern Australia.

Plant Life: Wide expanses of grasses dominate savannas, but occasional thorny trees, such as acacias, may occur. Fire is prevalent in this biome, so most plants have well-developed root systems that enable them to resprout quickly after a fire.

Animal Life: The world's greatest assemblages of large mammals occur in the savanna biome. Herds of antelope, zebra, and wildebeest are found, together with their associated predators: cheetah, lion, leopard, and hyena. Termite mounds dot the landscape in some areas. The extensive herbivory of large grazers, together with frequent fires, may help maintain savannas and prevent their development into forests.

Effects of Humans: Savanna soils are often poor because the occasional rain leaches nutrients out. Nevertheless, conversion of this biome to agricultural land is rampant, especially in Africa. Overstocking of land for domestic animals can greatly reduce grass coverage through overgrazing, turning the area desert-like. This process is known as **desertification**.

Temperate Grassland (Prairie)

Figure 54.26g

Temperate grassland in Wyoming State

Physical Environment: Annual rainfall is generally between 25 and 100 cm, too low to support a forest but higher than that in deserts. Temperatures in the winter often fall below −10°C, while summers may be very hot, approaching 30°C.

Location: Temperate grasslands include the prairies of North America, the steppes of Russia, the pampas of Argentina, and the veldt of South Africa. In addition to the limiting amounts of rain, fire and grazing animals may also prevent the establishment of trees in the temperate grasslands. Where temperatures rarely fall below freezing and most of the rain falls in the winter, chaparral, a fire-adapted community featuring shrubs and small trees, occurs. Chaparral is seen at around 30° latitude, where cool ocean waters moderate the climate, as along the coasts of California, South Africa, Chile, and southwest Australia and in countries surrounding the Mediterranean Sea. Some ecologists recognize chaparral as a distinct biome type.

Plant Life: From east to west in North America and from north to south in Asia, grasslands show differentiation along moisture gradients. In Illinois, with an annual rainfall of 80 cm, tall prairie grasses such as big bluestem and switchgrass grow to about 2 m high. Along the eastern base of the Rockies, 1,300 km to the west, where rainfall is only 40 cm, prairie grasses such as buffalo grass and blue grama rarely exceed 0.5 m in height. Similar gradients occur in South Africa and Argentina.

Animal Life: Where the grasslands remain, large mammals are the most prominent members of the fauna: bison and pronghorn in North America, wild horses in Eurasia, and large kangaroos in Australia. Burrowing animals such as North American gophers and African mole rats are also common.

Effects of Humans: Prairie soil is among the richest in the world, having 12 times the humus layer of a typical forest soil. Worldwide, most prairies have been converted to agriculture, and original grassland habitats are among the rarest biomes in the world.

Hot Desert

Figure 54.26h

The Namib Desert, Namibia

Physical Environment: Rainfall is less than 30 cm per year. Temperatures are variable, from below freezing at night to as much as 50°C in the day.

Location: Hot deserts are found around latitudes of 30° north and south. Prominent deserts include the Sahara of North Africa, the Kalahari and Namib of southern Africa, the Atacama of Chile, the Sonoran of northern Mexico and the southwest U.S., and the Simpson of Australia.

Plant Life: Three forms of plant life are adapted to deserts: annuals, succulents, and desert shrubs. Annuals circumvent drought by growing only when there is rain. Succulents, such as the saguaro cactus and other barrel cacti of the southwestern deserts, store water. Desert shrubs, such as the spraylike ocotillo, have short trunks, numerous branches, and small, thick leaves that can be shed in prolonged dry periods. In many plants, spines or volatile chemical compounds serve as a defense against water-seeking herbivores.

Animal Life: To conserve water, desert plants produce many small seeds, and animals that eat those seeds, such as ants, birds, and rodents, are common. Reptiles are numerous, because high temperatures permit these ectothermic animals to maintain a warm body temperature. Lizards and snakes are important predators of seed-eating mammals.

Effects of Humans: Ambitious irrigation schemes and the prolific use of underground water have allowed humans to develop deserts and grow crops there. Salinization, a buildup in the salt content of the soil that results from irrigation in areas of low rainfall, is prevalent. Off-road vehicles can disturb the fragile desert communities.

Cold Desert

Figure 54.26i

The Gobi Desert of Mongolia

Physical Environment: Precipitation is less than 25 cm a year and is often in the form of snow. Rainfall usually comes in the spring. In the daytime, temperatures can be high in the summer, 21–26°C, but average around freezing, −2 to 4°C, in the winter.

Location: Cold deserts are found in dry regions at middle to high latitudes, especially in the interiors of continents and in the rain shadows of mountains. Cold deserts are found in North America (the Great Basin Desert), in eastern Argentina (the Patagonian Desert), and in central Asia (the Gobi Desert).

Plant Life: Cold deserts are relatively poor in terms of numbers of plant species. Most plants are small in stature, being only between 15 and 120 cm tall. Many species are deciduous and spiny. The Great Basin Desert in Nevada, Utah, and bordering states is a cold desert dominated by sagebrush.

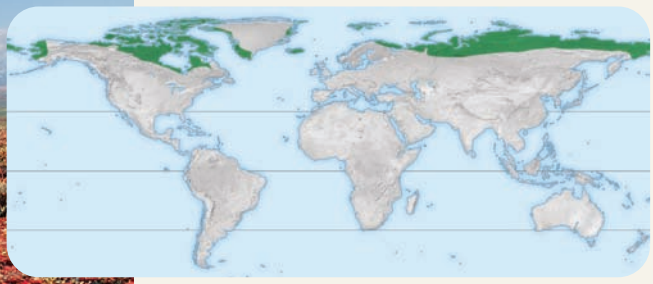
Animal Life: As in hot deserts, large numbers of plants produce small seeds on which numerous ants, birds, and rodents feed. Many species live in burrows to escape cold. In the Great Basin Desert, pocket mice, jackrabbits, kit fox, and coyote are common.

Effects of Humans: Agriculture is hampered because of low temperatures and low rainfall, and human populations are not extensive. If the top layer of soil is disturbed by human intrusions such as off-road vehicles, erosion occurs rapidly and even less vegetation is able to exist.

Terrestrial Biomes (continued)

Tundra

Figure 54.26j



Denali National Park in Alaska

Physical Environment: Precipitation is generally less than 25 cm per year and is often locked up as snow and unavailable for plants. Deeper water can be locked away for a large part of the year in **permafrost**, a layer of permanently frozen soil. The growing season is short, only 50–60 days. Summer temperatures are only 3–12°C, and even during the long summer days, the ground thaws to less than 1 m in depth. Midwinter temperatures average −32°C.

Location: Tundra (from the Finnish *tunturia*, meaning treeless plain) exists mainly in the Northern Hemisphere, north of temperate coniferous forest, because there is very little land area in the Southern Hemisphere at the latitude where tundra would occur.

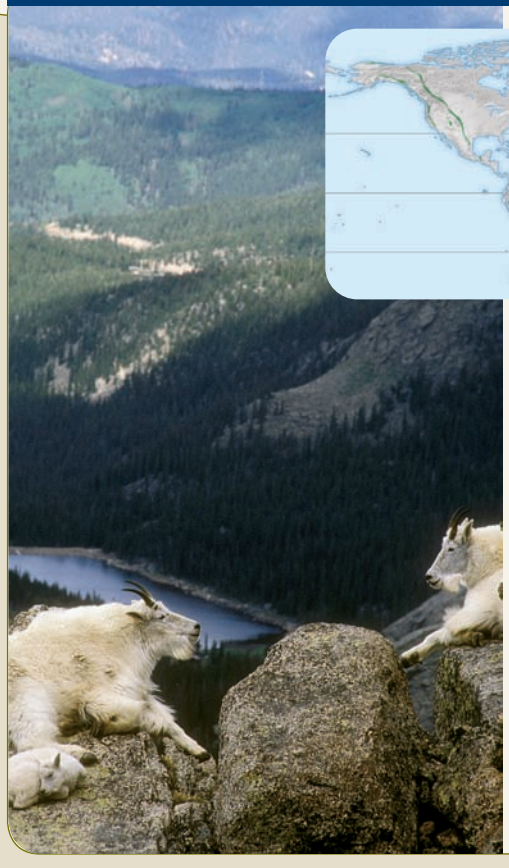
Plant Life: With so little available water, trees cannot grow. Vegetation occurs in the form of fragile, slow-growing lichens, mosses, grasses, sedges, and occasional shrubs, which grow close to the ground. Plant diversity is very low. In some places, desert conditions prevail because so little moisture falls.

Animal Life: Animals of the arctic tundra have adapted to the cold by having good insulation. Many birds, especially shorebirds and waterfowl, migrate. The fauna is much richer in summer than in winter. Many insects spend the winter at immature stages of growth, which are more resistant to cold than the adult forms. Larger animals include such herbivores as musk oxen and caribou in North America, called reindeer in Europe and Asia. Smaller animals include hares and lemmings. Common predators include arctic fox, wolves, and snowy owls, and polar bears near the coast.

Effects of Humans: Though this area is sparsely populated, mineral extraction, especially of oil, has the potential to significantly impact this biome. Ecosystem recovery from such damage would be very slow.

Mountain Ranges

Figure 54.26k



Rocky Mountains of Colorado

Physical Environment: Mountain ranges must be viewed differently than other biomes. Biome type relies predominantly on climate. On mountains, temperature decreases with increasing elevation through adiabatic cooling, as discussed previously. Thus, precipitation and temperature may change dramatically, depending on elevation and whether the mountainside is on the windward or leeward side.

Location: Mountain ranges exist in many areas of the world, but among the largest are the Himalayas in Asia, the Rockies in North America, and the Andes in South America.

Plant Life: A variety of biomes can be found on a single mountain range. Biome type may change from temperate forest through taiga and into tundra on an elevation gradient in the Rocky Mountains, and even from tropical forest to tundra on the highest peaks of the Andes in tropical South America. In tropical regions, daylight averages 12 hours per day throughout the year. Instead of a period of intense productivity, seen in arctic tundra, vegetation in the tropical alpine tundra exhibits slow but steady rates of photosynthesis and growth all year.

Animal Life: The animals of this biome are as varied as the number of habitats they contain. Generally, more species of plants and animals are found at lower elevations than at higher ones. At higher elevations, animals such as bighorn sheep and mountain goats have to be sure-footed to climb the craggy slopes and have skidproof pads on their hooves. Despite the often-strong winds, birds of prey, such as eagles, are frequent predators of the furry rodents found at higher elevations, including guinea pigs and marmots.

Effects of Humans: Logging and agriculture at lower elevations can cause habitat degradation. Because of the steep slopes, mountain soils are often well drained, thin, and especially susceptible to erosion following agriculture.

Aquatic Biomes

Aquatic Biomes Consist of Marine and Freshwater Regions

Within aquatic environments, several different biome types are also recognized, including marine aquatic biomes (intertidal zone, coral reef, and open ocean) and freshwater habitats (lakes, rivers, and wetlands). These biomes are distinguished primarily by differences in salinity, oxygen content, depth, current strength, and availability of light (Figures 54.27a–f). Freshwater habitats are traditionally divided into **lentic**, or standing-water habitats (from the Latin *lenis*, meaning calm), and **lotic**, or running-water habitats (from the Latin *lotus*, meaning washed).

Intertidal Zone

Figure 54.27a

Olympic Coast National Marine Sanctuary in Washington State

Physical Environment: The **intertidal zone**, the area where the land meets the sea, is alternately submerged and exposed by the daily cycle of tides. The resident organisms are subject to huge daily variations in temperature, light intensity, and availability of seawater.

Location: Throughout the world, the area where the land meets the sea consists of sandy shore, mudflats, or rocky shore. Three broad zones occur in a vertical direction, which is most evident on rocky shores. The upper littoral zone is submerged only during the highest tides. The midlittoral zone is submerged during the highest regular tide and exposed during the lowest tide each day. The lower littoral zone is exposed only during the lowest tide.

Plant Life: Plant life may be quite limited because the sand or mud is constantly shifted by the tide. Mangroves may colonize mudflats in tropical areas, and salt marsh grasses may colonize mudflats in temperate locations. On the rocky shore, green algae and seaweeds predominate.

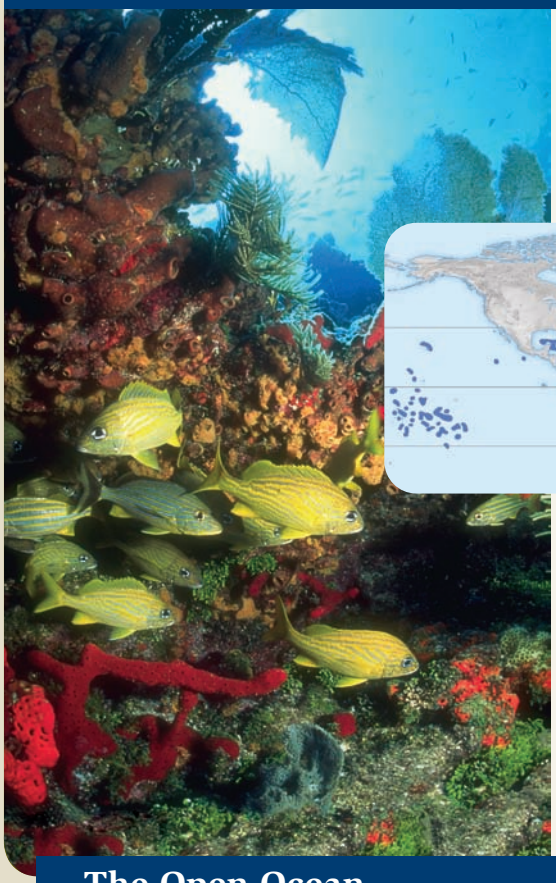
Animal Life: Animal life may be quite diverse. On the rocky shore, sea anemones, snails, hermit crabs, and small fishes live in tide pools. On the rock face, there may be a variety of limpets, mussels, sea stars, sea urchins, snails, sponges, tube worms, whelks, isopods, and chitons. At low tides, organisms may be dry and vulnerable to predation by a variety of animals, including birds and mammals. High tides bring predatory fishes. Sandy or muddy shores may contain burrowing marine worms, crabs, and small isopods.

Effects of Humans: Urban development has greatly reduced the beach area available to shorebirds and breeding turtles. Oil spills have greatly impacted some rocky intertidal areas.

Aquatic Biomes (continued)

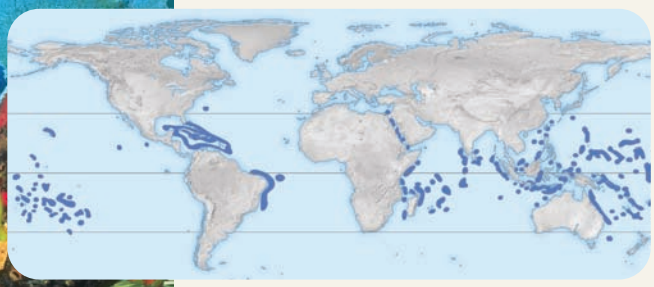
Coral Reef

Figure 54.27b



Caribbean coral reef

Physical Environment: Corals need warm water of at least 20°C but less than 30°C. They are also limited to the photic zone, where light penetrates. Sunlight is important because many corals harbor symbiotic algae, or dinoflagellates, that contribute nutrients to the animals and that require light to live.



Location: Coral reefs exist in warm tropical waters where there are solid substrates for attachment and water clarity is good. The largest coral reef in the world is the Great Barrier Reef off the Australian coastline, but other coral reefs are found throughout the Caribbean Sea, the Red Sea, and the Pacific and Indian Oceans.

Plant Life: Dinoflagellate algae live within the coral tissue, and a variety of red and green algae live on the coral reef surface.

Animal Life: An immense variety of microorganisms, invertebrates, and fishes live among the coral, making the coral reef one of the most interesting and species-rich biomes on Earth. Probably 30–40% of all fish species on Earth are found on coral reefs. Prominent herbivores include snails, sea urchins, and fishes. These are consumed by octopuses, sea stars, and carnivorous fishes. Many species are brightly colored, warning predators of their toxic nature.

Effects of Humans: Collectors have removed many corals and fishes for the aquarium trade, and marine pollution threatens water clarity in some areas. Perhaps the greatest threat to coral reefs is from global warming. Water temperatures that are too high (over 30°C) and high pH caused by elevated CO_2 levels both contribute to coral bleaching.

The Open Ocean

Figure 54.27c

Manta ray in the open ocean

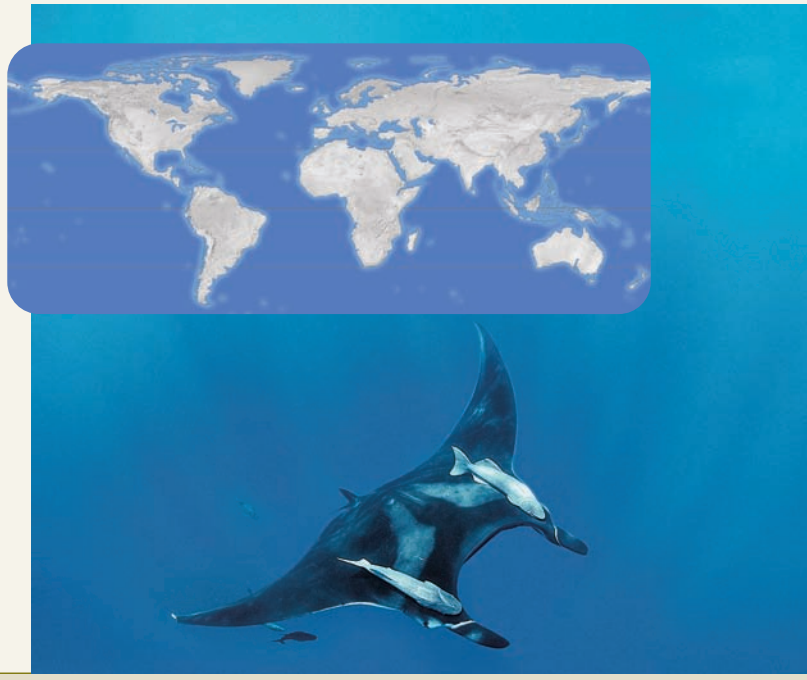
Physical Environment: In the open ocean, sometimes called the **pelagic zone**, water depth averages 4,000 m. Nutrient concentrations are typically low, though the waters may be periodically enriched by ocean **upwelling**, the circulation of cold, mineral-rich nutrients from deeper water to the surface. Pelagic waters are mostly cold, only warming near the surface.

Location: Across the globe, covering 70% of the Earth's surface.

Plant Life: In the photic zone, many microscopic photosynthetic organisms (**phytoplankton**) grow and reproduce. Phytoplankton account for nearly half the photosynthetic activity on Earth and produce much of the world's oxygen.

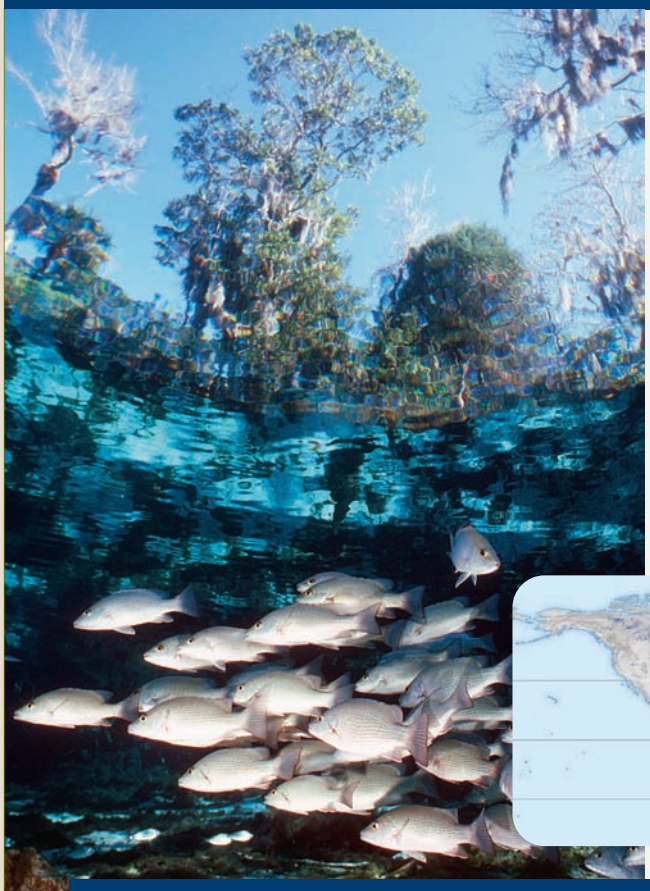
Animal Life: Open-ocean organisms include **zooplankton**, minute animal organisms consisting of some worms, copepods (tiny shrimplike creatures), small jellyfish, and small invertebrate and fish larvae that graze on the phytoplankton. The open ocean also includes free-swimming animals collectively called **nekton**, which can swim against the currents to locate food. Nekton includes large squids, fishes, sea turtles, and marine mammals. Only a few of these organisms live at any great depth. In some areas, a unique assemblage of animals is associated with deep-sea hydrothermal vents that spew hot (350°C) water rich in hydrogen sulfide. Large polychaete worms and other chemoautotrophic organisms exist together in this dark, oxygen-poor environment (refer back to Figure 22.3).

Effects of Humans: Oil spills and a long history of garbage disposal have polluted the ocean floors of many areas. Overfishing has caused many fish populations to crash, and the whaling industry has greatly reduced the numbers of most species of whales.



Lentic Habitats

Figure 54.27d



Everglades National Park, Florida

Physical Environment: The lentic habitat consists of still, often deep water. Its physical characteristics depend greatly on the surrounding land, which dictates what nutrients collect in the lake. Young lakes often start off clear and with little plant life. Such lakes are called **oligotrophic**. With age, the lake becomes richer in dissolved nutrients from erosion and runoff from surrounding land, with the result that cyanobacteria and algae spread, reducing the water clarity. Such lakes are termed **eutrophic**. The process of eutrophication occurs naturally but can be sped up by human activities (see Chapter 59).

Location: Throughout all the continents of the world.

Plant Life: In addition to free-floating cyanobacteria and algae, lentic habitats may have rooted vegetation, which often extends above the water surface (emergent vegetation), such as cattails, plus deeper-dwelling aquatic plants and algae.

Animal Life: Animals include fishes, frogs, turtles, crayfish, insect larvae, and many species of insects. In tropical and subtropical lakes, alligators and crocodiles are common.

Effects of Humans: Agricultural runoff, including fertilizers and sewage, can greatly increase lake nutrient levels and speed up the process of eutrophication, resulting in algal blooms and fish kills. In some areas, invasive species of invertebrates and fishes are outcompeting native species.

Lotic Habitats

Figure 54.27e

Fast-flowing river in the Pacific Northwest

Physical Environment: In lotic habitats, flowing water prevents nutrient accumulations and phytoplankton blooms. The current also mixes water thoroughly, providing a well-aerated habitat of relatively uniform temperature. The current, oxygen level, and clarity are greater at the source of a stream (its headwaters) than in the lower reaches of rivers. Nutrient levels are generally less in headwaters.

Location: On all continents except Antarctica.

Plant Life: In slow-moving streams and rivers, algae and rooted plants may be present; in swifter-moving rivers, leaves from surrounding forests are the primary food source for animals.

Animal Life: Lotic habitats have a fauna completely different from that of lentic waters. Animals are adapted to stay in place despite an often-strong current. Many of the smaller organisms are flat and attach themselves to rocks to avoid being swept away. Others live on the underside of large boulders, where the current is much reduced. Fish such as trout may be present in rivers with cool temperatures, high oxygen, and clear water. In warmer, murkier waters, catfish and carp may be abundant.

Effects of Humans: Animals of lotic systems are not well adapted for low-oxygen environments and thus are particularly susceptible to oxygen-reducing pollutants such as sewage. Dams across rivers have prevented the passage of migratory species such as salmon.

Aquatic Biomes (continued)

Wetlands

Figure 54.27f

Yellow Waters River, Kakadu National Park, Northern Territory, Australia

Physical Environment: At the margins of both lentic and lotic habitats, wetlands may develop. Wetlands are areas regularly saturated by surface water or groundwater. They range from marshes, treeless areas where herbaceous species predominate; to swamps, wet areas dominated by trees; and bogs, depressions dominated by marshes. Many wetlands are seasonally flooded when rivers overflow their banks or lake levels rise. Some wetlands also develop along estuaries, where rivers merge with the ocean, and high tides can flood the land. Because of generally high nutrient levels, oxygen levels are fairly low. Temperatures vary substantially with location.

Location: Worldwide, except in Antarctica.

Plant Life: Wetlands are among the most productive and species-rich areas in the world. In North America, floating plants such as lilies and rooted species such as sedges, cattails, cypress, and gum trees predominate.

Animal Life: Most wetlands are rich in animal species. Wetlands are a prime habitat for wading and diving birds. In addition, they are home to a profusion of insects, from mosquitoes to dragonflies. Vertebrate predators include many amphibians, reptiles, otters, and alligators.

Effects of Humans: Long mistakenly regarded as wasteland by humans, many wetlands have been drained and developed for housing and industry. Wetlands play a valuable role in protecting coastal communities from hurricanes, and the loss of wetlands in Louisiana contributed to the severity of effects from hurricane Katrina in 2005.

Summary of Key Concepts

54.1 The Scale of Ecology

- Ecologists study the interactions among organisms and between organisms and their environments. (Figure 54.1)
- The field of ecology can be subdivided into broad areas of organismal, population, community, and ecosystem ecology. (Figure 54.2)
- Organismal ecology considers how individuals are adapted to their environment and how the behavior of an individual organism contributes to its survival and reproductive success and the population density of the species.
- Population ecology explores those factors that influence a population's growth, size, and density. Community ecology studies how populations of species interact and form functional communities. (Figure 54.3)
- Ecosystem ecology examines the flow of energy and cycling of nutrients among organisms within a community and between organisms and the environment.

54.2 Ecological Methods Focus on Observation and Experimentation

- Ecological methods focus on observation and experimentation. Initially, ecologists may construct a possible web of interactions between species. (Figure 54.4)
- Interactions among species are often observed and analyzed graphically, and a hypothesis is formed. (Figure 54.5)
- Ecologists often test their hypotheses using well-replicated experiments. The results are often presented graphically and analyzed via a variety of statistical tests. (Figure 54.6)

54.3 The Environment's Impact on the Distribution of Organisms

- Abiotic factors such as temperature, wind, water, light, salinity, and pH can have powerful effects on ecological systems. (Table 54.1)
- Temperature exerts important effects on the distribution of organisms because of its effect on biological processes and the inability of most organisms to regulate their body temperature. (Figures 54.7, 54.8, 54.9)
- The greenhouse effect is the process in which short-wave solar radiation passes through the atmosphere to warm the Earth and is radiated back into the atmosphere as long-wave infrared radiation. Much of this radiation is absorbed by atmospheric gases and radiated back to the Earth's surface, causing its temperature to rise. (Figure 54.10)
- The major atmospheric gases causing the greenhouse effect are water vapor, carbon dioxide, methane, nitrous oxide, and chlorofluorocarbons. (Table 54.2)
- An increase in atmospheric gases is increasing the greenhouse effect, causing global warming, a gradual elevation of the Earth's surface temperature. Ecologists expect that global

warming will have a large effect on the distribution of the world's organisms. (Figure 54.11)

- Wind can amplify the effects of temperature and modify wave action. (Figure 54.12)
- The availability of water has an important effect on the abundance of organisms. (Figure 54.13)
- Light can be a limiting resource for plants in both terrestrial and aquatic environments. (Figure 54.14)
- The concentration of salts and the pH of soil and water can limit the distribution of organisms. (Figures 54.15, 54.16, 54.17)

54.4 Climate and Its Relationship to Biological Communities

- Global temperature differentials are caused by variations in incoming solar radiation and patterns of atmospheric circulation. (Figures 54.18, 54.19, 54.20, 54.21)
- Elevation and the proximity between a landmass and large bodies of water can similarly affect climate. (Figures 54.22, 54.23)

54.5 Biome Types Are Determined by Climate Patterns and Other Physical Variables

- Climate has a large effect on biomes, major types of habitats characterized by distinctive plant and animal life. (Figures 54.24, 54.25)
- Terrestrial biomes are generally named for their climate and vegetation type and include tropical rain forest, tropical deciduous forest, temperate rain forest, temperate deciduous forest, temperate coniferous forest (taiga), tropical grassland (savanna), temperate grassland (prairie), hot and cold deserts, and tundra. In mountain ranges, biome type may change on an elevation gradient. (Figure 54.26)
- Within aquatic environments, biomes include marine aquatic biomes (the intertidal zone, coral reef, and open ocean) and freshwater lakes, rivers, and wetlands. These are distinguished by differences in salinity, oxygen content, depth, current strength (lentic versus lotic), and availability of light. (Figure 54.27)

Assess and Discuss

Test Yourself

1. Which of the following is probably the most important factor in the distribution of organisms in the environment?
   a. light
   b. temperature
   c. salinity
   d. water availability
   e. pH
2. The greenhouse effect is
   a. a new phenomenon resulting from industrialization.
   b. due to the absorption of solar radiation by atmospheric gases.
   c. responsible for the natural warming of the Earth.
   d. all of the above.
   e. b and c only.
3. An examination of the temperature tolerances of locusts would best be described by which ecological subdiscipline?
   a. organismal ecology
   b. population ecology
   c. community ecology
   d. ecosystem ecology
   e. both a and b
4. Physics is to engineering as ecology is to
   a. biology.
   b. environmental science.
   c. chemistry.
   d. mathematics.
   e. statistics.
5. The most common biome type, by area occupied, is the
   a. open ocean.
   b. tropical rainforest.
   c. tundra.
   d. hot desert.
   e. lentic habitats.
6. What is the driving force that determines the circulation of the atmospheric air?
   a. temperature differences of the Earth
   b. winds
   c. ocean currents
   d. mountain ridges
   e. all of the above
7. In this biome, rainfall is between 25 cm and 100 cm and temperatures vary between −10°C in winter and 30°C in summer. Where are you?
   a. tropical rainforest
   b. tropical deciduous forest
   c. savanna
   d. prairie
   e. temperate deciduous forest
8. What characteristics are commonly used to identify the biomes of the Earth?
   a. temperature
   b. precipitation
   c. vegetation
   d. all of the above
   e. a and b only
9. Young lakes are often clear and with little plant life. Such lakes are called
   a. oligotrophic.
   b. eutrophic.
   c. lotic.
   d. lentic.
   e. pelagic.
10. Which gas contributes most to human-caused global warming?
    a. carbon dioxide
    b. nitrous oxide
    c. sulfur dioxide
    d. methane
    e. chlorofluorocarbons

Conceptual Questions

1. If mountains are closer to the sun than valleys, why aren't they hotter?
2. Explain the greenhouse effect.
3. In most locations on Earth, at about 30° latitude, air cools and descends, and hot deserts occur. Florida is situated between 31°N and 24°N. Why does it not support a desert biome?

Collaborative Questions

1. The so-called Telegraph fire, near Yosemite National Park, in 2008, was one of the worst in California that year. What could be done to prevent such a catastrophic fire in the park itself?
2. Based on your knowledge of biomes, identify the biome in which you live. In your discussion, list and describe the organisms that you have observed in your biome.

Behavioral Ecology

55

A chimpanzee (*Pan troglodytes*) using a stick to catch food.

Chapter Outline

After their young hatch, nesting black-headed gulls (*Larus ridibundus*) pick up the empty eggshells and carry them away from the nest. One might think that they are being neat and tidy or are minimizing the risk of bacterial infection to the chicks, but there is more to the behavior than this. The chicks and unhatched eggs are well camouflaged in the nest, but the white color of the empty eggshell quickly attracts the attention of predators such as crows that would kill and eat the chicks or remaining eggs. By removing the old eggshells, the gull parents are increasing the chances that their offspring—and thus their genes—will survive. Although this behavior is likely to be an instinctive activity of the gulls, it is promoted because birds that performed this activity had a higher rate of chick survival than those that didn't, ensuring that the genes that code for this behavior are passed on.

Behavior is the observable response of organisms to external or internal stimuli. In this chapter, we focus our attention on the field of **behavioral ecology**, the study of how behavior contributes to the differential survival and reproduction of organisms. Contemporary behavioral ecology builds upon earlier work that focused primarily on how organisms behave. In the early 20th century, scientific studies of animal behavior, termed **ethology** (from the Greek *ethos*, meaning habit or manner), focused on the specific genetic and physiological mechanisms of behavior. These factors are called **proximate causes**. For example, we could hypothesize that male deer rut or fight with other males in the fall because a change in day length stimulates the eyes, brain, and pituitary gland and triggers hormonal changes in their bodies. The founders of ethology, Karl von Frisch, Konrad Lorenz, and Niko Tinbergen, shared the 1973 Nobel Prize in Physiology or Medicine for their pioneering discoveries concerning the proximate causes of behavior.

However, we could also hypothesize that male deer fight to determine which deer get to mate with a female deer and pass on their genes. This hypothesis leads to a different answer than the one that is concerned with changes in day length. This answer focuses on the adaptive significance of fighting to the deer, that is, on the effect of a particular behavior on reproductive success. These factors are called **ultimate causes** of behavior. Since the 1970s, behavioral ecologists have focused more on understanding the ultimate causes of behavior.

In this chapter, we will explore the role of both proximate and ultimate causes of behavior. We begin the chapter by investigating how behavior is achieved, examining the roles of both genetics and the environment. In doing so, we will examine the important contributions of ethologists von Frisch, Lorenz, and Tinbergen. We consider how different behaviors are involved in movement, gathering food, and communication. Later, we investigate how organisms interact in groups, whether an organism can truly behave in a way that benefits others at a cost to itself, and how behavior shapes different mating systems. The chapter focuses on animal behavior, because the behavior of other organisms is more limited and less well understood.

55.1 The Impact of Genetics and Learning on Behavior

Behavior is controlled by both genetics and the environment, and in this chapter, we will discuss the influence of both. Determining to what degree a behavior is influenced by genes versus the environment will depend on the particular genes and environment examined. However, in a few cases, changes in behavior may be caused by variation in just one gene. Even if a given

behavior is influenced by many genes, if one gene is altered, it is possible that the entire behavior can change. To use the analogy of baking a cake, a change in one ingredient of the recipe may change the whole taste of the cake, but that does not mean that the one ingredient is responsible for the entire cake.

In this section, we begin by examining how genes can affect behavior and consider several examples of simple, genetically programmed behaviors. Later, we explore several types of learned behavior, including classical and operant conditioning and cognitive learning, and conclude the section by exploring an example of the interaction of genetics and learning on behavior.

Genomes & Proteomes Connection

Some Behavior Results from Simple Genetic Influences

An example of the effect of genes on complex behavior was demonstrated in W. C. Rothenbuhler's 1964 work on honeybees. Some strains of bees are termed hygienic; that is, they detect and remove diseased larvae from the nest. This behavior involves two distinct maneuvers: uncapping the wax cells and then discarding the dead larvae. Other strains are not hygienic and do not exhibit such behavior. Using genetic crosses, Rothenbuhler demonstrated that one gene (*u*) controlled cell uncapping and another gene (*r*) controlled larval removal. Double recessives (*uurr*) were hygienic strains, and double dominants (*UURR*) were nonhygienic strains. When the two strains were crossed, all the F_1 hybrids were nonhygienic (*UuRr*). When the F_1 hybrids were crossed with the pure hygienic strain (*uurr*), four different genotypes were produced, as Mendel's law of independent assortment predicts (Chapter 16): one-quarter of the offspring were hygienic (*uurr*), one-quarter were nonhygienic and showed neither behavior (*UuRr*), one-quarter uncapped the cells but failed to remove the larvae (*uuRr*), and one-quarter removed the larvae but only if the cells were uncapped for them (*Uurr*).

As a second example, Jennifer Brown and her colleagues showed how a single gene, *fosB*, controls nurturing behavior in mice. Normal mice, which carry the gene, clean their newborn pups, nurse them, and crouch over them to keep them warm. In 1996, Brown's group created mutant mice lacking the *fosB* gene. Despite fully functioning mammary glands, mutant mothers paid little attention to their newborn pups, which remained scattered around the cage and died within a few days. If the pups of the *fosB* mutants were placed with normal females, they thrived, but if normal pups were given to mutant mothers, they too were neglected.

Genes for behavior act on the development of the nervous system and musculature, physical traits that evolve through natural selection. Many genes are needed for the proper development and function of the nervous system and musculature. Even so, as described by Rothenbuhler's and Brown's work, variation in a single gene can have a dramatic impact on behavior.

Fixed Action Patterns Are Genetically Programmed

Behaviors that seem to be genetically programmed are referred to as **innate** (also called instinctual). Although we recognize that the expression of genes varies, often in response to environmental stimuli, some behavior patterns evidently are genetically quite fixed. Most individuals will exhibit the same behavior regardless of the environment. A spider will spin a specific web without ever seeing a member of its own species build one. The courtship behaviors of many bird species are so stereotyped as to be virtually identical.

A classic example of innate behavior is the egg-rolling response in geese (Figure 55.1). If an incubating goose notices an egg out of the nest, she will extend her neck toward the egg, get up, and then roll the egg back to the nest using her beak. Such behavior functions to improve fitness because it increases the survival of offspring. Eggs that roll out of the nest get cold and fail to hatch. Geese that fail to exhibit the egg-rolling response would pass on fewer of their genes to future generations.

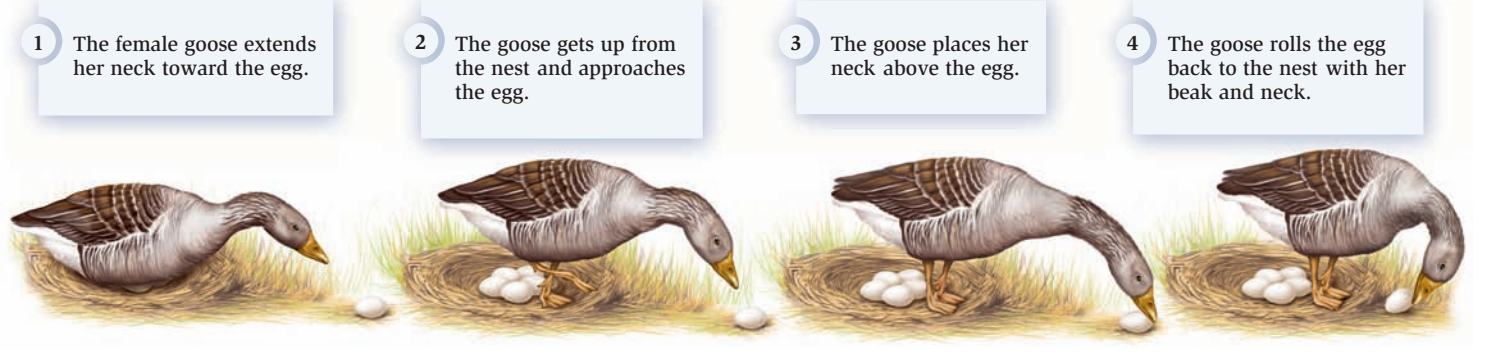

Figure 55.1 A fixed action pattern as an example of innate behavior. Female geese retrieve eggs that have rolled outside the nest through a set sequence of movements. The goose will complete this entire sequence even if a researcher takes the egg away before the goose has rolled it back to the nest.

Egg-rolling behavior is an example of what ethologists term a **fixed action pattern** (**FAP**), a behavior that, once initiated, will continue until completed. For example, if the egg is removed while the goose is in the process of rolling it back toward the nest, the goose still completes the FAP, as though she were rolling back the now-absent egg to the nest. The stimulus to initiate this behavior is obviously a strong one, which ethologists term a **sign stimulus**. The sign stimulus for the goose is that an egg had rolled out of the nest. According to ethologists, this stimulus acts on the goose's central nervous system, which provides a neural stimulus to initiate the motor program or FAP. Interestingly, any round object will elicit the egg-rolling response, from a wooden egg to a volleyball. Although sign stimuli usually have certain key components, they are not necessarily very specific.

Niko Tinbergen's study of male stickleback fish provides another classic example of an FAP. Male sticklebacks, which have a characteristic red belly, will attack other male sticklebacks that invade their territory. Tinbergen found that sticklebacks attacked small, unrealistic model fish having a red ventral surface (the sign stimulus), while ignoring a realistic male stickleback model that lacked a red underside (Figure 55.2).

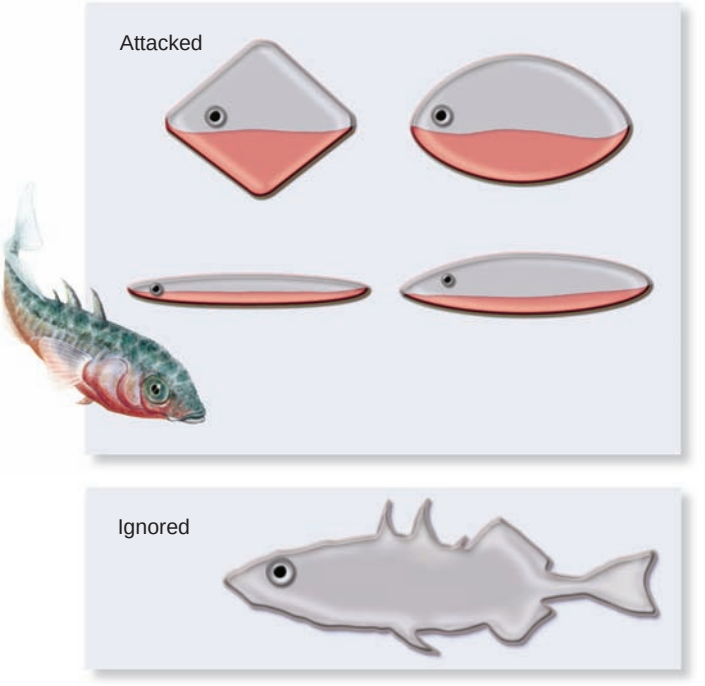

Figure 55.2 A fixed action pattern elicited by a sign stimulus. The sign stimulus for male sticklebacks to attack other males entering their territory is a red ventral surface. In experiments, male sticklebacks attacked all models that had a red underside, while ignoring a realistic model of a stickleback that lacked the red belly.

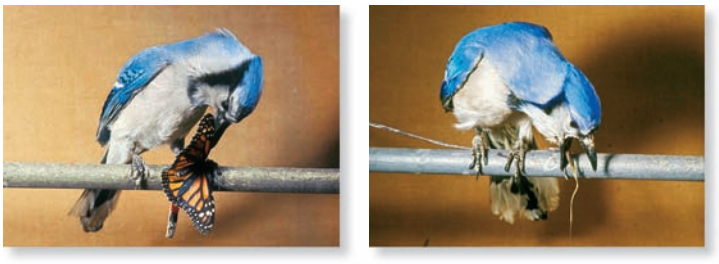
Conditioning Occurs When a Relationship Between a Stimulus and a Response Is Learned

Although many of the behavioral patterns exhibited by animals are largely innate, sometimes animals can make modifications to their behavior based on previous experience, a process that involves learning. Perhaps the simplest form of learning is **habituation**, in which an organism learns to ignore a repeated stimulus. For example, animals in African safari parks become habituated to the presence of vehicles containing tourists; these vehicles are neither a threat nor a benefit to them. After a while, birds can become habituated to the presence of a scarecrow, resulting in damage to crops. Habituation can be a problem at airports, where birds eventually ignore the alarm calls designed to scare them away from the runways.

Habituation is a form of nonassociative learning, a change in response to a repeated stimulus without association with a positive or negative reinforcement. Alternatively, an association may gradually develop between a stimulus and a response. Such a change in behavior is termed **associative learning**. In associative learning, a behavior is changed or conditioned through the association. The two main types of associative learning are termed classical conditioning and operant conditioning.

In **classical conditioning**, an involuntary response comes to be associated positively or negatively with a stimulus that did not originally elicit the response. This type of learning is generally associated with the Russian psychologist Ivan Pavlov. In his original experiments in the 1920s, Pavlov restrained a hungry dog in a harness and presented small portions of food at regular intervals. The dog would salivate whenever it smelled the food. Pavlov then began to sound a metronome when presenting the food. Eventually the dog would salivate at the sound of the metronome, whether or not the food was present. Pavlov termed the food the **unconditioned stimulus** for salivation, and the metronome was the **conditioned stimulus**. Likewise, he termed salivation in response to food as an **unconditioned response** and salivation in response to the metronome as a **conditioned response**. Classical conditioning is pervasive in human society and is widely observed in other animals. For example, many insects quickly learn to associate certain flower odors with nectar rewards and other flower odors with no rewards.

In **operant conditioning**, an animal's behavior is reinforced by a consequence, either a reward or a punishment. The classic example of operant conditioning is associated with the American psychologist B. F. Skinner, who placed laboratory animals, usually rats, in a specially devised cage with a lever that came to be known as a Skinner box. If the rat pressed on the lever, a small amount of food would be dispensed. At the beginning of the experiment, the rat would often bump into the lever by accident, eat the food, and continue exploring its cage. Later, it would learn to associate the lever with obtaining food. Eventually, if it was hungry, the rat would almost continually press the lever. Operant conditioning, also called trial-and-error learning, is common in animals. Often it is associated with negative rather than positive reinforcement. For example, toads will eventually refuse to strike at insects that sting, such as wasps and bees, and birds will learn to avoid bad-tasting butterflies (Figure 55.3).



(a) Blue jay eating monarch (b) Vomiting reaction

Figure 55.3 Operant conditioning, also known as trial-and-error learning. **(a)** A young blue jay will eat a monarch butterfly, not knowing that it is noxious. **(b)** After the first experience of vomiting after eating a monarch, a blue jay will avoid the insects in the future.

Concept check: What's the difference between operant conditioning and classical conditioning?

Cognitive Learning Involves Conscious Thought

Cognitive learning refers to the ability to solve problems with conscious thought and includes activities such as perception, analysis, judgment, recollection, and imagining. In the 1920s, psychologist Wolfgang Kohler conducted a series of classic experiments with chimpanzees that suggested animals could exhibit cognitive learning. In the experiments, a chimpanzee was left in a room with bananas hanging from the ceiling and out of reach (Figure 55.4). Also present in the room were several wooden boxes. At first, the chimp tried in vain to jump up and grab the bananas. After a while, however, it began to arrange the boxes one on top of another underneath the fruit. Eventually, the chimp climbed the boxes and retrieved the fruit. This clearly looks like an example of problem solving that involves cognitive learning.

Many other examples of such behavior have been observed. Chimps strip leaves off twigs and use the twigs to poke into ant nests, withdrawing the twig and licking the ants off (see chapter-opening photo). Captive ravens have been shown to retrieve meat suspended from a branch by a string, even though they have never encountered the problem before. They pull up on the string, step on it, and then pull up on the string again, repeating the process until the meat is within reach.

Both Genetics and Learning Influence Most Behaviors

Much of the behavior we have discussed so far has been presented as either innate or learned, but the behavior we observe in nature is a mixture of both. Bird songs present a good example. Many birds learn their songs as juveniles, when they hear their parents sing. If juvenile white-crowned sparrows are raised in isolation, their adult songs do not resemble the typical species-specific song (Figure 55.5). If they hear only the song of a different species, such as the song sparrow, they again sing a poorly developed adult song. However, if they hear the song of the white-crowned sparrow, they will learn to sing a fully developed white-crowned sparrow song. The birds are genetically programmed to learn, but they will sing the correct song only if the appropriate instructive program is in place to guide learning.

Another example of how innate behavior interacts with learning can occur during a limited time period of development, called a **critical period**. At this time, many animals develop irreversible species-specific behavior patterns. This process is called **imprinting**. One of the best examples of imprinting was demonstrated by the Austrian ethologist Konrad Lorenz in the 1930s. Lorenz noted that young birds of some species imprint

Figure 55.4 Cognitive behavior involving problem-solving ability. This chimp has devised a solution to the problem of retrieving bananas that were initially out of its reach.

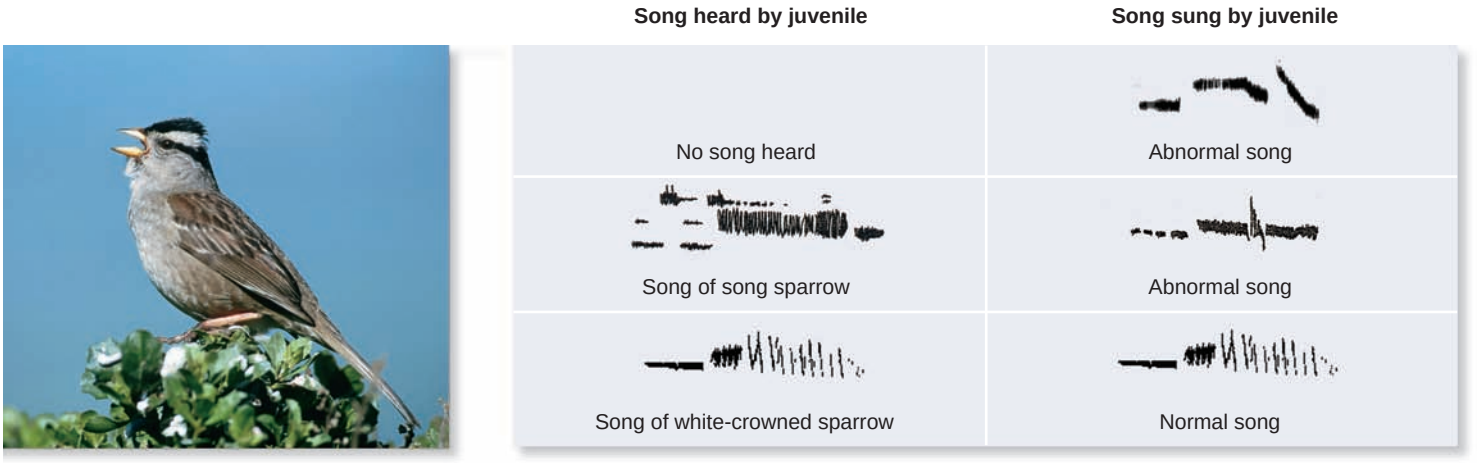


Figure 55.5 **The interaction between genetics and learning.** The lines represent the different sound frequencies produced by the birds over a short time interval. The juvenile white-crowned sparrow will sing an abnormal song if it is kept in isolation or hears only the song of a different species. However, the juvenile will sing the normal white-crowned sparrow song if exposed to it.

Concept check: *Cuckoos lay their eggs in other birds' nests, so their young are reared by parent birds of a different species. However, unlike the white-crowned sparrow, adult cuckoos always sing their own distinctive song, not that of the host species they hear as juveniles. How is this possible?*

on their mother during a critical period that is usually within a few hours after hatching. This behavior serves them well, because in many species of ducks and geese, it would be hard for the mother to keep track of all her offspring as they walk or swim. After imprinting takes place, the offspring keep track of the mother.

The survival of the young ducks requires that they quickly learn to follow their mother's movements. Lorenz raised greylag geese from eggs, and soon after they hatched, he used himself as the model for imprinting. As a result, the young goslings imprinted on Lorenz and followed him around (Figure 55.6). For the rest of their life, they preferred the company of Lorenz and other humans to geese. Studies have shown that even an object as foreign as a black box, watering can, or flashing light will be imprinted on if it is the first moving object the chick sees during the critical period. In nature, if young geese are not provided with any stimulus during this period, they will fail to imprint on anything, and without parental care, they will almost certainly die.

Figure 55.6 **Konrad Lorenz being followed by his imprinted geese.** Newborn geese follow the first object they see after hatching and later will follow that particular object only. They normally will follow their mother but can be induced to imprint on humans. The first thing these young geese saw after hatching was ethologist Konrad Lorenz.

Other animals imprint in different ways. Newborn shrews imprint on the scent of their mother. Mothers also can imprint on their own young within a few hours. For example, if sheep mothers are kept apart from their offspring for only a few hours after birth, they will reject them. In these situations, the innate behavior is the ability to imprint soon after birth, and the factors in the environment are the stimulus to which the imprinting is directed.

Finally, innate behavior can interact with learning during animal migration. Inexperienced juvenile birds will migrate in a particular direction but will fail to correct for deviations if they are blown off course. Experienced adult birds, on the other hand, can often correct for storm-induced displacement, indicating they have more complex navigational skills. There are many complex behaviors involved in movement and migration, as we will explore in the next section.

55.2 Local Movement and Long-Range Migration

Organisms need to find their way, both locally and over what can be extremely long distances. Locally, organisms continually need to locate sources of food, water, mates, and perhaps

nesting sites. Migration involves the longer-distance seasonal movement of animals, usually between overwintering areas and summer breeding sites; these are often hundreds or even thousands of kilometers apart. Several different types of behavior may be involved in these movements.

In this section, we begin by exploring local movement and, in particular, how one species uses landmarks to guide its movements. We then consider migration and examine the possible mechanisms used by migrating animals to find their way.

Local Movement Can Involve Kinesis, Taxis, and Memory

The simplest forms of movement are mere responses to stimuli. A **kinesis** is a movement in response to a stimulus, but one that is not directed toward or away from the source of the stimulus. A simple experiment often done in classrooms is to observe the activity levels of woodlice, sometimes called sow bugs or pill bugs, in dry areas and moist areas. The woodlice move faster in drier areas, and they slow down when they reach moist environments. This behavior tends to keep them in damper areas, which they prefer in order to avoid desiccation.

A **taxis** is a more directed type of response either toward or away from an external stimulus. Cockroaches exhibit negative phototaxis, meaning they tend to move away from light. Under low-light conditions, the photosynthetic unicellular flagellate *Euglena gracilis* shows positive phototaxis and moves toward a light source. Sea turtle hatchings are also strongly attracted to light. On emerging from their nests, they crawl toward the brightest location, traditionally the reflected moonlight on the ocean's surface. Lighted houses on the shore can disorient the hatchlings, however, and lead them to wander away from the ocean and succumb to dehydration, exhaustion, and predation. Male silk moths orient themselves in relation to wind direction (anemotaxis). If the air current carries the scent of a female moth, they will move upwind to locate it. Some freshwater fishes orient themselves to the currents of streams. Many fishes exhibit positive rheotaxis (from the Greek *rheos*, meaning current), in that they swim against the water current to prevent being washed downstream.

Sometimes memory and landmarks may be used to aid in local movements. Dutch-born ethologist Niko Tinbergen showed how the female digger wasp uses landmarks to relocate her nests, as described next.

Feature Investigation

Tinbergen's Experiments Show That Digger Wasps Use Landmarks to Find Their Nests

In the sandy, dry soils of Europe, the solitary female digger wasp (*Philanthus triangulum*) digs four to five nests in which to lay her eggs. Each nest stretches obliquely down into the ground for 40–80 cm. The wasp, also called a bee wolf, follows this by performing a sequence of apparently genetically programmed events. She catches and stings a honeybee, which paralyzes it; returns to the nest; drags the bee into the nest; and lays an egg on it. The egg hatches into a larva, which feeds on the paralyzed bee. However, the larva needs to ingest five to six bees before it is fully developed. This means the wasp must catch and sting four to five more bees for each larva. She can carry only one bee at a time. After each visit, the wasp must seal the nest with soil, find a new bee, relocate the nest, open it, and add the bee. How does the wasp relocate the nest after spending considerable time away? Niko Tinbergen observed the wasps hover and fly around the nest each time they took off. He hypothesized that they were learning the nest position by creating a mental map of the landmarks in the area.

To test his hypothesis, Tinbergen experimentally adjusted the landmarks around the burrow that the wasps might be using as cues (Figure 55.7). First, he put a ring of pinecones around the nest entrance to train the wasp to associate the pinecones with the nest. Then, when the wasp was out hunting, he

Figure 55.7 How Niko Tinbergen discovered the digger wasp's nest-locating behavior.

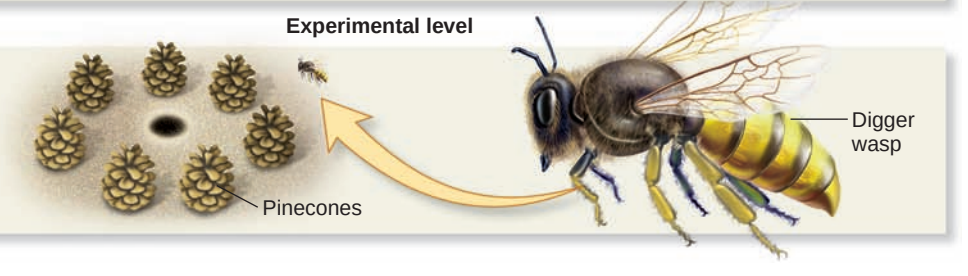
Concept check: *How would you test what type of spatial landmarks are used by female digger wasps?*

HYPOTHESIS Digger wasps (*Philanthus triangulum*) use visual landmarks to locate their nests.

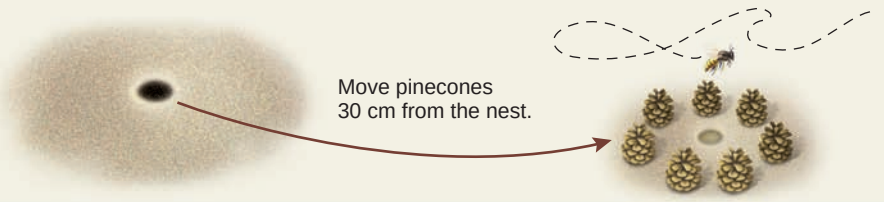
STARTING LOCATION The female digger wasp excavates an underground nest, to which she returns daily, bringing food to the larvae located inside.

Experimental level

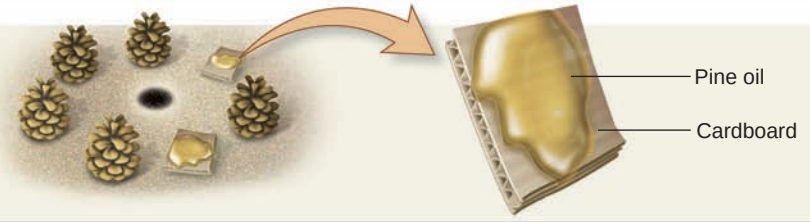
1 Place a ring of pinecones around the nest to train the wasp to associate pinecones with the nest.



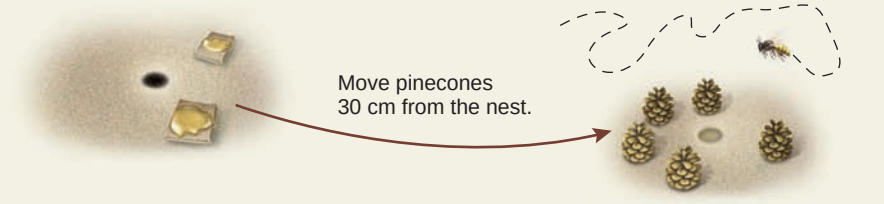
2 After the wasp leaves the nest to hunt, move the pinecones 30 cm from the real nest. The wasp returns and flies to the center of the pinecone circle instead of the real nest. Repeated experiments yield similar results (see data), indicating that the wasp uses landmarks as visual cues.



3 To test whether it is the shape or the smell of the pinecones that elicits the response, perform the same experiment as above, except use pinecones with no scent and add 2 small pieces of cardboard coated with pine oil.



4 After the wasp leaves the nest, move the pinecones 30 cm from the nest, but leave the scented cardboard at the nest. The wasps again fly to the pinecone nest (see data), indicating that it is the arrangement of cones, not their smell, that elicits the learning.



5 THE DATA*

Results from steps 1 and 2:

Wasp #	Number of return visits per wasp to real nest without pinecones	Number of return visits per wasp to sham nest with pinecones
1–17	0	~9

Results from steps 3 and 4:

Wasp #	Number of return visits per wasp to real nest with scented cardboard	Number of return visits per wasp to sham nest with pinecones
18–22	0	~6

*Seventeen wasps, numbered 1–17, were studied as described in steps 1 and 2. Five wasps, numbered 18–22, were studied as described in steps 3 and 4.

6 CONCLUSION Digger wasps remember the positions of visual landmarks and use them as aids in local movements.

7 SOURCE Tinbergen, N. 1951. The study of instinct. Clarendon Press, Oxford.

moved the circle of pinecones a distance from the real nest and constructed a sham nest, making a slight depression in the sand and mimicking the covered entrance of the burrow. On returning, the wasp flew straight to the sham nest and tried to locate the entrance. Tinbergen chased it away. When it returned, it again flew to the sham nest. Tinbergen repeated this nine times, and every time the wasp chose the sham nest. Tinbergen got the same result with 16 other wasps, and not once did they choose the real nest.

Next Tinbergen experimented with the type of stimulus that might be eliciting the learning. He hypothesized that the wasps could be responding to the distinctive scent of the pinecones rather than their appearance. He trained the wasps by placing a circle of pinecones that had no scent and two small pieces of cardboard coated in pine oil around the real nest. He then moved the cones to surround a sham nest and left the scented cardboard around the real nest. The returning wasps again ignored the real nest with the scented cardboard and flew

to the sham. He concluded that for the wasps, sight was apparently more important than smell in determining landmarks.

Experimental Questions

1. What observations were important for the development of Niko Tinbergen's hypothesis explaining how digger wasps located their nests?
2. How did Tinbergen test the hypothesis that the wasps were using landmarks to relocate the nest? What were the results?
3. Did the Tinbergen experiment rule out any other cue the wasps may have been using besides the sight of pinecones?

Migration Involves Long-Range Movement and More Complex Spatial Navigation

As well as learning to navigate over short-range distances, many animal species undergo **migration**, long-range seasonal movement. Migrations usually involve a movement away from a birth area to feed and a return to the birth area to breed, with the movement generally being linked to seasonal availability of food. For example, nearly half the birds of North America migrate to South America to escape the cold winters and feed, returning to North America in the spring to breed. Arctic terns that breed in Arctic Canada and Asia in summer migrate to the Antarctic to feed in the winter and then return to breed. This staggering journey involves up to a 40,000-km (25,000-mi) round-trip, most of it over the open ocean, during which the birds must stay airborne for days at a time!

Many mammals, including wildebeest and caribou, make migrations that track the appearance of new vegetation on which they feed. The monarch butterfly of North America migrates to overwinter in California, Mexico, and possibly south Florida and Cuba (Figure 55.8). An interesting point about the northward journey of the monarch is that it involves several generations of butterflies to complete. On their way back to the northern U.S. and Canada, the butterflies lay eggs and die. The caterpillars develop on milkweed plants, and the resultant adults continue to journey farther north. This cycle happens several times in the course of the return journey. The northward and southward migrations are unique in that none of the individuals has ever been to the destinations before; therefore, the ability to migrate must be an innate behavior.

How do migrating animals find their way? Three mechanisms may be involved: piloting, orientation, and navigation. In **piloting**, an animal moves from one familiar landmark to the next. For example, many whale species migrate between summer feeding areas and winter calving grounds. Gray whales migrate between the Bering Sea near Alaska to coastal areas of Mexico. Features of the coastline, including mountain ranges, and rivers, may aid in navigation. In **orientation**, animals have the ability to follow a compass bearing and travel in a straight line. **Navigation** involves the ability not only to follow a compass bearing but also to set or adjust it.

An experiment with starlings helps illuminate the difference between orientation and navigation (Figure 55.9). European starlings breed in Scandinavia and northeastern Europe and migrate in a southwest direction toward coastal France and southern England to spend the winter. Migrating starlings were captured and tagged in the Netherlands and then transported south to Switzerland and released. Juvenile birds, which had never made the trip before, flew southwest in their migration and were later recaptured in Spain. Adult birds, with more experience, returned to their normal wintering range by adjusting their course by approximately 90°. This implies that the adult birds can actually navigate, whereas the juveniles rely on orientation.

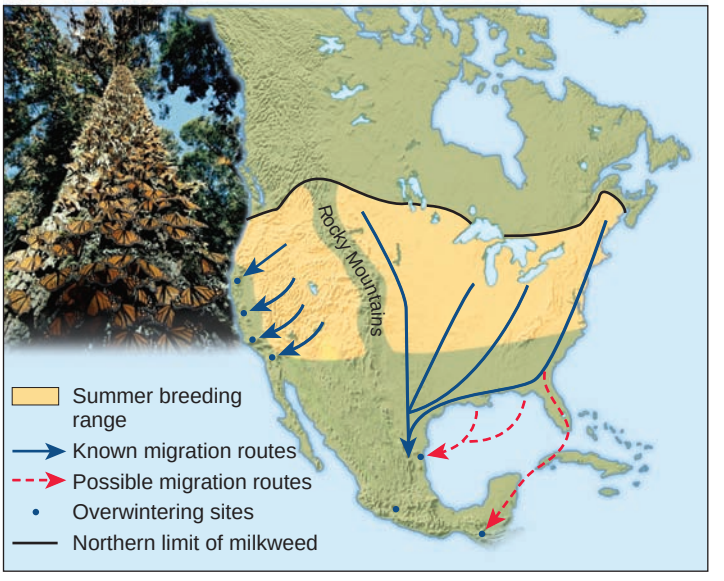


Figure 55.8 Monarch butterfly migration. Many monarch butterflies east of the Rocky Mountains migrate to a small area in Mexico to avoid the cold northern weather. Here they roost together in large numbers in fir trees (inset). Some butterflies may stay in Florida and Cuba. Butterflies west of the Rockies overwinter in mild coastal California locations.

Concept check: Why is this an unusual example of migration?

Many species use a combination of navigational reference points, including the position of the sun, the stars (for nighttime travel), and Earth's magnetic field. Homing pigeons have magnetite in their beaks that acts as a compass to tell direction (refer back to Section 43.4, Electromagnetic Sensing). Navigation by the sun or the stars also requires the use of a timing device to compensate for the ever-changing position of these reference points. Many migrants, therefore, possess the equivalent of an internal clock. Pigeons integrate their internal clock with the position of the sun. Researchers have altered the internal clock of pigeons by keeping them under artificial lights for certain periods of time. When the pigeons are released, they display predictable deviations in their flight. For every hour that their internal clock is shifted, the orientation of the birds shifts about 15°.

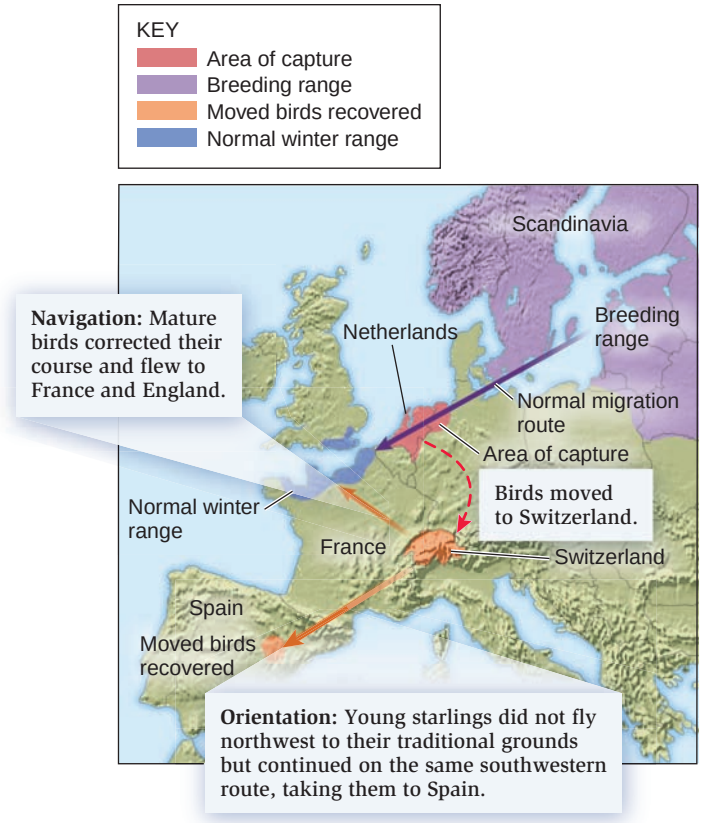

Figure 55.9 **Orientation versus navigation.** Starlings normally migrate from breeding grounds in Scandinavia and northeastern Europe through the Netherlands and northern Germany to overwintering sites in France and England. This involves a southwest flight. When juveniles were captured in the Netherlands and moved to Switzerland, they continued on in a southwestern direction and ended up in Spain. When adult birds were captured and moved, they changed course and flew to the normal overwintering areas.

Not all examples of animal migration are well understood. Green sea turtles feed off the coast of Brazil yet swim east for 2,300 km (1,429 mi) to lay their eggs on Ascension Island, an 8-km-wide island in the center of the Atlantic Ocean between Brazil and Africa. It is not known why the turtles lay their eggs on this speck of an island or how they succeed in finding it. Perhaps fewer predators exist on Ascension than on other beaches. A combination of magnetic orientation and chemical cues may help them find it. Thus, while scientists have made many discoveries about animal navigation, much remains to be learned about how animals acquire a map sense.

To a large extent, local and long-distance movement involves searching for food. In the next section, we will investigate how such foraging decisions are made.

55.3 Foraging Behavior

Food gathering, or foraging, often involves decisions about whether to remain at a resource patch and look for more food or look for a completely new patch. The analysis of these decisions is often performed in terms of **optimality theory**, which predicts that an animal should behave in a way that maximizes the benefits of a behavior minus its costs. In this case, the benefits are the nutritional or caloric value of the food items, and the costs are the energetic or caloric costs of movement. When the difference between the energetic benefits of food gathering and the energetic costs of food gathering is maximized, an organism is said to be optimizing its foraging behavior. Optimality theory can also be used to investigate other behavioral issues such as how large a territory to defend. Too small a territory would contain insufficient resources, such as food and mates, and too large a territory would be too energetically costly to defend. Theoretically, then, there is an optimal territory size for a given individual.

Optimal Foraging Entails Maximizing the Benefits and Minimizing the Costs of Food Gathering

Optimal foraging proposes that in a given circumstance, an animal seeks to obtain the most energy possible with the least expenditure of energy. The underlying assumption of optimal foraging is that natural selection favors animals that are maximally efficient at propagating their genes and at performing all other functions that serve this purpose. In this model, the more net energy an individual gains in a limited time, the greater the reproductive success.

Shore crabs (*Carcinus maenas*) will eat many different-sized mussels but tend to feed preferentially on intermediate-sized mussels, which give them the highest rate of energy return (Figure 55.10). Very large mussels yield more energy,

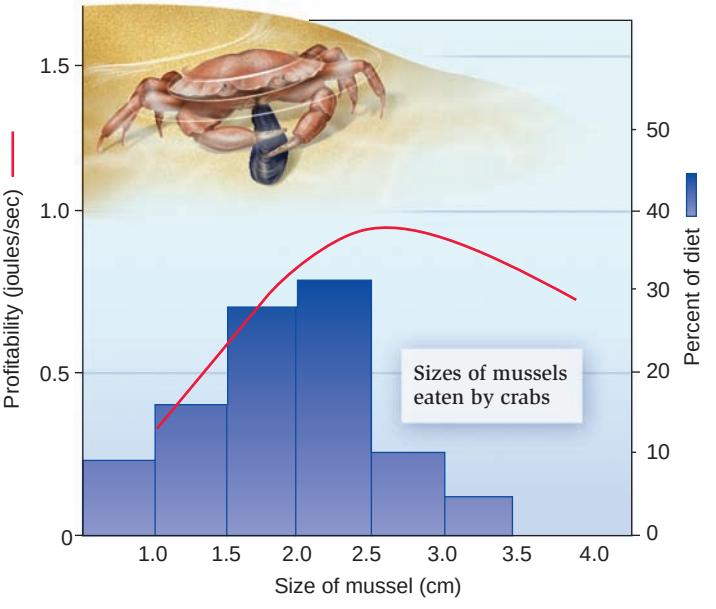

Figure 55.10 **Optimal foraging behavior in shore crabs.** In an aquarium setting, when offered a choice of equal numbers of each size mussel, shore crabs (*Carcinus maenas*) prefer intermediate-sized mussels that provide the highest rate of energy return. Profitability is the energy yield (joules) per second of time used in breaking open the shell.

(a) Golden-winged sunbird

(b) Cheetah

(c) Nesting gannets

Figure 55.11 **Differing territory sizes among animals.** **(a)** The golden-winged sunbird of East Africa (*Nectarinia reichenowi*) has a medium territory size that is dependent on the number of flowers it can obtain resources from and defend. **(b)** Cheetahs (*Acinonyx jubatus*) hunt over large areas and can have extensive territories. This male is urine-marking part of his territory in the southern Serengeti, near Ndutu, Tanzania. **(c)** Nesting gannets (*Morus bassanus*) have much smaller territories, in which each bird is just beyond the pecking range of its neighbor.

but they take so long for the crab to open that they are actually less profitable, in terms of energy yield per unit time spent, than smaller sizes. Very small mussels are easy to crack open but contain so little flesh that they are not worth the effort. This leaves intermediate-sized mussels as the preferred size. Of course, the intermediate-sized mussels may take a longer time to locate, because more crabs are looking for them, so crabs eat some less profitable but more frequently encountered sizes of mussels. The result is that the diet consists of mussels in a range of sizes around the preferred optimal size.

In some cases, animals do not forage optimally. For example, animals seek not only to maximize food intake but also to minimize the risk of predation. Some species may only dart out to take food from time to time. The risk of predation thus has an influence on foraging behavior. Many animals also maintain territories to minimize competition with other individuals and control resources, whether food, mates, or nesting sites. As we will see, defending these territories also has an energetic cost.

Defending Territories Has Costs and Benefits

Many animals or groups of animals, such as a pride of lions, actively defend a **territory**, a fixed area in which an individual or group excludes other members of its own species, and sometimes other species, by aggressive behavior or territory marking. Optimality theory predicts that territory owners tend to optimize territory size according to the costs and benefits involved. The primary benefit of a territory is that it provides exclusive access to a particular resource whether it be food, mates, or sheltered nesting sites. Large territories provide more of a resource or resources but may be costly to defend, while small territories that are less costly to defend may not provide enough.

In studies of the territorial behavior of the golden-winged sunbird (*Nectarinia reichenowi*) in East Africa, researchers Frank Gill and Larry Wolf measured the energy content of nectar as the benefit of maintaining a territory and compared it to the energy costs of activities such as perching, flying, and fighting (Figure 55.11a). Defending the territory ensured that other sunbirds did not take nectar from available flowers, thus increasing the amount of nectar in each flower. In defending a territory, the sunbird gained 780 calories a day in extra nectar content. However, the sunbird also spent 728 calories in defense of the territory, yielding a net gain of 52 calories a day and making territorial defense advantageous.

Territory size differs considerably among species. Because cheetahs need large areas to be able to hunt successfully, they establish large territories relative to their size (Figure 55.11b). In contrast, territories set up solely to defend areas for mating or nesting are often relatively small. For example, male sea lions defend small areas of beach. The preferred areas contain the largest amount of females and are controlled by the largest breeding bulls. The size of the territory of some nesting birds, such as gannets, is determined by how far the bird can reach to peck its neighbor without leaving its nest (Figure 55.11c).

Territories may be held for a season, a year, or the entire lifetime of the individual. Ownership of a territory needs to be periodically proclaimed; thus, communication between individuals is necessary for territory owners. This may involve various types of signaling, which we discuss next.

55.4 Communication

Communication is the use of specially designed signals or displays to modify the behavior of others. It may be used for many purposes, including defining territories, maintaining contact with offspring, courtship, and contests between males. The use of different forms of communication between organisms depends on the environment in which they live. For example, visual communication plays little role in the signals of nocturnal animals. Similarly, for animals in dense forests, sounds are of prime importance. Sound, however, is a temporary signal.

Scent can last longer and is often used to mark the large territories of some mammals. In this section, we outline the various types of communication—chemical, auditory, visual, and tactile—that occur among animals.

Chemical Communication Is Often Used to Mark Territories or Attract Mates

The chemical marking of territories is common among animals, especially among members of the canine and feline families (see Figure 55.11b). Scent trails are often used by social insects to recruit workers to help bring prey to the nest. Fire ants (genus *Solenopsis*) attack large, living prey, and many ants are needed to drag the prey back to the nest. The scout that finds the prey lays down a scent trail from the prey back to the nest. The scent excites other workers, which follow the trail to the prey. The scent marker is very volatile, and the trail effectively disappears in a few minutes to avoid mass confusion over old trails.

Animals frequently use chemicals to attract mates. Female moths attract males by powerful chemical attractants called **pheromones**. Male moths have receptors that can detect as little as a single molecule. Among social organisms, some individuals use pheromones to manipulate the behavior of others. For example, a queen bee releases pheromones that suppress the reproductive system of workers, which ensures that she is the only reproductive female in the hive.

Auditory Communication Is Often Used to Attract Mates and to Deter Competitors

Many organisms communicate by making sound. Because the Earth itself can absorb sound waves, sound travels farther in the air, which is why many birds and insects perch on branches or leaves when singing. Air is on average 14 times less turbulent at dawn and dusk than during the rest of the day, so sound carries farther then, which helps explain the preference of most animals for calling at these times. Some insects utilize the very plants on which they feed as a medium of song transmission. Many male leafhopper and planthopper insects vibrate their abdomens on leaves and create species-specific courtship songs that are transmitted by adjacent vegetation and are picked up by nearby females of the same species.

While many males use auditory communication to attract females, some females use calls to attract the attention of males. Female elephant seals use this behavior to their advantage. When a nondominant male attempts to mate with a female, she screams loudly, attracting the attention of the dominant male, which drives the nondominant male away. In this way, she is guaranteed a mating with the strongest male. Sound production can attract predators as well as mates. Some bats listen for the mating calls of male frogs to find their prey. Parasitic flies detect and locate chirping male crickets and then deposit larvae on or near them. The larvae latch onto and penetrate the cricket and eventually kill it. Sound may also be used by males during competition over females. In many animals, lower-pitched sounds come from larger males, so by calling to one another, males can gauge the size of their opponents and save energy that would be used in fighting.

Visual Communication Is Often Used in Courtship and Aggressive Displays

In courtship, animals use a vast number of visual signals to identify and select potential mates. Competition among males for the most impressive displays to attract females has led to elaborate coloration and extensive ornamentation in some species. For example, peacocks and males of many bird species have developed elaborate plumage to attract females.

Male fireflies have developed light flashes that are species specific with regard to number and duration of flashes (Figure 55.12). Females respond with a flash of their own. Such bright flashes are also bound to attract predators. Some female fireflies use mimicry to their advantage. Female *Photuris versicolor* fireflies mimic the flashing responses normally given by females of other species, such as *Photinus tanytoxus*, in order to lure the males of those species close enough to eat them.

Visual signals are also used to resolve disputes over territories or mates. Deer and antelope have antlers or horns that

(c) Waggle dance: The angle of the waggle to the vertical orientation of the honeycomb corresponds to the angle of the food source from the sun.

Figure 55.13 **Tactile communication among honeybees regarding food sources.** **(a)** Bees gather around a newly returned scout to receive information about nearby food sources. **(b)** If the food is less than 50 m away, the scout performs a round dance. **(c)** If the food is more than 50 m away, the scout performs a waggle dance, which conveys information about its location. If the dance is performed at a 30° angle to the right of the hive's vertical plane, then the food source is located at a 30° angle to the right of the sun.

they use to display and spar over territory and females. Most of these matches never develop into outright fights, because the males gauge their opponent's strength by the size of these ornaments. Among insects, the "horns" of rhinoceros beetles and the eye stems of stalk-eyed flies send similar signals.

Tactile Communication Is Used to Strengthen Social Bonds and to Convey Information About Food

Animals often use tactile communication to establish bonds between group members. Primates frequently groom one another, and canines and felines may nuzzle and lick each other. Many insects use tactile communication to convey information on the whereabouts of food. Members of the ant genus *Leptothorax* feed on immobile prey such as dead insects. When a scouting ant encounters such prey, it usually needs an additional worker to help bring it back to the nest. Rather than laying a scent trail, which is energetically costly, the scout ant recruits a helper and physically leads it to the food source. The helper runs in tandem with the scout, its antennae touching the scout's abdomen.

Perhaps the most fascinating example of tactile communication among animals is the dance of the honeybee, elegantly studied by German ethologist Karl von Frisch in the 1940s. Bees commonly live in large hives; in the case of the European honeybee (*Apis mellifera*), the hive consists of 30,000–40,000 individuals. The flowering plants on which the bees forage can be located miles from the hive and are distributed in a patchy manner, with any given patch usually containing many flowers that store more nectar and pollen than an individual bee can carry back to the nest. The scout bee that locates the resource patch returns to the hive and recruits more workers to join it (Figure 55.13a). Because it is dark inside the hive, the bee uses a tactile signal. The scout dances on the vertical side of a honeycomb, and the dance is monitored by other bees, which follow and touch her to interpret the message. If the food is relatively close to the hive, less than 50 m away, the scout performs a round dance, rapidly moving in a circle, first in one direction and then the other. The other bees know the food is relatively close at hand, and the smell of the scout tells them what flower species to look for (Figure 55.13b).

If the food is more than 50 m away, the scout will perform a different type of dance, called a "waggle dance." In this dance, the scout traces a figure 8, in the middle of which she waggles her abdomen and produces bursts of sound. Again, the other bees maintain contact with her. Occasionally, the scout will regurgitate a small sample of nectar so the bees know the type of food source they are looking for. The truly amazing part of the waggle dance is that the angle at which the central part of the figure 8 deviates from the vertical direction of the comb represents the same angle at which the food source deviates from the point at which the sun hits the horizon (Figure 55.13c). The direction is always up-to-date, because the bee adjusts the dance as the sun moves across the sky.

As we have seen, much communication occurs not only to defend territories but also to communicate information to other individuals in the population, including potential mates. Although living on your own and maintaining a territory has advantages, living in a group also has its benefits, including ready availability of mates and increased protection from predators. In the following section, we examine group living and the behavior it engenders.

55.5 Living in Groups

As we have seen, much of animal behavior is directed at other animals. Some of the more complex behavior occurs when animals live together in groups such as flocks or herds. If a central concern of ecology is to explain the distribution patterns of

organisms, then one of our most important tasks is to understand why there is such variation in the degree of sociality. Although congregations promote competition for food and increased disease transmission, there are benefits of group living that compensate for the costs involved. Many of these benefits relate to locating food sources, assistance in rearing offspring, mate access, and group defense against predators. Group living can reduce predator success in at least two ways: through increased vigilance and through protection in numbers.

Living in Large Groups May Reduce the Risk of Predation Because of Increased Vigilance

For many predators, success depends on surprise. If an individual is alerted to an attack, the predator's chance of success is lowered. A woodpigeon (*Columba palumbus*) in a flock will take to the air when it spots a goshawk (*Accipiter gentilis*). Once one pigeon takes flight, the other members of the flock are alerted and follow suit. If each individual in a group occasionally scans the environment for predators, the larger the group, the less time an individual forager needs to devote to vigilance and the more time it can spend feeding. This is referred to as the **many-eyes hypothesis** (Figure 55.14). Of course, cheating is a possibility, because some birds might never look up, relying on others to keep watch while they keep feeding. However, the individual that happens to be scanning when a predator approaches is most likely to escape, a fact that tends to discourage cheating.

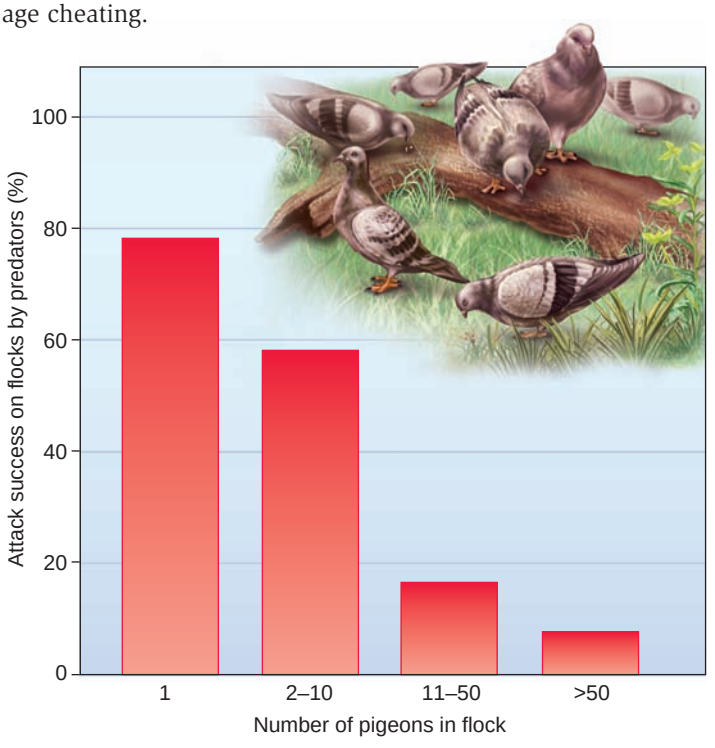

Figure 55.14 **Living in groups and the many-eyes hypothesis.** The larger the number of woodpigeons, the less likely an attack will be successful.

Concept check: *What other advantages are there to large groups of individuals when being attacked by a predator?*

Living in Groups Offers Protection by the "Selfish Herd"

Group living also provides protection in sheer numbers. Typically, predators take one prey animal per attack. In any given attack, an individual antelope in a herd of 100 has a 1 in 100 chance of being selected, whereas a single individual has a 1 in 1 chance. Large herds may be attacked more frequently than a solitary individual, but a herd is unlikely to attract 100 times more attacks than an individual, often because of the territorial nature of predators. Furthermore, large numbers of prey are able to defend themselves better than single individuals, which usually choose to flee. For example, groups of nesting black-headed gulls will mob a crow relentlessly, thereby reducing the crow's ability to steal the gulls' eggs.

Research has shown that within a group, each individual can minimize the danger to itself by choosing the location that is as close to the center of the group as possible. This was the subject of a famous paper, "The Geometry of the Selfish Herd," by the British evolutionary biologist W. D. Hamilton. The explanation of this type of defense is that predators are likely to attack prey on the periphery because they are easier to isolate visually. Many animals in herds tend to bunch close together when they are under attack, making it physically difficult for the predator to get to the center of the herd.

Overall, group size may be the result of a trade-off between the costs and benefits of group living. Although much group behavior serves to reduce predation, other complex behavior occurs in groups, including grooming behavior and behavior that appears to benefit the group at the expense of the individual. For example, a honeybee will sting a potential hive predator to discourage it. The bee's stinger is barbed, and once it has penetrated the predator's skin, the bee cannot withdraw it. The bee's only means of escape is to tear away part of its abdomen, leaving the stinger behind and dying in the process. In the next section, we explore the reasons for altruistic behavior, in which an individual incurs costs to itself for the benefit of others.

55.6 Altruism

In Chapter 23, we learned that a primary goal of an organism is to pass on its genes, yet we see many instances in which some individuals forego reproducing altogether, apparently to benefit the group. How do ecologists explain **altruism**, a behavior that appears to benefit others at a cost to oneself? In this section, we begin by discussing whether such behavior evolved for the good of the group or for the good of the individual. As we will see, most altruistic acts serve to benefit the individual's close relatives. We explore the concept of kin selection, which argues that acts of self-sacrifice indirectly promote the spread of an organism's genes, and see how this plays out in an extreme form in the genetics of social insect colonies. We conclude by examining reciprocal altruism as an attempt to explain the evolution of altruism among nonkin.

In Nature, Individual Selfish Behavior Is More Likely Than Altruism

One of the first attempts to explain the existence of altruism was called **group selection**, the premise that natural selection produces outcomes beneficial for the whole group or species. In 1962, the British ecologist V. C. Wynne-Edwards argued that a group containing altruists, each willing to subordinate its interests for the good of the group, would have a survival advantage over a group composed of selfish individuals. In concept, the idea of group selection seemed straightforward and logical: a group that consisted of selfish individuals would overexploit its resources and die out, while the fitness of a group with altruists would be enhanced.

In the late 1960s, the idea of group selection came under severe attack. Leading the charge was the biologist G. C. Williams, who argued that evolution acts through **individual selection**, which proposes that adaptive traits generally are selected for because they benefit the survival and reproduction of the individual rather than the group. Williams' arguments against group selection follow.

Mutation Mutant individuals that readily use resources for themselves or their offspring will have an advantage in a population where individuals limit their resource use. Consider a species of bird in which a pair lays only two eggs; that is, it has a clutch size of two, and the resources are not overexploited for the good of the group. Two eggs would ensure a replacement of the parent birds but would prevent a population explosion. Imagine a mutant bird arises that lays three eggs. If the population is not overexploiting its resources, sufficient food may be available for all three young to survive. If this happens, the three-egg genotype will eventually become more common than the two-egg genotype.

Immigration Even in a population in which all pairs laid two eggs and no mutations occurred to increase clutch size, selfish individuals that laid more could still immigrate from other areas. In nature, populations are rarely sufficiently isolated to prevent immigration of selfish mutants from other populations.

Individual Selection For group selection to work, some groups must die out faster than others. In practice, groups do not become extinct very frequently. Individuals die off more frequently than groups, so individual selection will be the more powerful evolutionary force.

Resource Prediction Group selection assumes that individuals are able to assess and predict future food availability and population density within their own habitat. There is little evidence that they can. For example, it is difficult to imagine that songbirds would be able to predict the future supply of the caterpillars that they feed to their young and adjust their clutch size accordingly.

Most ecologists accept individual gain as a more plausible result of natural selection than group selection. Population size is more often controlled by competition in which individuals strive to command as much of a resource as they can. Such selfishness can cause some seemingly surprising behaviors. For example, male Hanuman langurs (*Semnopithecus entellus*) kill infants when they take over groups of females from other males (Figure 55.15). The reason for the behavior is that when they are not nursing their young, females become sexually receptive much sooner, hastening the day when the male can father his own offspring. Infanticide ensures that the male will father more offspring, and the genes governing this tendency spread by natural selection.

Figure 55.15 **Infanticide as selfish behavior.** Male Hanuman langurs (*Semnopithecus entellus*) can act aggressively toward the young of another male, even killing them, hastening the day the females come into estrus and the time when the males can father their own offspring. Note that the mother is running with the infant.

If individual selfishness is more common than group selection, how do we account for what appear to be examples of altruism in nature?

Apparent Altruistic Behavior in Nature Is Often Associated with Kin Selection

Because all offspring have copies of their parents' genes, parents taking care of their young are actually caring for copies of their own genes. Genes for altruism toward one's young are favored by natural selection and will become more numerous in the next generation, because offspring have copies of those same genes.

The probability that any two individuals will share a copy of a particular gene is a quantity, *r*, called the **coefficient of relatedness**. During meiosis in a diploid species, any given copy of a gene has a 50% chance of segregating into an egg or sperm. A mother and father are on average related to their children by an amount $r = 0.5$, because half of a child's genes come from its mother and half from its father. By similar reasoning, brothers or sisters are related by an amount $r = 0.5$ (they share half their mother's genes and half their father's); grandchildren and grandparents, by 0.25; and cousins, by 0.125 (Figure 55.16). In 1964, ecologist W. D. Hamilton realized the

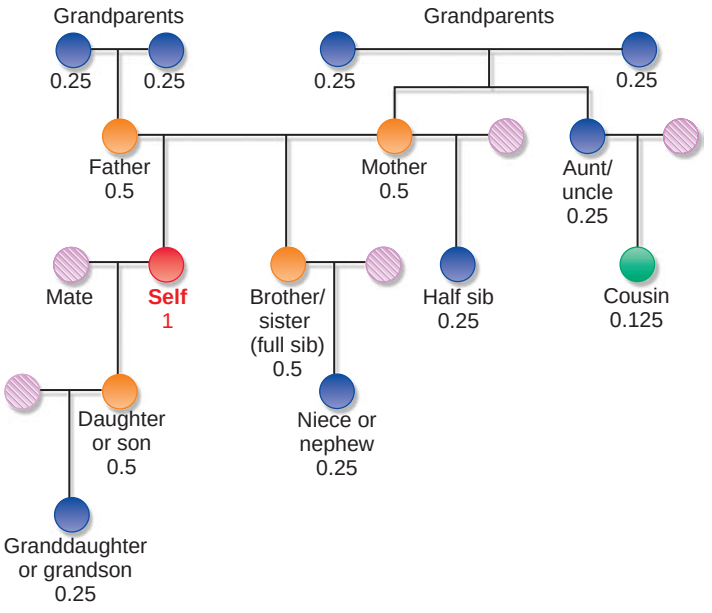

Figure 55.16 **Degree of genetic relatedness to self in a diploid organism.** Pink hatched circles represent completely unrelated individuals.

Concept check: *In theory, should you sacrifice your life to save two sisters or nine cousins?*

implication of the coefficient of relatedness for the evolution of altruism. An organism not only can pass on its genes through having offspring, but also can pass them on through ensuring the survival of siblings, nieces, nephews, and cousins. This means an organism has a vested interest in protecting its brothers and sisters, and even their offspring.

The term **inclusive fitness** is used to designate the total number of copies of genes passed on through one's relatives, as well as one's own reproductive output. Selection for behavior that lowers an individual's own fitness but enhances the reproductive success of a relative is known as **kin selection**. Hamilton proposed that an altruistic gene will be favored by natural selection when

$$rB > C$$

where r is the coefficient of relatedness of donor (the altruist) to the recipient, B is the benefit received by the recipient of the altruism, and C is the cost incurred by the donor. This is known as **Hamilton's rule**.

Imagine two sisters who are not yet mothers. One has a rare kidney disease and needs a transplant from her sister. Let's assume both sisters will have two children of their own. The risk of the transplant to the donor involves a 1% chance of dying, but the benefit to the recipient involves a 90% chance of living and having children. In this example, $r = 0.5$, $B = 0.9 \times 2 = 1.8$, and $C = 0.01 \times 2 = 0.02$. Because the genetic benefit (rB) of 0.9 is much greater than the genetic cost (C) of 0.02, it makes evolutionary sense to proceed with the transplant. While humans are unlikely to do this type of calculation before deciding whether to risk their lives to save their siblings from a life-threatening event, this example shows how such behavior could arise and spread in nature.

Let's examine a situation involving altruism within a group of animals. Many insect larvae, especially caterpillars, are soft-bodied creatures. They rely on possessing a bad taste or toxin to deter predators and advertise this condition with bright warning colors. For example, noxious *Datana ministra* caterpillars, which feed on oaks and other trees, have bright red and yellow stripes and adopt a specific posture with head and tail ends upturned when threatened (Figure 55.17). Unless it is born with an innate avoidance of this prey type, a predator has to kill and eat one of the caterpillars in order to learn to avoid similar individuals in the future. It is of no personal use to the unlucky caterpillar to be killed. However, animals with warning colors often aggregate in kin groups because they hatch from the same egg mass. In this case, the death of one individual is likely to benefit its siblings, which are less likely to be attacked in the future, and thus its genes will be preserved. This explains why the genes for bright color and a warning posture are successfully passed on from generation to generation. In a case where $r = 0.5$, B might be 50, and $C = 1$, the benefit of 25 is greater than 1, so the genes for this behavior will be favored by natural selection.

A common example of altruism in social animals occurs when a sentry raises an alarm call in the presence of a predator. This behavior has been observed in Belding's ground squirrels (*Spermophilus beldingi*). The squirrels feed in groups, with certain individuals acting as sentries and watching for predators. As a predator approaches, the sentry typically gives an alarm call, and the group members retreat into their burrows. Similar behavior occurs in prairie dogs (*Cynomys* spp.) (Figure 55.18). In drawing attention to itself, the caller is at a higher risk of being attacked by the predator. However, in many groups, those closest to the sentry are most likely to be offspring or brothers or sisters; thus, the altruistic act of alarm calling is reasoned to be favored by kin selection. Supporting this is the observation that most alarm calling is done by females, because they are more likely to stay in the colony where they were born

Figure 55.17 **Altruistic behavior or kin selection?** *Datana ministra* caterpillars exhibit a bright, striped warning pattern to advertise their bad taste to predators.

Concept check: *Why do these caterpillars congregate in clusters?*

Figure 55.18 **Alarm calling, a possible example of kin selection.** This prairie dog sentry is emitting an alarm call to warn other individuals, which are often close kin, of the presence of a predator. It is believed that by doing so, the sentry draws attention away from the others but becomes an easier target itself.

and have kin nearby, whereas the males are more apt to disperse far from the colony.

Altruism in Social Insects Arises Partly from Genetics and Partly from Lifestyle

Perhaps the most extreme form of altruism is the evolution of sterile castes in social insects, in which the vast majority of females, known as workers, rarely reproduce themselves but instead help one reproductive female (the queen) to raise offspring, a phenomenon called **eusociality**. The explanation of eusociality lies partly in the particular genetics of most social insect reproduction. Females develop from fertilized eggs and are diploid, the product of fertilization of an egg by a sperm. Males develop from unfertilized eggs and are haploid.

Such a system of sex determination is called the **haplodiploid system** (refer back to Figure 16.14). If they have the same parents, each daughter receives an identical set of genes from her haploid father. The other half of a female's genes comes from her diploid mother, so the coefficient of relatedness (r) of sisters is 0.50 (from father) + 0.25 (from mother) = 0.75. The result is that females are more related to their sisters (0.75) than they would be to their own offspring (0.50). This suggests it is evolutionarily advantageous for females to stay in the nest or hive and care for other female offspring of the queen, which are their full sisters.

Elegant though these types of explanations are, they do not provide the whole picture. Large eusocial colonies of termites exist, but termites are diploid, not haplodiploid. In this case, how do we account for the existence of eusociality?

In the 1970s, Richard Alexander suggested it was the particular lifestyle of these animals, rather than genetics, that promoted eusociality. He argued that in a normal diploid organism, females are related to their daughters by 0.50 and to their sisters by 0.50, so it should matter little to them whether they rear siblings or daughters of their own. He predicted, well before eusociality was discovered to occur in mammals, that a eusocial mammalian species could exist when certain conditions were met, including that the nests or burrows be enclosed and subterranean, in order to house a large colony, and that the colony have a food supply such as large tubers and roots. In addition, the soil would need to be hard, dry clay to keep the colony safe from digging predators. He proposed that the colony would be defended by a few members of the colony willing to give their lives in defense of others, and he posited the existence of mechanisms by which a queen could manipulate other individuals.

At the time, Alexander had no idea that a mammal with such characteristics existed. Surprisingly, subsequent discoveries confirmed the existence of a eusocial mammal that satisfied all of the predictions of Alexander's model: the naked mole rat (*Heterocephalus glaber*). Naked mole rats are diploid species that live in arid areas of Africa in large underground colonies where only one female, the queen, produces offspring (Figure 55.19). A renewable food supply is present in the form of tubers of the plant *Pyrenacantha kaurabassana*. These weigh up to 50 kg and can provide food for a whole colony, though the food would be insufficient if all the mole rats reproduced. Because the burrows are hard packed, there are few ways to attack them, and a heroic effort by a mole rat blocking the entrance can effectively stop a predator (commonly a rufous-beaked snake). The queen mole rat does indeed manipulate the colony members; she suppresses reproduction in other females by producing a pheromone in her urine that is passed around the colony by grooming. Hence, the mole rats seem to have evolved the appropriate behavior to exploit this ecological niche. As Alexander argued, lifestyle characteristics can provide an explanation for the evolution of eusociality in species such as termites and naked mole rats, in which both sexes are diploid.

Figure 55.19 **A naked mole rat colony (*Heterocephalus glaber*).** In this mammalian species, most females do not reproduce; only the queen (shown resting on workers) has offspring.

Unrelated Individuals May Engage in Altruistic Acts If the Altruism Is Likely to Be Reciprocated

Even though we have argued that kin selection can explain instances of apparent altruism, cases of altruism are known to exist between unrelated individuals. What drives this type of behavior appears to be a "You scratch my back, I'll scratch yours" type of reciprocal altruism, in which the cost to the animal of behaving altruistically is offset by the likelihood of a return benefit. This occurs in nature, for example, when unrelated chimps groom each other.

Researcher Gerald Wilkinson has noted that female vampire bats exhibit reciprocal altruism via food sharing. Vampire bats can die after 60 hours without a blood meal, because they can no longer maintain their correct body temperature. Adult females will share their food with their young, the young of other females, and other unrelated females that have not fed. The females and their dependent young roost together in groups of 8 to 12. A hungry female will solicit food from another female by approaching and grooming her. The female being groomed then regurgitates part of her blood meal for the other. The roles of blood donor and recipient are often reversed, and Wilkinson showed that unrelated females are more likely to share with those that had recently shared with them. The probability of a female getting a free lunch is decreased because the roost consists of individuals that remain associated with each other for long periods of time.

55.7 Mating Systems

In many species, the majority of males seem superfluous because one male mates with many females in a local area. If one male can mate with many females, why in most species does the sex ratio remain at approximately 1 to 1? The answer lies with natural selection. Let's consider a hypothetical population that contains 10 females to every male; each male mates, on average, with 10 females. A parent whose children were exclusively sons could expect to have 10 times the number of grandchildren compared to a parent with the same number of daughters. Under such conditions, natural selection would favor the spread of genes for male-producing tendencies, and males would become prevalent in the population. If the population were mainly males, females would be at a premium, and natural selection would favor the spread of genes for female-producing tendencies. Such constraints operate on the numbers of both male and female offspring, keeping the sex ratio at about 1:1. This idea was developed in 1930 by the geneticist Ronald Fisher and has come to be known as Fisher's principle.

Even though the sex ratio is fairly even in most species, that doesn't mean that one female always mates with one male, or vice versa. In many species, mating is **promiscuous**, with each female mating with a different male every year or breeding season. In other species, more lasting pair bonds develop between individuals. In this section, we examine the characteristics of different types of mating systems that occur among animals. Then we explore the role of sexual selection, a type of natural selection in which competition for mates drives the evolution of certain traits.

Figure 55.20 Female choice of males based on nuptial gifts. A male hangingfly, on the left, has presented a nuptial gift, a small moth, to a female, and now mates with her while she consumes the meal.

Sexual Selection Involves Mate Choice and Mate Competition

As we learned in Chapter 24, **sexual selection** promotes traits that will improve an organism's mating success. You will recall that sexual selection can take two forms. In intersexual selection, members of one sex, usually females, choose mates based on particular characteristics, such as the color of plumage or the sound of a courtship song. In intrasexual selection, members of one sex, usually males, compete over partners, and the winner performs most of the matings (refer back to Figure 24.7). Let's explore each of these in a little more detail.

Intersexual Selection Females have many different ways to choose their prospective mates. Female hangingflies (genus *Hylobittacus*) demand a nuptial gift of a food package, an insect prey item that the male has caught (Figure 55.20). Such a nutrient-rich gift may permit females to produce more eggs. The bigger the gift, the longer it takes the female to eat it and the longer the male can copulate with her. Females will not mate with males that do not offer such a package. Female spiders and mantids will sometimes eat their mate during or after copulation, with the male's body constituting the ultimate nuptial gift.

Males may also have parenting skills that females desire. Among 15-spined sticklebacks (*Spinachia spinachia*), males perform cleaning, guarding, and fanning the offspring. Males display their parental skills through body shakes during courtship, and females prefer to mate with males that shake their bodies the most energetically, apparently using this cue to assess the quality of the male as a potential father.

Often, females choose mates without the offering of obvious material benefits and make their choices based on plumage color or courtship display. The male African long-tailed widowbird (*Euplectes progne*) has long tail feathers that he displays to females via aerial flights. Researcher Malte Andersson

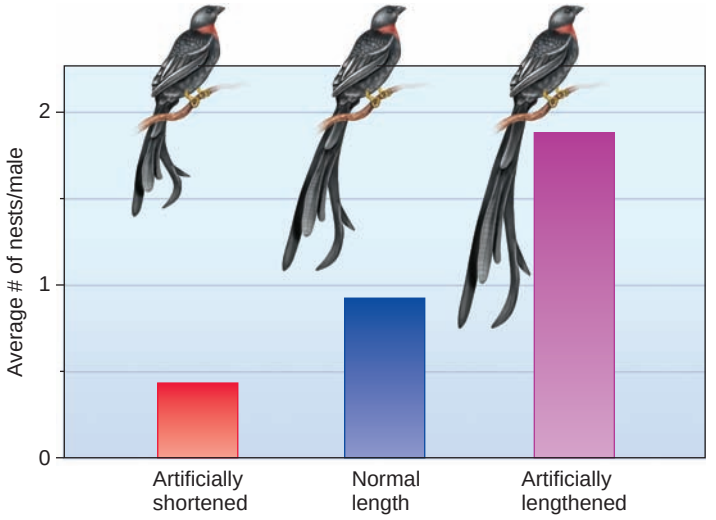

Figure 55.21 **Female choice based on male appearance.** Males with artificially lengthened tails mate with more females and, therefore, have more nests than males with a normal or artificially shortened tail.

Concept check: *Why do you think it is rarer for female birds or mammals to have more colorful plumage or elaborate adornments than males of the same species?*

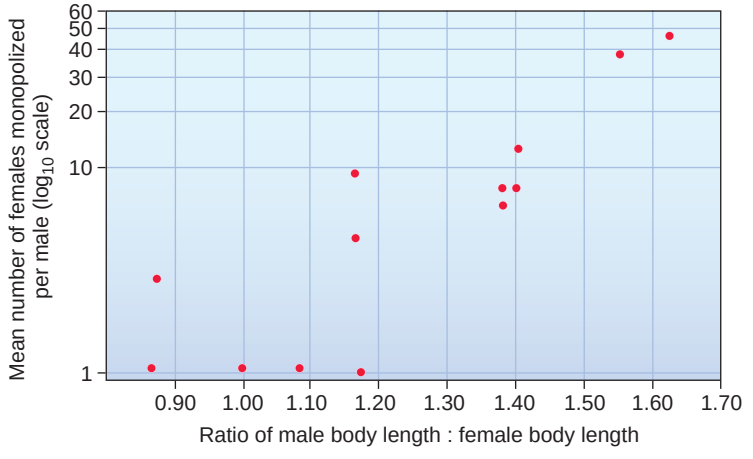
experimentally shortened the tails of some birds by clipping their tail feathers, and he lengthened the tails of others by taking the clippings and sticking them onto other birds with superglue. Males with experimentally lengthened tails attracted four times as many females as males with shortened tails, and they fathered more clutches of eggs (Figure 55.21).

Some researchers have suggested ornaments such as excessively long tail feathers function as a sign of an individual's genetic quality, in that the bearer must be very healthy in order to afford this energetically costly trait. This hypothesis is called the handicap principle. However, in some species of birds, other important benefits may be associated with plumage quality. Bright colors are often caused by pigments called carotenoids that help stimulate the immune system to fight diseases. In zebra finches and red jungle fowl, colorful plumage has been associated with heightened resistance to disease, suggesting that females that choose such males are choosing genetically healthier mates.

On rare occasions, a sex role reversal occurs, and the male discriminates among females. In the Mormon cricket (*Anabrus simplex*), males mate only once because they provide a nutrient-rich nuptial gift of a spermatophore to females, which is energetically costly to produce. Here, males choose heavier females to mate with because these females have more eggs, and the males can father more offspring.

Intrasexual Selection In many species, females do not actively choose their preferred mate; instead, they mate with competitively superior males. In such cases, dominance is determined by fighting or by ritualized sparring. Outcomes may be dictated by the size of weapons, such as antlers or horns, or by body size. In the southern elephant seal (*Mirounga leonina*), females haul up onto the beach to give birth and gain safe haven for their pups from marine predators. Following birth, they are ready to mate. In this situation, dominant males are able to command a substantial group of females and constantly lumber across the beach to fight other males and defend their harem. Over the course of many generations, such competition results in an increased body size. Thus, in species with male–male competition, males are often substantially larger than females (Figure 55.22).

Large body size does not always guarantee paternity. Smaller male elephant seals may intercept females in the ocean and attempt to mate with them there, rather than on the beach,



(a) Relationship between body size and mating success

(b) Male competition for mates

Figure 55.22 **Large male size and mating success.** **(a)** In elephant seals, the larger the male, in relation to female size, the greater the number of females that can be mated with and monopolized. **(b)** These male elephant seals are fighting to maintain control of their female harems.

Concept check: *During fights between males, some pups are crushed as the males lumber across the beach. Why aren't the males careful to avoid the pups?*

where the competitively dominant males patrol. Such "satellite" males, which are unable to acquire and defend territories, move around the edge of the mating arena. For example, small male frogs hang around ponds waiting to intercept females headed toward the call of dominant males. Thus, even though competitively dominant males father most offspring, smaller males can have reproductive success.

In Monogamous Mating Systems, Males and Females Are Paired for at Least One Reproductive Season

Mating success is also dependent on the type of mating system involved. In **monogamy**, each individual mates exclusively with one partner over at least a single breeding cycle and sometimes for longer. Males and females do not exhibit much **sexual dimorphism**, a pronounced difference in the morphologies of the two sexes within a species, and are generally similar in body size and structure (Figure 55.23a). Several hypotheses explain the existence of monogamy. The first is the **mate-guarding hypothesis**, which suggests that males stay with a female to protect her from being fertilized by other males. Such a strategy may be advantageous when receptive females are widely scattered and difficult to find.

The **male-assistance hypothesis** maintains that males remain with females to help them rear their offspring. Monogamy is common among birds, about 70% of which are socially monogamous; that is, the pairings remain intact during at least one breeding season. According to the male-assistance hypothesis, monogamy is prevalent in birds because eggs and chicks take a considerable amount of parental care. Most eggs need to be incubated continuously if they are to hatch, and chicks require almost continual feeding. It is therefore in the male's best interest to help raise his young, because he would have few surviving offspring if he did not.

The **female-enforced monogamy hypothesis** suggests that females stop their male partners from being polygynous. Male and female burying beetles (*Nicrophorus defodiens*) work together to bury small, dead animals, which will provide a food resource for their developing offspring. Males will release pheromones to attract other females to the site. However, while an additional female might increase the male's fitness, the additional developing offspring might compete with the offspring of the first female, decreasing her fitness. As a result, on smelling these pheromones, the first female will interfere with the male's attempts at signaling, preserving the monogamous relationship.

Recent research by Larry Young and Elizabeth Hammock has shown that social behavior such as fidelity may have a genetic basis. These researchers found that fidelity of male voles depends on the length of microsatellites, short repeating genetic sequences, in a gene that codes for a key hormone receptor. Adult male voles with the long version of the microsatellite were more apt to form pair bonds with female partners and nurture their offspring than were voles with the short version.

In Polygynous Mating Systems, One Male Mates with Many Females

In **polygyny** (Greek, meaning many females), one male mates with more than one female in a single breeding season. Physiological constraints often dictate that female organisms must care for the young. Because of these constraints, at least in many organisms with internal fertilization, such as mammals and some fishes, males are able to desert and mate with more females. Polygynous systems are therefore associated with uniparental care of young, with males contributing little. Sexual dimorphism is typical in polygynous mating systems, particularly when males engage in competition over mates (Figure 55.23b). Sexual maturity is often delayed in males that fight because of the considerable time it takes to reach a sufficiently large size to compete for females.

Polygyny is influenced by the spatial or temporal distribution of breeding females. In cases where all females are sexually receptive within the same narrow period of time, little

(a) Monogamous species

(b) Polygynous species

(c) Polyandrous species

Figure 55.23 **Sexual dimorphism in body size and mating system.** **(a)** In monogamous species, such as these Manchurian cranes, *Grus japonensis*, males and females do not exhibit pronounced sexual dimorphism and appear very similar. **(b)** In polygynous species, such as white-tailed deer, *Odocoileus virginianus*, males are bigger than females and have large horns with which they engage in combat over females. **(c)** In polyandrous species, females are usually bigger, as with these golden silk spiders, *Nephila clavipes*.

opportunity exists for a male to garner all the females for himself. Where female reproductive receptivity is spread out over weeks or months, there is much more opportunity for males to mate with more than one female. For example, females of the common toad (*Bufo bufo*) all lay their eggs within a week, and males generally have time to mate with only one female. In contrast, female bullfrogs (*Rana catesbeiana*) have a breeding season of several weeks, and males may mate with as many as six females in a season.

Resource-Based Polygyny Where some critical resource is patchily distributed and in short supply, certain males may dominate the resource and breed with more than one visiting female. In the lark bunting (*Calamospiza melanocorys*), which mates in North American grasslands, males arrive at the grasslands first, compete for territories, and then display with special courtship flight patterns and songs to attract females. The major source of nestling death in this species is overheating from too much exposure to the sun. Prime territories are therefore those with abundant shade, and some males with shaded territories attract two females, even though the second female can expect no help from the male in the process of rearing young. Males in some exposed territories remain bachelors for the season. From the dominant male's point of view, resource-based polygyny is advantageous; from the female's point of view, there may be costs. Although by choosing dominant males, a female may be gaining access to good resources, she will have to share these resources with other females.

Harem Mating Structures Sometimes males defend a group of females without commanding a resource-based territory. This pattern is more common when females naturally congregate in groups or herds, perhaps to avoid predation, as with southern elephant seals (see Figure 55.22). Usually the largest and strongest males command most of the matings, but being a harem master is usually so exhausting that males may only manage to remain the dominant male for a year or two.

Communal Courting Polygynous mating can occur where neither resources nor harems are defended. In some instances, particularly in birds and mammals, males display in designated communal courting areas called **leks** (Figure 55.24). Females come to these areas specifically to find a mate, and they choose a prospective mate after the males have performed elaborate displays. Most females seek to mate with the best male, so a few of the flashiest males perform the vast majority of the matings. At a lek of the white-bearded manakin (*Manacus manacus*) of South America, one male accounted for 75% of the 438 matings where there were as many as 10 males. A second male mated 56 times (13% of matings), while six others mated only a total of 10 times.

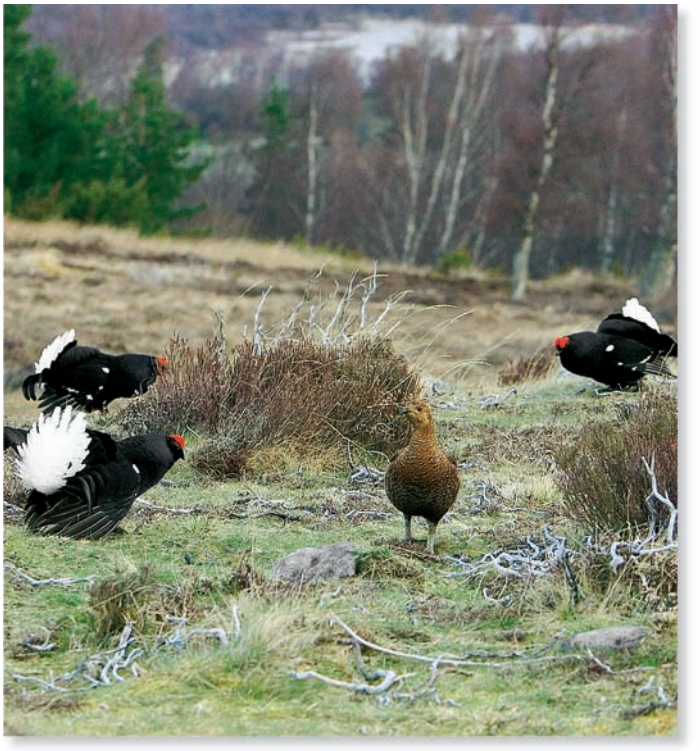


Figure 55.24 **Male birds at a lek.** Black grouse (*Tetrao tetrix*) congregate at a moorland lek in Scotland in April. Females visit the leks, and males display to them.

In Polyandrous Mating Systems, One Female Mates with Many Males

In most systems in which one individual mates with more than one individual of the opposite sex, the polygamous sex is the male. The opposite condition, **polyandry** (Greek, meaning many males), in which one female mates with several males, is more rare. Nevertheless, it occurs in some species of birds, fishes, and insects. Sexual dimorphism is present, with the females being the larger of the sexes (see Figure 55.23c). In the Arctic tundra, the summer season is short but very productive, providing a bonanza of insect food for 2 months. The productivity of the breeding grounds of the spotted sandpiper (*Actitis macularia*) is so high that the female becomes rather like an egg factory, laying up to five clutches of four eggs each in 40 days. Her reproductive success is limited not by food but by the number of males she can find to incubate the eggs, and females compete for males, defending territories where the males sit.

Polyandry is also seen in some species where egg predation is high and males are needed to guard the nests. For example, in the pipefish (*Syngnathus typhle*), males have brood pouches that provide eggs with safety and a supply of oxygen- and nutrient-rich water. Females produce enough eggs to fill the brood pouches of two males and may mate with more than one male.

Ultimately, as we have seen, most behaviors have evolved to maximize an individual's reproductive output. In a successful group of individuals, this leads to population growth. But we are not knee-deep in sandpipers or elephant seals, so there must be some constraints on reproductive output. In Chapter 56, we next turn to the realm of population ecology to explore how populations grow and what factors limit their growth.

Summary of Key Concepts

55.1 The Impact of Genetics and Learning on Behavior

- Behavior is usually due to the interaction of an organism's genes and the environment.
- Genetically programmed behaviors are termed innate and often involve a sign stimulus that initiates a fixed action pattern. (Figures 55.1, 55.2)
- Organisms can often make modifications to their behavior based on previous experience, a process called learning. Some forms of learning include habituation, classical conditioning, operant conditioning, and cognitive learning. (Figures 55.3, 55.4)
- Much behavior is a mixture of innate and learned behaviors. A good example of this occurs in a process called imprinting, in which animals develop strong attachments that influence subsequent behavior. (Figures 55.5, 55.6)

55.2 Local Movement and Long-Range Migration

- The simplest forms of local movement involve kinesis, taxis, and memory. (Figure 55.7)
- Many animals undergo long-range seasonal movement called migration in order to feed or breed. They do this using three proposed mechanisms: piloting, the ability to move from one landmark to the next; orientation, the ability to follow a compass bearing; and navigation, the ability to set, follow, and adjust a compass bearing. (Figures 55.8, 55.9)

55.3 Foraging Behavior

- Animals use complex behavior in food gathering or foraging. Optimality theory views foraging behavior as a compromise between the costs and benefits involved.
- The theory of optimal foraging assumes that animals modify their behavior to keep the ratio of their energy uptake to energy expenditure high. (Figure 55.10)
- The size of a territory, a fixed area in which an individual or group excludes other members of its own species, tends to be optimized according to the costs and benefits involved. (Figure 55.11)

55.4 Communication

- Communication is a form of behavior. The use of different forms of communication between organisms depends on the environment in which they live.
- Chemical communication often involves marking territories; auditory and visual forms of communication are often used to attract mates. A fascinating form of tactile communication involves the dance of the honeybee. (Figures 55.12, 55.13)

55.5 Living in Groups

- Many benefits of group living relate to defense against predators, offering protection through sheer numbers and through what is called the many-eyes hypothesis or the geometry of the selfish herd. (Figure 55.14)

55.6 Altruism

- Infanticide is an example of selfish behavior. (Figure 55.15)
- Altruism is behavior that benefits others at a cost to oneself. One of the first hypotheses to explain altruism, called group selection, suggested that natural selection produced outcomes beneficial for the group. Biologists now believe that most apparently altruistic acts are often associated with outcomes beneficial to those most closely related to the individual, a concept termed kin selection. (Figures 55.16, 55.17, 55.18)
- Altruism among eusocial animals may arise partly from the unique genetics of the animals and partly from lifestyle. (Figure 55.19)
- Altruism is known to exist among nonrelated individuals that live in close proximity for long periods of time.

55.7 Mating Systems

- Sexual selection takes two forms: intersexual selection, in which the female chooses a mate based on particular characteristics, or intrasexual selection, in which males compete with one another for the opportunity to mate with a female. (Figures 55.20, 55.21, 55.22)
- Several types of mating systems are found among animals, including monogamy, polygyny, and polyandry. (Figure 55.23)
- Polygynous mating can often occur in situations where males dominate a resource, defend groups of females (harems), or display in common courting areas called leks. (Figure 55.24)

Assess and Discuss

Test Yourself

1. What is the proximate cause of male deer fighting over females?
   a. to determine their supremacy over other males
   b. to injure other males so that these other males cannot mate with females
   c. to maximize the number of genes they pass on
   d. because changes in day length stimulate this behavior
   e. because fighting helps rid the herd of weaker individuals
2. Geotaxis is a response to the force of gravity. Fruit flies placed in a vial will move to the top of the vial. This is an example of _____ geotaxis.
   a. positive
   b. neutral
   c. innate
   d. negative
   e. learned
3. Certain behaviors seem to have very little environmental influence. Such behaviors are the same in all individuals regardless of the environment and are referred to as _____ behaviors.
   a. genetically programmed
   b. instinctual
   c. innate
   d. all of the above
   e. b and c only

4. Patrick has decided to teach his puppy a few new tricks. Each time the puppy responds correctly to Patrick's command, the puppy is given a treat. This is an example of
   a. habituation.
   b. classical conditioning.
   c. operant conditioning.
   d. imprinting.
   e. orientation.
5. Whales have magnetite in their retinas, which aids in navigation during migration by
   a. piloting.
   b. locating the position of the sun.
   c. use of the Earth's magnetic fields.
   d. locating the positions of the stars.
   e. none of the above.
6. For group living to evolve, the benefits of living in a group must be greater than the costs of group living. Which of the following is an example of a benefit of living in a group?
   a. reduced spread of disease and/or parasites
   b. increased food availability
   c. reduced competition for mates
   d. decreased risk of predation
   e. all of the above
7. The modification of behavior based on prior experience is called
   a. a fixed action pattern.
   b. learning.
   c. navigation.
   d. adjustment behavior.
   e. innate.
8. When an individual behaves in a way that reduces its own fitness but increases the fitness of others, the organism is exhibiting
   a. kin selection.
   b. group selection.
   c. altruism.
   d. selfishness.
   e. ignorance.
9. In ants, which employ a haplodiploid mating system, fathers are related to sons by $r =$
   a. 0
   b. 0.125
   c. 0.25
   d. 0.5
   e. 0.75
10. In a polygynous mating system,
    a. one male mates with one female.
    b. one female mates with many different males.
    c. one male mates with many different females.
    d. many different females mate with many different males.

Conceptual Questions

1. Define ethology.
2. Why does male parental care occur in only 7% of fishes and amphibian families with internal fertilization but in 69% of families with external fertilization?
3. Describe the distinguishing features of the different mating systems.

Collaborative Questions

1. Whooping cranes (*Grus americana*) are an endangered species that are bred in captivity to increase their numbers. One problem is that these cranes are migratory. In the absence of other cranes, can you think of an innovative way human researchers might have used crane behavior to ensure their safe passage to overwintering sites?
2. Discuss several ways in which organisms communicate with each other.

Population Ecology

56

Chapter Outline

A population of black-footed ferrets in Meeteetse, Wyoming.

The last known population of black-footed ferrets, *Mustela nigripes*, was discovered in 1981 near Meeteetse, Wyoming. Shortly thereafter, all but 18 of the 100 known ferrets in Meeteetse died of canine distemper. The remainder were captured between 1985 and 1987, inoculated against distemper, and bred in captivity. Seven females were used as genetic founders for the captive population, with the intent of reestablishing the population in the wild later on. Since then, populations have been established in Arizona, Colorado, Montana, South Dakota, Utah, Wyoming, and Chihuahua, Mexico.

In Wyoming, an area called Shirley Basin was one of those targeted for reintroductions of captive-born animals. During 1991 to 1994, Shirley Basin received 228 ferrets, but distemper again triggered a decline in the population size. By 1997, only 5 ferrets were found. Extinction seemed imminent. Monitoring efforts, which might disturb the animals, decreased. Surprisingly, by 2003, a total of 52 animals were found, and by 2006, 223 were present. How did the population increase this fast?

A **population** can be defined as a group of interbreeding individuals occupying the same area at the same time. In this way, we can think of a population of water lilies in a particular lake, the lion population in the Ngorongoro crater in Africa, or the human population of New York City. The boundaries of a population can be a little difficult to define, though they may correspond to geographic features such as the boundaries of a lake or forest or be contained within a mountain valley or a certain island. Individuals may enter or leave a population, such as the human population of New York City or the deer population in North Carolina. Thus, populations are often fluid entities, with individuals moving into (immigrating) or out of (emigrating) an area.

This chapter explores **population ecology**, the study of what factors affect population size and how these factors change over space and time. To study populations, we need to employ some of the tools of **demography**, the study of birth rates, death rates, age distributions, and the sizes of populations. We begin our discussion by examining the ways that ecologists measure and categorize populations. We will explore characteristics of populations and how growth rates are determined by the number of reproductive individuals in the population and their fertility rate. These data are used to construct simple mathematical models that allow us to analyze and predict population growth. We will also look at the factors that limit the growth of populations and conclude the chapter by using the population concepts and models to explore the growth of human populations.

56.1 Understanding Populations

Within their areas of distribution, organisms occur in varying numbers. We recognize this pattern by saying a plant or animal is "rare" in one place and "common" in another. For more precision, ecologists quantify distribution further and talk in terms of population **density**, the numbers of organisms in a given unit area or volume. Population growth affects population density, and knowledge of both can help us make decisions about the management of species. How long will it take for a population of an endangered species to recover to a healthy level if we protect it from its most serious threats? For example, how quickly will the ferret populations increase in Wyoming? A knowledge of population growth rates and population densities would allow us to predict future ferret population sizes. Since 1994, several large parts of Georges Bank, an area of the sea floor in the North Atlantic that was once one of the world's

richest fishing grounds, have been closed to commercial fishing because of overfishing. How many fishes can we reasonably trawl from the sea and still ensure that an adequate population will exist for future use? Such information is vital in making determinations of size limits, catch quotas, and length of season for fisheries to ensure an adequate future population size.

In this section, we will examine density and other characteristics of populations within their habitats. We will also discuss the different reproductive strategies organisms use and how ecologists assign individuals to different groups called age classes.

Ecologists Use Many Different Methods to Quantify Population Density

The simplest method to measure population density is to visually count the number of organisms in a given area. We can reasonably do this only if the area is small and the organisms are relatively large. For example, we can readily determine the number of gumbo limbo trees (*Bursera simaruba*) on a small island in the Florida Keys. Normally, however, population ecologists calculate the density of plants or animals in a small area and use this figure to estimate the total abundance over a larger area.

For plants, algae, or other sessile organisms such as intertidal animals, it is fairly easy to count numbers of individuals per square meter or, for larger organisms such as trees, numbers per hectare (an area of land equivalent to 2.471 acres). However, many plant individuals are clonal; that is, they grow in patches of genetically identical individuals, so that rather than count individuals, we can also use the amount of ground covered by plants as an estimate of vegetation density.

Plant ecologists use a sampling device called a **quadrat**, a square frame that often, but not always, measures 50 x 50 cm and encloses an area of 0.25 m^2 (Figure 56.1a). They then count the numbers of plants of a given species inside the quadrat to obtain a density estimate per m^2. For example, if you counted densities of 20, 35, 30, and 15 plants in four quadrats, you could reliably say that the density of this species was 25 individuals per 0.25 m^2, or 100 individuals per m^2. For larger plants, such as trees, a quadrat would be ineffective. To count such organisms, many ecologists perform a **line transect**, in which a long piece of string is stretched out and any tree along its length is counted. For example, to count tree species on larger islands in the Florida Keys, we could lay out a 100-m line transect and count all the trees within 1 m on either side of the transect. In effect, this transect is little more than a long thin quadrat encompassing 200 m^2. By performing five such transects, we could obtain estimates of tree density per 1,000 m^2 and then extrapolate that to a number per hectare or per island.

Several different sampling methods exist for quantifying the density of animals, which are more mobile than plants. Suction traps, like giant aerial vacuum cleaners, can suck flying insects from the sky. Pitfall traps set into the ground can catch species such as spiders, lizards, or beetles wandering over the surface, (Figure 56.1b). Sweep nets can be passed over vegetation to dislodge and capture the insects feeding there. Mist nets, consisting of very fine netting spread between trees, can entangle flying birds and bats (Figure 56.1c). Baited snap traps, such as mouse traps, or live traps can snare terrestrial animals (Figure 56.1d). Population density can thus be estimated as the number of animals caught per trap or per unit area where a given number of traps are set, for example, 10 traps per 100 m^2 of habitat.

Sometimes population biologists will capture animals and then tag and release them (Figure 56.2). The rationale behind the **mark-recapture technique** is that after the tagged animals are released, they mix freely with unmarked individuals and within a short time are randomly mixed within the population. The population is resampled, and the numbers of marked and unmarked individuals are recorded. We assume that the ratio of marked to unmarked individuals in the second sample is the

(a) Quadrat (b) Pitfall trap (c) Mist net (d) Live mammal trap

Figure 56.1 **Sampling techniques.** **(a)** Quadrats are frequently used to count the number of plants per unit area. **(b)** Pitfall traps set into the ground catch wandering species such as beetles and spiders. **(c)** Mist nets consisting of very fine mesh entangle birds or bats. **(d)** Baited live traps catch terrestrial animals, including Komodo dragons, as here on Rinca Island, Indonesia.

Figure 56.2 The mark-recapture technique to estimate population size. An ear tag identifies this Rocky Mountain goat (*Oreamnos americanus*) in Olympic National Park, Washington. Recapture of such marked animals permits estimates of population size.

Concept check: If we mark 110 Rocky Mountain goats and recapture 100 goats, 20 of which have ear tags, what is the estimate of the total population size?

same as the ratio of marked individuals in the first sample to the total population size. Thus,

$$\frac{\text{Number of individuals marked in first catch}}{\text{Total population size, } N} = \frac{\text{Number of marked recaptures in second catch}}{\text{Total number of second catch}}$$

Let's say we catch 50 largemouth bass in a lake and mark them with colored fin tags. A week later, we return to the lake and catch 40 fish and 5 of them are previously tagged fish. If we assume no immigration or emigration has occurred, which is quite likely in a closed system like a lake, and we assume there have been no births or deaths of fish, then the total population size is given by rearranging the equation:

$$\text{Total population size, } N = \frac{\text{Number of marked individuals in first catch} \times \text{Total number of second catch}}{\text{Number of marked recaptures in second catch}}$$

Using our data,

$$N = \frac{50 \times 40}{5} = \frac{2{,}000}{5} = 400$$

From this equation, we estimate that the lake has a total population size of 400 largemouth bass. This could be useful information for game and fish personnel who wish to know the total size of a fish population in order to set catch limits.

However, the mark-recapture technique can have drawbacks. Some animals that have been marked may learn to avoid the traps. Recapture rates will then be low, resulting in an overestimate of population size. Imagine that instead of 5 tagged fish out of 40 recaptured fish, we get only 2 tagged fish. Now our population size estimate is 2,000/2 = 1,000, a dramatic increase in our population size estimate. On the other hand, some animals can become trap-happy, particularly if the traps are baited with food. This would result in an underestimate of the population size.

Because of the limitations of the mark-recapture technique, ecologists also use other, more novel methods to estimate population density. For some larger terrestrial or marine species, captured animals can be fitted with radio-collars and followed telemetrically, using an antennal tracking device. Their home ranges can be determined and population estimates developed based on the area of available habitat. For many species with valuable pelts, we can track population densities through time by examining pelt records taken from trading stations. We can also estimate relative population density by examining catch per unit effort, which is especially valuable in commercial fisheries. We can't easily expect to count the number of fishes in an area of ocean, but we can count the number caught, say, per 100 hours of trawling. For some species that leave easily recognizable fecal pellets, like rabbits or deer, we can count pellet numbers, and, if we know the pellet production per individual and how long pellets last in the environment, we can estimate population size. For frogs or birds, we can count chorusing or singing individuals. We can also count leaf scars or chewed leaves and, if we know the responsible herbivores and the rates of herbivory, use these as an estimate of the density of the animals that damage them.

Patterns of Spacing Individuals within a population can show different patterns of **dispersion**; that is, they can be clustered together or spread out to varying degrees. The three basic kinds of dispersion patterns are clumped, uniform, and random. We can visualize these patterns by imagining people in a meeting room. If some people know each other, they get together in small groups, creating a clumped pattern. If people do not know each other and are perhaps even wary of each other, they might maintain a certain minimum personal distance between themselves to produce a uniform dispersion. If nobody thinks or cares about their position relative to anyone else, we would get a random dispersion.

The type of dispersion observed in nature can tell us a lot about what processes shape group structure. The most common dispersion pattern is **clumped**, because resources in nature tend to be clustered. For example, certain plants may do better in moist conditions, and moisture is greater in low-lying areas (Figure 56.3a). Social behavior between animals that aggregate into flocks or herds reflects a clumped pattern.

On the other hand, competition may cause a **uniform** dispersion pattern between individuals, as between trees in a

(a) Clumped (b) Uniform (c) Random

Figure 56.3 **Three types of dispersion.** **(a)** A clumped distribution pattern, as in these plants clustered around an oasis, often results from the uneven distribution of a resource, in this case, water. **(b)** A uniform distribution pattern, as in these nesting black-browed albatrosses (*Diomedea melanophris*) on the Falkland Islands, may be a result of competition or social interactions. **(c)** A random distribution pattern, as in these bushes at Leirhnjukur Volcano in Iceland, is the least common form of spacing.

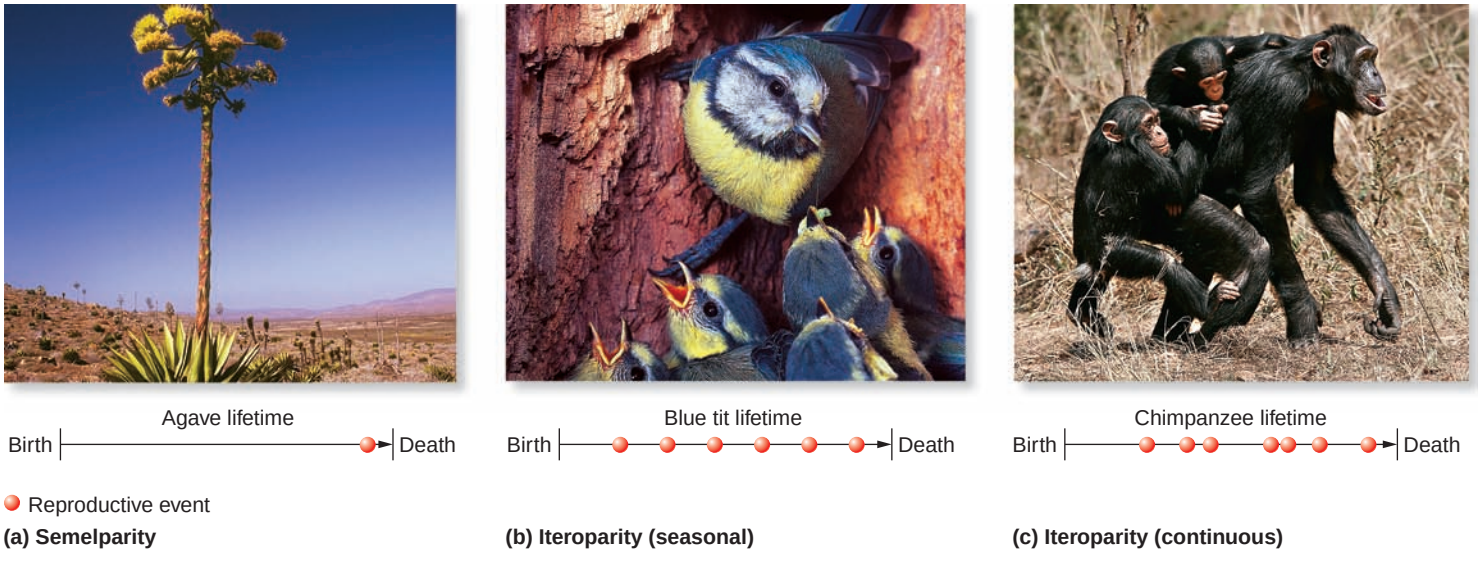
Concept check: *What is the distribution pattern of students in a half-empty classroom?*

forest. At first, the pattern of trees and seedlings may appear random as seedlings develop from seeds dropped at random, but competition between roots may cause some trees to be outcompeted by others, causing a thinning out and resulting in a relatively uniform distribution. Thus, the dispersion pattern starts out random but ends up uniform. Uniform dispersions may also result from social interactions, as between some nesting birds, which tend to keep an even distance from each other (Figure 56.3b).

Perhaps the rarest dispersion pattern is **random**, because resources in nature are rarely randomly spaced. Where resources are common and abundant, as in moist, fertile soil, the dispersion patterns of plants may lack a pattern (Figure 56.3c).

Reproductive Strategies To better understand how populations grow in size, let's consider their reproductive strategies. Some organisms produce all of their offspring in a single reproductive event. This pattern, called **semelparity** (from the Latin *semel*, meaning once, and *parere*, meaning to bear), is common in insects and invertebrates and also occurs in organisms such as salmon, bamboo grasses, and agave plants (Figure 56.4a). These individuals reproduce once only and die. Semelparous organisms may live for many years before reproducing, like agaves, or they may be annual plants that develop from seed, flower, and drop their own seed within a year.

Other organisms reproduce in successive years or breeding seasons. The pattern of repeated reproduction at intervals



(a) Semelparity (b) Iteroparity (seasonal) (c) Iteroparity (continuous)

Figure 56.4 **Differences in reproductive strategies.** Species such as **(a)** agave plants (*Agave shawii*) are semelparous, meaning they breed once in their lifetime and then die. This contrasts with **(b)** blue tits (*Parus caeruleus*) and **(c)** chimpanzees (*Pan troglodytes*), which are iteroparous and breed more than once in their lifetime.

throughout the life cycle is called **iteroparity** (from the Latin *itero*, meaning to repeat). It is common in most vertebrates, perennial plants, and trees. Among iteroparous organisms, much variation occurs in the number of reproductive events and in the number of offspring per event. Many species, such as birds or trees in temperate areas, have distinct breeding seasons (seasonal iteroparity) that lead to distinct generations (Figure 56.4b). For a few species, individuals reproduce repeatedly and at any time of the year. This is termed continuous iteroparity and is exhibited by some tropical species, many parasites, and many primates (Figure 56.4c).

Why do species reproduce in a semelparous or iteroparous mode? The answer may lie in part in environmental uncertainty. If survival of juveniles is very poor and unpredictable, then selection favors repeated reproduction and long reproductive life to increase the chance that juveniles will survive in at least some years. This is often referred to as bet-hedging. If the environment is stable, then selection favors a single act of reproduction, because the organism can devote all its energy to making offspring, not maintaining its own body. Under favorable circumstances, annual plants produce more seeds per unit biomass than trees, which have to invest a lot of energy in maintenance. However, when the environment becomes stressful, annuals run the risk of their seeds not germinating. They must rely on some seeds successfully lying dormant and germinating after the environmental stress has ended.

Age Classes The reproductive strategy employed by an organism has a strong effect on the subsequent age classes of a population. Semelparous organisms often produce groups of same-aged young called **cohorts** that grow at similar rates. Iteroparous organisms generally have many young of different ages because the parents reproduce frequently. The age classes of populations can be characterized by specific categories, such as years in mammals, stages (eggs, larvae, or pupae) in insects, or size in plants.

We expect that a population increasing in size should have a large number of young, whereas a decreasing population should have few young. An imbalance in age classes can have a profound influence on a population's future. For example, in an overexploited fish population, the larger, older reproductive age classes are often removed. If the population experiences reproductive failure for 1 or 2 years, there will be no young fish to move into the reproductive age class to replace the removed fish, and the population may collapse. Other populations experience removal of younger-age classes. In the Florida Keys, where populations of Key deer are high, they overgraze the vegetation and eat many young Gumbo limbo trees, leaving older trees, whose foliage is too tall for them to reach (Figure 56.5). This can have disastrous effects on the future population of trees, for while the forest might consist of healthy mature trees, when these die, there will be no replacements. To accurately examine how populations grow, we need to examine and understand the demography of the population.

56.2 Demography

One way to determine how a population will change is to examine a cohort of individuals from birth to death. For most animals and plants, this involves marking a group of individuals in a population as soon as they are born or germinate and following

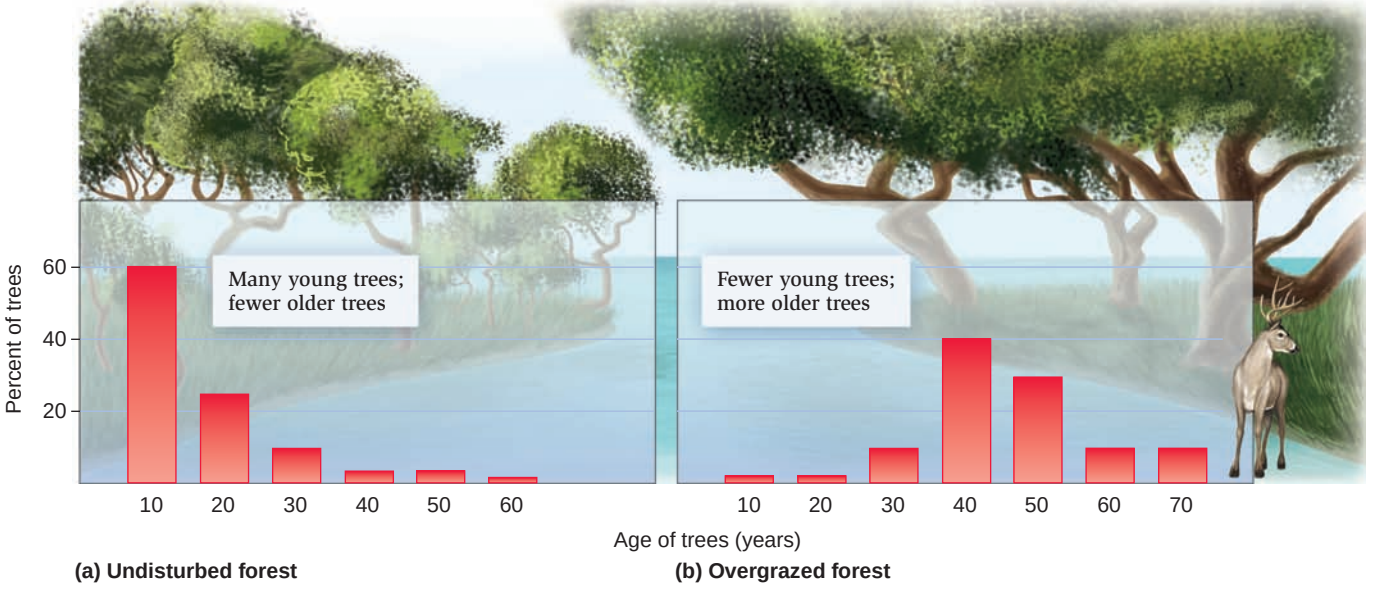


Figure 56.5 **Theoretical age distribution of two populations of Gumbo limbo trees in the Florida Keys.** **(a)** Age distribution of an island with no Key deer with numerous young trees, many of which die as the trees age and compete with one another for resources, leaving relatively few big, older trees. **(b)** Age distribution of a forest where overgrazing by Key deer has reduced the abundance of young trees, leaving only trees in the older age classes.

their fate through their lifetime. For some long-lived organisms such as tortoises, elephants, or trees, this is impractical, so a snapshot approach is used, in which researchers examine the age structure of a population at one point in time. Recording the presence of juveniles and mature individuals, researchers use this information to construct a **life table**, a table providing data on the number of individuals alive in each particular age class. Age classes can be created for any time period, but they often represent 1 year. Males are not usually included in these tables, because they are typically not the limiting factor in population growth. **Demography** is the study of how births and deaths change population sizes over time. In this section, we will determine how to construct life tables and plot survivorship curves, which show at a glance the general pattern of population survival over time. With a knowledge of life tables and additional information on birth rates, we can predict how populations will grow.

Life Tables and Survivorship Curves Summarize Survival Patterns

Let's examine a life table for the North American beaver (*Castor canadensis*). Prized for their pelts, by the mid-19th century, these animals had been hunted and trapped to near extinction. Beavers began to be protected by laws in the 20th century, and populations recovered in many areas, often growing to what some considered to be nuisance status. In Newfoundland, Canada, legislation supported trapping as a management technique. From 1964 to 1971, trappers provided mandibles from which teeth were extracted for age classification. If many mandibles were obtained from, say, 1-year-old beavers, then such animals were probably common in the population. If the number of mandibles from 2-year-old beavers was low, then we know there was high mortality for the 1-year-old age class. From the mandible data, researchers constructed a life table (Table 56.1). The number of individuals alive at the start of the time period (in this case, a year) is referred to as n_x, where n is the number, and x refers to the particular age class. By subtracting the value of n_x from the number alive at the start of the previous year, we can calculate the number dying in a given age class or year, d_x. Thus $d_x = n_x - n_{x+1}$. For example, in Table 56.1, 273 beavers were alive at the start of their sixth year (n_5), and only 205 were alive at the start of the seventh year (n_6); thus, 68 died during the sixth year: $d_5 = n_5 - n_6$, or $d_5 = 273 - 205 = 68$.

A simple but informative exercise is to plot numbers of surviving individuals at each age, creating a **survivorship curve** (Figure 56.6). The value of n_x, the number of individuals, is typically expressed on a log scale. Ecologists use a log scale to examine rates of change with time, not change in absolute numbers. Although we could accomplish the same thing with a linear scale, the use of logs makes it easier to examine a wide range of population sizes. For example, if we start with 1,000 individuals and 500 are lost in year 1, the log of the decrease is

$$\log_{10}1{,}000 - \log_{10}500 = 3.0 - 2.7 = 0.3 \text{ per year}$$

If we start with 100 individuals and 50 are lost, the log of the decrease is similarly

$$\log_{10}100 - \log_{10}50 = 2.0 - 1.7 = 0.3 \text{ per year}$$

In both cases, the rates of change are identical, even though the absolute numbers are different. Plotting the n_x data on a log scale ensures that regardless of the size of the starting

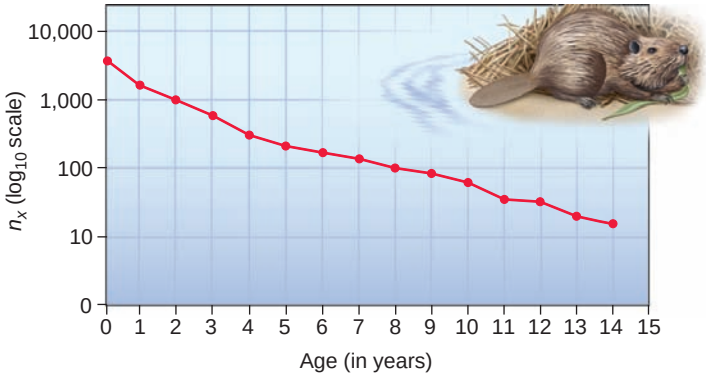

Figure 56.6 **Survivorship curve for the North American beaver.** The survivorship curve is generated by plotting the number of surviving individuals, n_x, from any given cohort of young, usually measured on a log scale, against age. This survivorship curve shows a fairly uniform rate of decline through time.

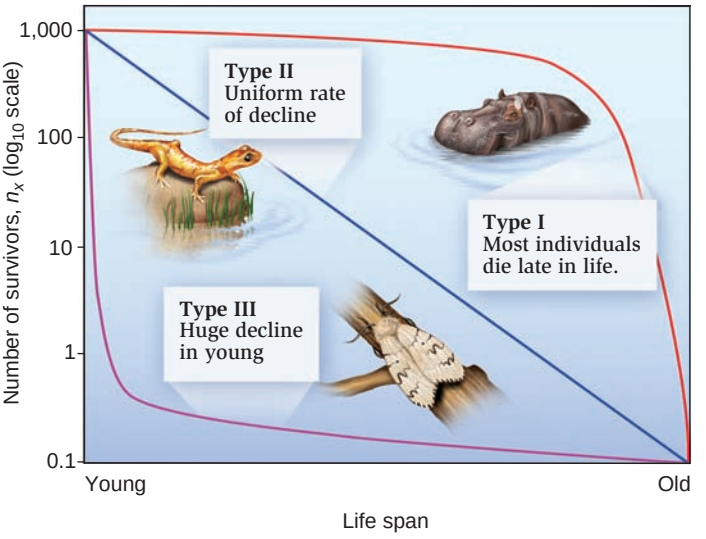

Figure 56.7 **Idealized survivorship curves.**

Concept check: *Which type of survivorship curve would you expect in (a) mussels and (b) turtles?*

population, the rate of change of one survivorship curve can easily be compared to that of another species.

Survivorship curves generally fall into one of three patterns (Figure 56.7). In a type I curve, the rate of loss for juveniles is relatively low, and most individuals are lost later in life, as they become older and more prone to sickness and predators (see Feature Investigation that follows). Organisms that exhibit type I survivorship have relatively few offspring but invest much time and resources in raising their young. Many large mammals, including humans, exhibit type I curves. At the other end of the scale is a type III curve, in which the rate of loss for juveniles is relatively high, and the survivorship curve flattens out for those organisms that have avoided early death. Many fishes and marine invertebrates fit this pattern. Most of the juveniles die or are eaten, but a few reach a favorable habitat and thrive. For example, once they find a suitable rock face on which to attach themselves, barnacles grow and survive very well. Many insects and plants also fit the type III survivorship curve, because they lay many eggs or release hundreds of seeds, respectively. Type II curves represent a middle ground, with fairly uniform death rates over time. Species with type II survivorship curves include many birds, small mammals, reptiles, and some annual plants. The North American beaver population exhibits this survivorship curve. Keep in mind, however, that these are generalized curves and that few populations fit them exactly.

Feature Investigation

Murie's Collections of Dall Mountain Sheep Skulls Permitted Accurate Life Tables to Be Constructed

The Dall mountain sheep (*Ovis dalli*) lives in mountainous regions, including the Arctic and sub-Arctic regions of Alaska. In the late 1930s, the U.S. National Park Service was bombarded with public concerns that wolves were responsible for a sharp decline in the population of Dall mountain sheep in Denali National Park (then Mt. McKinley National Park). Shooting the wolves was advocated as a way of increasing the number of sheep. Because meaningful data on sheep mortality were nonexistent, the Park Service enlisted biologist Adolph Murie to collect relevant information. In addition to spending many hours observing interactions between wolves and sheep, Murie also collected sheep skulls, determining the sheep's age at death by counting annual growth rings on the horns.

In 1947, Edward Deevey put Murie's data in the form of a life table that listed each age class and the number of skulls in it (Figure 56.8). Although Murie had collected 608 skulls, Deevey expressed the data per 1,000 individuals to allow for comparison with other life tables. From the data, Deevey constructed a survivorship curve. For the Dall mountain sheep in Denali National Park, there was a slight initial decline in survivorship as young lambs were lost; then the survivorship curve flattened out, indicating that the sheep survived well through about age 7 or 8. Then the number of sheep declined rapidly as they aged. These data underlined what Murie had previously observed, which was that wolves preyed primarily on the most vulnerable members of the sheep population—the youngest and the oldest. Such predation would not be expected to dramatically reduce the sheep population. The Park Service ultimately ended a limited wolf-control program that had been in effect since 1929.

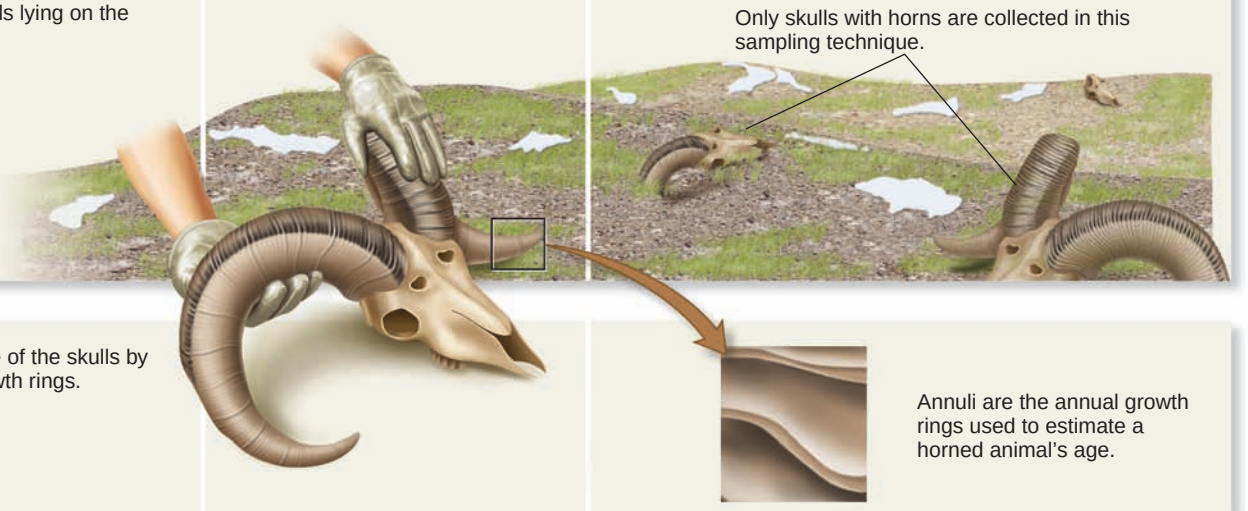
Figure 56.8 Examining the survivorship curve of a Dall mountain sheep population reveals information on the cause of death.

HYPOTHESIS Culling the wolf population would protect reproductively active adults in the Dall mountain sheep population.

STARTING LOCATION Denali National Park (formerly known as Mt. McKinley National Park) in Alaska, where wolf predation of sheep is common.

Experimental level | **Conceptual level**

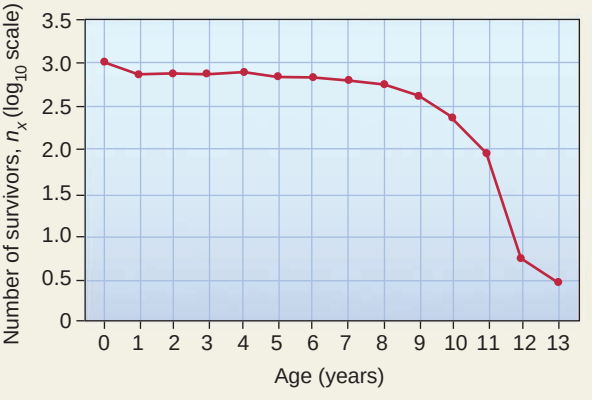
1 Collect sheep skulls lying on the ground.



2 Determine the age of the skulls by counting their growth rings.

Annuli are the annual growth rings used to estimate a horned animal's age.

3 Organize the data into a life table (see step 4) and construct a survivorship curve using the data.



Survivorship curve for the Dall mountain sheep shows the number of sheep alive in each age class on a log scale, plotted against age in years.

4 THE DATA

Results used in step 3:

Age class	Number alive, n_x	$\log_{10} n_x$	Age class	Number alive, n_x	$\log_{10} n_x$
0–1	1,000	3.00	7–8	640	2.81
1–2	801	2.90	8–9	571	2.76
2–3	789	2.90	9–10	439	2.64
3–4	776	2.89	10–11	252	2.40
4–5	764	2.88	11–12	96	1.98
5–6	734	2.86	12–13	6	0.78
6–7	688	2.84	13–14	3	0.48

5 **CONCLUSION** Most Dall mountain sheep die when very young or very old. Culling the wolf population would not greatly increase sheep survival.

Experimental Questions

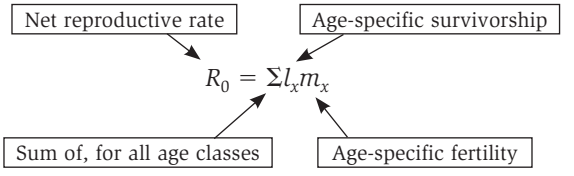
1. What problem led to the study conducted by Murie on the Dall mountain sheep population of Denali National Park?
2. Describe the survivorship curve developed by Deevey based on Murie's data.
3. How did the Murie and Deevey data affect the decision of the Park Service on the control of the wolf population?

Age-Specific Fertility Data Can Help to Predict Population Growth

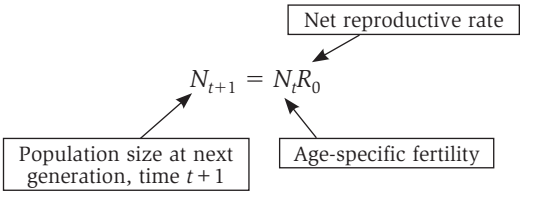
To calculate how a population grows, we need information on birth rates as well as mortality and survivorship rates. For any given age, we can determine the proportion of female offspring that are born to females of reproductive age. Using these data, we can determine an **age-specific fertility rate**, called m_x. For example, if 100 females of a given age produce 75 female offspring, $m_x = 0.75$. With this additional information, we can calculate the growth rate of a population.

First, we use the survivorship data to find the proportion of individuals alive at the start of any given age class. This age-specific survivorship rate, termed l_x, equals n_x/n_0, where n_0 is the number alive at time 0, the start of the study, and n_x is the number alive at the beginning of age class x. Let's return to the beaver life table in Table 56.1. The proportion of the original beaver population still alive at the start of the sixth age class, l_5, equals $n_5/n_0 = 273/3{,}695$, or 0.074. This means that 7.4% of the original beaver population survived to age 5. Next we multiply the data in the two columns, l_x and m_x, for each row, to give us a column l_xm_x, an average number of offspring per female. This column represents the contribution of each age class to the overall population growth rate. An examination of the beaver age-specific fertility rates illustrates a couple of general points. First, for this beaver population in particular, and for many organisms in general, there are no babies born to young females. As females mature sexually, age-specific fertility goes up, and it remains fairly high until later in life, when females reach postreproductive age.

The number of offspring born to females of any given age class depends on two things: the number of females in that age class and their age-specific fertility rate. Thus, although fertility of young beavers is very low, there are so many females in the age class that l_xm_x for 1-year-olds is quite high. Age-specific fertility for older beavers is much higher, but the relatively few females in these age classes cause l_xm_x to be low. Maximum values of l_xm_x occur for females of an intermediate age, 3–4 years old in the case of the beaver. The overall growth rate per generation is the number of offspring born to all females of all ages, where a generation is defined as the mean period between birth of females and birth of their offspring. Therefore, to calculate the generational growth rate, we sum all the values of l_xm_x, that is, Σl_xm_x, where the Σ symbol means "sum of." This summed value, R_0, is called the **net reproductive rate**.



To calculate the future size of a population, we simply multiply the number of individuals in the population by the net reproductive rate. Thus, the population size in the next generation, N_{t+1}, is determined by the number in the population now, at time t, which is given by N_t, multiplied by R_0.



Let's consider an example in which the number of beavers alive now, N_t, is 1,000, and $R_0 = 1.1$. This means the beaver population is reproducing at a rate that is 10% greater than simply replacing itself. The size of the population next generation, N_{t+1}, is given by

$$N_{t+1} = N_t R_0$$
$$N_{t+1} = 1{,}000 \times 1.1$$
$$= 1{,}100$$

Therefore, the number of beavers in the next generation is 1,100, and the population will have grown larger.

In determining population growth, much depends on the value of R_0. If $R_0 > 1$, then the population will grow. If $R_0 < 1$, the population is in decline. If $R_0 = 1$, the population size stays the same, and we say it is at **equilibrium**. In the case of the

beavers, Table 56.1 reveals that $R_0 = 0.938$, which is less than 1, and, therefore, the population is declining. This is valuable information, because it tells us that at that time, the beaver population in Newfoundland needed more protection (perhaps in the form of bans on trapping and hunting) in order to attain a population level at equilibrium.

Because of the effort involved in calculating R_0, the net reproductive rate, ecologists sometimes use a shortcut to predict population growth. Imagine a bird species that breeds annually. To measure population growth, ecologists count the number of birds in the population, N_0. Let's say $N_0 = 100$. The next year, ecologists count 110 birds in the same population, so $N_1 = 110$. The **finite rate of increase**, λ, is the ratio of the population size from one year to the next, calculated as

$$\lambda = N_1/N_0$$

In this case, $\lambda = 1.10$. λ is often given as percent annual growth, and t is a number of years. Let's consider a population of birds growing at a rate of 5% per year. After 5 years, how many birds would there be?

$$N_t = 100,\ \lambda = 1.05, \text{ and } t = 5$$
$$\text{therefore, } N_{t+5} = 100\ (1.05)^5 = 127.6$$

What's the difference between R_0 and λ? R_0 represents the net reproductive rate per generation. λ represents the finite rate of population change over some time interval, often a year. Where species are annual breeders that live 1 year, such as annual plants, $R_0 = \lambda$. For species that breed for multiple years, $R_0 \neq \lambda$. Just as

$$N_t = N_0 R_0{}^t, \text{ where } t = \text{a number of generations}$$
$$\text{so } N_t = N_0 \lambda^t, \text{ where } t = \text{a number of time intervals}$$

Populations grow when R_0 or $\lambda > 1$; populations decline when R_0 or $\lambda < 1$; and they are at equilibrium when R_0 or $\lambda = 1$.

56.3 How Populations Grow

Life tables can provide us with accurate information about how populations can grow from generation to generation. However, other population growth models can provide us with valuable insights into how populations grow over shorter time periods. The most simple of these assumes that populations grow if, for any given time interval, the number of births is greater than the number of deaths. In this section, we will examine two different types of these simple models. The first assumes resources are not limiting, and it results in prodigious growth. The second, and perhaps more biologically realistic, assumes resources are limiting, and it results in limits to growth and eventual stable population sizes. We then consider how other factors might limit population growth, such as natural enemies, and discuss the overall life history strategies exhibited by different species that enable them to exist on Earth.

Knowing the Per Capita Growth Rate Helps Predict How Populations Will Grow

The change in population size over any time period can be written as the number of births per unit time interval minus the number of deaths per unit time interval.

For example, if in a population of 1,000 rabbits, there were 100 births and 50 deaths over the course of 1 year, then the population would grow in size to 1,050 the next year. We can write this formula mathematically as

$$\frac{\text{Change in numbers}}{\text{Change in time}} = \text{Births} - \text{Deaths}$$

or

$$\frac{\Delta N}{\Delta t} = B - D$$

The Greek letter delta, Δ, indicates change, so that ΔN is the change in number, and Δt is the change in time; B is the number of births per time unit; and D is the number of deaths per time unit.

Often, the numbers of births and deaths are expressed per individual in the population, so the birth of 100 rabbits to a population of 1,000 would represent a per capita birth rate, b, of 100/1,000, or 0.10. Similarly, the death of 50 rabbits in a population of 1,000 would be a per capita death rate, d, of 50/1,000, or 0.05. Now we can rewrite our equation giving the rate of change in a population.

$$\frac{\Delta N}{\Delta t} = bN - dN$$

For our rabbit example,

$$\frac{\Delta N}{\Delta t} = 0.10 \times 1{,}000 - 0.05 \times 1{,}000 = 50$$

so if $\Delta t = 1$ year, the rabbit population would increase by 50 individuals in a year.

Ecologists often simplify this formula by representing $b - d$ as r, the **per capita growth rate**. Thus, $bN - dN$ can be written as rN. Because ecologists are also interested in population growth rates over very short time intervals, so-called instantaneous growth rates, instead of writing

$$\frac{\Delta N}{\Delta t}$$

they write

$$\frac{dN}{dt}$$

which is the notation of differential calculus. The equations essentially mean the same thing, except that dN/dt reflects very short time intervals. Thus,

$$\frac{dN}{dt} = rN = (0.10 - 0.05)N = 50$$

Exponential Growth Occurs When the Per Capita Growth Rate Remains Above Zero

How do populations grow? Clearly, much depends on the value of the per capita growth rate, r. When $r < 0$, the population decreases; when $r = 0$, the population remains constant; and when $r > 0$, the population increases. When $r = 0$, the population is often referred to as being at equilibrium, where no changes in population size will occur and there is **zero population growth**.

Even if r is only fractionally above 0, population increase is rapid, and when plotted graphically, a characteristic J-shaped curve results (Figure 56.9). We refer to this type of population growth as geometric, or **exponential growth**. When conditions are optimal for the population, r is at its maximum rate and is called the **intrinsic rate of increase** (denoted r_{max}). Thus, the rate of population growth under optimal conditions is $dN/dt = r_{max}N$. Again, the larger the value of r_{max}, the steeper the slope of the curve. Because population growth depends on the value of N as well as the value of r, the population increase is even greater as time passes.

How do field data fit this simple model for exponential growth? Population growth cannot go on forever, as envisioned under exponential growth. But initially at least, in a new and expanding population where resources are not limited, exponential growth is often observed. Let's look at a few examples. Tule elk (*Cervus elaphus nannodes*) is a subspecies of elk that is native to California. Hunted nearly to extinction in the 19th century, less than a dozen individuals survived on a private ranch. In the 20th century, reintroductions resulted in the recovery of tule elk to around 3,500 individuals. One reintroduction was made in March 1978 at Point Reyes National Seashore in California, where 10 animals—2 males and 8 females—were released. By 1993, the herd had reached 214 individuals, and it continued to grow in an exponential fashion until 1998, when the herd size stood at 549 (Figure 56.10a). This was deemed an excessive number for the size of the available habitat, and animals were removed to begin herds in other locations. Since then, herd size at Point Reyes has been maintained at around 350.

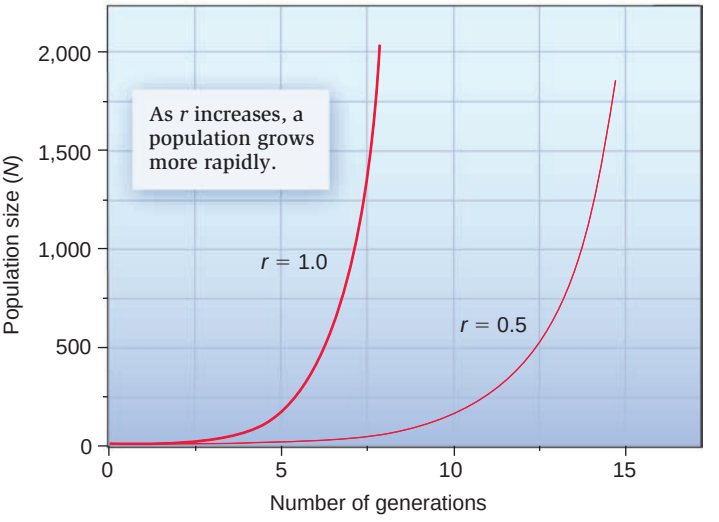


Figure 56.9 **Exponential population growth.** As the value of r increases, the slope of the curve gets steeper. In theory, a population with unlimited resources could grow indefinitely.

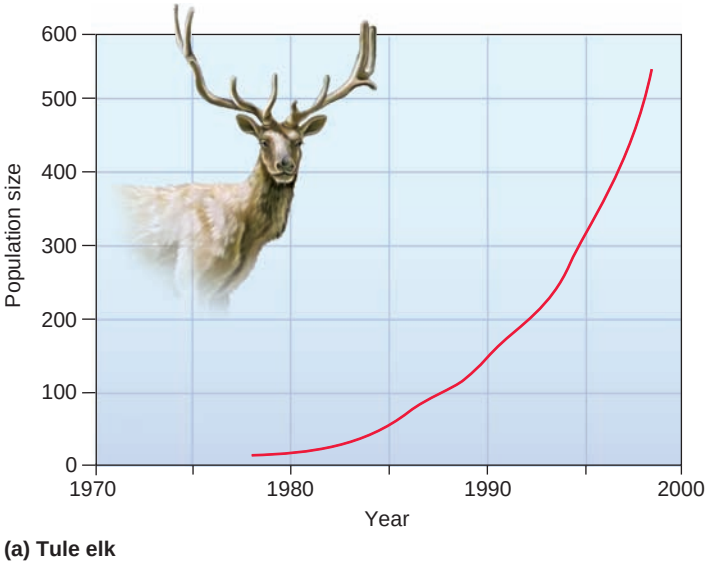
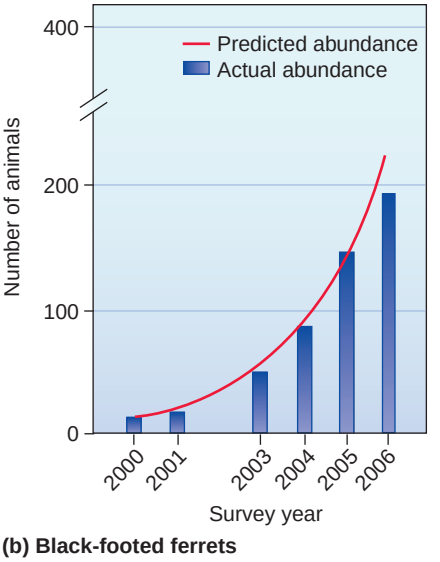
The growth of the recovering black-foot ferret population in Wyoming that we mentioned at the beginning of the chapter also fit the exponential growth pattern (Figure 56.10b). The ferrets had been reintroduced in 1991, but the population declined and languished for many years. However, from 2000 to 2006, the population grew in an exponential fashion. A value of $r = 0.47$ was calculated for the increase in population size of the ferrets during those years. Ecologists have noted that in some cases, populations seem to languish at low levels before conditions become favorable for population growth.



(a) Tule elk



(b) Black-footed ferrets

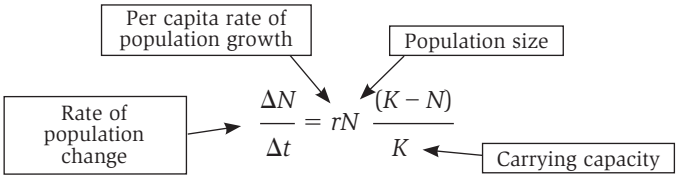
Figure 56.10 **Exponential growth following reintroduction of a population into a habitat.** **(a)** A population of tule elk (*Cervus elaphus nannodes*) reintroduced to Point Reyes National Seashore in 1978 fits a pattern of exponential growth. **(b)** Black-footed ferrets reintroduced to Shirley Basin, Wyoming, since 2000.

The growth of some introduced species also seems to fit the pattern of exponential growth. The rapid expansion of rabbits after their introduction into South Australia in the late 19th century is a case in point. In 1859, Thomas Austin received two dozen European rabbits from England. Rabbit gestation lasts a mere 31 days, and in South Australia, each doe could produce up to 10 litters of at least six young each year. The rabbits had essentially no enemies and ate the grass used by sheep and other grazing animals. Even when two-thirds of the population was shot for sport, which was the purpose of the initial introduction, the population grew into the millions within a few short years. By 1875, rabbits were reported on the west coast of Australia, having moved over 1,760 km across the continent despite the deployment of huge, thousand-kilometer-long fences ("rabbit-proof fences") meant to contain them.

Finally, one of the most prominent examples of exponential growth is the growth of the global human population, which, because of its great importance, we will examine separately in Section 56.4.

Logistic Growth Occurs in Populations in Which Resources Are Limited

Despite its applicability to rapidly growing populations, the exponential growth model is not appropriate in many situations. The model assumes unlimited resources, which is not typically the case in the real world. For most species, resources become limiting as populations grow, and the per capita growth rate decreases. The upper boundary for the population size is known as the **carrying capacity** (***K***). A more realistic equation to explain population growth, one that takes into account the amount of available resources, is



where $(K - N)/K$ represents the proportion of the carrying capacity that is unused by the population. This equation is called the **logistic equation**.

As the population size, N, grows, it moves closer to the carrying capacity, K, with fewer available resources for population growth. At large values of N, the value of $(K - N)/K$ becomes small, and population growth is small. If $K = 1{,}000$, $N = 900$, and $r = 0.1$, then

$$\frac{dN}{dt} = (0.1)(900) \times \frac{(1{,}000 - 900)}{1{,}000}$$

$$\frac{dN}{dt} = 9$$

In this instance, population growth is 9 individuals per unit of time.

Let's consider how an ecologist would use the logistic equation. First, the value of K would come from intense field and laboratory work where researchers would determine the amount of resources, such as food, needed by each individual and then determine the amount of available food in the wild. Field censuses would determine N, and field censuses of births and deaths per unit time would provide r. When this type of population growth is plotted over time, an S-shaped growth curve results (Figure 56.11). This pattern, in which the growth of a population slows down as it approaches K, is called **logistic growth**.

Does the logistic growth model provide a better fit to growth patterns of plants and animals in the wild than the exponential model, which is also shown in Figure 56.11? In some instances, such as laboratory cultures of bacteria and yeasts, the logistic growth model provides a very good fit (Figure 56.12). In nature, however, variations in temperature, rainfall, or resources cause changes in carrying capacity and thus in population size. The uniform conditions of temperature, moisture, and resource levels of the laboratory do not usually exist. Therefore, there are relatively few examples of logistic growth outside of the laboratory.

Is the logistic model of little value because it fails to describe population growth accurately? Not really. It is a useful starting point for thinking about how populations grow, and it seems intuitively correct. However, the carrying capacity is a difficult feature of the environment to identify for most species, and it also varies temporally, according to local climate patterns. For these reasons, logistic growth is difficult to measure accurately.

Also, as we will discover, populations are affected by interactions with other species. In Chapter 57, we will examine how

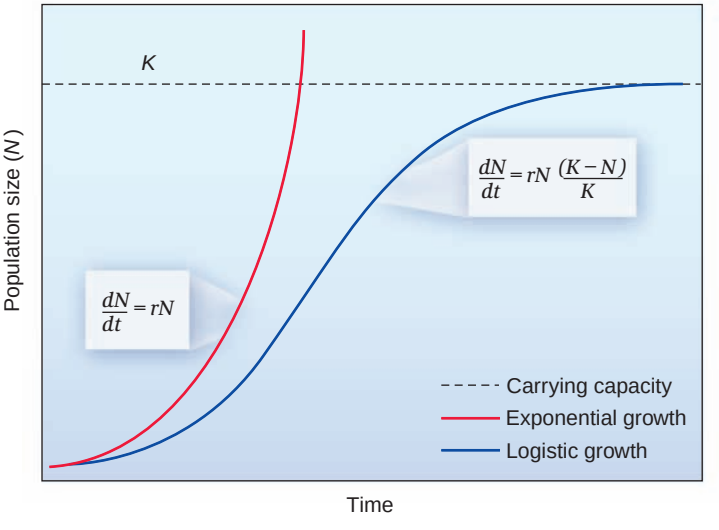


Figure 56.11 **Exponential versus logistic growth.** Exponential (J-shaped) growth occurs in an environment with unlimited resources, whereas logistic (S-shaped) growth occurs in an environment with limited resources.

Concept check: *What is the population growth per unit of time when r = 0.1, N = 200, and K = 500?*

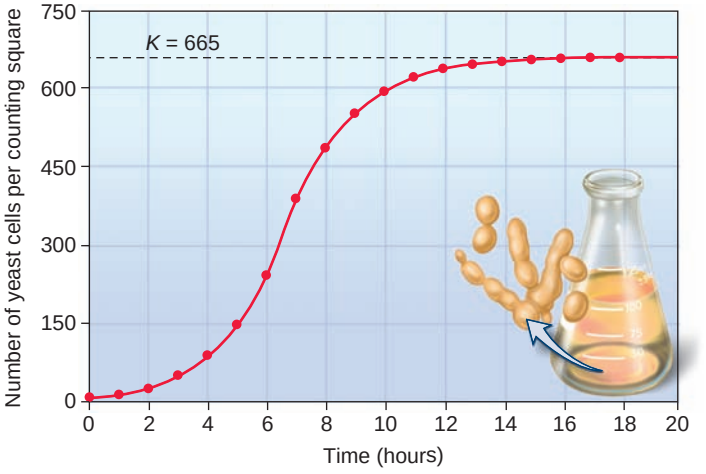

Figure 56.12 **Logistic growth of yeast cells in culture.** Early tests of the logistic growth curve were validated by growth of yeast cells in laboratory cultures. These populations showed the typical S-shaped growth curve.

predators, parasites, and competitors affect population densities and explore situations in which species interactions commonly limit population growth. As described next, such population reductions are often influenced by a process known as density dependence.

Density-Dependent Factors May Regulate Population Sizes

A **density-dependent factor** is a mortality factor whose influence increases with the density of the population. Parasitism, predation, and competition are some of the many density-dependent factors that may reduce the population densities of living organisms and stabilize them at equilibrium levels. Such factors can be density dependent in that their impact depends on the density of the population; they kill relatively more of a population when densities are higher and less of a population when densities are lower. For example, many predators develop a visual search image for a particular prey. When a prey is rare, predators tend to ignore it and kill relatively few. When a prey is common, predators key in on it and kill relatively more. In England, for example, predatory shrews kill proportionately more moth pupae in leaf litter when the pupae are common compared to when they are rare. Density-dependent mortality may also occur as population densities increase and competition for scarce resources increases, reducing offspring production or survival. Parasitism may also act in a density-dependent manner. Parasites are able to pass from host to host more easily as the host's densities increase. Disease is often more common in denser populations.

Density dependence can be detected by plotting mortality, expressed as a percentage, against population density (Figure 56.13). If a positive slope results and mortality increases with density, the factor tends to have a greater effect on dense populations than on sparse ones and is clearly acting in a density-dependent manner.

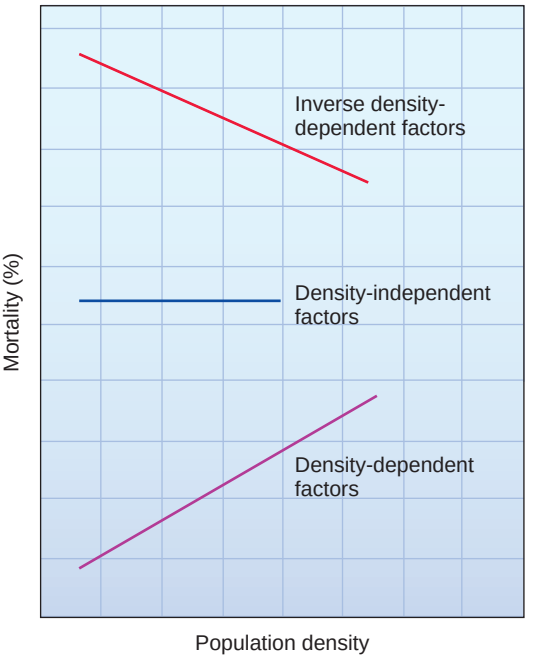

Figure 56.13 **Three ways that factors affect mortality in response to changes in population density.** For a density-dependent factor, mortality increases with population density; for a density-independent factor, mortality remains unchanged. For an inverse density-dependent factor, mortality decreases as a population increases in size.

Concept check: *Which types of factors tend to stabilize populations at equilibrium levels?*

A **density-independent factor** is a mortality factor whose influence is not affected by changes in population size or density. When mortality is plotted against density, a flat line results. In general, density-independent factors are physical factors, including weather, drought, freezes, floods, and disturbances such as fire. For example, in hard freezes, the same proportion of organisms such as birds or plants are usually killed, no matter how large the population size. However, even physical factors such as weather can act in a density-dependent manner. For example, in an environment where there were many beavers and a limited number of rivers to dam, some individuals would not have a lodge. In such a situation, a cold winter could kill a high percentage of beavers. If, on the other hand, there were few beavers, most would have a lodge to provide them with protection from a hard freeze. In this case, the cold would kill a lower percentage.

Determining which factors act in a density-dependent fashion has large practical implications. Foresters, game managers, and conservation biologists alike are interested in learning how to maintain populations at equilibrium levels. For example, if a specific disease were to act in a density-dependent manner on white-tailed deer, there wouldn't be much point in game managers attempting to kill off predators such as mountain lions to increase herd sizes for hunters, because proportionately more deer would be killed by disease.

Finally, a mortality factor that decreases with increasing population size is considered an **inverse density-dependent factor**.

In this case, a negative slope results when mortality is plotted against density. For example, if a territorial predator such as a lion always killed the same number of wildebeest prey, regardless of wildebeest density, it would be acting in an inverse density-dependent manner, because it is taking a smaller proportion of the population at higher density. Some mammalian predators, being highly territorial, often act in this manner on herbivore density.

Thus, natural enemies can act in a density-dependent manner and limit the sizes of prey populations, or they can act in a density-independent or even inverse density-dependent manner and not regulate them. To make generalizations about which factors control populations in nature, we need to know the prevalence of density-dependent factors in natural systems.

Which factors tend to act in a density-dependent manner? In the 1980s, a broad review of many research studies, which considered 51 populations of insects, 82 populations of large mammals, and 36 populations of small mammals and birds, showed a wide variety of density-dependent factors. No single process such as parasitism, competition, or predation could be regarded as a regulatory factor of overriding importance. Even for individual taxa, such as insects, density dependence varied from parasitism and predation to competition and abiotic factors. This finding is disconcerting to ecologists interested in population management, because it means that generalizations about which factors are likely to act in a density-dependent manner are not easily made. Each population has to be analyzed on a case-by-case basis.

Life History Strategies Incorporate Traits Relating to Survival and Competitive Ability

The population parameters we have discussed—including iteroparity versus semelparity, exponential versus logistic growth, and density-dependent versus density-independent factors—have important implications for how populations grow and indeed for the reproductive success of populations and species. These reproductive strategies can be viewed in the context of a much larger picture of life history strategies, sets of physiological and behavioral features that incorporate not only reproductive traits but also survivorship and length of life characteristics, habitat type, and competitive ability.

When comparing many different species, life history strategies follow a continuum. At the one end are species, termed ***r*-selected species**, that have a high rate of per capita population growth, *r*, but poor competitive ability (Figure 56.14a). An example is a weed, such as a dandelion, that produces huge numbers of tiny seeds and therefore has a high value of *r*. Weeds exist in disturbed habitats such as gaps in a forest canopy where trees have blown down, allowing light to penetrate to the forest floor. An *r*-selected species such as a weed grows quickly and reaches reproductive age early, devoting much energy to producing a large number of seeds that disperse widely. These weed species generally remain small, and individuals do not live long. Populations pass a few generations in the light gap before it closes.

At the other end are species, termed ***K*-selected species**, that have more or less stable populations adapted to exist at or near the carrying capacity, *K*, of the environment (Figure 56.14b). An example is an oak tree that exists in a mature forest. Oak trees grow slowly and reach reproductive age late, having to devote much energy to growth and maintenance. A *K*-selected species like a tree grows large and shades out *r*-selected species like weeds, eventually outcompeting them. Such trees live a long time and produce seeds repeatedly every year when mature. These seeds are bigger than those of *r*-selected species, but do not disperse widely. Acorns contain a large food reserve that helps them grow, whereas dandelion seeds must rely on whatever nutrients they can gather from the soil.

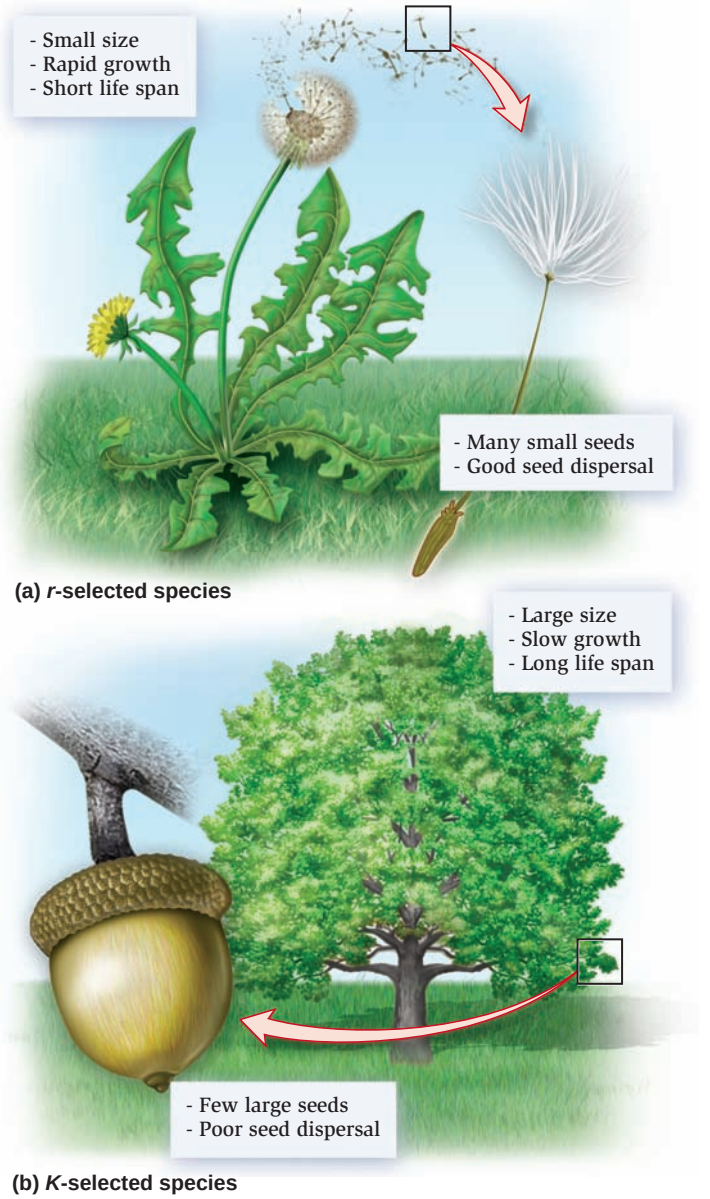

Figure 56.14 **Life history strategies.** Differences in traits of a dandelion **(a)** and an oak tree **(b)** illustrate some of the differences between *r*- and *K*-selected species.

Table 56.2 Characteristics of *r*- and *K*-Selected Species

Life history feature	*r*-selected species	*K*-selected species
Development	Rapid	Slow
Reproductive rate	High	Low
Reproductive age	Early	Late
Body size	Small	Large
Length of life	Short	Long
Competitive ability	Weak	Strong
Survivorship	High mortality of young	Low mortality of young
Population size	Variable	Fairly constant
Dispersal ability	Good	Poor
Habitat type	Disturbed	Not disturbed
Parental care	Low	High

Although the weed–tree example is a useful way to think about the *r*- and *K*-selection continuum, other organisms can be *r*- or *K*-selected, too. Insects are mostly *r*-selected species that produce many young and have short life cycles. Mammals, such as elephants, that grow slowly, have few young, and reach large sizes are typical of *K*-selected species. Table 56.2 compares the general characteristics of *r*- and *K*-selected species.

In a human-dominated world, almost every life history attribute of a *K*-selected species sets it at risk of extinction. First, *K*-selected species tend to be larger, so they need more habitat in which to live. Florida panthers need huge tracts of land to establish their territories and hunt for deer. There is room for only about 22 panthers on publicly owned land in South Florida. Privately owned land currently supports another 50 panthers. As the amount of land shrinks through development, so does the number of panthers. *K*-selected species tend to have fewer offspring, so their populations cannot recover as fast from disturbances such as fire or overhunting. California condors, for example, produce only a single chick every other year. *K*-selected species breed at a later age, and their generation time and time to grow from a small population to a larger population is long. Gestation time in elephants is 22 months, and elephants take at least 7 years to become sexually mature. Large trees, such as the giant sequoia; large terrestrial mammals, such as elephants, rhinoceroses, and grizzly bears; and large marine mammals, such as blue whales and sperm whales, all run the risk of extinction. Interestingly, the coast redwood seems to be an exception, a fact perhaps attributable to its unusual genome (see the following Genomes & Proteomes Connection).

What are the advantages to being a *K*-selected species? In a world not disturbed by humans, *K*-selected species would fare well. However, in a human-dominated world, many *K*-selected species are selectively logged or hunted, or their habitat is altered, and the resulting small population sizes make extinction a real possibility.

Genomes & Proteomes Connection

Hexaploidy Increases the Growth of Coast Redwood Trees

Besides having the world's most massive tree, the giant sequoia (*Sequoiadendron giganteum*), California is also home to the world's tallest tree, the coast redwood (*Sequoia sempervirens*), a towering giant that can grow to over 90 m and can live for up to 2,000 years (Figure 56.15). These trees are currently confined to a relatively small 700-km strip along the Pacific coast from California to southern Oregon, an area characterized by year-long moderate temperatures, heavy winter rains, and dense summer fog. Interestingly, because this climate was far more common in an earlier era, these trees were once dispersed throughout the Northern Hemisphere.

How is this huge species different from other tree species? In 1948, researchers made the startling discovery that the tree is a hexaploid; that is, each of its cells contains six sets of chromosomes, with 66 chromosomes in total. (Keep in mind that humans have two sets of chromosomes in every cell.) While hexaploidy is not unknown in grasses and shrubs, it is unusual in trees and particularly gymnosperms. Of all the conifers on Earth, the coast redwood is the only known hexaploid. Having this quality means each tree may have several different alleles for any given gene, which leads to a very genetically diverse population. Molecular biologist Chris Brinegar has found that hardly any two trees have exactly the same genetic constitution. Such genetic diversity allows greater adaptation to environmental conditions and more adaptations against insect or fungal pests. Indeed, living redwoods have no known lethal diseases, and pests do not cause significant damage. What's more, with six sets of genes, trees also have the potential for great variety in their gene products, the proteins, which may help explain their prodigious growth. It grows faster than any conifer on Earth, and this is why it is an exception to most *K*-selected species.

56.4 Human Population Growth

In 2006, the world's population was estimated to be increasing at the rate of 146 people every minute: 2 in developed nations and 144 in less-developed nations. The United Nations' 2006 projections pointed to a world population stabilizing at around 10 billion near the year 2150, as would happen with logistic growth. However, until now, human population growth has better fit an exponential growth pattern than a logistic one. In this section, we examine human population growth trends in more detail and discuss how knowledge of the human population's age structure can help predict its future growth. We then investigate the carrying capacity of the Earth for humans and explore how the concept of an ecological footprint, which measures human resource use, can help us determine this carrying capacity.

Figure 56.15 The coast redwood (*Sequoia sempervirens*)—a hexaploid conifer. The coast redwood can grow to over 90 m, and the oldest living trees are over 2,000 years old. Their great genetic variation may help explain their incredible growth and longevity.

Human Population Growth Fits an Exponential Pattern

Until the beginning of agriculture and the domestication of animals, about 10,000 B.C.E., the average rate of population growth was very low. With the establishment of agriculture, the world's population grew to about 300 million by 1 C.E. and to 800 million by the year 1750. Between 1750 and 1998, a relatively tiny period of human history, the world's human population surged from 800 million to 6 billion (Figure 56.16). In 2009, the number of humans was estimated at 6.7 billion, with more than two people added to the world's population every second. Considering this phenomenal increase in growth, the two biggest questions are when and at what level will the human population level off?

Human populations can exist at equilibrium densities in one of two ways:

1. *High birth and high death rates.* Before 1750, this was often the case, with high birth rates offset by deaths from wars, famines, and epidemics.
2. *Low birth and low death rates.* In Western Europe, beginning in the 18th century, better health and living conditions reduced the death rate. Eventually, social changes such as increasing education for women and marriage at a later age reduced the birth rate.

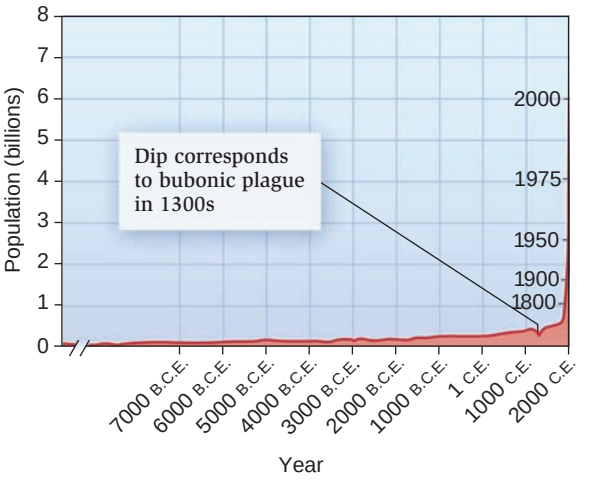

Figure 56.16 The growth pattern of the human population through history. If, and when, human population growth will level off are issues of considerable debate.

The shift in birth and death rates with development is known as the **demographic transition** (Figure 56.17). In the first stage of the transition, birth and death rates are both high, and the population is in equilibrium. In the second stage of this transition, which first occurred in Western Europe beginning in the late 18th century, the death rate declines first, while the birth rate remains high. High rates of population growth result. In the third stage, the birth rates drop and death rates stabilize, so population growth rates become lower. In the fourth stage, both birth and death rates are low, and the population is again at equilibrium.

The pace of the demographic transition between countries differs, depending on culture, economics, politics, and religion. This is illustrated by comparing the demographic transition in Sweden and Mexico (Figure 56.18). In Mexico, the demographic transition occurred more recently and was typified by a faster decline in the death rate, reflecting rapid improvements in public health. A relatively longer lag occurred between the decline

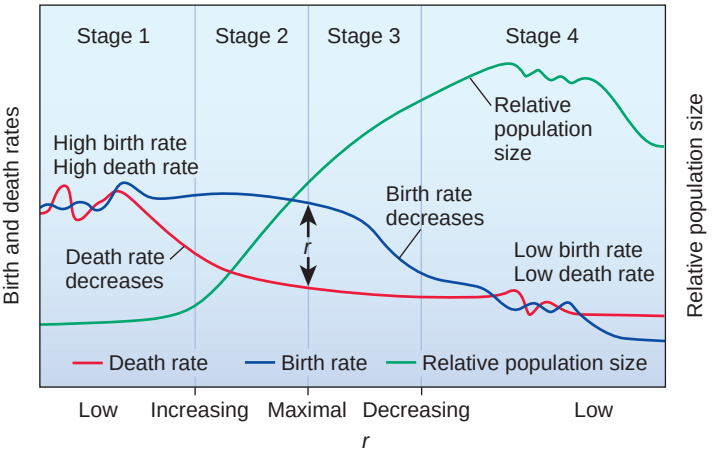

Figure 56.17 The classic stages of the demographic transition. The difference between the birth rate and the death rate determines the rate of population increase or decrease.

in the death rate and the decline in the birth rate, however, with the result that Mexico's population growth rate is still well above Sweden's, perhaps reflecting differences in culture or the fact that in Mexico, the demographic transition is not yet complete.

Knowledge of a Population's Age Structure Can Help Predict Its Future Growth

Changes in the age structure of a population also characterize the demographic transition. In all populations, **age structure** refers to the relative numbers of individuals of each defined age group. This information is commonly displayed as a population pyramid (Figure 56.19). In West Africa, for example, children under the age of 15 make up nearly half of the population, creating a pyramid with a wide base and narrow top. Even if fertility rates decline, there will still be a huge increase in the population as these young people move into childbearing age. The age structure of Western Europe is much more balanced. Even if the fertility rate of young women in Western Europe increased to a level higher than that of their mothers, the annual numbers of births would still be relatively low because of the low number of women of childbearing age.

Human Population Fertility Rates Vary Widely Around the World

Most estimates propose that the human population will grow to between 10 and 11 billion people by the middle of the 22nd century. Global population growth can be examined by looking

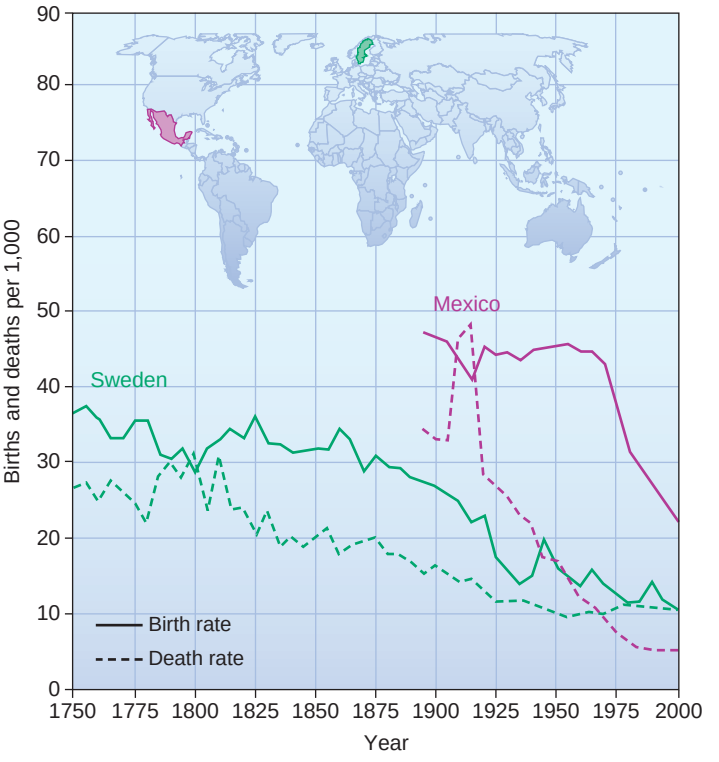

Figure 56.18 The demographic transition in Sweden and Mexico. Although the demographic transition began earlier in Sweden than it did in Mexico, the transition was more rapid in Mexico, and the overall rate of population increase remains higher. (The spike in the death rate in Mexico prior to 1920 is attributed to the turbulence surrounding the Mexican Revolution.)

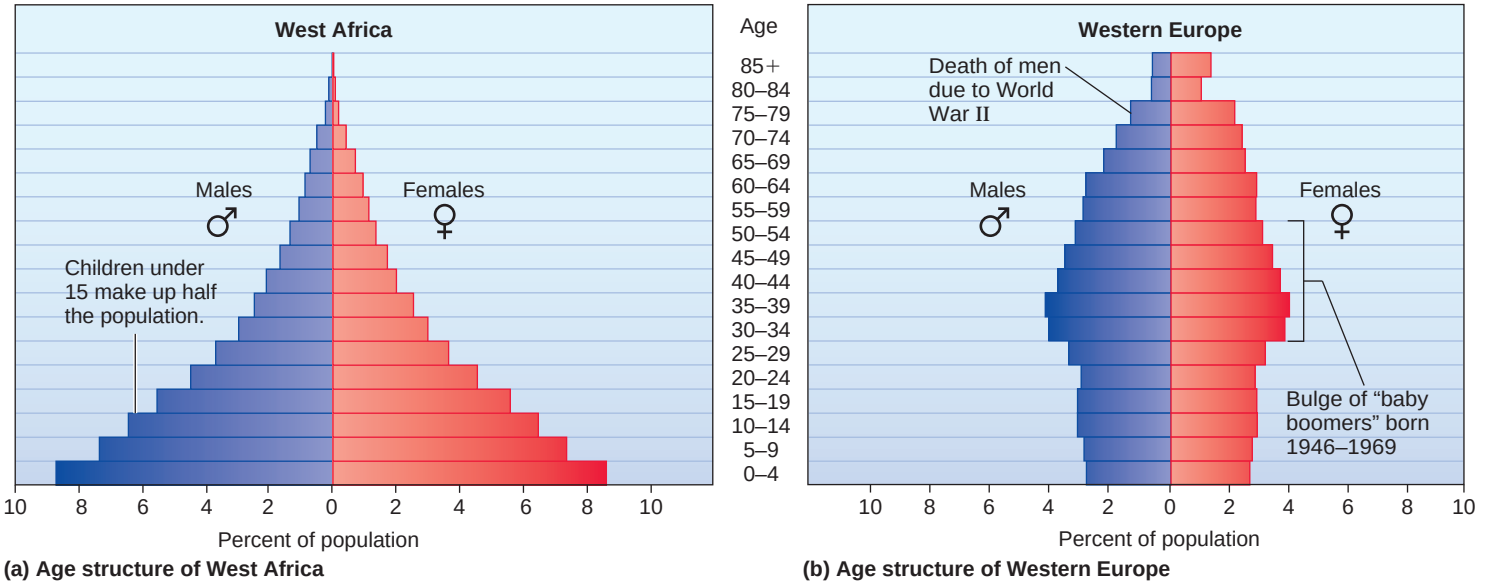

(a) Age structure of West Africa

(b) Age structure of Western Europe

Figure 56.19 The age structure of human populations in West Africa and Western Europe, as of 2000. **(a)** In developing areas of the world such as West Africa, there are far more children than any other age group. Population growth is rapid. **(b)** In the developed countries of Western Europe, the age structure is more evenly distributed. The bulge represents those born in the post-World War II baby boom, when birth rates climbed due to stabilization of political and economic conditions. Population growth is close to zero.

Concept check: *If the population pyramid in (a) was inverted, what would you conclude about the age structure of the population?*

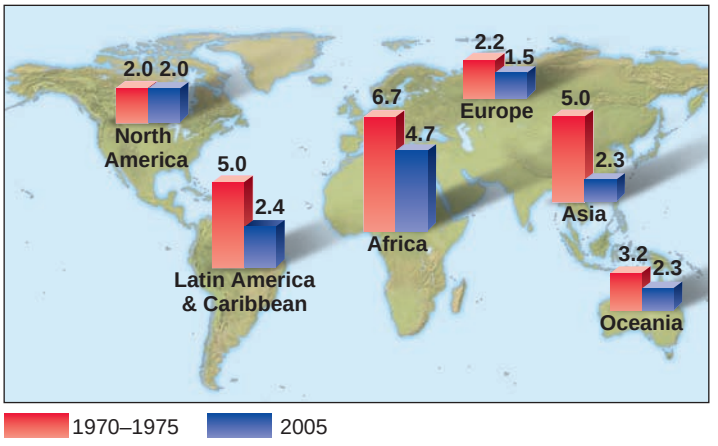

Figure 56.20 **Total fertility rates (TFRs) among major regions of the world.** Data refer to the average number of children born to a woman during her lifetime.

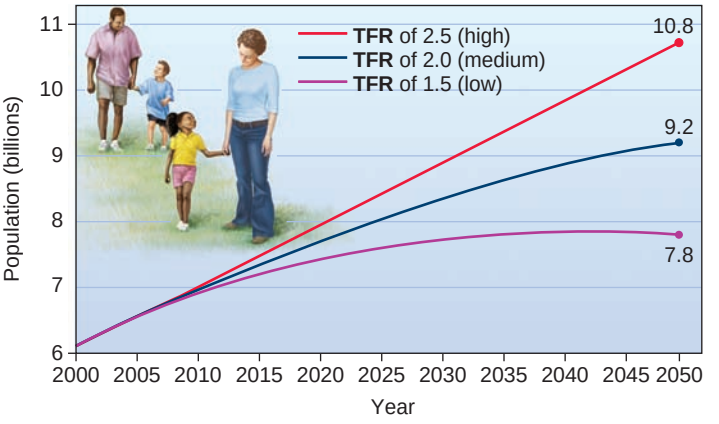

Figure 56.21 **Population predictions for 2000–2050, using three different total fertility rates (TFRs).**

at the **total fertility rate** (**TFR**), the average number of live births a woman has during her lifetime (Figure 56.20). The total fertility rate differs considerably between geographic areas. In Africa, the total fertility rate of 4.67 in 2007 has declined substantially since the 1970s, when it was around 6.7 children per woman. In Latin America and Southeast Asia, the rates have declined considerably from the 1970s and are now at around 2.37 and 2.34, respectively. Most countries in Europe and North America have a TFR of less than 2.0; in Russia, fertility rates have dropped to 1.34. In China, while the TFR is only 1.7, the population there will still continue to increase until at least 2025 because of the large number of women of reproductive age. Although the global TFR has declined from 4.47 in the 1970s to 2.59 in 2007, this is still greater than the average of 2.3 needed for zero population growth. The replacement rate is slightly higher than 2.0, to replace mother and father, due to natural mortality prior to reproduction. The replacement rate varies globally, from 2.1 in developed countries to between 2.5 and 3.3 in developing countries.

The wide variation in fertility rates makes it difficult to predict future population growth. The 2006 United Nations report shows world population projections to the year 2050 for three different growth scenarios: low, medium, and high (Figure 56.21). The three scenarios are based on three different assumptions about fertility rate. Using a low fertility rate estimate of only 1.5 children per woman, the population would reach a maximum of about 7.8 billion people by 2050. A more realistic assumption may be to use the fertility rate estimate of 2.0 or even 2.5, in which case the population would continue to rise to 9.2 or 10.8 billion, respectively.

The Concept of an Ecological Footprint Helps Estimate Carrying Capacity

What is the Earth's carrying capacity for the human population, and when will it be reached? Estimates have been quite varied. Much of the speculation on the upper boundary of the world's population size centers on lifestyle. To use a simplistic example, if everyone on the planet ate meat extensively and drove large cars, then the carrying capacity would be a lot less than if people were vegetarians and used bicycles as their main means of transportation.

In the 1990s, researcher Mathis Wackernagel and his coworkers calculated how much land is needed for the support of each person on Earth. Everybody has an impact on the Earth, because they consume the land's resources, including crops, wood, fossil fuels, minerals, and so on. Thus, each person has an **ecological footprint**, the aggregate total of productive land needed for survival in a sustainable world. The average footprint size for everyone on the planet is about 3 hectares (1 ha = 10,000 m^2), but a wide variation is found around the globe (Figure 56.22). The ecological footprint of the average Canadian is 7.5 hectares versus about 10 hectares for the average American.

In most developed countries, the largest component of land is for energy, followed by food and then forestry. Much of the land needed for energy serves to absorb the CO_2 emitted by the use of fossil fuels. If everyone required 10 hectares, as the average American does, we would need three Earths to provide us with the needed resources. Many people in less-developed countries are much more frugal in their use of resources. However, globally we are already beyond the Earth's carrying capacity for humans if we were to live in a sustainable manner. This is possible because many people currently live in an unsustainable manner, using supplies of nonrenewable resources, such as groundwater and fossil fuels.

What's your personal ecological footprint? Several different calculations are available on the Internet that you can use to find out. A rapidly growing human population combined with an increasingly large per capita ecological footprint makes it increasingly difficult to preserve other species on the planet, a subject we will examine further in our discussion of conservation biology (Chapter 60).

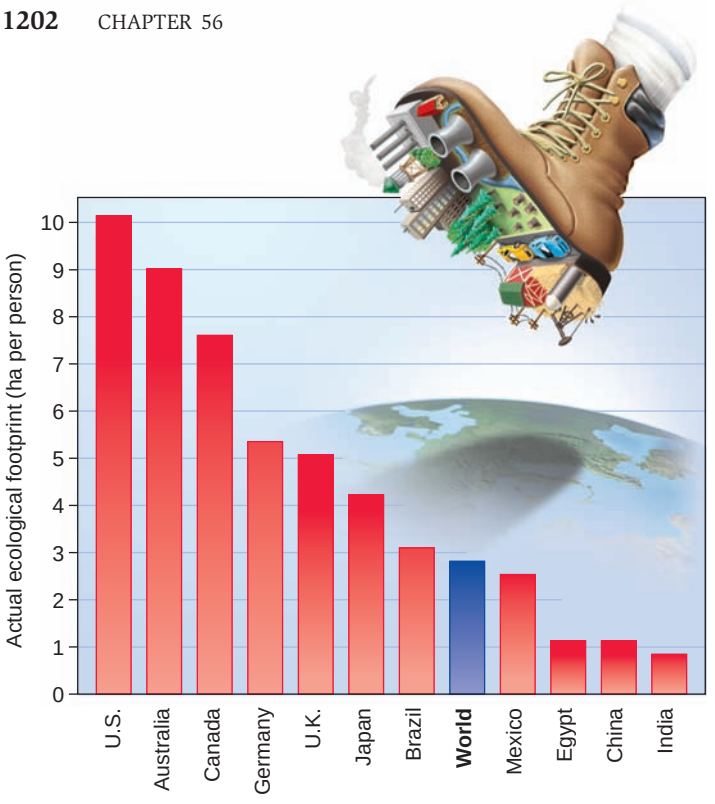

Figure 56.22 **Ecological footprints of different countries.** The term ecological footprint refers to the amount of productive land needed to support the average individual of that country.

Concept check: *What is your ecological footprint?*

Summary of Key Concepts

56.1 Understanding Populations

- Population ecology studies how populations grow and what factors promote and limit growth.
- Ecologists measure population density, the numbers of organisms in a given unit area, in many ways, including the mark-capture technique. (Figures 56.1, 56.2)
- Individuals within populations show different patterns of dispersion, including clumped (the most common), uniform, and random. Individuals also exhibit different reproductive strategies, and populations have different age classes. (Figures 56.3, 56.4, 56.5)

56.2 Demography

- Life tables summarize the survival pattern of a population. (Table 56.1)
- Survivorship curves illustrate life tables by plotting the numbers of surviving individuals at different ages. (Figures 56.6, 56.7, 56.8)
- Age-specific fertility and survivorship data help determine the overall growth rate per generation, or the net reproductive rate (R_0).

56.3 How Populations Grow

- The per capita growth rate (r) helps determine how populations grow over any time period.
- When r is > 0, exponential (J-shaped) growth occurs. Exponential growth can be observed in an environment where resources are not limited. (Figures 56.9, 56.10)
- Logistic (S-shaped) growth takes into account the upper boundary for a population, called carrying capacity, and occurs in an environment where resources are limited. (Figures 56.11, 56.12)
- Variations in temperature, rainfall, or resource quantity or quality cause changes in carrying capacities, and thus the idealized logistic growth model does not describe all populations.
- Density-dependent factors are mortality factors whose influence varies with population density. Density-independent factors are those whose influence does not vary with density. (Figure 56.13)
- Life history strategies are a set of features including reproductive traits, survivorship and length of life characteristics, and competitive ability.
- Life history strategies can be viewed as a continuum, with *r*-selected species (those with a high rate of population growth but poor competitive ability) at one end and *K*-selected species (those with a lower rate of population growth but better competitive ability) at the other. (Figures 56.14, 56.15, Table 56.2)

56.4 Human Population Growth

- Up to the present, human population growth has fit an exponential growth pattern. (Figure 56.16)
- Human populations have been moving from states of high birth and death rates to low birth and death rates, a shift called the demographic transition. (Figures 56.17, 56.18)
- Differences in the age structure of a population, the numbers of individuals in each age group, are also characteristic of the demographic transition. (Figure 56.19)
- Although they have been declining worldwide, total fertility rates (TFRs) differ markedly in less-developed and more-developed countries. Predicting the growth of the human population depends on the total fertility rate that is projected. (Figures 56.20, 56.21)
- The ecological footprint refers to the amount of productive land needed to support each person on Earth. Because people in many countries live in a nonsustainable manner, globally we are already in an ecological deficit. (Figure 56.22)

Assess and Discuss

Test Yourself

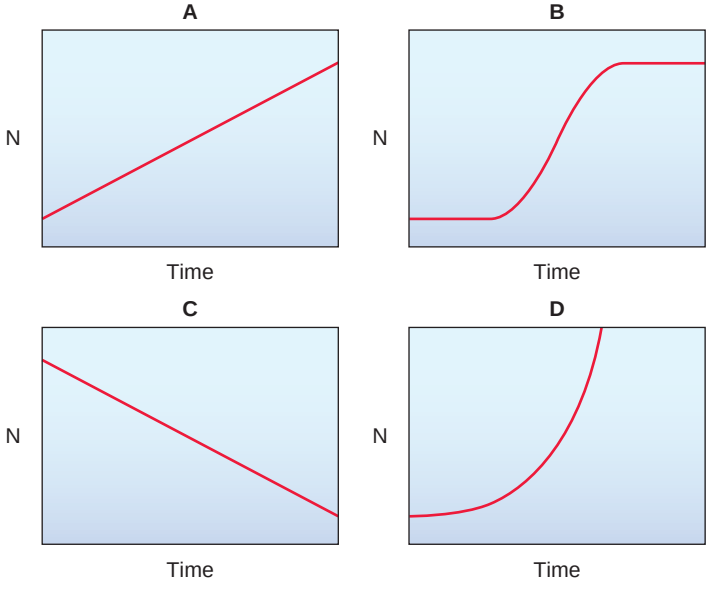
1. A student decides to conduct a mark-recapture experiment to estimate the population size of mosquitofish in a small pond near his home. In the first catch, he marked 45 individuals. Two weeks later, he captured 62 individuals, of which 8 were marked. What is the estimated size of the population based on these data?
   a. 134 c. 558 e. 22,320
   b. 349 d. 1,016

Questions 2–4 refer to the table that follows:

Age	n_x	d_x	l_x	m_x	$l_x m_x$
0	100	35	1.00	0	0
1	65	?	0.65	0	0
2	45	15	?	3	1.35
3	30	20	0.30	1	?
4	10	10	0.10	1	0.10
5	0	0	0.00	1	0.0

2. How many individuals die between their first and second birthday?
   a. 65 c. 35 e. 20
   b. 45 d. 25
3. What proportion of newborns survive to age 2?
   a. 0.55 c. 0.35 e. 0.15
   b. 0.45 d. 0.20
4. What is the net reproductive rate?
   a. 5 c. 1.75 e. 0.80
   b. 2.5 d. 1.45
5. _____ survivorship curves are usually associated with organisms that have high mortality rates in the early stages of life.
   a. Type I c. Type III e. Types II and III
   b. Type II d. Types I and II
6. If the net reproductive rate (R_0) is equal to 0.5, what assumptions can we make about the population?
   a. This population is essentially not changing in numbers.
   b. This population is in decline.
   c. This population is growing.
   d. This population is in equilibrium.
   e. none of the above
7. The maximum number of individuals a certain area can sustain is known as
   a. the intrinsic rate of growth. d. the logistic equation.
   b. the resource limit. e. the equilibrium size.
   c. the carrying capacity.

Questions 8 and 9 refer to the following generalized growth patterns as plotted on arithmetic scales. Match the following descriptions with the patterns indicated below.



Each pattern may be used once, more than once, or not at all.

8. Which pattern is found where a population exhibits a constant per capita growth rate?
   a. A d. D
   b. B e. none of the above
   c. C
9. Which pattern is found where a population is heading toward extinction?
   a. A d. D
   b. B e. none of the above
   c. C
10. The amount of land necessary for survival for each person in a sustainable world is known as
    a. the sustainability level. d. survival needs.
    b. an ecological impact. e. all of the above.
    c. an ecological footprint.

Conceptual Questions

1. Define population and population ecology.
2. Describe and list the assumptions of the mark-recapture technique.
3. Using the logistic equation, calculate population growth when $K = 1{,}000$, $N = 500$, and $r = 0.1$ and when $K = 1{,}000$, $N = 100$, and $r = 0.1$. Compare the results to those shown in Section 56.3, where $K = 1{,}000$, $N = 900$, and $r = 0.1$.

Collaborative Questions

1. Discuss the two main extremes of life history strategies.
2. Describe where students on campus might show each type of dispersion pattern, and explain why this might occur.

Species Interactions

57

Chapter Outline

An example of species interactions. This shark is feeding on a ray, which, in turn, feeds on bay scallops.

In 2007, Ransom Myers and his colleagues showed that overfishing severely depleted the numbers of 11 shark species that occurred along the eastern seaboard of the U.S. Several shark species had declined by over 99% since the 1950s. Because of strong interactions between the sharks and other marine species, this drastic reduction of the shark population had at least two other effects. First, there was a large increase in the main prey species of the sharks, rays and skates. Second, the increase in rays and skates reduced the densities of their prey, bay scallops (*Argopecten irradians*). Such losses contributed to the closure of the bay scallop industry in North Carolina.

In this chapter, we turn from considering populations on their own to investigating how they interact with populations of other species that live in the same locality. Such species interactions can take a variety of forms (Table 57.1). **Competition** is an interaction that affects both species negatively (−/−), as both species compete over food or other resources. Sometimes this interaction is quite one-sided, where it is detrimental to one species and neutral to the other, an interaction called **amensalism** (−/0). **Predation**, **herbivory**, and **parasitism** all have a positive effect on one species and a negative effect on the other (+/−). However, although predators always kill their prey, the hosts of parasites and herbivores often survive their attacks. **Mutualism** is an interaction in which both species benefit (+/+), whereas **commensalism** benefits one species and leaves the other unaffected (+/0). Last is the interaction, or rather lack of interaction, termed **neutralism**, when two species occur together but do not interact in any measurable way (0/0). Neutralism may be quite common, but few researchers have quantified its occurrence.

To illustrate how species interact in nature, let's consider a rabbit population in a woodland community (Figure 57.1). To determine what factors influence the size and density of the rabbit population, we need to understand each of its possible species interactions. For example, the rabbit population could be limited by the quality of available food. It is also likely that other species, such as deer, use the same resource and thus compete with the rabbits. The rabbit population could be limited by predation from foxes or by the virus that causes the disease myxomatosis, which is usually spread by fleas and mosquitoes. It is also possible that other associations, such as mutualism or commensalism, may occur.

This chapter examines each of these species interactions in turn, beginning with competition, an important interaction among species. We conclude with a discussion of conceptual models of species interactions that ecologists use when trying to determine which factors are most important in controlling population densities within ecological systems.

Table 57.1 Summary of the Types of Species Interactions

Nature of interaction	Species 1*	Species 2*
Competition	−	−
Amensalism	−	0
Predation, herbivory, parasitism	+	−
Mutualism	+	+
Commensalism	+	0
Neutralism	0	0

*+ = positive effect; − = negative effect; 0 = no effect.

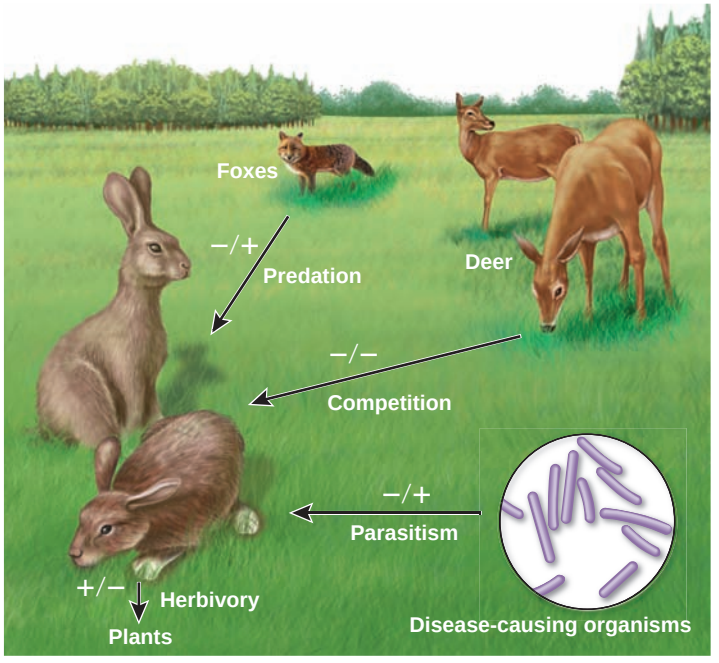

Figure 57.1 **Species interactions.** These rabbits can interact with a variety of species, experiencing predation by foxes, competition with deer for food, and parasitism from various disease-causing organisms. The species interaction known as herbivory also occurs when rabbits feed on various plants. The effects of each species on the other are shown by the terms assigned to the arrows, as discussed in the text.

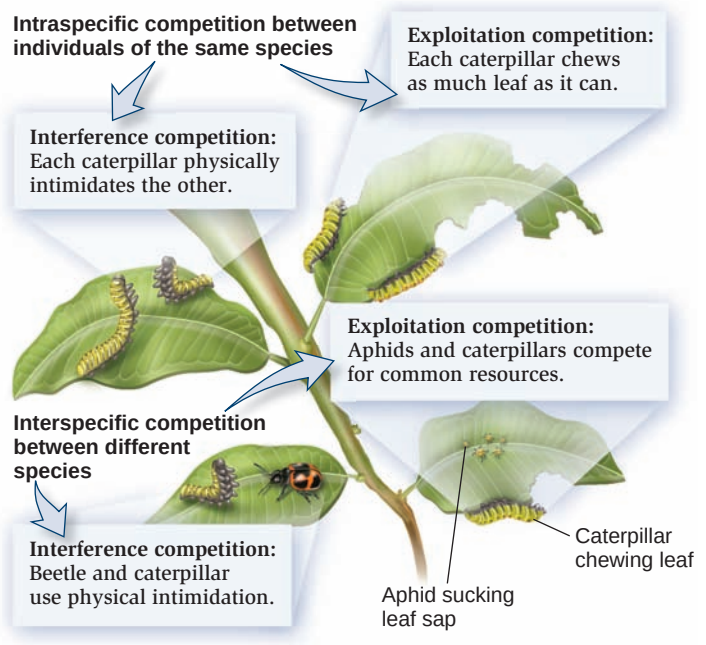

Figure 57.2 **The different types of competition in nature.**

Concept check: *How would you classify competition between vultures feeding on roadkill?*

57.1 Competition

In this section, we will see how ecologists have studied different types of competition and how they have shown that the competitive effects of one species on another can change as the environment changes or as different predators or parasites are present. Although species may compete for resources, we will also learn how sufficient differences in lifestyle or morphology can exist that reduce the overlap in their ecological niches, thus allowing them to coexist.

Several Different Types of Competition Occur in Nature

Several different types of competition are found in nature (Figure 57.2). Competition may be **intraspecific**, between individuals of the same species, or **interspecific**, between individuals of different species. Competition can also be characterized as exploitation competition or as interference competition. In **exploitation competition**, organisms compete indirectly through the consumption of a limited resource, with each obtaining as much as it can. For example, when fly maggots compete in a mouse carcass, not all the individuals can command enough of the resource to survive and become adult flies. In **interference competition**, individuals interact directly with one another by physical force or intimidation. Often this force is ritualized into aggressive behavior associated with territoriality (as discussed in Chapter 55). In these cases, strong individuals survive and take the best resource, and weaker ones perish or, at best, survive under suboptimal conditions.

Competition between species is not always equal. In many cases, one species has a detrimental effect on another but is unaffected itself. Such interactions are called amensalism. An extreme asymmetric competition can be observed between plants, where one species secretes and produces chemicals from its roots that inhibit the growth of another species. In Chapter 54's Feature Investigation, we saw how diffuse knapweed, an introduced species, secretes root chemicals called allelochemicals into the surrounding environment that kill the roots of native grass species. This phenomenon is termed **allelopathy**.

Researchers have established that one of the best methods of studying competition between two species is to temporarily remove one of them and examine the effect on the other species. A now-classic example of this method involved a study of the interactions between two species of barnacles conducted on the west coast of Scotland, as described next.

Feature Investigation

Connell's Experiments with Barnacle Species Showed That One Species Can Competitively Exclude Another in a Natural Setting

The most direct method of assessing the effect of competition is to remove individuals of species A and measure the response of species B. Often, however, such manipulations are difficult to conduct outside the laboratory. If individuals of species A are removed, what is to stop them from migrating back into the area of removal?

In 1954, ecologist Joseph Connell conducted an experiment that overcame this problem. *Chthamalus stellatus* and *Semibalanus balanoides* (formerly known as *Balanus balanoides*) are two species of barnacles that dominate the Scottish coastline. Each organism's ecological niche on the intertidal zone was well defined. *Chthamalus* occurs in the upper intertidal zone, and *Semibalanus* is restricted to the lower intertidal zone. Connell sought to determine what the range of *Chthamalus* adults might be in the absence of competition from *Semibalanus* (Figure 57.3).

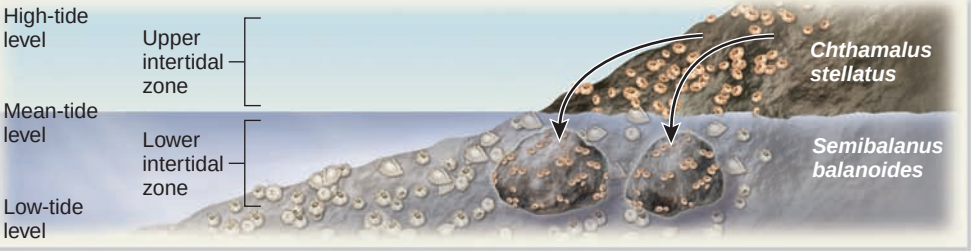
Figure 57.3 Connell's experimental manipulation of species indicated the presence of competition.

HYPOTHESIS Adult *Chthamalus stellatus* were being competitively excluded from the lower intertidal zone by the species *Semibalanus balanoides*.

STARTING LOCATION The intertidal zone of the rocky shores of the Scottish coast, where the two species of barnacles occur.

Experimental level

1 Transfer rocks containing young and mature *Chthamalus* from the upper intertidal zone to the lower intertidal zone, and fasten them down in the new location with screws.

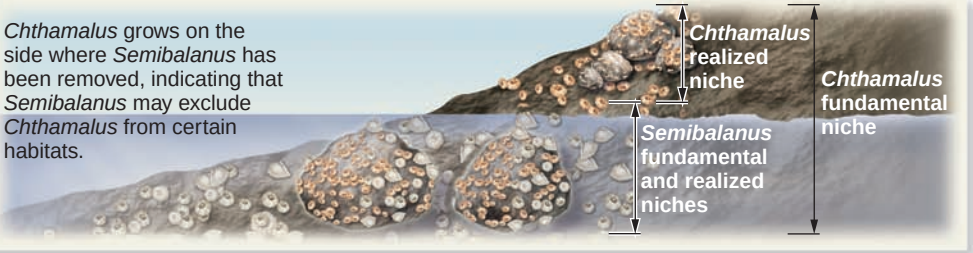


2 Allow *Semibalanus* to colonize the rocks.

3 After the colonization period is over, remove *Semibalanus* from half of each rock with a needle (leaving the other half undisturbed). Return the rocks to the lower intertidal zone, and fasten them down once again.

4 Monitor the survival of *Chthamalus* on both sides of the rocks.

Chthamalus grows on the side where *Semibalanus* has been removed, indicating that *Semibalanus* may exclude *Chthamalus* from certain habitats.



5 THE DATA

Rock No.	Side of rock	% *Chthamalus* mortality over 1 year	
		Young barnacles	Mature barnacles
13b	*Semibalanus* removed	35	0
	Semibalanus not removed	90	31
12a	*Semibalanus* removed	44	37
	Semibalanus not removed	95	71
14a	*Semibalanus* removed	40	36
	Semibalanus not removed	86	75

6 CONCLUSION The data from this study indicate that *Semibalanus* is found on the lower rock face because it outcompetes *Chthamalus*. Other studies indicate that *Chthamalus* occupies the upper rock face because it is more resistant to desiccation.

7 SOURCE Connell, J.H. 1961. The influence of interspecific competition and other factors on the distribution of the barnacle *Chthamalus stellatus*. *Ecology* 42:710–732.

To do this, Connell obtained rocks from high on the rock face, just below the high-tide level, where only *Chthamalus* grew. These rocks already contained young and mature *Chthamalus*. He then moved the rocks into the *Semibalanus* zone, fastened them down with screws, and allowed *Semibalanus* to also colonize them. Once *Semibalanus* had colonized these rocks, he took the rocks out, removed all the *Semibalanus* organisms from one side of the rocks with a needle, and then returned the rocks to the lower intertidal zone, screwing them down once again. As seen in the data, the mortality of *Chthamalus* on rock halves with *Semibalanus* was fairly high. On the *Semibalanus*-free halves, however, *Chthamalus* survived well.

In other studies, Connell also monitored survival of natural patches of both barnacle species where both occurred on the intertidal zone at the upper margin of the *Semibalanus* distribution. In a period of unusually low tides and warm weather, when no water reached any barnacles for several days, desiccation became a real threat to the barnacles' survival. During this time, young *Semibalanus* suffered a 92% mortality rate, and older individuals, a 51% mortality rate. At the same time, young *Chthamalus* experienced a 62% mortality rate compared with a rate of only 2% for more-resistant older individuals. Clearly, *Semibalanus* is not as resistant to desiccation as *Chthamalus* and could not survive in the upper intertidal zone where *Chthamalus* occurs. *Chthamalus* is more resistant to desiccation than *Semibalanus* and can be found higher in the intertidal zone. Thus, while the lower limit of *Chthamalus* was set by competition with *Semibalanus*, the upper limit was controlled by desiccation.

Although the potential distribution, the fundamental niche, of *Chthamalus* extends over the entire intertidal zone, its actual distribution, the realized niche, is restricted to the upper zone. Connell's experiments were among the first to show that in a natural environment, one species can actually outcompete another, affecting its distribution within a habitat.

Experimental Questions

1. Describe the realized niches for the two species of barnacles used in Connell's experiment.
2. Outline the procedure that Connell used in the experiments.
3. How did Connell explain the presence of *Chthamalus* in the upper intertidal zone if *Semibalanus* was shown to outcompete the species in the first experiment?

The Outcome of Competition Can Vary with Changes in the Biotic and Abiotic Environments

Using experiments to temporarily remove individuals of one species and examine the results on the remaining species, as Connell did, is often the most direct method to investigate the effects of competition. It is especially valuable to do such manipulations in the field, because organisms can then also interact with all other organisms in their environment, or, as ecologists say, natural variation can be factored in.

Alternatively, in laboratory experiments, the investigator can often control and vary important factors systematically. In the late 1940s, biologist Thomas Park began a series of experiments examining competition between two flour beetles, *Tribolium castaneum* and *Tribolium confusum*, in which he systematically varied temperature, moisture, and a variety of other factors. These beetles were well suited to study in the laboratory, because large colonies could be grown in relatively small containers containing dry food medium. Thus, many replicates of each experiment were possible to confirm that results were consistent.

Park conducted the experiments by putting the same number of beetles of both species into a container and counting the number of each type that were still alive after a given time interval. *T. confusum* usually won, but in initial experiments, the beetle cultures were infested with a protozoan parasite called *Adelina triboli* that killed some beetles and preferentially killed *T. castaneum* individuals, influencing the outcome. In these experiments, *T. confusum* won in 66 out of 74 replicates (89%) because it was more resistant to the parasite. In subsequent experiments, the parasite was removed, and *T. castaneum* won in 12 out of 18 replicates (67%). Two things were evident from this experiment. First, the presence of a parasite (a biotic factor) was shown to alter the outcome of competition. Second, with or without the parasite, there was no absolute victor. For example, even with the parasite present, sometimes *T. castaneum* won. Thus, some random variation, which we call stochasticity, was evident when these species competed.

Park then began to vary the abiotic environment and found that competitive ability was greatly influenced by environmental factors (Figure 57.4). Generally, *T. confusum* did better in dry conditions, and *T. castaneum*, in moist conditions. However, *T. confusum* also won in cold-wet conditions. Once again, some stochasticity occurred, and victory was not absolute. Later, it was found that the mechanism of competition was largely predation of eggs and pupae by larvae and adults, which, as they ate the flour medium, would also bite the stationary eggs and pupae, killing them. In general, the species were mutually antagonistic; that is, they bit more eggs and pupae of the other species than they did of their own.

Park's important series of experiments illustrated that the results of competition could vary as a function of at least three factors: parasites, temperature, and moisture. The experiments also showed how much stochasticity occurred, even in controlled laboratory conditions.

Field Studies Show Competition Occurs Frequently in Nature

By reviewing studies that have investigated competition in nature, we can see how frequently it occurs and in what particular circumstances it is most important. In a 1983 review of field studies by Joseph Connell, competition was found in 55% of 215 species surveyed, demonstrating that it is indeed frequent in nature. Generally in studies of single pairs of species utilizing the same resource, competition is almost always reported (90%), whereas in studies involving more species, the frequency of competition drops to 50%. Why should this be the case? Imagine a resource such as a series of different-sized grains with four species—ants, beetles, mice, and birds—feeding on it (Figure 57.5a). The ants feed on the smallest grain, the beetles and mice on the intermediate sizes, and the birds, on the largest. If only adjacent species competed with each other, competition would be expected only between the ant–beetle, beetle–mouse, and mouse–bird. Thus, competition would be found in only three out of the six possible species pairs (50%). Naturally, the percent would vary according to the number of species on the resource spectrum. If there were only three species along the spectrum, we would expect competition in two of the three pairs (67%). If there were just two species utilizing the resource spectrum, however, we would expect competition in almost 100% of the cases (Figure 57.5b).

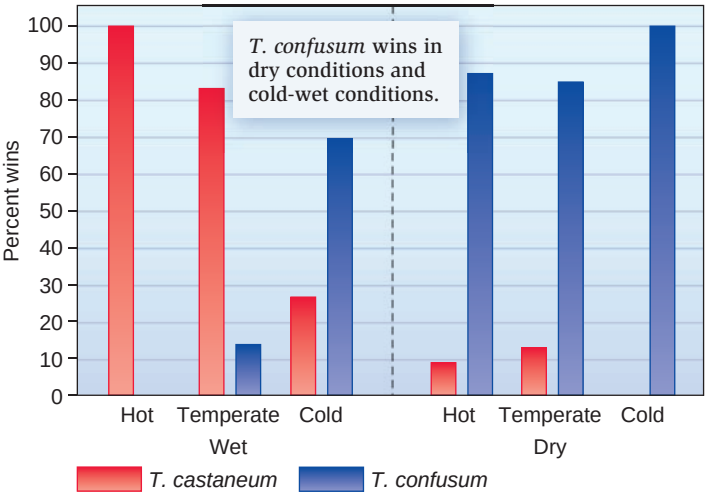


Figure 57.4 Influence of abiotic factors on competition between *T. castaneum* and *T. confusum*. Results of competition between the flour beetles *Tribolium castaneum* and *Tribolium confusum* show that each species usually performs better in a given habitat; for example, *T. confusum* does better in dry conditions.

Some other general patterns were evident from Connell's review. Plants showed a high degree of competition, perhaps because they are rooted in the ground and cannot easily escape or perhaps because they are competing for the same set of limiting nutrients—water, light, and minerals. Marine organisms tended to compete more than terrestrial ones, perhaps because many of the species studied lived in the intertidal zone and were attached to the rock face, in a manner similar to that of plants. Because the area of the rock face is limited, competition for space is quite important, as we saw with Connell's work with barnacles in Scotland.

Species May Coexist If They Do Not Occupy Identical Niches

Although competition is common, researchers have proposed several mechanisms by which two competing species can coexist. One states that similar species can coexist if they occupy different niches. In 1934, the Russian microbiologist Georgyi Gause began to study competition between three protist species, *Paramecium aurelia*, *Paramecium bursaria*, and *Paramecium caudatum*, all of which fed on bacteria and yeast, which, in turn, fed on an oatmeal medium in a culture tube in the laboratory. The bacteria occurred more in the oxygen-rich upper part of the culture tube, and the yeast in the oxygen-poor lower part of the tube. Because each species was a slightly different size, Gause calculated population growth as a combination of numbers of individuals per milliliter of solution multiplied by

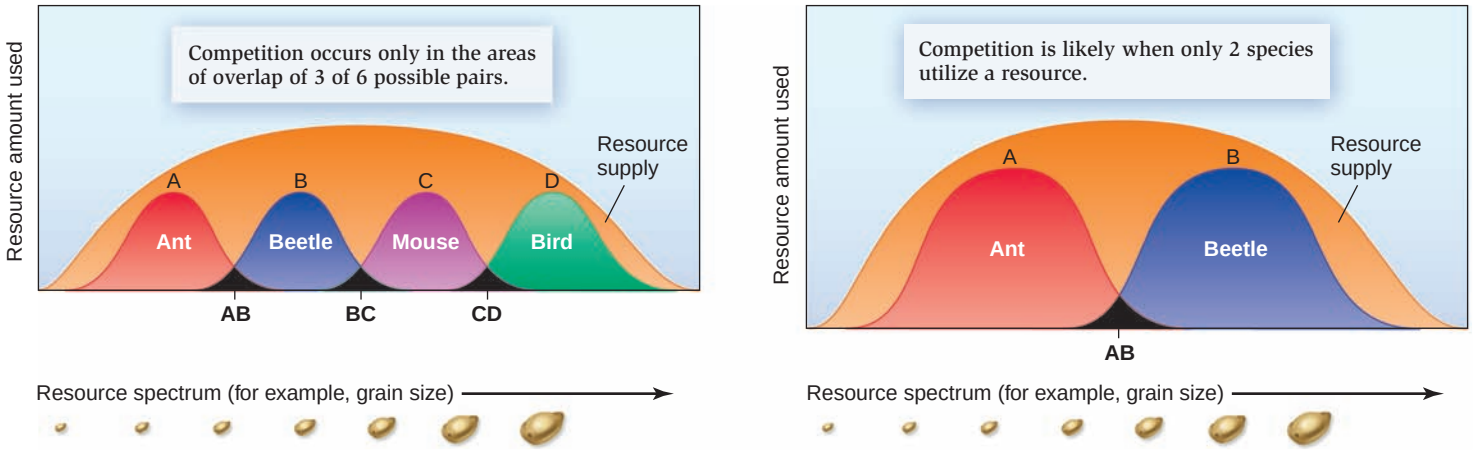

Figure 57.5 **The frequency of competition according to the number of species involved.** **(a)** Resource supply and utilization curves of four species, A, B, C, and D, along the spectrum of a hypothetical resource such as grain size. If competition occurs only between species with adjacent resource utilization curves, competition would be expected between three of the six possible pairings: A and B; B and C; and C and D. **(b)** When only two species utilize a resource set, competition would nearly always be expected between them.

Concept check: *If five species utilized the resource set in part (a), what percent of the interactions would be competitive?*

their unit volume to give a population volume for each species. When grown separately, population volume of all three *Paramecium* species followed a logistic growth pattern (Figure 57.6a). When Gause cultured *P. caudatum* and *P. aurelia* together, *P. caudatum* went extinct (Figure 57.6b). Both species utilized bacteria as food, but *P. aurelia* grew at a rate six times faster than *P. caudatum* and was better able to convert the food into offspring.

However, when Gause cultured *P. caudatum* and *P. bursaria* together, neither went extinct (Figure 57.6c). The population volume of each was much less compared to when they were grown alone, because some competition occurred between them. Gause discovered, however, that *P. bursaria* was better able to utilize the yeast in the lower part of the culture tubes. From these experiments, Gause concluded that two species with exactly the same requirements cannot live together in the same place and use the same resources, that is, occupy the same niche. His conclusion was later termed the **competitive exclusion principle**.

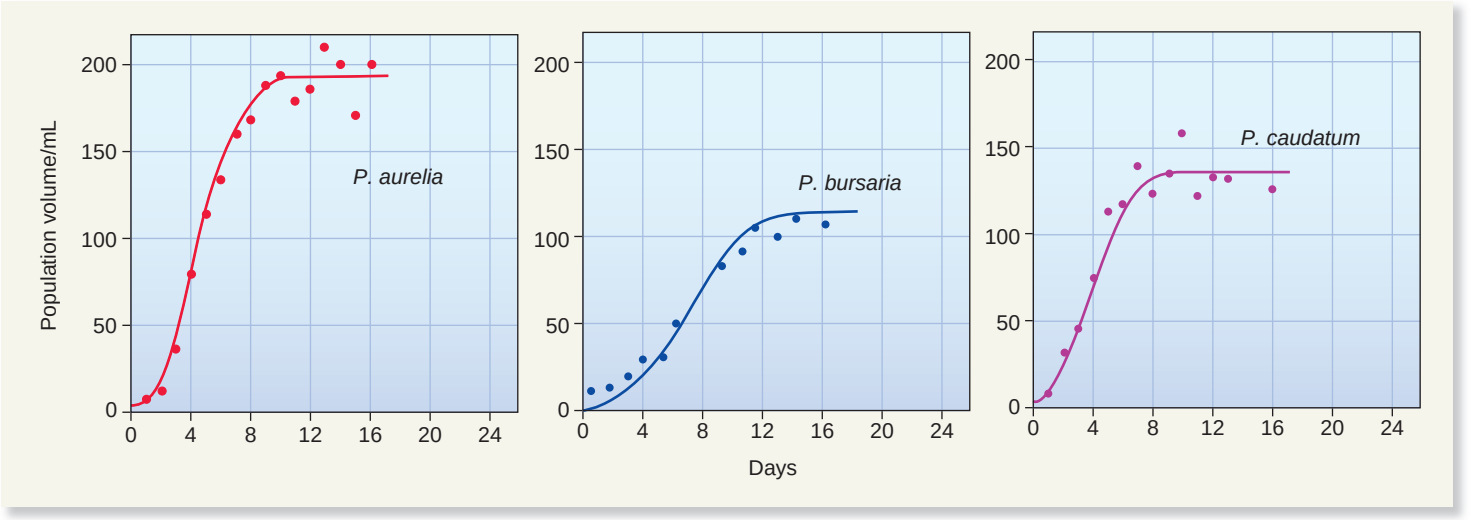
If complete competitors drive one species to local extinction, at least in the laboratory, how different do two species have to be to coexist, and in what features do they usually differ? To address such questions, in 1958, ecologist Robert MacArthur examined coexistence between five species of warblers feeding within spruce trees in New England. All belonged to the genus *Dendroica*, so one would expect these closely related bird species to compete strongly, possibly sufficiently strongly to cause extinctions. MacArthur found that the species occupied different heights and portions in the tree, and therefore, each probably fed on a different range of insects (Figure 57.7). In addition, the Cape May warbler fed on flying insects and tended to remain on the outside of the trees.

The term **resource partitioning** describes the differentiation of niches, both in space and time, that enables similar species to coexist in a community, just as the five species of warblers feeding in different parts of a spruce tree. We can think of resource partitioning as reflecting the results of past competition, in which competition leads the inferior competitor to eventually occupy a different niche. British ornithologist David Lack examined competition and coexistence among about 40 species of British passerines, or perching birds (Figure 57.8). As a group, these perching birds had fairly similar lifestyles. Most segregated according to some resource factor, with habitat being the most common one. For example, although all the passerines fed on insects, some would feed exclusively in grasslands, others in forests, some low to the ground, and others high in trees, where the insects present would likely be different. Birds also segregated by size—so bigger species would take different-sized food than smaller species—and by feeding habit—with some feeding on insects on tree branches, others on tree trunks, and so on. Some species also fed in different winter ranges, while others occurred in different parts of the country (separation by geography). About 15% of bird species showed no segregation at all.

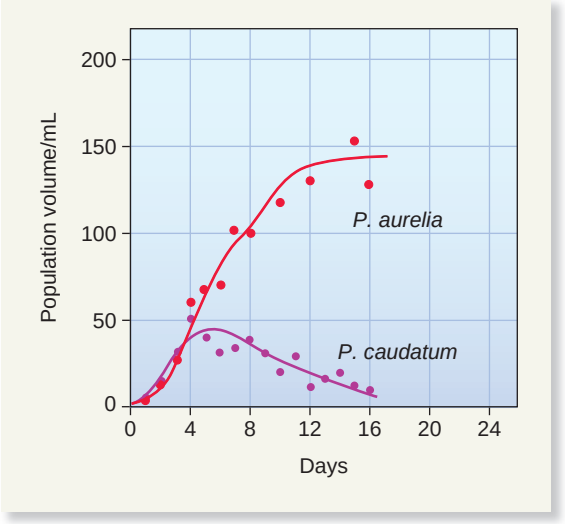
What about the species that do not appear to live in different habitats or have different food habits? To answer this question, researchers have looked at differences in physical form, or morphology, between coexisting species.

Morphological Differences May Allow Species to Coexist

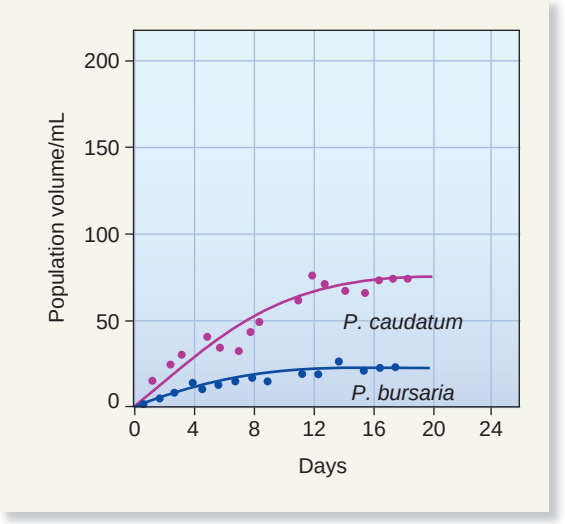
Although the competitive exclusion principle acknowledges that complete competitors cannot coexist, some partial level of competition may exist that is not severe enough to drive one of the competitors to extinction or to a different niche. In 1959, biologist G. Evelyn Hutchinson examined the sizes of mouthparts or other body parts important in feeding and compared their sizes



(a) Each *Paramecium* species grown alone



(b) Competition between *P. aurelia* and *P. caudatum*



(c) Competition between *P. caudatum* and *P. bursaria*

Figure 57.6 Competition among *Paramecium* species. **(a)** When grown alone, each of three species, *Paramecium aurelia*, *Paramecium bursaria*, and *Paramecium caudatum*, grows according to the logistic model. **(b)** When *P. aurelia* is grown with *P. caudatum*, the density of *P. aurelia* is lowered compared to when grown alone, and *P. caudatum* goes extinct. **(c)** When *P. caudatum* is grown with *P. bursaria*, the population densities of both are lowered, but they coexist.

between species when they were **sympatric** (occurring in the same geographic area) and **allopatric** (occurring in different geographic areas). Hutchinson's hypothesis was that when species were sympatric, each species tended to specialize on different types of food. This was reflected by differences in the size of body parts associated with feeding, also called feeding characters. The tendency for two species to diverge in morphology and thus resource use because of competition is called **character displacement**. Alternatively, in areas where species were allopatric, there was no need to specialize on a particular prey type, so the size of the feeding character did not evolve to become larger or smaller; rather it retained a "middle of the road" size that allowed species to exploit the largest range of prey size distribution.

One of the classic cases of character displacement involves a study of Galápagos finches, several closely related species of finches Charles Darwin discovered on the Galápagos Islands (refer back to the Feature Investigation in Chapter 23). When two species, *Geospiza fortis* and *Geospiza fuliginosa*, are sympatric, their beak sizes (bill depths) are different: *G. fortis* has a larger bill depth, which enables it to feed on bigger seeds, whereas *G. fuliginosa* has a smaller bill depth, which enables it to crack small seeds more efficiently. However, when both species are allopatric, that is, existing on different islands, their bills are more similar in depth. Researchers studying *Geospiza* concluded that the bill depth differences evolved in ways that minimized competition.

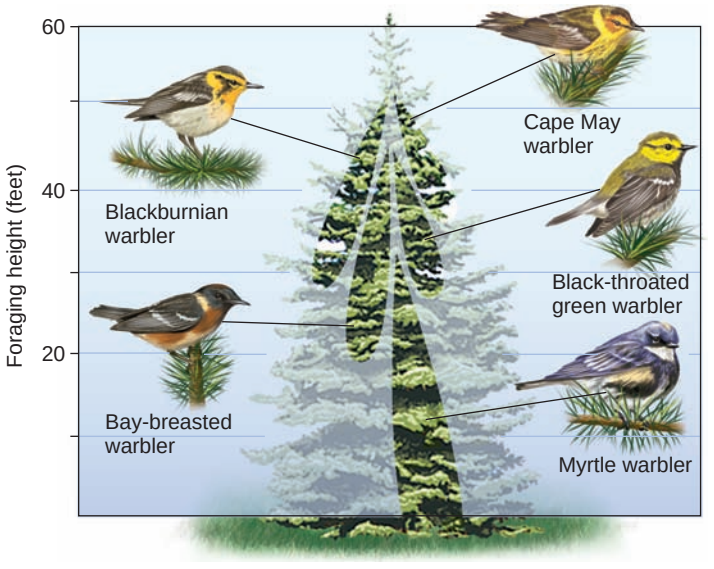


Figure 57.7 **Resource partitioning.** Among five species of warblers feeding in North American spruce trees, each species prefers to feed at a different height and portion of the tree, thus reducing competition.

How great do differences between characters have to be in order to permit coexistence? Hutchinson noted that the ratio between feeding characters when species were sympatric (and thus competed) averaged about 1.3 (Table 57.2). In contrast, the ratio between feeding characters when species were allopatric (and did not compete) was closer to 1.0. Hutchinson proposed that the value of 1.3, a roughly 30% difference, could be used as an indication of the amount of difference necessary to permit two species to coexist. One problem with Hutchinson's ratio is that some differences of 1.3 between similar species might have evolved for reasons other than competition. Some ecologists have argued that we should not conclude that a 30% difference is a strong indicator of coexistence. Nevertheless, while the actual ratio may be disputed, Hutchinson's findings have shown that competition in nature can cause character displacement.

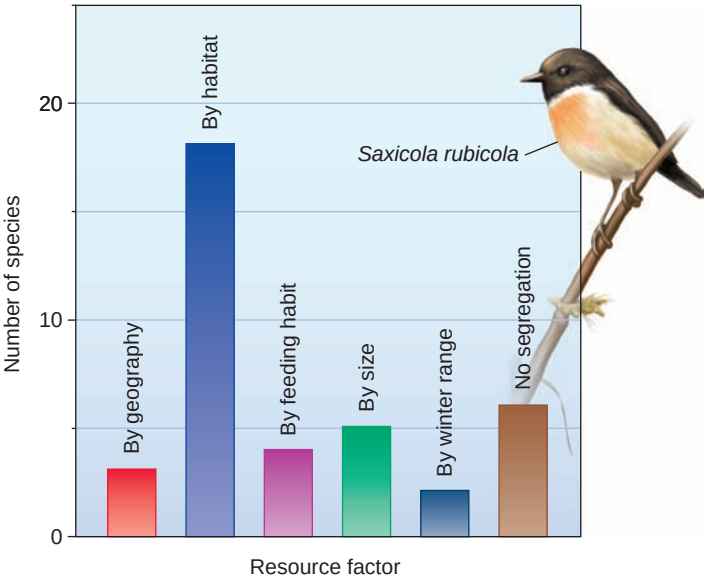

Figure 57.8 **Segregation according to resource factor.** Among 40 species of passerine birds, most segregation is by habitat, followed by size, feeding habit, geography, and type of winter range they forage in. In about 15% of cases, no obvious segregation was observed. More than half of all bird species, including *Saxicola rubicola*, are passerines, also known as perching birds.

Concept check: *Do you think these results for passerine birds are typical for most other species? For example, do most other species segregate by habitat?*

57.2 Predation, Herbivory, and Parasitism

Predation, herbivory, and parasitism are interactions that have a positive effect for one species and a negative effect for the other. These categories of species interactions can be classified according to how lethal they are for the prey and the length of association between the consumer and prey (Figure 57.9).

Table 57.2 Comparison of Feeding Characters of Sympatric and Allopatric Species

		Measurement (mm) when		Ratio* when	
Animal (character)	**Species**	**Sympatric**	**Allopatric**	**Sympatric**	**Allopatric**
Weasels (skull)	*Mustela erminea*	50.4	46.0	1.28	1.07
	Mustela ivalis	39.3	42.9		
Mice (skull)	*Apodemus flavicollis*	27.0	26.7	1.09	1.04
	Apodemus sylvaticus	24.8	25.6		
Nuthatches (beak)	*Sitta tephronota*	29.0	25.5	1.23	1.02
	Sitta neumayer	23.5	26.0		
Galápagos finches (beak)	*Geospiza fortis*	12.0	10.5	1.43	1.13
	Geospiza fuliginosa	8.4	9.3		

*Ratio of the larger to smaller character.

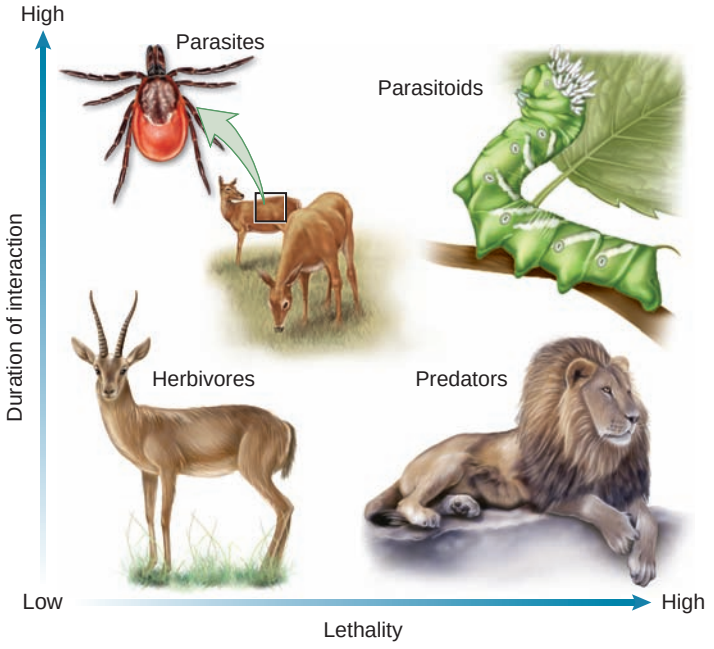

Figure 57.9 **Possible interactions between populations.** Lethality represents the probability that an interaction results in the death of the prey. Duration represents the length of the interaction between the consumer and the prey.

Concept check: *Where might omnivores fit in this figure?*

Each has particular characteristics that set it apart. Herbivory usually involves nonlethal predation on plants, whereas predation generally results in the death of the prey. Parasitism, like herbivory, is typically nonlethal and differs from predation in that the adult parasite typically lives and reproduces for long periods in or on the living host, as in Chinese liver flukes (refer back to Figure 33.9). Parasitoids, insects that lay eggs in living hosts, have features in common with both predators and parasites. They always kill their prey, as predators do, but unlike predators, which immediately kill their prey, parasitoids kill the host more slowly. Parasitoids are common in the insect world and include parasitic wasps and flies that feed on many other insects.

In this section, we begin by looking at antipredator strategies and how, despite such strategies, predation remains a factor affecting the density of prey. We survey the strategies plants use to deter herbivores and how, in turn, herbivores overcome host plant defenses. Finally, we investigate parasitism, which may be the predominant lifestyle on Earth, and explore the growing role of genomics in the fight against parasites.

Animals Have Evolved Many Antipredator Strategies

The variety of strategies that animals have evolved to avoid being eaten suggests that predation is a strong selective force. Common strategies include chemical defense; forms of camouflage and mimicry; displays of intimidation; agility; armor; and altering of reproductive patterns, as in masting.

Chemical Defense A great many species have evolved chemical defenses against predation. One of the classic examples of a chemical defense involves the bombardier beetle (*Stenaptinus insignis*), which has been studied by Tom Eisner and coworkers. These beetles possess a reservoir of hydroquinone and hydrogen peroxide in their abdomen. When threatened, they eject the chemicals into an "explosion chamber," where the subsequent release of oxygen causes the whole mixture to be violently ejected as a hot spray (about 88°C, or 190°F) that can be directed at the beetle's attackers (Figure 57.10a). Many other arthropods, such as millipedes, also have chemical sprays, and the phenomenon is also found in vertebrates, as anyone who has had a close encounter with a skunk can testify.

Often associated with a chemical defense is an **aposematic coloration**, or warning coloration, which advertises an organism's unpalatable taste. For instance, the ladybird beetle's bright red color warns of the toxic defensive chemicals it exudes when threatened, and many tropical frogs have bright warning coloration that calls attention to their skin's lethality (Figure 57.10b). In the 1960s, entomologist Lincoln Brower and coworkers showed that after inexperienced blue jays ate a monarch butterfly and suffered a violent vomiting reaction, they learned to associate the striking orange-and-black appearance of the butterfly with a noxious reaction (refer back to Figure 55.3). Monarch butterfly caterpillars feed exclusively on milkweed, which contains toxic chemicals called cardiac glycosides that pass into the caterpillars. Other animals, such as rattlesnakes, synthesize toxins using their own metabolic processes.

Cryptic Coloration **Cryptic coloration** is an aspect of camouflage, the blending of an organism with the background of its habitat. Cryptic coloration is a common method of avoiding detection by predators. For example, many grasshoppers are green and blend in with the foliage on which they feed. Stick insects mimic branches and twigs with their long, slender bodies. In most cases, these animals stay perfectly still when threatened, because movement alerts a predator. Maintenance of a fixed body posture is referred to as catalepsis. Cryptic coloration is prevalent in the vertebrate world, too. Many sea horses adopt a body shape and color pattern that are similar to the environment in which they are found (Figure 57.10c).

Mimicry **Mimicry**, the resemblance of a species (the mimic) to another species (the model), also secures protection from predators. There are two major types of mimicry. In **Müllerian mimicry**, two or more toxic species converge to look the same, thus reinforcing the basic distasteful design. One example is the black and yellow striped bands of several different types of bees and wasps. Müllerian mimicry is also found among noxious Amazonian butterflies. The viceroy butterfly (*Limenitis archippus*) and the monarch butterfly (*Danaus plexippus*) are examples of Müllerian mimicry. Both species are unpalatable and look similar, but the viceroy can be distinguished from the monarch by a black line that crosses its wings.

Batesian mimicry is the mimicry of an unpalatable species (the model) by a palatable one (the mimic). Some of the

(a) As it is held by a tether attached to its back, this bombardier beetle (*Stenaptinus insignis*) directs its hot, stinging spray at a forceps "attacker."

(b) Aposematic coloration advertises the poisonous nature of this blue poison arrow frog (*Dendrobates azureus*) from South America.

(c) Cryptic coloration allows this Pygmy sea horse (*Hippocampus bargibanti*) from Bali to blend in with its background.

(d) In this example of Batesian mimicry, an innocuous scarlet king snake (*Lampropeltis triangulum*) (left) mimics the poisonous coral snake (*Micrurus nigrocinctus*) (right).

(e) In a display of intimidation, this porcupine fish (*Diodon hystrix*) puffs itself up to look threatening to its predators.

Figure 57.10 Antipredator adaptations.

Concept check: *According to the classification of species interactions in Table 57.1, how would you classify Batesian and Müllerian mimicry?*

best examples involve flies, especially hoverflies of the family Syrphidae, which are striped black and yellow and resemble stinging bees and wasps but are themselves harmless. Among vertebrates, the nonvenomous scarlet king snake (*Lampropeltis triangulum*) mimics the venomous coral snake (*Micrurus nigrocinctus*), thereby gaining protection from would-be predators (Figure 57.10d).

Displays of Intimidation Some animals put on displays of intimidation in an attempt to discourage predators. For example, a cat arches its back to make itself appear larger, frilled lizards extend their collars when frightened to create this same effect, and porcupine fish inflate themselves to large proportions when threatened (Figure 57.10e). All of these animals use displays to deceive potential predators about the ease with which they can be eaten.

Fighting Though many animals developed horns and antlers for sexual selection, they can also be used in defense against predators (refer back to Figure 34.25). Invertebrate species often have powerful claws, pincers, or, in the case of scorpions, venomous stingers that can be used in defense as well as offense.

Agility Some groups of insects, such as grasshoppers, have a powerful jumping ability to escape the clutches of predators. Many frogs are prodigious jumpers, and flying fish can glide above the water to escape their pursuers.

Armor The shells of tortoises and turtles are a strong means of defense against most predators, as are the quills of porcupines (refer back to Figure 34.23c). Many beetles have a tough exoskeleton that protects them from attack from other arthropod predators such as spiders.

Masting **Masting** is the synchronous production of many progeny by all individuals in a population to satiate predators and thereby allow some progeny to survive. Masting is more commonly discussed in relation to seed predation in trees, which tend to have years of unusually high seed production that reduces predation. However, a similar phenomenon is exhibited by the emergence of 13-year and 17-year periodical cicadas (genus *Magicicada*). These insects are termed periodical because the emergence of adults is highly synchronized to occur once every 13 or 17 years. Adult cicadas live for only a few weeks, during which time females mate and deposit eggs on the twigs of trees. The eggs hatch 6 to 10 weeks later, and

the nymphs drop to the ground and begin a long subterranean development, feeding on the contents of the xylem of roots. Because the xylem is low in nutrients, it takes many years for nymphs to develop, though there appears to be no physiological reason why some cicadas couldn't emerge after, say, 12 years of feeding, and others after 14. Their synchrony of emergence is thought to maximize predator satiation. Worth noting in this context is the fact that both 13 and 17 are prime numbers, and thus predators on a shorter multiannual cycle cannot repeatedly utilize this resource. For example, a predator that bred every 3 years could not rely on cicadas always being present as a food supply.

How common is each of these defense types? No one has done an extensive survey of the entire animal kingdom. However, in 1989, Brian Witz surveyed studies that documented antipredator mechanisms in arthropods, mainly insects. By far the most common antipredator mechanisms were chemical defenses and associated aposematic coloration, noted in 51% of the examples. All other types of defense mechanisms occurred with considerably less frequency.

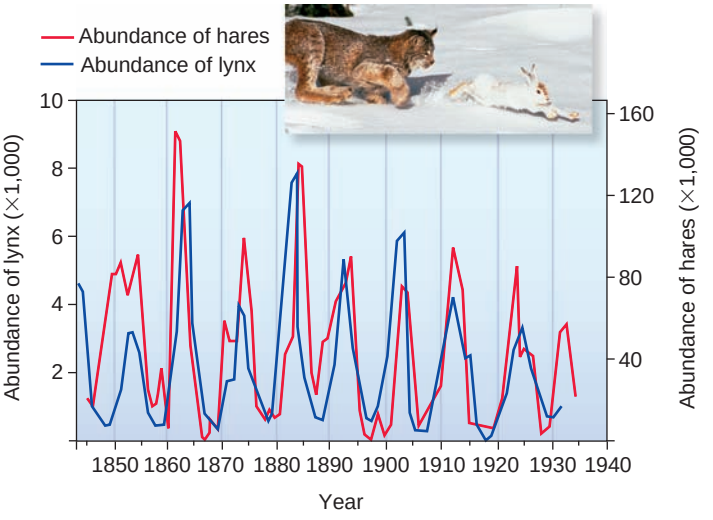

Figure 57.11 **Effect of predator on prey populations.** The 9- to 11-year oscillation in the abundance of the snowshoe hare (*Lepus americanus*) and the Canada lynx (*Lynx canadensis*) was revealed from pelt trading records of the Hudson's Bay Company.

Despite the Impressive Array of Defenses, Predators Can Still Affect Prey Densities

The importance of predation on prey populations may be dependent on whether the system is donor controlled or predator controlled. In a donor-controlled system, prey supply is determined by factors other than predation, such as food supply, so that removal of predators has no significant effect on prey density. Examples include predators that feed on intertidal communities in which space is the limiting factor that controls prey populations.

In a predator-controlled system, the action of predator feeding eventually reduces the supply of prey. Therefore, the removal of predators would probably result in large increases in prey abundance. Research studies have shown that predators can have a significant effect on prey populations. Considerable data exist on the interaction of the Canada lynx (*Lynx canadensis*) and its prey, snowshoe hares (*Lepus americanus*), because of the value of the pelts of both animals. In 1942, British ecologist Charles Elton analyzed the records of furs traded by trappers to the Hudson's Bay Company in Canada over a 100-year period. Analysis of the records showed that a dramatic 9- to 11-year cycle existed for as long as records had been kept (Figure 57.11). As hare density increases, there is an increase in density of the lynx, which then depresses hare numbers. This is followed by a decline in the number of lynx, and the cycle begins again. By tracking individual hares by using radio collars, researchers were able to determine that 90% of individuals died of predation. However, more recent research has shown that hare densities may increase in times of food surpluses. When researchers added food supplements to large experimental areas containing both hares and lynxes, the hare densities increased threefold but still continued to cycle.

Invasive species provide striking examples of the effects of predators. The brown tree snake (*Boiga irregularis*) was inadvertently introduced by humans to the island of Guam, in Micronesia, shortly after World War II. The growth and spread of its population over the next 40 years closely coincided with a precipitous decline in the island's forest birds. On Guam, the snake had no natural predators to control it. Because the birds on Guam did not evolve with the snake, they had no defenses against it. Eight of the island's 11 native species of forest birds went extinct by the 1980s, such as the Guam rail and Micronesian kingfisher (Figure 57.12).

One of the biggest reductions in prey in response to predation has been the systematic decline of various whale species as a result of the human whaling industry. The history of whaling has been characterized by a progression from larger, more valuable or easily caught species to smaller, less valuable or easily caught ones, as numbers of the original targets have been depleted (Figure 57.13). Belatedly, the International Whaling Commission enacted a moratorium on all commercial whaling in 1986. Following the moratorium, the populations of some whales have increased. Blue whales are thought to have quadrupled their numbers off the California coast during the 1980s, and numbers of the California gray whales have recovered to prewhaling levels, showing the impact that an absence of a predator can have.

Ecologists have found that in nearly 1,500 predator-prey studies, over two-thirds (72%) showed a large depression of prey density by predators. Thus, we can conclude that in the majority of cases, predators influence the abundance of their prey in their native environment. The variety of antipredator mechanisms discussed earlier also shows how predation is important enough to select for the evolution of chemical defenses, camouflage, and mimicry in prey. Taken together, these data indicate that predation is a powerful force in nature.

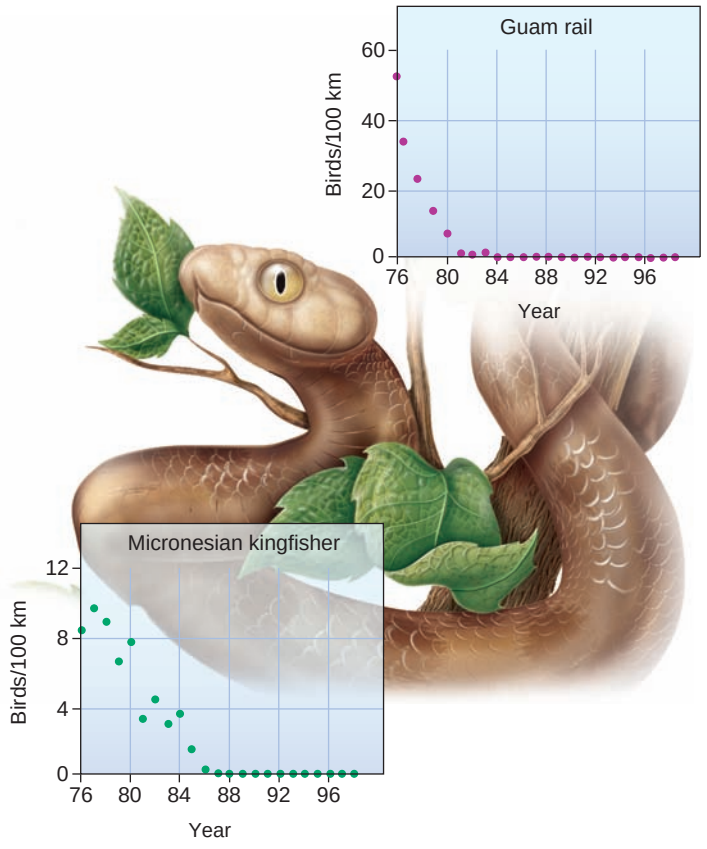

Figure 57.12 **Predation by an invasive species.** Population trends for two native Guam birds, as indicated by 100-km roadside surveys conducted from 1976 to 1998, show a precipitous decline because of predation by the introduced brown tree snake.

Concept check: *Why can invasive predators have such strong effects on native prey?*

Plants and Herbivores May Be Engaged in an Evolutionary Arms Race

Herbivory involves the predation of plants or similar life forms such as algae. Such predation can be lethal to the plants, especially for small species, but often it is nonlethal, because many plant species, particularly larger ones, can regrow. We can distinguish two types of herbivores: generalist herbivores and specialist herbivores. Generalist herbivores can feed on many different plant species and are usually mammals. Specialist herbivores are often restricted to one or two species of host plants and are typically insects. There are, however, exceptions. Pandas are specialists because they feed only on bamboo, and koalas specialize on eucalyptus trees. On the other hand, grasshoppers are generalists, because they feed on a wide variety of plant species, including agricultural crops.

Plants present a luscious green world to any organism versatile enough to use it, so why don't herbivores eat more of the food available to them? After all, unlike most animals, plants cannot move to escape being eaten. Two hypotheses have been

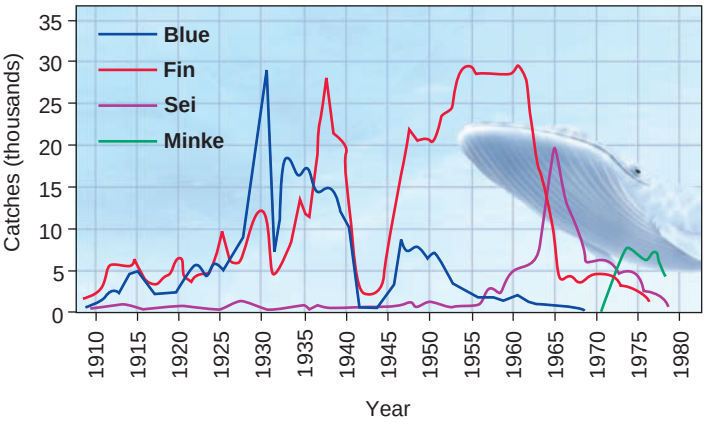

Figure 57.13 **Sequential decline of whale catches in the Antarctic due to human predation.** Whale catches are believed to be directly related to whale population sizes. The catches of the blue whale, the first species to be strongly affected by human predation, started a precipitous decline in the 1940s, as the whale was hunted to very low levels. Humans then began hunting more-abundant fin whales, and then sei and minke whales, as each species became depleted.

proposed to answer the question of why more plant material is not eaten. First, predators and parasites may keep herbivore numbers low, thereby sparing the plants. The many examples of the strength of predation provide evidence for this view. Second, the plant world is not as helpless as it appears. The sea of green is armed with defensive spines, tough cuticles, noxious chemicals, and more. Let's take a closer look at plant defenses against herbivores and the ways that herbivores attempt to overcome them.

Plant Defenses Against Herbivores As described in Chapter 7, an array of unusual and powerful chemicals is present in plants, including alkaloids (nicotine in tobacco, morphine in poppies, cocaine in coca, and caffeine in coffee), phenolics (lignin in wood and tannin in leaves), and terpenoids (in peppermint) (Figure 57.14a–c, also refer back to Figure 7.17). Such compounds are not part of the primary metabolic pathway that plants use to obtain energy. They are therefore referred to as **secondary metabolites**. Most of these chemicals are bitter tasting or toxic, and they deter herbivores from feeding. The staggering variety of secondary metabolites in plants, over 25,000, may be testament to the large number of organisms that feed on plants. In an interesting twist, many of these compounds have medicinal properties that are beneficial to humans (see Chapter 7).

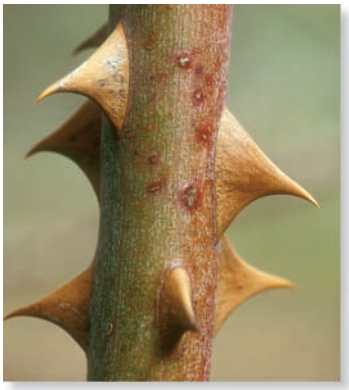
In addition to containing chemical compounds, many plants have an array of mechanical defenses, such as thorns and spines (Figure 57.14d). In other cases, an organism may provide a plant physical protection against herbivores in return for resources such as light, water, nutrients, or nesting sites (as we will see in Section 57.3).

An understanding of plant defenses is of great use to agriculturalists. The better that crops are defended against pests,

(a) Alkaloids in tobacco

(b) Phenolics in tea

(c) Terpenoids in peppermint



(d) Thorns on rose stems

Figure 57.14 **Defenses against herbivory.** Plants possess an array of unusual and powerful chemicals, including **(a)** alkaloids, such as nicotine in tobacco, **(b)** phenolics, such as tannins in tea leaves (near Mount Fuji, Japan), and **(c)** terpenoids in peppermint leaves. **(d)** Mechanical defenses include plant spines and thorns, as on this shrub, *Rosa multiflora*.

Concept check: Of the defenses shown here, which type of defense would be most effective in deterring invertebrate herbivores?

the higher the crop yield. The ability of plants to prevent herbivory via either chemical or mechanical defenses is also known as **host plant resistance**. One serious problem associated with commercial development of host plant resistance is that it may take a long time to breed into plants—between 10 and 15 years. This is because of the long time it takes to identify the responsible chemicals and develop the resistant genetic lines. Also, resistance to one pest may come at the cost of increasing susceptibility to other pests. Finally, some pest strains can overcome the plant's mechanisms of resistance.

Despite these problems, host plant resistance is a good tactic for the farmer. After the initial development of resistant varieties, the cost is minimal. Perhaps more importantly, host plant resistance reduces the need for chemical insecticides and is less environmentally harmful, generally having few side effects on other species in the community. About 75% of cropland in the U.S. utilizes pest-resistant plant varieties, most of these being resistant to plant pathogens. Bt corn is a variety of corn that has been genetically modified to incorporate a gene from the soil bacterium *Bacillus thuringiensis* (Bt) that encodes a protein, Bt toxin, that is toxic to some insects. Genetic engineers have also produced Bt cotton, Bt tomato, and genetically modified varieties of many other crop species.

Overcoming Plant Resistance Herbivores can often overcome plant defenses. They can detoxify many poisons, mainly by two chemical pathways: oxidation and conjugation. Oxidation, the most important of these mechanisms, occurs in the liver of mammals and in the midgut of insects. It involves catalysis of the secondary metabolite to a corresponding alcohol by a group of enzymes known as mixed-function oxidases (MFOs). Conjugation, often the next step in detoxification, occurs by uniting the harmful compound or its oxidation product with another molecule to create an inactive and readily excreted product.

In addition, certain chemicals that are toxic to generalist herbivores actually increase the growth rates of adapted specialist species, which put the chemicals to good use in their own metabolic pathways. The Brassicaceae, the plant family that includes mustard, cabbage, and other species, contains acrid-smelling mustard oils called glucosinolates, the most important one of which is sinigrin. Large white butterflies (*Pieris brassicae*) preferentially feed on cabbage over other plants. They are able to detoxify even high levels of sinigrin. If newly hatched larvae are fed an artificial diet, they do much better when sinigrin is added to it. When larvae are fed cabbage leaves on hatching from eggs and are later switched to an artificial diet without sinigrin, they starve rather than eat. In this case, the secondary metabolite has become an essential feeding stimulant.

A good method to estimate the effects of herbivory on plant populations is to remove the herbivores and examine subsequent growth and reproductive output. Analyses of hundreds of such experiments have yielded several interesting generalizations. First, herbivory in aquatic systems is more extensive than in terrestrial ones. Aquatic systems contain species, such as algae, that are especially susceptible to herbivory, presumably because these organisms are the least sophisticated in terms of their ability to manufacture complex secondary metabolites. In terms of terrestrial systems, grasses and shrubs are significantly affected by herbivores, but woody plants such as trees are less so. Large and long-lived trees can draw on large resource reserves to buffer the impact of herbivores.

Second, invertebrate herbivores such as insects have a stronger effect on plants than vertebrate herbivores such as mammals, at least in terrestrial systems. Thus, while one might consider large grazers like bison in North America or antelopes in Africa to be of huge importance in grasslands, it is more likely that grasshoppers are the more significant herbivores because of their sheer weight of numbers. In forests, invertebrate grazers such as caterpillars have greater access to canopy leaves than vertebrates and are also likely to have a greater effect.

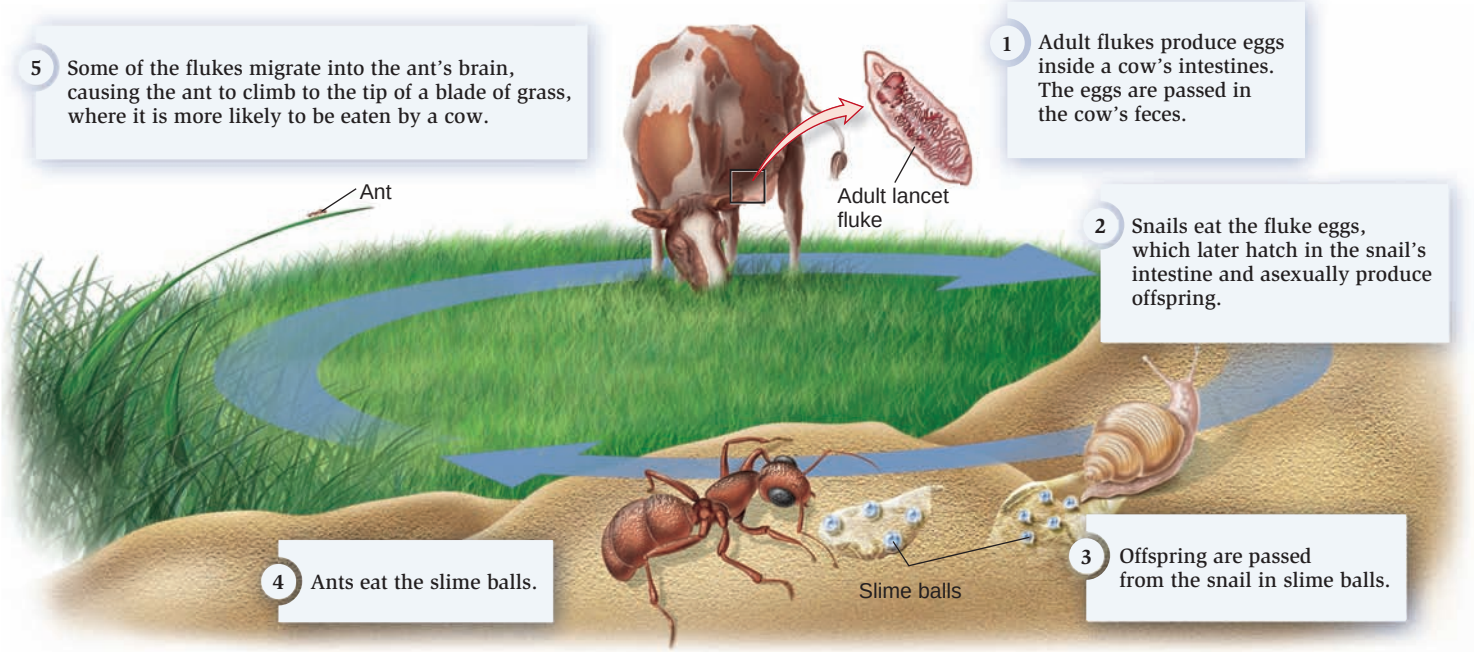


Figure 57.15 **The life cycle of the lancet fluke.** The lancet fluke (*Dicrocoelium dendriticum*) causes behavioral changes in ants (one of its three hosts) that increase its transmission rate.

Parasitism Might Be the Predominant Lifestyle on Earth

When one organism feeds on another but does not normally kill it outright, the organism is termed a **parasite**, and the prey a **host**. Some parasites remain attached to their hosts for most of their life. For example, tapeworms spend their entire adult life inside the host's alimentary canal and even reproduce within their host. Others, such as the lancet fluke, have more complex life cycles that require multiple hosts (Figure 57.15). Some, such as ticks and leeches, drop off their hosts after prolonged periods of feeding. Others, like mosquitoes, remain attached for relatively short periods.

Some flowering plants are parasitic on other plants. **Holoparasites** lack chlorophyll and are totally dependent on the host plant for their water and nutrients. One famous holoparasite is the tropical *Rafflesia arnoldii*, which lives most of its life within the body of its host, a *Tetrastigma* vine, which grows in rain forests (Figure 57.16). Only the *Rafflesia* flower develops externally. It is a massive flower, 1 m in diameter and the largest known in the world. **Hemiparasites** generally do photosynthesize, but they depend on their hosts for water and mineral nutrients. Mistletoe (*Viscum album*) is a hemiparasite that grows on the stems of trees. Hemiparasites usually have a broader range of hosts than do holoparasites, which may be confined to a single or a few host species.

Parasites that feed on one species or just a few closely related hosts are termed **monophagous**. By contrast, **polyphagous** species can feed on many different host species, often from more than one family. We can also distinguish parasites

Figure 57.16 **A holoparasite.** *Rafflesia arnoldii*, the world's biggest flower, lives as a holoparasite in Indonesian rain forests.

as **microparasites** (for example, pathogenic bacteria), which multiply within their hosts, sometimes within the cells, and **macroparasites** (such as schistosomes), which live in the host but release infective juvenile stages outside the host's body. Usually, the host has a strong immunological response to microparasitic infections. For macroparasitic infections, however, the immunological response is short-lived. Such infections tend to be persistent, and the hosts are subject to continual reinfection.

Last, we can distinguish **ectoparasites**, such as ticks and fleas, which live outside of the host's body, from **endoparasites**, such as pathogenic bacteria and tapeworms, which live inside the host's body. Problems of definition arise with regard

to plant parasites, which seem to straddle both camps. For example, some parasitic plants, such as dodder (*Cuscuta pentagona*), an orange, stringlike plant, exist partly outside of the host's body and partly inside (refer back to Figure 37.22). Outgrowths called haustoria penetrate inside the host plant to tap into nutrients. Being endoparasitic on a host seems to require greater specialization than ectoparasitism. Therefore, ectoparasitic animals such as leeches feed on a wider variety of hosts than do endoparasites such as liver flukes.

As we have seen throughout this textbook, parasitism is a common way of life. There are vast numbers of species of parasites, including bacteria, protozoa, flatworms (flukes and tapeworms), nematodes, and various arthropods (ticks, mites, and fleas). Parasites may outnumber free-living species by four to one. Most plant and animal species harbor many parasites. For example, leopard frogs have nematodes in their ears and veins, and flukes in their bladders, kidneys, and intestines. A free-living organism that does not harbor parasitic individuals of a number of species is a rarity.

As with studies of other species interactions, a direct method to determine the effect of parasites on their host population is to remove the parasites and to reexamine the population. However, this is difficult to do, primarily because of the small size and unusual life histories of many parasites, which makes them difficult to remove from a host completely. The few cases of experimental removal confirm that parasites can reduce host population densities. The nests of birds such as blue tits are often infested with parasitic blowfly larvae that feed on the blood of nestlings. In 1997, Sylvie Hurtrez-Bousses and colleagues experimentally reduced blowfly larval parasites of young blue tits in nests in Corsica. Parasite removal was cleverly achieved by taking the nests from 145 nest boxes, removing the young, microwaving the nests to kill the parasites, and then returning the nests and chicks to the wild. The success of chicks in microwaved nests was compared to that in nonmicrowaved (control) nests. The parasite-free blue tit chicks had greater body mass at fledging, the time when feathers first grow (Figure 57.17). Perhaps more important was that complete nest failure, that is, death of all chicks, was much higher in control nests than in treated nests.

Because parasite removal studies are difficult to do, ecologists have also examined the strength of parasitism as a mortality factor by studying introduced parasite species. Evidence from natural populations suggests that introduced parasites have substantial effects on their hosts. For example, chestnut blight, a fungus from Asia, was accidentally introduced to New York around 1904. By the 1950s, the airborne fungus had significantly reduced the density of American chestnut trees (*Castanea dentata*) in North Carolina (Figure 57.18). Eventually, it eliminated nearly all chestnut trees across North America. In Europe and North America, Dutch elm disease has similarly devastated populations of elms. The disease wiped out 25 million of Britain's original 30 million elm trees between the 1960s and the 1990s. In Italy, canker has had similar severe effects on cypress. The creation of transgenic plants through recombinant DNA methods is a recent development in the fight against plant diseases.

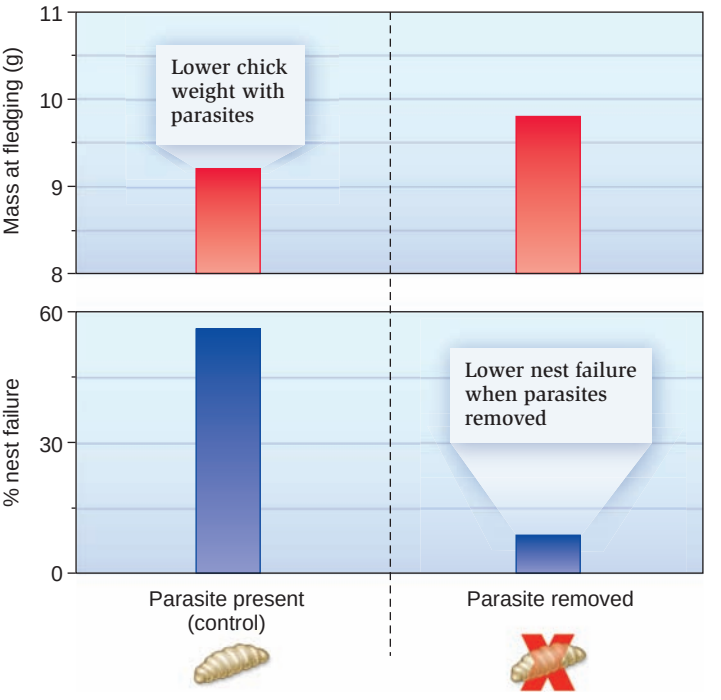

Figure 57.17 **Parasite removal experiments.** The left side shows the results when blowfly larva were present in the nests of young blue tits. The right side shows the results when these parasites were removed.

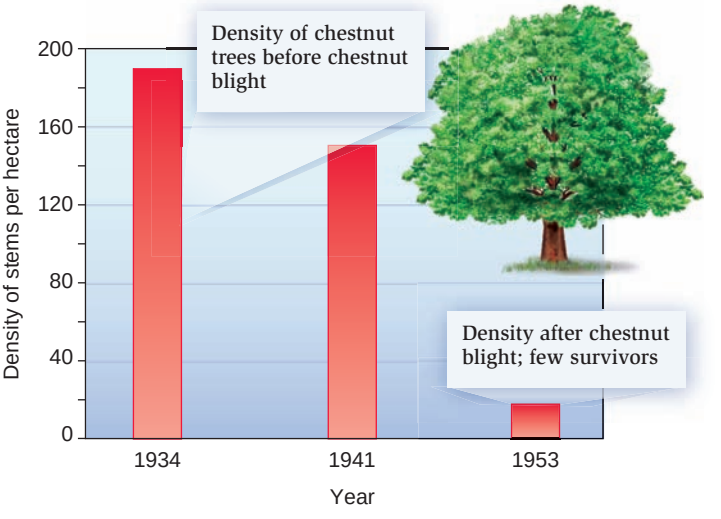

Figure 57.18 **Effects of introduced parasites on American chestnut trees.** The reduction in density of American chestnut trees in North Carolina following the 1904 introduction of chestnut blight disease from Asia shows the severe effect that parasites can have on their hosts. By the 1950s, this once-prevalent species was virtually eliminated.

Genomes & Proteomes Connection

Transgenic Plants May Be Used in the Fight Against Plant Diseases

Many important native forest trees, which are also grown in urban landscapes, have been almost entirely wiped out by diseases spread by the importation of exotic plants. Sudden oak death is a recently recognized disease that is killing tens of thousands of oak trees and other plant species in California. The symptoms vary between species but include leaf spots, oozing of a dark sap through the bark, and twig dieback (Figure 57.19). Although sudden oak death is a forest disease, the organism causing this disease is known to infect many woody ornamental plants, such as rhododendrons, that are commonly sold by nurseries. In March 2004, a California nursery was found to have unknowingly shipped plants infected with sudden oak death to all 50 states. Following this discovery, California nurseries halted shipments of trees to other states in an attempt to stop the spread of the disease, originally thought to have been imported on rhododendrons. In 2004, scientists mapped out the genome sequence of the disease-carrying fungus, *Phytophthora ramorum*. Identifying the genes and their proteins may help scientists develop specific diagnostic tests to quickly detect the presence of sudden oak death in trees, which is currently impossible to detect until a year or more after the tree is infected.

Scientists hope for much from the field of genomics in their fight against plant parasites that cause diseases. Many scientists have suggested limited, cautious transfer of resistance genes from the original host species in the source regions of the disease to newly threatened species. Original host species have usually evolved over millions of years of exposure to these diseases and have acquired genes that provide resistance. In the regions of recent introduction of parasites, there has been no selection for resistance, so the host plants are often killed en masse. Transgenic trees that have received pathogen resistance-enhancing genes could be produced and then be replanted in forests or urban areas. An advantage of this technique over traditional cross-breeding strategies involving two different species is that transgenic methods involve the introduction of fewer genes to the native species. Also, fewer tree generations would be required to develop resistance. For example, using traditional breeding technology, Asian chestnut trees (*Castanea mollissima*) are being bred with American chestnuts (*Castanea dentata*) to reduce the susceptibility of the latter to chestnut blight. The resultant hybrid is often significantly altered in appearance from the traditional American chestnut, and the process takes more than a decade to produce trees that are ready to plant. Transgenic technology could minimize these drawbacks. William Powell and colleagues are working to enhance the American chestnut's resistance by inserting a gene taken from wheat. The gene, which encodes an enzyme called oxalate oxidase, destroys a toxin produced by the fungus that causes chestnut blight.

57.3 Mutualism and Commensalism

In this section, we will examine the major types of mutualism and commensalism, interactions that are beneficial to at least one of the species involved. In mutualism, both species gain from the interaction. For example, in mutualistic pollination systems, the plant benefits by the transfer of pollen, and the pollinator typically gains a nectar meal. In commensalism, one species benefits, and the other remains unaffected. For example, in some forms of seed dispersal, barbed seeds are transported to new germination sites in the fur of mammals. The seeds benefit, but the mammals are generally unaffected.

It is interesting to note that humans have entered into mutualistic relationships with many species. For example, the association of humans with plants has resulted in some of the most far-reaching ecological changes on Earth. Humans have planted huge areas of the Earth with crops, allowing these plant populations to reach densities they never would on their own. In return, the crops have led to expanded human populations because of the increased amounts of food they provide.

Mutualism Is an Association Between Two Species That Benefits Both Species

Many close associations are known between species in which both species benefit. For example, leaf-cutting ants of the group

Attini, of which there are about 210 species, enter into a mutualistic relationship with a fungus. A typical colony of about 9 million ants has the collective biomass of a cow and harvests the equivalent of a cow's daily requirement of fresh vegetation. Instead of consuming the leaves directly, the ants chew them into a pulp, which they store underground as a substrate on which the fungus grows. The ants shelter and tend the fungus, helping it reproduce and grow and weeding out competing fungi. In turn, the fungus produces specialized structures known as gongylidia, which serve as food for the ants. In this way, the ants circumvent the chemical defenses of the leaves, which are digested by the fungus.

The ant-fungus mutualism, which permits both species to live in close association, utilizing a common resource, is known as a **trophic mutualism**, where both species receive a benefit of resources. Other different types of mutualisms occur in nature. Some of these are **defensive mutualisms**, often involving an animal defending a plant or an herbivore. **Dispersive mutualisms** include plants and pollinators that disperse their pollen, and plants and fruit eaters that disperse the plant's seeds.

Defensive Mutualism One of the most commonly observed mutualisms occurs between ants and aphids. Aphids are fairly defenseless creatures and are easy prey for most predators. The aphids feed on plant sap and have to process a significant amount of it to get their required nutrients. In doing so, they excrete a lot of fluid, and some of the sugars still remain in the excreted fluid, which is called honeydew. The ants drink the honeydew and, in return, protect the aphids from an array of predators, such as ladybird beetle larvae, by driving the predators away. In some cases, the ants herd the aphids like cattle, moving them from one area to another (Figure 57.20a).

In other cases, ants enter into a mutualistic relationship with a plant itself. One of the most famous cases involves acacia trees in Central America, whose large thorns provide food and nesting sites for ants (Figure 57.20b). In return, the ants bite and discourage both insect and vertebrate herbivores from feeding on the trees. They also trim away foliage from competing plants and kill neighboring plant shoots, ensuring more light, water, and nutrient supplies for the acacias. In this case, neither species can live without the other, a concept called **obligatory mutualism**. This contrasts with **facultative mutualism**, in which the interaction is beneficial but not essential to the survival and reproduction of either species. For example, ant-aphid mutualisms are generally facultative. Both species benefit from the association, but each could live without the other.

Dispersive Mutualism Many examples of plant-animal mutualisms involve pollination and seed dispersal. From the plant's perspective, an ideal pollinator would be a specialist, moving quickly among individuals but retaining a high fidelity to a plant species. Two ways that plant species in an area promote the pollinator's species fidelity is by synchronized flowering within a species and by sequential flowering of different species through the year. The plant should provide just enough nectar to attract a pollinator's visit. From the pollinator's perspective, it would be best to be a generalist and obtain nectar and pollen from as many flowers as possible in a small area, thus minimizing the energy spent on flight between patches. This suggests that although mutualisms are beneficial to both species, their optimal needs are quite different.

Mutualistic interactions are also highly prevalent in the seed-dispersal systems of plants. Fruits provide a balanced diet of proteins, fats, and vitamins. In return for this juicy meal, animals unwittingly disperse the enclosed seeds, which pass through the digestive tract unharmed. Fruits eaten by birds and mammals often have attractive colors (Figure 57.21); those dispersed by nocturnal bats are not brightly colored but instead give off a pungent odor that attracts the bats.

(a) An ant defending aphids in exchange for food

(b) Ants defending an acacia plant in exchange for food and shelter

Figure 57.20 Defensive mutualism. This form of mutualism involves species that receive food or shelter in return for providing protection. **(a)** This red carpenter ant, *Camponotus pennsylvanicus*, tends aphids feeding on a twig. The ants receive sugar-rich honeydew produced by the aphids, and, in return, they protect the aphids from predators. **(b)** Ants, usually *Pseudomyrmex ferruginea*, make nests inside the large, hornlike thorns of the bull's horn acacia and defend the plant against insects and mammals. In return, the acacia (*Acacia collinsii*) provides two forms of food to the ants: protein-rich granules called Beltian bodies and nectar from extrafloral nectaries (nectar-producing glands that are physically apart from the flower).

Concept check: Is the relationship between red carpenter ants and aphids an example of facultative or obligatory mutualism?

Figure 57.21 **Dispersive mutualism.** This blackbird (*Turdus merula*) is an effective seed disperser.

(a) An orchid without nectar mimicking a female bee **(b) Seed dispersal via hooked seeds**

Figure 57.22 **Commensalisms.** **(a)** Bee orchids (*Ophrys apifera*) mimic the shape of a female bee. Male bees copulate with the flowers, transferring pollen but getting no nectar reward. **(b)** Hooked seeds of burdock (*Arctium minus*) have lodged in the fur of a white-footed mouse (*Peromyscus leucopus*). The plant benefits from the relationship by the dispersal of its seeds, and the animal is not affected.

In Commensalism, One Partner Receives a Benefit While the Other Is Unaffected

Commensalism is an interaction between species in which one benefits and the other is neither helped nor harmed. Such is the case when orchids or other epiphytes grow in forks of tropical trees. The tree is unaffected, but the orchid gains support and increased exposure to sunlight and rain. Cattle egrets feed in pastures and fields among cattle, whose movements stir up insect prey for the birds. The egrets benefit from the association, but the cattle generally do not. One of the best examples of commensalism involves **phoresy**, in which one organism uses a second organism for transportation. Hummingbird flower mites feed on the pollen of flowers and travel between flowers in the nostrils (nares) of hummingbirds. The flowers the mites inhabit live only a short while before dying, so the mite relocates by scuttling into the nares of visiting hummingbirds and hitching a ride to the next flower. When the hummingbird visits a new flower, the mite disembarks. Presumably, the hummingbirds are unaffected.

Some commensalisms involve one species "cheating" on the other without harming it. In the bogs of Maine, the grass-pink orchid (*Calopogon pulchellus*) produces no nectar, but it mimics the nectar-producing rose pogonia (*Pogonia ophioglossoides*) and is therefore still visited by bees. Another example involves bee orchids (*Ophrys apifera*) that mimic the appearance and scent of female bees. Males pick up and transfer pollen while trying to copulate with the flowers (Figure 57.22a). The stimuli of flowers of the bee orchid are so effective that male bees prefer to mate with them even in the presence of actual female bees! Many plants have essentially cheated their potential mutualistic seed-dispersal agents out of a meal by developing seeds with barbs or hooks that lodge in the animals' fur or feathers rather than their stomachs (Figure 57.22b). In these cases, the plants receive free seed dispersal, and the animals receive nothing, except perhaps minor annoyance. This type of relationship is fairly common; most hikers and dogs have at some time gathered spiny or sticky seeds as they wandered through woods or fields.

57.4 Conceptual Models

In this chapter, we have seen that interactions between species, such as competition, predation, and parasitism, are important in nature. How can we determine which of these factors, along with abiotic factors such as temperature and moisture, are the most important in influencing population size? The question is one asked by many applied biologists, such as foresters, marine biologists, and conservation biologists, who are interested in maximizing a population's size, as well as ecologists in general.

Some ecologists stress the importance of so-called bottom-up factors, such as plant or prey quality and abundance in controlling herbivores and the predators that feed on them. Others stress the importance of top-down factors, such as predators and parasites, acting to control their animal or plant prey (Figure 57.23). For example, in the beginning of the chapter, we noted how a decline in the size of shark populations along the east coast had led to an increase in their main prey, rays and skates, and a decrease in bay scallops, the prey of rays and skates. This is a top-down effect known as a trophic cascade, because its effects cascade down to all feeding levels of the system. In this section, we will briefly discuss some of the evidence for the existence of bottom-up versus top-down control and examine conceptual models where both mechanisms are deemed important.

Bottom-Up Control Suggests Food Limitation Influences Population Densities

At least two lines of evidence suggest that bottom-up effects are important in limiting population sizes. First, we know there is

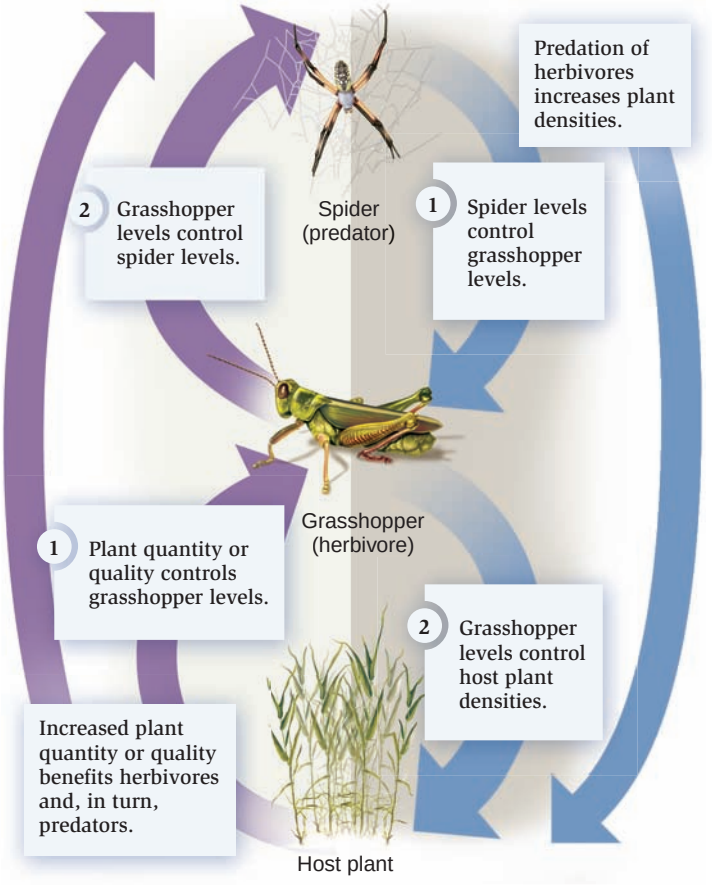

Figure 57.23 **Bottom-up control versus top-down control.** **(a)** Bottom-up control proposes that host plant quantity or quality limits the density of herbivores, such as grasshoppers, which, in turn, sets limits on the abundance of predators, such as spiders. Taken together, this means that high quantity and quality of host plants would result in increased numbers of predators because of higher densities of the herbivores they prey on. **(b)** Top-down control proposes that predators limit the number of herbivores, which, in turn, increases host plant density. Taken together, this means that high levels of predation would result in high densities of host plants because there would be fewer herbivores.

Concept check: *You add fertilizer to a bush, and this increases spider density on the bush. What is this an example of?*

a progressive lessening of available energy passing from plants through herbivores to carnivores and to secondary carnivores (carnivores that eat other carnivores). This line of evidence, based on the thermodynamic properties of energy transfer, suggests that the quantity and quality of plants regulates the population size of all other species that rely on them.

Second, much evidence supports the **nitrogen-limitation hypothesis** that organisms select food in terms of the nitrogen content of the tissue. This is largely due to the different proportions of nitrogen in plants and animals. Animal tissue generally contains about 10 times as much nitrogen as plant tissue. For this reason, animals favor high-nitrogen plants. Fertilization has repeatedly been shown to benefit herbivores. Nearly 60% of 186 studies investigating the effects of fertilization on herbivores reported that increasing a plant's tissue nitrogen concentration through fertilization had strong positive effects on herbivore population sizes, survivorship, growth, and fecundity.

Top-Down Control Suggests Natural Enemies Influence Population Densities

Top-down models suggest that predators control populations of their prey (ultimately, herbivores) and that these herbivores control plant populations. Supporting evidence comes from the world of biological control, where natural enemies are released to control agricultural pests such as weeds. Many weeds are invaders that were accidentally introduced to an area from a different country, as seeds that lodge in ships' ballasts or in agricultural shipments. Over 50% of the 190 major weeds in the U.S. are invaders from outside the country. Many of these weeds have become separated from their native natural enemies, which is one reason the weeds become so prolific. Because chemical control is expensive and may have unwanted environmental side effects, many land managers have reverted to biological control, in which the invading weed is reunited with its native natural enemy.

Ecologists have seen many successes in the biological control of weeds. St. John's wort (*Hypericum perforatum*), a pest in California pastures, was controlled by two beetles from its homeland in Europe. Likewise, alligator weed has been controlled in Florida's rivers by the alligatorweed flea beetle (*Agasicles hygrophila*) from South America. The prickly pear cactus (*Opuntia stricta*) provides a prime example of effective biological control of a weed. The cactus was imported into Australia in the 19th century and quickly established itself as a major pest of rangeland. The small cactus moth (*Cactoblastis cactorum*) was introduced in the 1920s and, within a short time, successfully saved hundreds of thousands of acres of valuable rangeland from being overrun by the cacti (Figure 57.24). The numerous examples showing that pest populations are controlled when

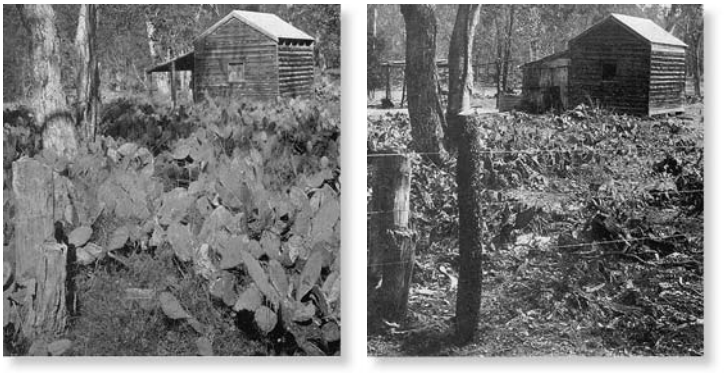

Figure 57.24 **Successful biological control of prickly pear cactus.** The prickly pear cactus (*Opuntia stricta*) in Chinchilla, Australia, **(a)** before and **(b)** after control by the cactus moth (*Cactoblastis cactorum*).

Table 57.3 Primary Mortality Factors According to the Availability of Plant Biomass

	Low → Plant biomass → High			
Taxa	**Plants only**	**Plants and herbivores**	**Plants, herbivores, and carnivores**	**Plants, herbivores, carnivores, and secondary carnivores**

Herbivores		Competition	Predation	Competition
Carnivores			Competition	Predation
Secondary carnivores				Competition

reunited with their natural enemies provide strong evidence of top-down control in nature.

Modern Models Suggest Both Top-Down and Bottom-Up Effects Are Important

More recently, different models have been proposed that take into account the effects of both natural enemies and limited resources on species. In 1981, Laurie Oksanen and coworkers suggested that the strength of mortality factors varies with availability of plant biomass involved, a model they termed the ecosystem exploitation hypothesis (Table 57.3). Thus, for very simple systems where mainly plants exist, such as Arctic tundra, not enough plant material is available to support herbivores, and plants must be resource limited (that is, limited by competition with each other). As plant biomass increases, some herbivores can be supported, but there are too few herbivores to support carnivores. In the absence of carnivores, levels of herbivory can be quite high. Plant abundance becomes limited primarily by herbivory, not competition. The abundance of herbivores, in the absence of carnivores, is limited by competition for plant resources.

As plant biomass increases still further and herbivores become common, carnivores become abundant and reduce the number of herbivores, which, in turn, increases plant abundance. Plants, being abundant, endure severe competition for resources, but herbivores, suffering high rates of mortality from natural enemies, are not abundant enough to compete. The predators, being limited only by the availability of their prey, are also common and thus experience competition. With the availability of yet more plant biomass, additional taxa such as secondary carnivores can be supported, which changes the relative importance of mortality factors among all taxa. Ecologists are currently examining the degree to which such a model holds true in nature.

Species interactions can clearly be very important in influencing both the growth of both individual populations and the structure of communities, groups of species living in a particular area. What factors determine the numbers of species in a given area? What factors influence the stability of a community, and what are the effects of disturbances on community structure? In the next chapter, on community ecology, we will explore these and other questions.

Summary of Key Concepts

57.1 Competition

- Species interactions can take a variety of forms that differ based on their effect on the species involved. (Figure 57.1, Table 57.1)
- Competition can be categorized as intraspecific (between individuals of the same species) or interspecific (between individuals of different species). Competition can also be categorized as exploitation competition or interference competition. (Figure 57.2)
- One species can exclude the other in a natural environment, affecting its distribution within a habitat. (Figure 57.3)
- Laboratory and field experiments show that competition occurs frequently in nature and varies as a function of both biotic and abiotic factors. (Figures 57.4, 57.5)
- The competitive exclusion hypothesis states that two species with the same resource requirements cannot occupy the same niche. (Figure 57.6)
- Resource partitioning and morphological differences between species allow them to coexist in a community. (Figures 57.7, 57.8, Table 57.2)

57.2 Predation, Herbivory, and Parasitism

- The many antipredator strategies that animals have evolved suggest that predation is a strong selective force. Of these strategies, chemical defense and aposematic coloration are the most common. (Figures 57.9, 57.10)
- Despite these defenses, oscillations in predator-prey cycles, the effect of introduced species, and examples of human predation illustrate that predators can have a large effect on prey densities. (Figures 57.11, 57.12, 57.13)
- Plants have also evolved an array of defenses against herbivores, termed host plant resistance, which includes chemical defenses, such as secondary metabolites, and mechanical defenses, such as thorns and spines. (Figure 57.14)
- Parasitism is a common lifestyle on Earth, and some parasites have complex life cycles involving multiple hosts. (Figures 57.15, 57.16)
- Evidence from experimental removal of parasites and from the study of introduced plant and animal parasites confirms that parasites can greatly reduce prey densities. (Figures 57.17, 57.18, 57.19)

57.3 Mutualism and Commensalism

- Mutualism is an association between two species that benefits both. Defensive mutualisms typically involve an animal defending either a plant or herbivore; dispersive mutualisms involve plants and pollinators that disperse their pollen, and plants and fruit eaters that disperse the plant's seeds. (Figures 57.20, 57.21)
- In commensal relationships, one partner receives a benefit while the other is not affected. (Figure 57.22)

57.4 Conceptual Models

- Conceptual models of species interactions describe the importance of factors such as competition and predation. Bottom-up models propose that plant quality or quantity regulates the abundance of all herbivore and predator species; top-down models propose that the abundance of predators controls herbivore and plant densities. (Figures 57.23, 57.24)
- Modern models, which incorporate components of both bottom-up and top-down models, propose that mortality varies according to productivity of plant biomass. (Table 57.3)

Assess and Discuss

Test Yourself

1. A species interaction in which one species benefits but the other species is unharmed is called
   a. mutualism.
   b. amensalism.
   c. parasitism.
   d. commensalism.
   e. mimicry.
2. Two species of birds feed on similar types of insects and nest in the same tree species. This is an example of
   a. intraspecific competition.
   b. interference competition.
   c. exploitation competition.
   d. mutualism.
   e. none of the above.
3. According to the competitive exclusion hypothesis,
   a. two species that use the exact same resource show very little competition.
   b. two species with the same niche cannot coexist.
   c. one species that competes with several different species for resources will be excluded from the community.
   d. all competition between species results in the extinction of at least one of the species.
   e. none of the above is correct.
4. In Lack's study of British passerine birds, different species seem to segregate based on resource factors, such as location of prey items. This differentiation among the niches of these passerine birds is known as
   a. competitive exclusion.
   b. intraspecific competition.
   c. character displacement.
   d. resource partitioning.
   e. allelopathy.
5. Divergence in morphology that is a result of competition is termed
   a. competitive exclusion.
   b. resource partitioning.
   c. character displacement.
   d. amensalism.
   e. mutualism.
6. Tapeworms have
   a. low lethality and low duration of interaction.
   b. low lethality and high duration of interaction.
   c. high lethality and low duration of interaction.
   d. high lethality and high duration of interaction.
   e. none of the above.
7. Ticks are regarded as
   a. monophagous endoparasites.
   b. monophagous ectoparasites.
   c. polyphagous endoparasites.
   d. polyphagous ectoparasites.
   e. none of the above.
8. Batesian mimicry differs from Müllerian mimicry in that
   a. in Batesian mimicry, both species possess the chemical defense.
   b. in Batesian mimicry, one species possesses the chemical defense.
   c. in Müllerian mimicry, one species has several different mimics.
   d. in Müllerian mimicry, one species has several different chemical defenses.
   e. in Batesian mimicry, cryptic coloration is always found.
9. Deadly nightshade is protected from herbivores by
   a. the alkaloid capsaicin.
   b. the alkaloid atropine.
   c. the phenolic anthocyanin.
   d. the phenolic tannin.
   e. the terpenoid β-carotene.
10. Parasitic plants that rely solely on their host for nutrients are called
    a. hemiparasites.
    b. fungi.
    c. holoparasites.
    d. monophagous.
    e. polyphagous.

Conceptual Questions

1. Define the competitive exclusion hypothesis.
2. Distinguish between Müllerian and Batesian mimicry.
3. Why don't we see more evidence of plants being eaten by herbivores?

Collaborative Questions

1. Discuss how the reintroduction of wolves in Yellowstone National Park might be beneficial.
2. Discuss several antipredator strategies that animals have evolved.

Chapter Outline

Community Ecology

58

Krakatau and neighboring islands. Many of the species formerly present on Krakatau have returned following the 1883 eruption that covered the island in volcanic dust.

A massive volcanic explosion in 1883 on the island of Krakatau in Indonesia destroyed two-thirds of the island, originally 11-km long and covered in tropical rain forest. Life on the remaining part was eradicated, suffocated by tens of meters of red-hot ash. Nine months after the eruption, the first reported colonist was a spider spinning its web. By 1896, there were 11 species of ferns and 15 species of flowering plants, mainly grasses. Most plant species at that time had been wind or sea dispersed. By the 1920s, 40 years after the original eruption, birds had become abundant and had dispersed additional plant species via their seeds. Ecologists have been examining the return of different species to the island ever since.

So far in this unit, we have examined ecology in terms of the behavior of individual organisms, the growth of populations, and interactions between pairs of species. Most populations, however, exist not on their own, but together with populations of many other species. This assemblage of many populations that live in the same place at the same time is known as a **community**. For example, a tropical forest community consists of not only tree species, vines, and other vegetation, but also the insects that pollinate them, the herbivores that feed upon the plants, and the predators and parasites of the herbivores. Communities can occur on a wide range of scales, and one community can be nested within another. For example, the tropical forest community also encompasses smaller communities, such as the water-filled recesses of bromeliads, which form a microhabitat for different species of insects and their larvae. Both of these entities—the tropical forest and the bromeliad tank—are viable communities, depending on one's frame of reference with regard to scale.

Community ecology is the study of how groups of species interact and form functional communities. In Chapter 57, we considered the interactions between individual species. In this chapter, we widen our focus to explore the factors that influence the number and abundance of species in a community. We begin by examining the nature of ecological communities. Are communities loose assemblages of species that happen to live in the same place at the same time, or are they more tightly organized groups of mutually dependent species? We explore why, on a global scale, the number of species is usually greatest in the tropics and declines toward the poles.

Community ecology also addresses what factors act to stabilize the number and abundance of species in a community. However, ecologists recognize that communities may change, for example, following a disturbance such as a fire or a volcanic eruption. This recovery tends to occur in a predictable way, which ecologists have termed succession. In certain situations—for example, on islands recovering from physical disturbance—the structure of the community tends toward an equilibrium determined by the balance between the rates of immigration and extinction.

58.1 Differing Views of Communities

Ecologists have long held differing views on the nature of a community and its structure and functions. Some of the initial work in the field of community ecology considered a community to be equivalent to a superorganism, in much the same way that the body of an animal is more than just a collection of organs. In this view, individuals, populations, and communities have a stable relationship to each other that resembles the associations found

between cells, tissues, and organs. American botanist Frederic Clements, the champion of this viewpoint, suggested in 1905 that ecology was to the study of communities what physiology was to the study of individual organisms. This view of community, with predictable and integrated associations of species separated by sharp boundaries, is termed the **organismic model**, which depicts the ecological community as a superorganism.

Clements's ideas were challenged in 1926 by botanist Henry Allan Gleason. Gleason proposed an **individualistic model**, which described a community as an assemblage of species coexisting primarily because of similarities in their physiological requirements and tolerances. Although acknowledging that some assemblages of species were fairly uniform and stable over a given region, Gleason suggested that distinctly structured ecological communities usually do not exist. Instead, communities are loose assemblages of species distributed independently along an environmental gradient. Viewed in this way, communities do not necessarily have sharp boundaries, and associations of species are much less predictable and integrated than in Clements's organismic model.

By the 1950s, many ecologists had abandoned Clements's view in favor of Gleason's. In particular, Robert Whittaker's studies proposed the **principle of species individuality**, which stated that each species is distributed according to its physiological needs and population dynamics; that most communities intergrade, or merge into one another gradually; and that competition does not create distinct vegetational zones. For example, let's consider an environmental gradient such as a moisture gradient on an uninterrupted slope of a mountain. Whittaker proposed that four hypotheses could explain the distribution patterns of plants and animals on the gradient (Figure 58.1):

1. Competing species, including dominant plants, exclude one another along sharp boundaries. Other species evolve toward a close, perhaps mutually beneficial association with the dominant species. Communities thus develop along the gradient, each zone containing its own group of interacting species giving way at a sharp boundary to another assemblage of species. This corresponds to Clements's organismic model.
2. Competing species exclude one another along sharp boundaries but do not become organized into groups of species with parallel distributions.
3. Competition does not usually result in sharp boundaries between species. However, the adaptation of species to similar physical variables will result in the appearance of groups of species with similar distributions.
4. Competition does not usually produce sharp boundaries between species, and the adaptation of species to similar physical variables does not produce well-defined groups of species with similar distributions. The centers and boundaries of species populations are scattered along the environmental gradient. This corresponds to Gleason's individualistic model.

To test these possibilities, Whittaker examined the vegetation on various mountain ranges in the western U.S. He sampled plant populations along an elevation gradient from the tops of the mountains to the bases and collected data on physical variables, such as soil moisture.

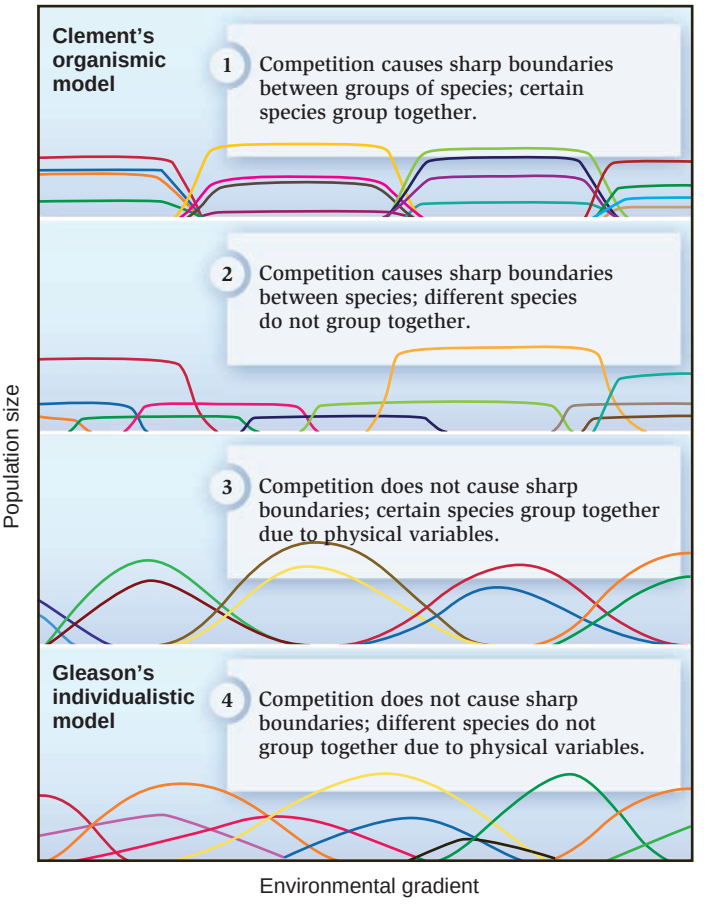

Figure 58.1 **Four hypotheses for the distribution patterns of plants and animals along an environmental gradient.** Each curve in each part of the figure represents one species and the way its population might be distributed along an environmental gradient.

The results supported the fourth hypothesis, that competition does not produce sharp boundaries between species and that adaptation to physical variables does not result in defined groups of species. Whittaker concluded that his observations agreed with Gleason's predictions that (1) each species is distributed in its own way, according to its genetic, physiological, and life cycle characteristics; and (2) most communities grade into each other continuously rather than form distinct, clearly separated groups. The composition of species at any one point in an environmental gradient was largely determined by abiotic factors such as temperature, water, light, pH, and salt concentrations (features discussed in Chapter 54).

Even though most communities intergrade along environmental gradients such as a mountain slope, ecologists recognize distinct differences between communities. The community at the top of a mountain will be quite different from that at the bottom, so distinguishing between communities on a broad scale is useful. Also, some sharp boundaries between groups of species sometimes do exist, especially related to physical differences such as water quality and soil type that cause distinct communities to develop. For example, serpentine soils are rich

Figure 58.2 **An example of a sharp boundary between two communities.** In New Zealand's Dun Mountain area, the sparse vegetation on the serpentine soil on the left contrasts with that of the beech forest on the nonserpentine soil on the right.

in metals, including magnesium, iron, and nickel, but poor in plant nutrients. The species that have adapted to these harsh conditions form a unique community restricted to this area (Figure 58.2). Such sharp boundaries are not common between neighboring communities.

58.2 Patterns of Species Richness

One method to analyze communities is to determine the number of species in each community, or **species richness**. The number of species of most taxa varies according to latitudinal gradient, generally increasing from polar areas to temperate areas and reaching a maximum in the tropics. For example, the species richness of North American birds increases from Arctic Canada to Panama (Figure 58.3). A similar pattern exists for mammals and reptiles. Species richness is also influenced by topographical variation. More mountains mean more hilltops, valleys, and differing habitats; thus, there is an increased number of birds in the mountainous western U.S. In contrast, species richness is reduced by the peninsular effect, in which the number of species decreases as a function of distance from the main body of land.

Many hypotheses for the latitudinal gradient of species richness have been advanced. We will consider four of the most important, which propose that communities diversify with increased time, area, productivity, respectively, and that diversity is maximized in areas of intermediate disturbance. Although they are treated separately here, these hypotheses are not mutually exclusive. All four can contribute to patterns of species richness.

The Time Hypothesis Suggests Communities Diversify with Age

Many ecologists argue that communities diversify, or gain species, with time. Therefore temperate regions have less rich communities than tropical ones because they are younger and have only more recently (relatively speaking) recovered from recent

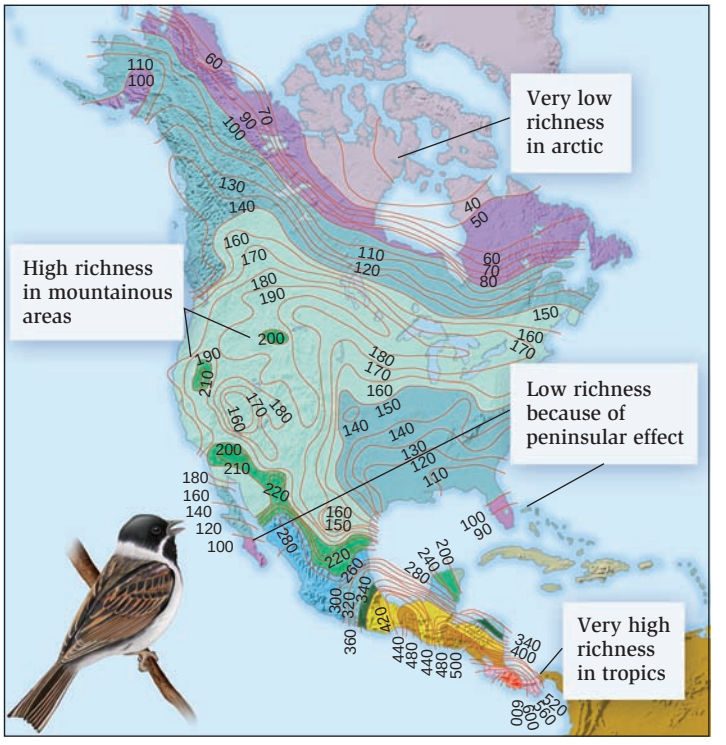

Figure 58.3 **Species richness of birds in North America.** The values indicate the numbers of different species in a given area. Contour lines show equal numbers of bird species, with colors indicating incremental changes. Note the pronounced latitudinal gradient toward the tropics and the high diversity in California and northern Mexico, regions of considerable topographical variation and habitat diversity.

glaciations and severe climatic disruption. The time hypothesis proposes that resident species of the temperate zone have not yet evolved new forms to exploit vacant niches. In addition, it suggests that species that could possibly live in temperate regions have not migrated back from the unglaciated areas into which the ice ages drove them.

In support of the time hypothesis, ecologists compared the species richness of bottom-dwelling invertebrates, such as worms, in historically glaciated (covered with ice) and unglaciated lakes in the Northern Hemisphere that occur at similar latitudes. Lake Baikal in Siberia is an ancient, unglaciated temperate lake and contains a very diverse fauna. For example, 580 species of invertebrates are found in the bottom zone. Great Slave Lake, a comparable-sized lake in northern Canada that was once glaciated, contains only four species in the same zone.

However, ecologists recognize drawbacks to the time hypothesis. For example, the time hypothesis may help explain variations in the species richness of terrestrial organisms, but it has limited applicability to marine organisms. Although we might not expect terrestrial species, particularly plants, to redistribute themselves quickly following a glaciation—especially if there is a physical barrier like the English Channel to overcome—there seems to be no reason that marine organisms

couldn't relatively easily shift their distribution patterns during glaciations, yet the polar-equatorial gradient of species richness still exists in marine habitats.

The Area Hypothesis Suggests Large Areas Support More Species

The **area hypothesis** proposes that larger areas contain more species than smaller areas because they can support larger populations and a greater range of habitats. Much evidence supports the area hypothesis. For example, in 1974, Donald Strong showed that insect species richness on tree species in Britain was better correlated with the area over which a tree species could be found than with time of habitation since the last ice age (Figure 58.4). The relationship between the amount of available area and the number of species present is called the **species-area effect**. Some introduced tree species, such as apple and lime, were relatively new to Britain, but they bore many different insect species, a fact Strong argued did not support the time hypothesis. This means that, on average, an individual willow tree standing next to an individual maple tree in the same location would support an order of magnitude more insect species because of its greater abundance in that habitat.

The large, climatically similar area of the tropics has been proposed as a reason why the tropics have high species richness. However, the area hypothesis seems unable to explain why, if increased richness is linked to increased area, more species are not found in certain regions such as the vast contiguous landmass of Asia. Furthermore, although tundra may be the world's largest land biome, it has low species richness. Finally, the largest marine system, the open ocean, which has the greatest volume of any habitat, has fewer species than tropical nearshore waters, which have a relatively small volume.

The Productivity Hypothesis Suggests That More Energy Permits the Existence of More Species

The **productivity hypothesis** proposes that greater production by plants results in greater overall species richness. An increase in plant productivity, the total weight of plant material produced over time, leads to an increase in the number of herbivores and hence an increase in the number of predator, parasite, and scavenger species. Production itself is influenced by factors such as temperature and rainfall, because many plants grow better where it is warm and wet. For example, in 1987, David Currie and colleagues showed that the species richness of trees in North America is best predicted by the **evapotranspiration rate**, the rate at which water moves into the atmosphere through the processes of evaporation from the soil and transpiration of plants, both of which are influenced by the amount of solar energy (Figure 58.5).

Once again, however, there are exceptions to this rule. Some tropical seas, such as the southeast Pacific off of Colombia and Ecuador, have low productivity but high species richness. On the other hand, the sub-Antarctic Ocean has a high productivity but low species richness. Estuarine areas, where rivers empty into the sea, are similarly very productive yet low in species, presumably because they represent stressful environments for many organisms that are alternately inundated by fresh water and salt water with daily changes in the tide. Some lakes that are polluted with fertilizers also have high productivity but low species richness.

In 1993, Robert Latham and Robert Ricklefs showed that although patterns of tree richness in North America support the productivity hypothesis, the pattern does not hold for broad comparisons between continents. For example, the temperate forests of eastern Asia support substantially higher numbers of tree species (729) than do climatically similar areas of North

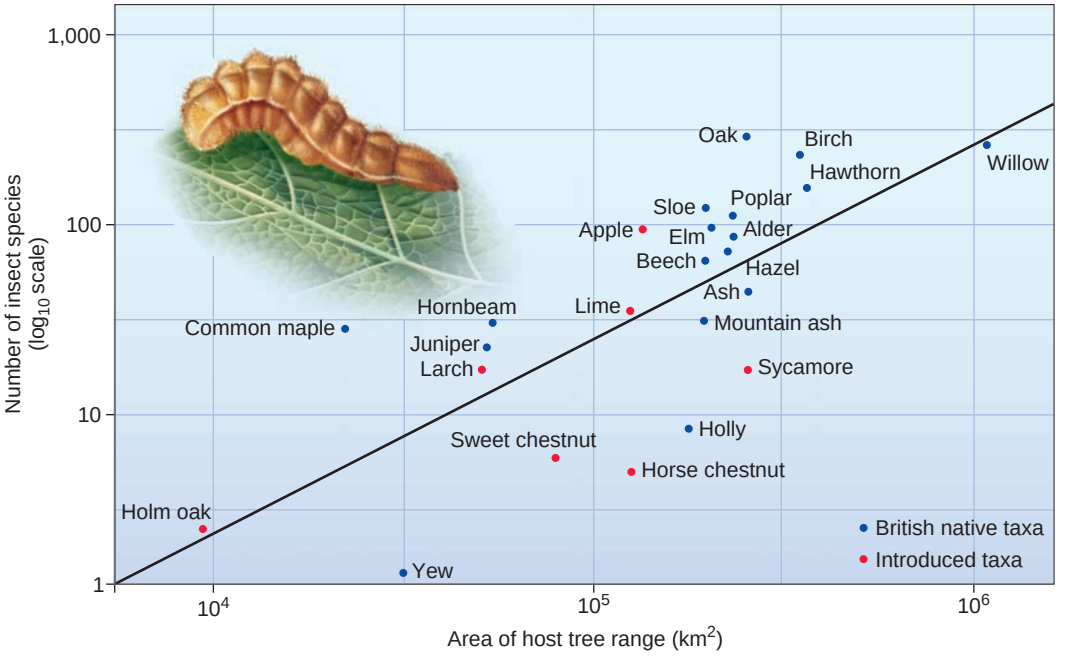

Figure 58.4 Relationship between insect species richness on British host trees and area. A positive correlation is found between insect species richness and the host tree's present range (in km^2). Here, the range represents an area in Britain known to contain trees.

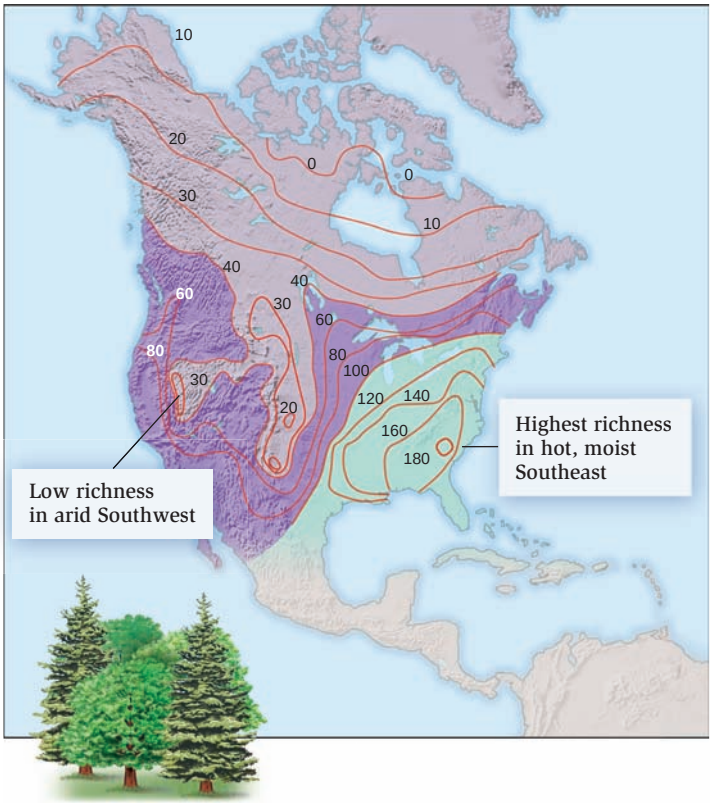

Figure 58.5 **Tree species richness in North America.** Contour lines show equal numbers of tree species, with colors indicating incremental changes. Tree species richness and evapotranspiration rates are highest in the southeast.

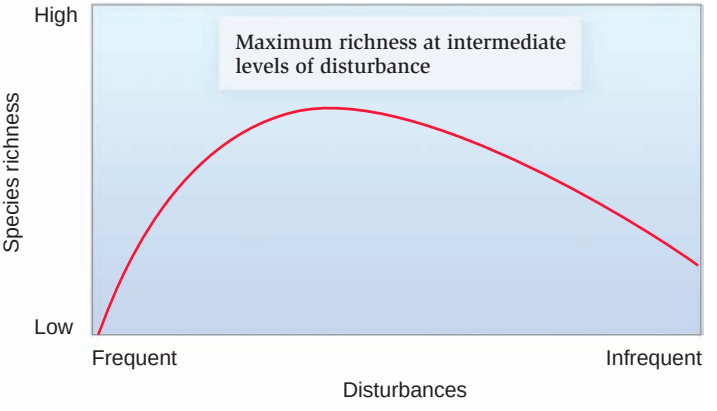
Concept check: *Why doesn't the species richness of trees increase in mountainous areas of the West, as it does for birds?*

America (253) or Europe (124). These three areas have different evolutionary histories and different neighboring areas from which species might have invaded.

The Intermediate-Disturbance Hypothesis Proposes That Moderately Disturbed Communities Contain More Species

Ecologist Joseph Connell has argued that the highest numbers of species are maintained in communities with intermediate levels of disturbance, a concept called the **intermediate-disturbance hypothesis** (Figure 58.6a). Disturbance in communities may be brought about by many different phenomena such as droughts, fires, floods, and hurricanes or by species interactions such as herbivory, predation, or parasitism. Recall from Chapter 56 that some species, termed *r*-selected species, are better dispersers than other species and that *K*-selected species are better competitors. Connell reasoned that at high levels of disturbance, only colonists that were *r*-selected species would survive, giving rise to low species richness. This is because these species would be the only ones able to disperse quickly to a highly disturbed area. At low rates of disturbance, competitively dominant *K*-selected species would outcompete all other species, which would also yield low species richness. The most species rich communities would lie somewhere in between.

Connell argued that natural communities fit into this model fairly well. Tropical rain forests and coral reefs are both examples of communities with high species richness. Coral reefs exhibit highest species richness in areas disturbed by hurricanes, and the richest tropical forests occur where disturbance by storms causes landslides and tree falls. The fall of a tree creates a hole in the rain forest canopy known as a light gap, where direct sunlight is able to reach the rain forest floor. The light gap is rapidly colonized by *r*-selected species, such as small herbaceous plants, which are well adapted for rapid growth. Although these pioneering species grow rapidly, they are eventually overtaken by *K*-selected species, such as mature trees, which fill in the gap in the canopy (Figure 58.6b). Although events such as hurricanes and tree falls are fairly



(a) Relationship between species richness and disturbances

(b) Light gap in a tropical rain forest

Figure 58.6 **The intermediate-disturbance hypothesis of community organization.** **(a)** This hypothesis proposes that species richness is highest at intermediate levels of disturbances caused by events such as fires or windstorms. **(b)** A light gap in a tropical rain forest in Costa Rica promotes the growth of small herbaceous species until trees colonize the light gap and gradually grow over and outcompete the smaller species.

Concept check: *According to the intermediate-disturbance hypothesis, why are there so many species in the tropics?*

frequent events in these communities, their occurrence in any one area is usually of intermediate frequency.

In 1979, Wayne Sousa provided an elegant experimental verification of the intermediate-disturbance hypothesis in the marine intertidal zone. He found that small boulders, which were easily disturbed by waves, carried a mean of 1.7 sessile plant and animal species. These frequently moving boulders crushed or dislodged most colonizing species. Large boulders, which were rarely moved by waves, had a mean of 2.5 species. On these boulders, competitively dominant species supplanted many other species. Sousa found that intermediate-sized boulders had the most species, an average of 3.7 species per boulder, because they contained a mix of *r*- and *K*-selected species. To test the hypothesis, Sousa cemented small boulders to the shoreline and obtained an increase in species richness to near the value for large boulders, showing that the resulting number of species was a result of rock stability, not rock size.

When comparing the time, area, productivity, and intermediate disturbance hypotheses, each has some evidence to support it and some to contradict it. Different processes may occur over different scales. On a regional scale, we know that the time since the last glaciation has the potential to change patterns of species richness. On a more local scale, area, productivity of available habitat, and disturbance level may be important. At any given point on the globe, species richness may be affected by the interaction of these different factors.

58.3 Calculating Species Diversity

So far, we have discussed communities in terms of variations in species richness. However, to measure species diversity, ecologists need to take into account not only the number of species in a community but also their frequency of occurrence, or **relative abundance**. For example, consider two hypothetical communities, A and B, both with two species and 100 total individuals.

	Number of individuals of species 1	Number of individuals of species 2
Community A	99	1
Community B	50	50

The species richness of community B equals that of community A, because they both contain two species. However, community B is considered more diverse because the distribution of individuals between species is more even. One would be much more likely to encounter both species in community B than in community A, where one species dominates. **Species diversity** can be considered the community measure that incorporates both species number and relative abundance.

To measure the species diversity of a community, ecologists calculate what is known as a diversity index. Although many different indices are available, the most widely used is the **Shannon diversity index** (H_S), which is calculated as

$$H_S = -\Sigma p_i \ln p_i$$

where p_i is the proportion of individuals belonging to species i in a community, ln is the natural logarithm, and the Σ is a summation sign. For example, for a species in which there are 50 individuals out of a total of 100 in the community, p_i is 50/100, or 0.5. The natural log of 0.5 is −0.693. For this species, $p_i \ln p_i$ is then $0.5 \times -0.693 = -0.347$. For a hypothetical community with 5 species and 100 total individuals, the Shannon diversity index would be calculated as follows:

	Species	Abundance	p_i		$p_i \ln p_i$
	1	50	0.5		−0.347
	2	30	0.3		−0.361
	3	10	0.1		−0.230
	4	9	0.09		−0.217
	5	1	0.01		−0.046
Total	5	100	1.00	$\Sigma\, p_i \ln p_i$	−1.201

In this example, even the rarest species, species 5, contributes some value to the index. If a community had many rare species, their contributions would accumulate. This makes the Shannon diversity index very valuable to conservation biologists, who often study rare species and their importance to the community. Remember, too, that in the equation, the negative sign in front of the summation changes these values to positive, so the index actually becomes 1.201, not −1.201.

Values of the Shannon diversity index for real communities often fall between 1.5 and 3.5, with the higher the value, the greater the diversity. Table 58.1 calculates the diversity of two bird communities in Indonesia with similar species richness but differing species abundance. The bird communities were surveyed in a pristine unlogged forest or in a selectively logged lowland forest. To document diversity, biologist Stuart Marsden established census stations in the two types of forest and recorded the type and number of all bird species for a number of 10-minute periods. Although a greater number of individual birds was seen in the logged areas (2,358) compared to unlogged ones (1,824), a high proportion of the individuals in the logged areas (0.386) belonged to just one species, *Nectarinia jugularis*. Although only one more bird species was found in the unlogged area than in the logged area, calculation of the Shannon diversity index showed a higher diversity of birds in the unlogged area, 2.284 versus 2.037, which is a considerable difference, considering the logarithmic nature of the index.

An accurate determination of community diversity depends on detailed knowledge of which and how many of each species are present. This is relatively easy to determine for communities of vertebrates and some invertebrates, but it is much more difficult for microbial communities. Yet knowledge of microbial communities is of great importance, because microbes carry out vital functions such as nitrogen fixation and decomposition. As described next, with the advent of modern molecular tools, our knowledge of the diversity of microbial communities is beginning to expand.

Table 58.1 Shannon Diversity Index of Bird Species on Logged and Unlogged Sites in Indonesia

	Unlogged			Logged		
Species	***N***	p_i	$p_i \ln p_i$	***N***	p_i	$p_i \ln p_i$
Nectarinia jugularis, Olive-backed sunbird	410	0.225	−0.336	910	0.386	−0.367
Ducula bicolor, Pied imperial pigeon	230	0.126	−0.261	220	0.093	−0.221

Genomes & Proteomes Connection

Metagenomics May Be Used to Measure Community Diversity

Bacteria are abundant members of all communities and are vital to their functioning. They serve as food sources for other organisms and participate in the decomposition process. However, most microorganisms are taxonomically unknown, mainly because they cannot be cultivated on known culture media. The field of **metagenomics** seeks to identify and analyze the collective microbial genomes contained in a community of organisms, including those that are not easily cultured in the laboratory. This technique has been in existence only since the early 1990s, but significant progress has already been made in providing data that have advanced our understanding of which bacteria are present in various communities and how they function.

The process involves four main steps (Figure 58.7). First, an environmental sample containing an unknown number of bacterial species is collected, and its DNA is isolated from the cells using chemical or physical methods. Because the genomic DNA of each species is relatively large, it is cut up into fragments with restriction enzymes (see Chapter 20). Second, the fragments are combined with vectors, small units of DNA that can be inserted into a model laboratory organism, usually a bacterium. The third step begins with transformation in which the DNA from step 2 is taken up into bacterial cells. Individual bacteria are then grown on a selective media so that only the transformed cells survive. Each cell will grow into a colony of cloned cells. A collection of thousands of clones, each containing a different piece of microbial DNA, is called a metagenomic library. Lastly, the DNA from the metagenomic library is analyzed. In some cases, expression of the new DNA results in the synthesis of a new protein that changes the phenotype of the host, for example, a new enzyme that is detected by a chemical technique or an unusual color or shape in the model organism.

In 2004, Jill Banfield and colleagues used metagenomics techniques to identify the five dominant species of bacteria living at temperatures of 42°C (107°F) and pH 0.8 in the acidic wastewater (the same pH as battery acid) from a mine in California. They detected 2,033 proteins from these species, including proteins from the most abundant bacterial species, a *Leptospirillum* group II bacteria. This represented the first large-scale proteomics-level expression of a natural microbial community. One of the proteins, a cytochrome, oxidizes iron and probably influences the rate of breakdown of acid mine drainage products. Many other proteins appear responsible for defending against free radicals, suggesting that this is an important metabolic trait for persistence in the acidic environment. The hope is that the team can now identify enzymes and metabolic pathways that will help in the cleanup of this and other environmentally contaminated sites in the future.

58.4 Species Diversity and Community Stability

A community is often seen as stable when little to no change can be detected in the number of species and their abundance over a given time period. The community may then be said to be in equilibrium. The frame of reference for detecting change may encompass a study of a few years or, preferably, several decades. For example, long-term data from Bookham Common, England, revealed that the number of species of birds remained stable for nearly 30 years. Community stability is an important consideration in conservation biology. A decrease in the stability of a community over time may alert biologists to a possible problem. In the 1970s, the populations of many bird species in the U.S. and Europe declined precipitously. Raptor species such as peregrine falcons, bald eagles, and osprey were particularly hard hit. Eventually, the decline was traced to use of the pesticide DDT (dichlorodiphenyltrichloroethane), which caused eggshells to become thin and break before the birds could hatch. After DDT was banned later in the decade, raptor species began to recover.

In this section, we consider the relationship between species richness and community stability. We begin by exploring the question of whether communities with more species are more stable than communities with fewer species. We then examine the link between diversity and stability, using evidence from the field. Finally, we look at the relationship from a different angle and consider whether or not stable communities are more species rich than communities that have been disturbed.

The Diversity-Stability Hypothesis States That Species-Rich Communities Are More Stable Than Those with Fewer Species

Community stability may be viewed in several different ways. Some communities, such as extreme deserts, are considered stable because they are resistant to change by anything other than water. Other communities, such as river communities, are considered stable because they can recover quickly after a disturbance, such as pollution, being cleansed by the rapid flow of fresh water. Lake communities, on the other hand, may be seen as less stable because there is no drainage outlet and pollutants can accumulate quickly.

Because maintaining community stability is seen as important, much research has gone into understanding the factors that enhance it. This work has produced the prevailing idea that species-rich communities are more stable than species-poor communities. Even so, ecologists debate the effects of species richness. For example, are species-rich communities more resistant to invasion by introduced species, such as weeds, than species-poor communities?

The link between species richness and stability was first explicitly proposed by the English ecologist Charles Elton in the 1950s. He suggested that a disturbance in a species-rich community would be cushioned by large numbers of interacting

species and would not produce as drastic an effect as it would on a species-poor community. Thus, an introduced predator or parasite could cause extinctions in a species-poor system but possibly not in a more diverse system, where its effects would be buffered by interactions with more species in the community. Elton argued that outbreaks of pests are often found on cultivated land or land disturbed by humans, both of which are species-poor communities with few naturally occurring species. His argument became known as the **diversity-stability hypothesis**.

However, some ecologists began to challenge Elton's association of diversity with stability. Mathematical models showed that communities with higher diversity tended to be less, not more, stable. Ecologists pointed out many examples of introduced species that have assumed pest proportions in species-rich areas, including rabbits in Australia and pigs in North America. They noted that disturbed or cultivated land may suffer from pest outbreaks not because of its simple nature but because individual species, including introduced species, often have no natural enemies in the new environment, in contrast to the long associations between native species and their natural enemies. For example, in Europe, coevolved predators such as foxes prevent rabbit populations from increasing to pest proportions. What was needed was research to determine if a link existed between diversity and stability.

In 1996, ecologist David Tilman reported the relationship between species richness and stability from an 11-year study of 207 grassland plots in Minnesota that varied in their species richness. He measured the biomass of every species of plant, in each plot, at the end of every year and obtained the average species biomass. He then calculated how much this biomass varied from year to year through a statistical measure called the coefficient of variation. Less variation in biomass signified community stability. Year-to-year variation in plant community biomass was significantly lower in plots with greater plant species richness (Figure 58.8). The results showed that greater diversity enhances community stability.

Tilman suggested that diversity stabilizes communities because they are more likely to contain disturbance-resistant species that, in the event of a disturbance, could grow and compensate for the loss of disturbance-sensitive species. For example, when a change in climate such as drought decreased the abundance of competitively dominant species that thrived in normal conditions, unharmed drought-resistant species increased in mass and replaced them. Such declines in the number of susceptible species and compensatory increases in other species acted to stabilize total community biomass.

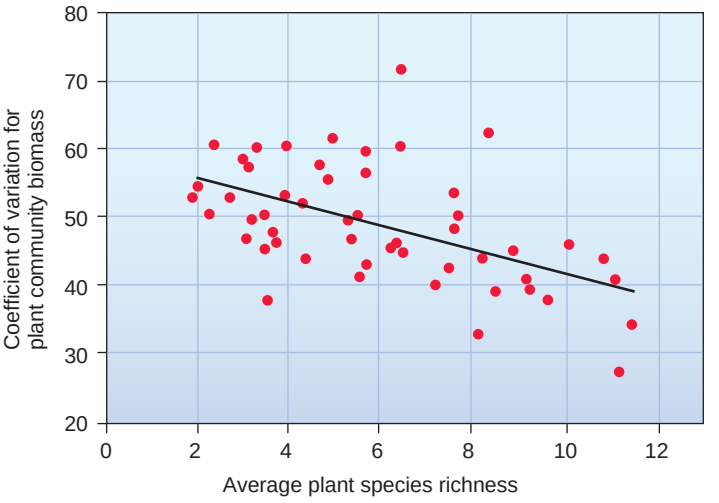

Figure 58.8 **Biomass variation and species richness.** Tilman's 11-year study of grassland plots in Minnesota revealed that year-to-year variability in community biomass was lower in species-rich plots. Each dot represents an individual plot. Only the plots from one field are graphed.

58.5 Succession: Community Change

At 8:32 a.m. on May 18, 1980, Mount St. Helens, a previously little-studied peak in the Washington Cascades, erupted. The blast felled trees over a 600-km^2 area, and the landslide that followed—the largest in recorded history—destroyed everything in its path, killing nearly 60 people and millions of animals. However, as with Krakatau, noted at the beginning of this chapter, much of the area has experienced a relatively rapid recovery of plant and animal communities (Figure 58.9).

Ecologists have developed several terms to describe how community change occurs. The term **succession** describes the gradual and continuous change in species composition and community structure over time. **Primary succession** refers to succession on a newly exposed site that has no biological legacy in terms of plants, animals, or microbes, such as bare ground caused by a volcanic eruption or the sediment created by the retreat of glaciers. In primary succession on land, the plants must often build up the soil, and thus a long time—even hundreds of years—may be required for the process. Only a tiny proportion of the Earth's surface is currently undergoing primary succession, for example, around Mount St. Helens and the volcanoes in Hawaii and off the coast of Iceland, and behind retreating glaciers in Alaska and Canada.

Secondary succession refers to succession on a site that has already supported life but has undergone a disturbance, such as a fire, tornado, hurricane, or flood (as in the 2004 tsunami in Indonesia). In terrestrial areas, soil is already present. Clearing a natural forest and farming the land for several years is an example of a severe forest disturbance that does not kill all native species. Some plants and many soil bacteria, nematodes, and insects are still present. Secondary succession will occur if farming is ended. The secondary succession in abandoned farmlands (also called old fields) can lead to a pattern of vegetation quite different from one that develops after primary succession following glacial retreat. For example, the plowing and added fertilizers, herbicides, and pesticides may have caused substantial changes in the soil of an old field, allowing species that require a lot of nitrogen to colonize. These species would not be present for many years in newly created glacial soils.

(a) 1980 (b) 1997

Figure 58.9 **Succession on Mount St. Helens.** **(a)** The initial blast occurred on May 18, 1980. **(b)** By 1997, 17 years later, many of the areas initially flattened by the blast and covered in ash developed low-lying vegetation, and new trees sprouted up between the old dead tree trunks.

Frederic Clements is often viewed as the founder of successional theory as well as the organismic model of ecological communities. His work in the early 20th century emphasized succession as proceeding to a distinct end point, or **climax community**. Each phase of succession is called a **sere**, or seral stage. The initial sere is known as the pioneer seral stage. Although disturbance can return a community from a later seral stage to an earlier seral stage, generally the community headed toward climax.

Three mechanisms of succession are discussed here. While Clements's depiction of succession focused on a process termed facilitation, two other mechanisms of succession—inhibition and tolerance—have since been described. Let's examine the evidence for each of them.

Facilitation Assumes Each Invading Species Creates a More Favorable Habitat for Succeeding Species

A key assumption of Clements is that each colonizing species makes the environment a little different—a little shadier or a little richer in soil nitrogen—so that it becomes more suitable for other species, which then invade and outcompete the earlier residents. This process, known as **facilitation**, continues until the most competitively dominant species has colonized, when the community is at climax. The composition of the climax community for any given region is thought to be determined by climate and soil conditions.

Succession following the gradual retreat of Alaskan glaciers is often used as a specific example of facilitation as a mechanism of succession. Over the past 200 years, the glaciers in Glacier Bay have undergone a dramatic retreat of nearly 100 km (Figure 58.10). Succession in Glacier Bay follows a distinct pattern of vegetation. As glaciers retreat, they leave moraines, deposits of stones, pulverized rock, and debris that serve as soil. In Alaska, the bare soil has a low nitrogen content and scant organic matter. In the pioneer stages, the soil is first colonized by a black crust of cyanobacteria, mosses, lichens, horsetails (*Equisetum variegatum*), and the occasional river beauty (*Epilobium*

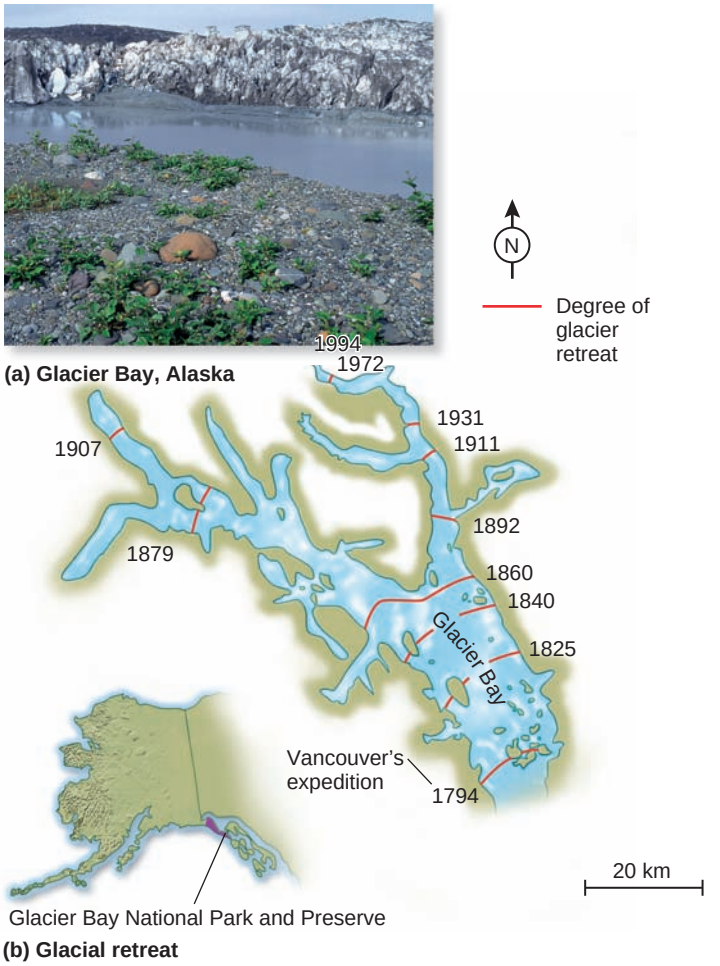

Figure 58.10 **The degree of glacier retreat at Glacier Bay, Alaska, since 1794.** **(a)** Primary succession begins on the bare rock and soil evident at the edges of the retreating glacier. **(b)** The lines reflect the position of the glacier in 1794 and its subsequent retreat northward.

Concept check: *Why do ecologists sometimes view walking through Glacier Bay as the equivalent of being in a time machine?*

latifolium) (Figure 58.11a). Because the cyanobacteria are nitrogen fixers, the soil nitrogen increases a little, but soil depth and litterfall (fallen leaves, twigs, and other plant material) are still minimal. At this stage, there may be a few seeds and seedlings of dwarf shrubs of the rose family commonly called mountain avens (*Dryas drummondii*), alders (*Alnus sinuata*), and spruce, but they are rare. After about 40 years, mountain avens dominates the landscape (Figure 58.11b). Soil nitrogen increases, as does soil depth and litterfall, and alder trees begin to invade.

At about 60 years, alders form dense, close thickets (Figure 58.11c). Alders have nitrogen-fixing bacteria that live mutualistically in their roots and convert nitrogen from the air into a biologically useful form. Soil nitrogen dramatically increases, as does litterfall. Spruce trees (*Picea sitchensis*) begin to invade at about this time. After about 75 to 100 years, the spruce trees begin to overtop the alders, shading them out. The litterfall is still high, and the large volume of needles turns the soil acidic. The shade causes competitive exclusion of many of the original understory species, including alder, and only mosses carpet the ground. At this stage, seedlings of western hemlock (*Tsuga heterophylla*) and mountain hemlock (*Tsuga mertensiana*) may also occur. After 200 years, a mixed spruce-hemlock climax forest results (Figure 58.11d).

What other evidence is there of facilitation? Experimental studies of early primary succession on Mount St. Helens, which show that decomposition of fungi allows mosses and other fungi to colonize the soil, provide evidence of facilitation. In New England salt marshes, *Spartina* grass facilitates the establishment of beach plant communities by stabilizing the rocky substrate and reducing water velocity, which enables other seedlings to emerge. Succession on sand dunes also supports the facilitation model, in that pioneer plant species stabilize the sand dunes and facilitate the establishment of subsequent plant species. The foredunes, those nearest the shoreline, are the most frequently disturbed and are maintained in a state of early succession, while more stable communities develop farther away from the shoreline.

Succession also occurs in aquatic communities. Although soils do not develop in marine environments, facilitation may still be encountered when one species enhances the quality of settling and establishment sites for another species. When experimental test plates used to measure settling rates of marine organisms were placed in the Delaware Bay, researchers discovered that certain cnidarians enhanced the attachment of tunicates, and both facilitated the attachment of mussels, which were the dominant species in the community. In this

Concept check: *Is facilitation the only mechanism fueling succession at Glacier Bay?*

experiment, the smooth surface of the test plates prevented many species from colonizing, but once the surface became rougher, because of the presence of the cnidarians, many other species were able to colonize. In a similar fashion, early colonizing bacteria, which create biofilms on rock surfaces, can facilitate succession of other organisms.

Inhibition Implies That Early Colonists Prevent Later Arrivals from Replacing Them

Although data on succession in some communities fit the facilitation model, researchers have proposed alternative hypotheses of how succession may operate. In the process known as **inhibition**, early colonists prevent colonization by other species. For example, removing the litter of *Setaria faberi*, an early successional plant species in New Jersey old fields, causes an increase in the biomass of a later species, *Erigeron annuus*. The release of toxic compounds from decomposing *Setaria* litter or physical obstruction by the litter itself blocks the establishment of *Erigeron*. Without the litter present, *Erigeron* dominates and reduces the biomass of *Setaria*. Plant species that grow in dense thickets, such as some grasses, ferns, vines, pine trees, and bamboo, can inhibit succession, as can many introduced plant species.

Inhibition has been seen as the primary method of succession in the marine intertidal zone, where space is limited. In this habitat, early successional species are at a great advantage in maintaining possession of valuable space. In 1974, ecologist Wayne Sousa created an environment for testing how succession works in the intertidal zone by scraping rock faces clean of all algae or putting out fresh boulders or concrete blocks. The first colonists of these areas were the green algae *Ulva*. By removing *Ulva* from the substrate, Sousa showed that the large red alga *Chondracanthus canaliculatus* was able to colonize more quickly (Figure 58.12). The results of Sousa's study indicate that early colonists can inhibit rather than facilitate the invasion of subsequent colonists. Succession may eventually occur because early colonizing species, such as *Ulva*, are more susceptible to the rigors of the physical environment and to attacks by herbivores, such as crabs (*Pachygrapsus crassipes*), than later successional species, such as *Chondracanthus*.

Tolerance Suggests That Early Colonists Neither Facilitate nor Inhibit Later Colonists

In 1977, researchers Joseph Connell and Ralph Slatyer proposed a third mechanism of succession, which they termed **tolerance**. In this process, any species can start the succession, but the eventual climax community is reached in a somewhat orderly fashion. The species that establish and remain do not change the environment in ways that either facilitate or inhibit subsequent colonists. Species have differing tolerances to the intensity of competition that results as more species accumulate. Relatively competitive-intolerant species are more successful early in succession when the intensity of competition is low and resources are abundant. Relatively competition-tolerant species appear later in succession and at climax. Connell and Slatyer found the best evidence for the tolerance model in Frank Egler's

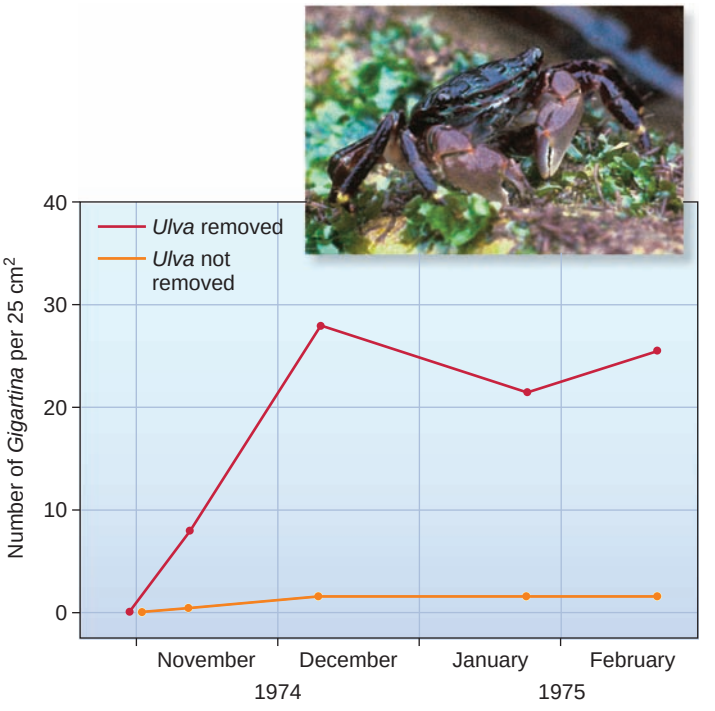

Figure 58.12 Inhibition as a primary method of succession in the marine intertidal zone. Removing *Ulva* from intertidal rock faces allowed colonization by *Chondracanthus*. The inset shows *Chondracanthus* on a rock face with the striped shore crab *Pachygrapsus crassipes*, a herbivore.

earlier work on floral succession. In the 1950s, Egler showed that succession in plant communities is determined largely by species that already exist in the ground as buried seeds or old roots. Whichever species germinates first or regenerates from roots initiates the succession sequence. Germination or root regeneration, in turn, depends on the timing of a disturbance. For example, an early-season tree fall would promote early germinating species to grow in the subsequent light gap, whereas a late-season tree fall would promote the growth of late germinating species. As succession proceeds, earlier germinating or regenerating species may be outcompeted by different species.

The key distinction between the three models is in the manner in which succession proceeds. In the facilitation model, species replacement is facilitated by previous colonists; in the inhibition model, it is inhibited by the action of previous colonists; and in the tolerance model, species may be affected by previous colonists, but they do not require them (Figure 58.13). The type of model followed depends on the community in question. Subsequent research has suggested that other factors may also influence succession, especially on islands. The study of succession on islands is often referred to as island biogeography, which is described next.

58.6 Island Biogeography

In the 1960s, two eminent ecologists, Robert MacArthur and E. O. Wilson, developed a comprehensive model to explain the process of succession on new islands, where a gradual buildup of species proceeds from a sterile beginning. Their model, termed the **equilibrium model of island biogeography**, holds

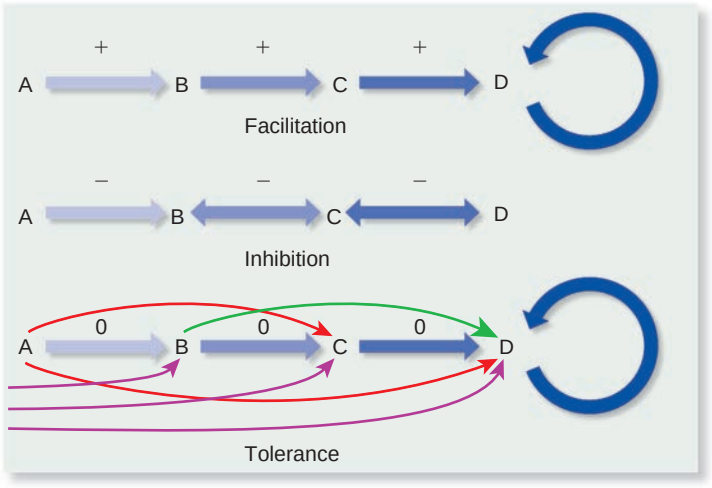

Figure 58.13 **Three models of succession.** A, B, C, and D represent four stages or seres. D represents the climax community. An arrow indicates "is replaced by," and + = facilitation, − = inhibition, and 0 = no effect. The facilitation model is the classic model of succession. In the inhibition model, much depends on which species gets there first. The tolerance model is similar to the facilitation model, in that later species may be facilitated by earlier species, but they can also invade in their absence. The colored arrows show that succession may bypass some stages in the tolerance model.

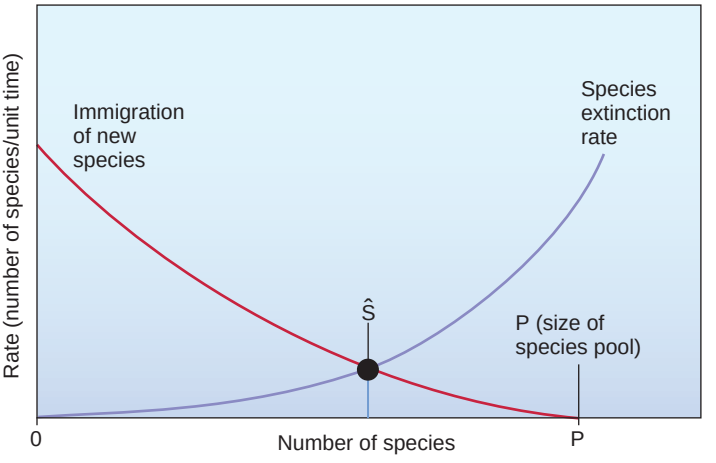
Concept check: *Inhibition implies competition between species with early-arriving species tending to outcompete later arrivals, at least for a while. Does competition or mutualism feature more prominently in facilitation?*

that the number of species on an island tends toward an equilibrium number that is determined by the balance between two factors: immigration rates and extinction rates. In this section, we explore island biogeography and how well the model's predictions are supported by experimental data.

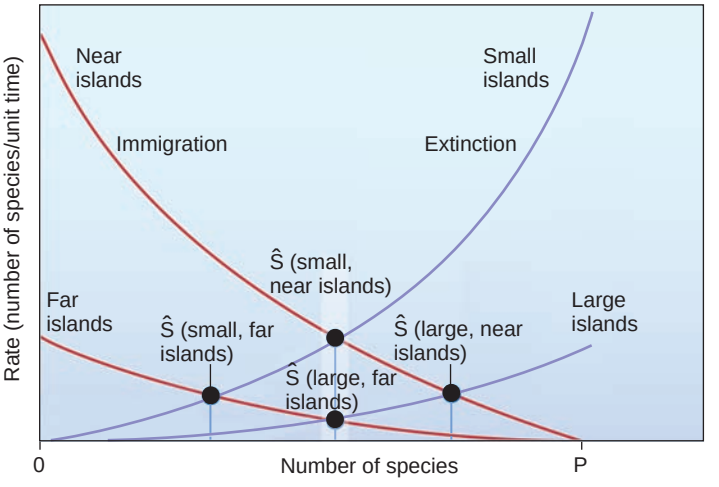
The Island Biogeography Model Suggests That During Succession, Gains in Immigration Are Balanced by Losses from Extinction

MacArthur and Wilson's model of island biogeography suggests that species repeatedly arrive on an island and either thrive or become extinct. The rate of immigration of new species is highest when no species are present on the island. As the number of species accumulates, the immigration rate decreases, since subsequent immigrants are more likely to represent species already present on the island. The rate of extinction is low at the time of first colonization, because few species are present and many have large populations. With the addition of new species, the populations of some species diminish, so the probability of extinction by chance alone increases. Over time, the number of species tends toward an equilibrium, $\hat{S}$, in which the rates of immigration and extinction are equal. Species may continue to arrive and go extinct, but the number of species on the island remains approximately the same.

MacArthur and Wilson reasoned that when plotted graphically, both the immigration and extinction lines would be curved, for several reasons (Figure 58.14a). First, species arrive on islands at different rates. Some organisms, including plants with seed dispersal mechanisms and winged animals, are more mobile than others and will arrive quickly. Other organisms will arrive more slowly. This pattern causes the immigration curve to start off steep but get progressively shallower. On the other hand, extinctions rise at accelerating rates, because as later species arrive, competition increases and more species are likely to go extinct. As noted previously, earlier-arriving species tend to be *r*-selected species, which are better dispersers, whereas later-arriving species are generally *K*-selected species, which are better competitors. Later-arriving species usually outcompete earlier-arriving ones, causing an increase in extinctions.



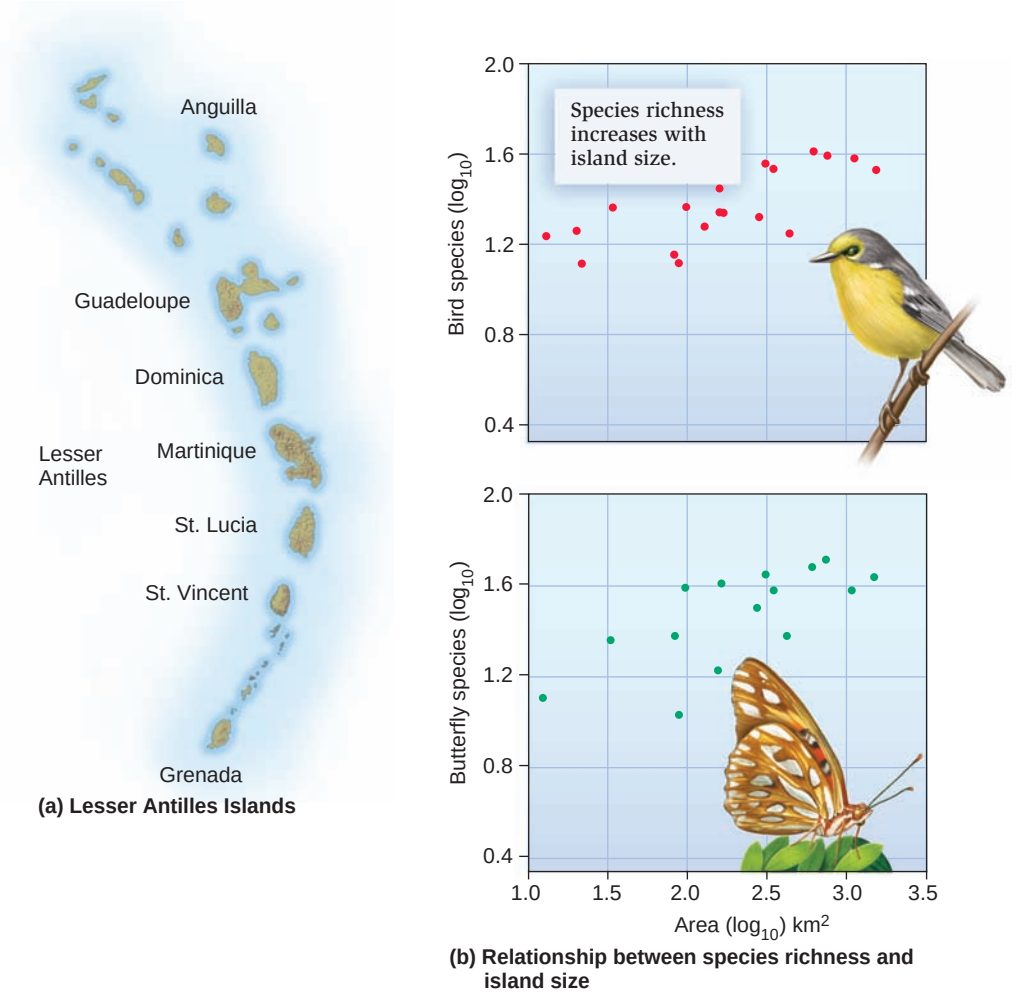
(a) Effects of immigration and extinction on species number



(b) Added effects of island size and proximity to the mainland

Figure 58.14 **MacArthur and Wilson's equilibrium model of island biogeography.** **(a)** The interaction of immigration rate and extinction rate produces an equilibrium number of species on an island, $\hat{S}$. $\hat{S}$ can vary from 0 species to P species, the total number of species available to colonize. **(b)** $\hat{S}$ varies according to the island's size and distance from the mainland. An increase in distance (near to far) lowers the immigration rate. An increase in island area (small to large) lowers the extinction rate.

Concept check: *Can you think of a scenario where there would be large numbers of species on a small island?*



(a) Lesser Antilles Islands

(b) Relationship between species richness and island size

Figure 58.15 **Species richness and island size.** **(a)** The Lesser Antilles extend from Anguilla in the north to Grenada in the south. **(b)** On these islands, the number of bird and butterfly species increases with the area of an island.

Concept check: *How large is the change in bird species richness across islands in the Lesser Antilles?*

The strength of the island biogeography model was that it generated several testable predictions:

1. The number of species should increase with increasing island size. This concept is also known as the species-area effect (see Figure 58.4). Extinction rates would be greater on smaller islands because population sizes would be smaller and more susceptible to extinction (Figure 58.14b).
2. The number of species should decrease with increasing distance of the island from the mainland, or the **source pool**, the pool of potential species available to colonize the island. Immigration rates would be greater on islands near the source pool because species do not have as far to travel (Figure 58.14b).
3. The turnover of species should be considerable. The number of species on an island might remain relatively constant, but the composition of the species should vary over time as new species colonize the island and others become extinct.

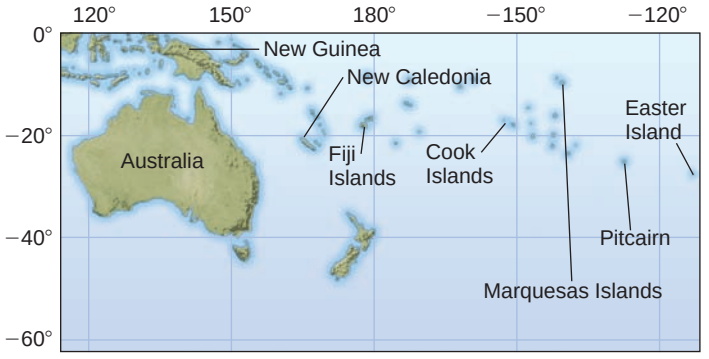
Let's examine these predictions one by one and see how well the data support them.

Species-Area Relationships

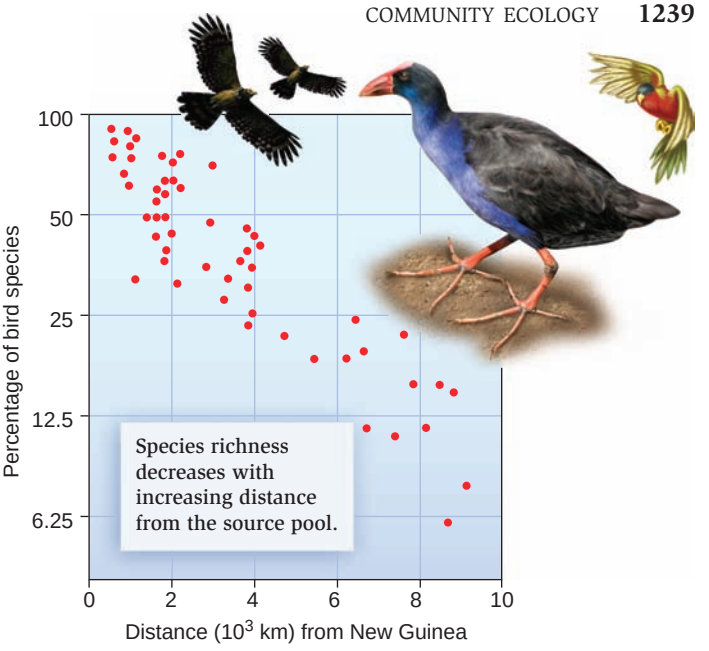
The West Indies has traditionally been a key location for ecologists studying island biogeography. This is because the physical geography and the plant and animal life of the islands are well known. Furthermore, the Lesser Antilles, from Anguilla in the north to Grenada in the south, enjoy a similar climate and are surrounded by deep water (Figure 58.15a). In 1999, Robert Ricklefs and Irby Lovette summarized the available data on the richness of species of four groups of animals—birds, bats, reptiles and amphibians, and butterflies—over 19 islands that varied in area over two orders of magnitude (13 km^2 to 1,510 km^2). In each case, a positive correlation occurred between area and species richness (Figure 58.15b). Note that these relationships are traditionally plotted on a double logarithmic scale, a so-called log-log plot, in which the horizontal axis is the logarithm to the base 10 of the area and the vertical axis is the logarithm to the base 10 of the number of species. A linear plot of the area versus the number of species would be difficult to produce, because of the wide range of area and richness of species involved. Logarithmic scales condense this variation to manageable limits.

Species-Distance Relationships

MacArthur and Wilson provided evidence for the effect of the distance of an island from a source pool of colonists, usually the mainland. In studies of the numbers of lowland forest bird species in Polynesia, they found that the number of species decreased with the distance from the source pool of New Guinea (Figure 58.16). They expressed the richness of bird



(a) New Guinea and neighboring islands



(b) Relationship between species richness and distance from source

Figure 58.16 **Species richness and distance from the source pool.** **(a)** Map of Australia, New Guinea, and these Polynesian Islands: New Caledonia, Fiji Islands, Cook Islands, Marquesas Islands, Pitcairn, and Easter Island. **(b)** The numbers of bird species on the islands decreases with increasing distance from the source pool, New Guinea. The species richness is expressed as the percentage of bird species on New Guinea.

species on the islands as a percentage of the number of bird species found on New Guinea. A significant decline in this percentage was observed with increasing distance. More-distant islands contained lower numbers of species than nearer islands. This research substantiated the prediction of species richness declining with increasing distance from the source pool.

Species Turnover

Studies involving species turnover on islands are difficult to perform because detailed and complete species lists are needed over long periods of time, usually many years and often decades. The lists that do exist are often compiled in a casual way and are not usually suitable for comparison with more modern data. In 1980, British researcher Francis Gilbert reviewed 25 investigations carried out to demonstrate turnover and found a lack of this type of rigor in nearly all of them. Furthermore, most of the observed turnover in these studies, usually less than 1% per year, or less than one species per year, appeared to be due to immigrants that never became established, not due to the extinction of well-established species. More recent studies have revealed similar findings. Most studies suggest that the rates of turnover are low, giving little conclusive support to the third prediction of the equilibrium model of island biogeography.

Feature Investigation

Simberloff and Wilson's Experiments Tested the Predictions of the Equilibrium Model of Island Biogeography

In the 1960s, Daniel Simberloff and E. O. Wilson conducted possibly the best test of the equilibrium model of island biogeography ever performed, using islands in the Florida Keys. They surveyed small red mangrove (*Rhizophora mangle*) islands, 11–25 m in diameter, for all terrestrial arthropods. They then enclosed each island with a plastic tent and had the islands fumigated with methyl bromide, a short-acting insecticide, to remove all arthropods on them. The tents were removed, and periodically thereafter Wilson and Simberloff surveyed the islands to examine recolonization rates. At each survey, they counted all the species present, noting any species not there at the previous census and the absence of others that were previously there but had presumably gone extinct (results for four of the islands are shown in Figure 58.17). In this way, they estimated turnover of species on islands.

After 250 days, all but one of the islands had a similar number of arthropod species as before fumigation, even though population densities were still low. The data indicated that

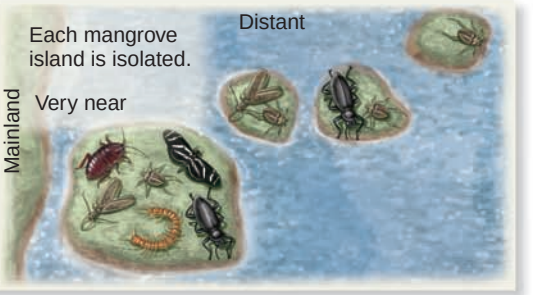
Figure 58.17 **Simberloff and Wilson's experiments on the equilibrium model of biogeography.**

HYPOTHESIS Island biogeography model predicts higher species richness for islands closer to the mainland and significant turnover of species on islands.

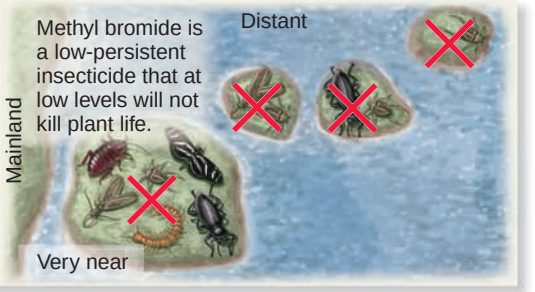
STARTING LOCATION Mangrove islands in the Florida Keys.

Experimental level **Conceptual level**

1 Take initial census of all terrestrial arthropods on 4 mangrove islands. Erect a framework over each mangrove island.

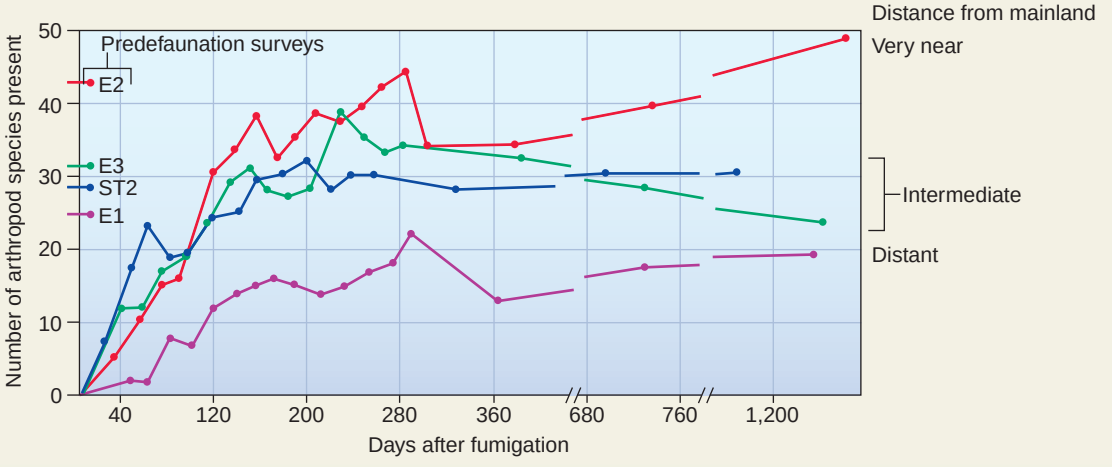


2 Cover the framework with tents and fumigate with methyl bromide to kill all arthropod species.



3 Remove the tents and conduct censuses every month to monitor recolonization of arthropods and to determine extinction rates.

4 THE DATA Island E2 was closest to the mainland and supported the highest number of species both before and after fumigation. E3 and ST2 were at an intermediate distance from the mainland, and E1 was the most distant.



5 CONCLUSION Island distance from the mainland influences species richness on mangrove islands in the Florida Keys. However, species turnover is minimal, and species richness changes little following initial recolonization.

6 SOURCE Simberloff, D.S. 1978. Colonization of islands by insects: immigration, extinction and diversity. pp. 139–153 in L.A. Mound and N. Waloff (eds.). Diversity of insect faunas. *Blackwell Scientific Publications*, Oxford, U.K.

recolonization rates were higher on islands nearer to the mainland than on far islands—as the island biogeography model predicts. However, the data, which consisted of lists of species on islands before and after extinctions, provided little support for the prediction of substantial turnover. Rates of turnover were low, only 1.5 extinctions per year, compared to the 15 to 40 species found on the islands within a year. Wilson and Simberloff concluded that turnover probably involves only a small subset of transient or unimportant species, with the more-important species remaining permanent after colonization.

Experimental Questions

1. What was the purpose of Simberloff and Wilson's study?
2. Why did the researchers conduct a thorough species survey of arthropods before experimental removal of all the arthropod species?
3. What did the researchers conclude about the relationship between island proximity to the mainland and species richness and turnover?

MacArthur and Wilson's equilibrium model of island biogeography has stimulated much research that confirms the strong effects of area and distance on species richness. However, species turnover appears to be low rather than considerable, which suggests that succession on most islands is a fairly orderly process. This means that colonization is not a random process and that the same species seem to colonize first and other species gradually appear in the same order.

It is also important to note that the principles of island biogeography have been applied to wildlife preserves, which are essentially islands in a sea of developed land, either agricultural fields or urban sprawl. Conservationists have therefore utilized island biogeography modeling in the design of nature preserves, a topic we will return to in Chapter 60.

In this chapter, we have seen how important species richness is to community function. It affects not only stability but, as we shall see, many other features of a community and its surrounding environment, such as nutrient uptake, biomass, and productivity. In order to know how diversity affects these properties, we need to understand the basic processes of energy flow and chemical cycling through a community and its environment, and for that we next turn to a discussion of ecosystems ecology in Chapter 59.

Summary of Key Concepts

58.1 Differing Views of Communities

- Community ecology studies how groups of species interact and form functional communities. Ecologists have differing views on the nature of a community. In one view, communities are tightly organized groups of mutually dependent species, and in another, they are loose assemblies of species that happen to live in the same place at the same time. (Figure 58.1)
- Although many observations support the idea that communities are loose assemblages of species, sharp boundaries between groups of species do exist, especially related to physical differences that cause distinct communities to develop. (Figure 58.2)

58.2 Patterns of Species Richness

- The number of species of most taxa varies according to geographic location, generally increasing from polar areas to tropical areas. (Figure 58.3)
- Varying hypotheses for the polar-equatorial gradient have been advanced, including the time hypothesis, the area hypothesis, the productivity hypothesis, and the intermediate disturbance hypothesis. (Figures 58.4, 58.5, 58.6)

58.3 Calculating Species Diversity

- The most widely used measure of the diversity of a community, called the Shannon diversity index, takes into account both species richness and species abundance. (Table 58.1)
- The field of metagenomics seeks to identify and analyze the genomes contained in a community of microorganisms. (Figure 58.7)

58.4 Species Diversity and Community Stability

- Community stability is an important consideration in ecology. The diversity-stability hypothesis maintains that species-rich communities are more stable than communities with fewer species.
- Tilman's field experiments, which showed that year-to-year variation in plant biomass decreased with increasing species diversity, established a link between diversity and stability. (Figure 58.8)

58.5 Succession: Community Change

- Succession describes the gradual and continuous change in community structure over time. Primary succession refers to succession on a newly exposed site with no prior biological legacy; secondary succession refers to succession on a site that has already supported life but has undergone a disturbance. (Figures 58.9, 58.10)
- Three mechanisms have been proposed for succession. In facilitation, each species facilitates or makes the environment more suitable for subsequent species. In inhibition, initial species inhibit later colonists. In tolerance, any species can start the succession, and species replacement is unaffected by previous colonists. (Figures 58.11, 58.12, 58.13)

58.6 Island Biogeography

- In the equilibrium model of island biogeography, the number of species on an island tends toward an equilibrium number determined by the balance between immigration rates and extinction rates. (Figure 58.14)
- The model predicts that the number of species increases with increasing island size; that the number of species decreases with distance from the source pool; and that turnover is high. (Figures 58.15, 58.16)

- Simberloff and Wilson's experiments on mangrove islands in the Florida Keys provided support for the first tenet of the island biogeography model but refuted the third tenet. (Figure 58.17)

Assess and Discuss

Test Yourself

1. A community with many individuals but few different species would exhibit
   a. low abundance and high species complexity.
   b. high stability.
   c. low species richness and high abundance.
   d. high species diversity.
   e. high abundance and high species richness.
2. Which of the following statements best represents the productivity hypothesis regarding species richness?
   a. The larger the area, the greater the number of species that will be found there.
   b. Temperate regions have a lower species richness due to the lack of time available for migration after the last ice age.
   c. The number of species in a particular community is directly related to the amount of available energy.
   d. As invertebrate productivity increases, species richness will increase.
   e. Species richness is not related to primary productivity.
3. Ecologists began to question Elton's link of increased stability to increased diversity because
   a. mathematical models showed communities with high diversity had high stability.
   b. cultivated land undergoes few outbreaks of pests.
   c. highly disturbed areas have high numbers of species.
   d. pest outbreaks are caused by lack of long associations with natural enemies, not because they occur in simple systems.
   e. all of the above.
4. Metagenomics is a field of study that
   a. determines the similarities of the genomes of all species in a community.
   b. focuses on the microbial genomes contained in a community.
   c. compares the genomes of similar species in different communities.
   d. none of the above
   e. both a and b
5. Extreme fluctuations in species abundance
   a. lead to more diverse communities.
   b. are usually seen in early stages of community development.
   c. may increase the likelihood of extinction.
   d. have very little effect on species richness.
   e. are characteristic of stable communities.
6. Which of the following statements best represents the relationship between species diversity and community disturbance?
   a. Species diversity and community stability have no relationship.
   b. Communities with high levels of disturbance are more diverse.
   c. Communities with low levels of disturbance are more diverse.
   d. Communities with intermediate levels of disturbance are more diverse.
   e. Communities with intermediate levels of disturbance are less diverse.
7. The process of primary succession occurs
   a. around a recently erupted volcano.
   b. on a newly plowed field.
   c. on a hillside that has suffered a mudslide.
   d. on a recently flooded riverbank.
   e. on none of the above.
8. Early colonizers excluding subsequent colonists from moving into a community is referred to as
   a. facilitation.
   b. competitive exclusion.
   c. secondary succession.
   d. inhibition.
   e. natural selection.
9. A tree falls in a forest in spring and flowers germinate in the light gap. Following a tree fall in autumn, different species of flowers germinate in the light gaps. This illustrates the principle of
   a. facilitation.
   b. tolerance.
   c. inhibition.
   d. primary succession.
   e. climax communities.
10. On which types of island would you expect species richness to be greatest?
    a. small, near mainland
    b. small, distant from mainland
    c. large, near mainland
    d. large, distant from mainland
    e. Species richness is equal on all these types of islands.

Conceptual Questions

1. Define a community and community ecology.
2. List some possible ecological disturbances, their likely frequency in natural communities, and the severity of their effects.
3. When is a community in equilibrium?

Collaborative Questions

1. Distinguish between the time hypothesis, area hypothesis, and productivity hypothesis as explanations for the latitudinal gradient in species richness.
2. Calculate the species diversity of the following four communities. Which community has the highest diversity? What is the maximum diversity each community could have?

	Relative abundance of species				
Community	Species 1	Species 2	Species 3	H_S	Maximum possible diversity
1	90	10	—		
2	50	50	—		
3	80	10	10		
4	33.3	33.3	33.3

Chapter Outline

Ecosystem Ecology

59

Mandara Lake Oasis, Libya.

Familiar backyard earthworms are known for their ability to convert organic matter such as dead leaves into rich humus, improving soil fertility. However, earthworms are not native everywhere. North American glaciations exterminated earthworms from hardwood forests in Wisconsin and Minnesota some 11,000 to 14,000 years ago. In the absence of earthworms, fungi and bacteria dominated decomposition, a thick forest floor formed, and carbon built up in the soil. Exotic earthworms from Europe and Asia initially were introduced into Wisconsin and Minnesota by European settlers and have continued to be transported to the area through a range of human activities, including the dumping of fishing bait. Organisms that are beneficial in one location can be destructive when introduced to another, and earthworms are no exception. In northern forests, the worms accelerate the cycling of nutrients through the soil, drastically altering the structure of the forest floor soil and releasing soil carbon to the atmosphere. According to Cindy Hale, a biologist who has been studying the effect of earthworms on northern hardwood forests, "They have a cascading effect on plants, animals, and soil organisms. And we know they're causing significant damage to some forests. Their effect could be really profound."

The term **ecosystem** was coined in 1935 by the British plant ecologist A. G. Tansley to include not only the biotic community of organisms in an area but also the abiotic environment affecting that community. **Ecosystem ecology** is concerned with the movement of energy and materials through organisms and their communities. Just like the concept of a community, the ecosystem concept can be applied at any scale. A small pond inhabited by protozoa and insect larvae is an ecosystem, and an oasis with its plants, frogs, fishes, and birds constitutes another. Most ecosystems cannot be regarded as having definite boundaries. Even in a clearly defined pond ecosystem, species may be moving in and out (Figure 59.1). Nevertheless, studying ecosystem ecology allows us to use the common currency of energy and chemicals, or nutrients, to compare the functions between and within ecosystems.

In investigating the different processes of an ecosystem, at least three major constituents can be measured: energy flow, biomass production, and biogeochemical cycling. We begin the chapter by exploring **energy flow**, the movement of energy through

Figure 59.1 **A small ecosystem.** Even in this pond ecosystem, frogs or other species such as birds may move in and out, importing or exporting nutrients and energy with them.

an ecosystem. In examining energy flow, our main task will be to document the complex networks of feeding relationships, called food webs, and to measure the efficiency of energy transfer between organisms in an ecosystem.

Next, we will focus on the measurement of **biomass**, a quantitative estimate of the total mass of living matter in a given area, usually measured in grams or kilograms per square meter. We will examine the amount of biomass produced through photosynthesis, termed primary production, and the amount of biomass produced by the organisms that are the consumers of primary production.

The functioning of an ecosystem can sometimes be most limited by the availability of a scarce chemical or mineral. In the last section, we will examine the movement of chemicals through ecosystems, called **biogeochemical cycles**, and explore the cycling of elements, such as phosphorus, carbon, nitrogen, and sulfur, and the effects that human activities are having on these ecosystem-wide processes.

59.1 Food Webs and Energy Flow

Most organisms either make their own food using energy from sunlight or feed on other organisms. Simple feeding relationships between organisms can be characterized by an unbranched **food chain**, a linear depiction of energy flow, with each organism feeding on and deriving energy from the preceding organism. Each feeding level in the chain is called a **trophic level** (from the Greek *trophos*, meaning feeder), and different species feed at different levels. In a food-chain diagram, an arrow connects each trophic level with the one above it (Figure 59.2).

In this section, we will consider trophic relationships and the flow of energy in a food chain and also examine a food web, a more complex model of interconnected food chains. We will then explore two of the most important features of food webs—chain length and the pyramid of numbers—and learn how the passage of nutrients through food webs can result in the accumulation of harmful chemicals in the tissues of organisms at higher trophic levels.

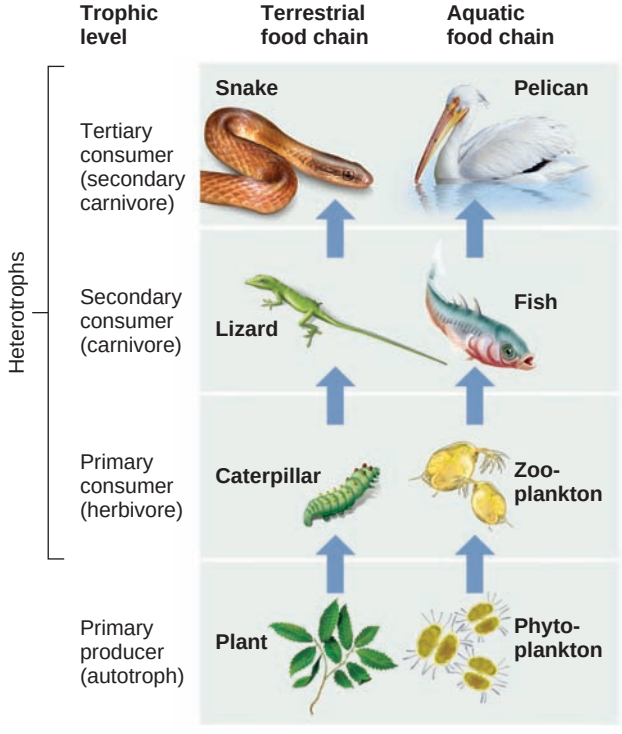

Figure 59.2 **Food chains.** Two examples of the flow of food energy up the trophic levels: a terrestrial food chain and an aquatic food chain.

The Main Trophic Levels Within Food Chains Consist of Primary Producers, Primary Consumers, and Secondary Consumers

Food chains typically consist of organisms that obtain energy in different ways. **Autotrophs** harvest light or chemical energy and store that energy in carbon compounds. Most autotrophs, including plants, algae, and photosynthetic bacteria, use sunlight for this process. These organisms, called **primary producers**, form the base of the food chain. They produce the energy-rich organic molecules upon which nearly all other organisms depend. However, not all primary producers utilize sunlight; some organisms, called chemoautotrophs, obtain their energy by oxidizing inorganic compounds such as sulfides.

Organisms in trophic levels above the primary producers are termed **heterotrophs**. These organisms receive their nutrition by eating other organisms. Organisms that obtain their food by consuming primary producers are termed **primary consumers** and include most protists, all animals, and even some plants such as mistletoe, which is parasitic on other plants. Animals that eat plants are also called **herbivores**. Organisms that eat primary consumers are **secondary consumers**. Animals that eat other animals are also called **carnivores** (from the Latin *carn*, meaning flesh). Organisms that feed on secondary consumers are **tertiary consumers**, and so on. Thus, energy enters a food chain through primary producers, via photosynthesis, and is passed up the food chain to primary, secondary, and tertiary consumers (Figure 59.2).

At each trophic level, many organisms die before they are eaten. Much energy from the first trophic level, such as the plants, goes unconsumed by herbivores. Instead, unconsumed plants die and decompose in place. This material, along with dead remains of animals and waste products, is called **detritus**. Consumers that get their energy from detritus, called **detritivores**, or **decomposers**, break down dead organisms from all trophic levels (Figure 59.3). In terrestrial systems, detritivores probably carry out 80–90% of the consumption of plant matter, with different species working in concert to extract most of

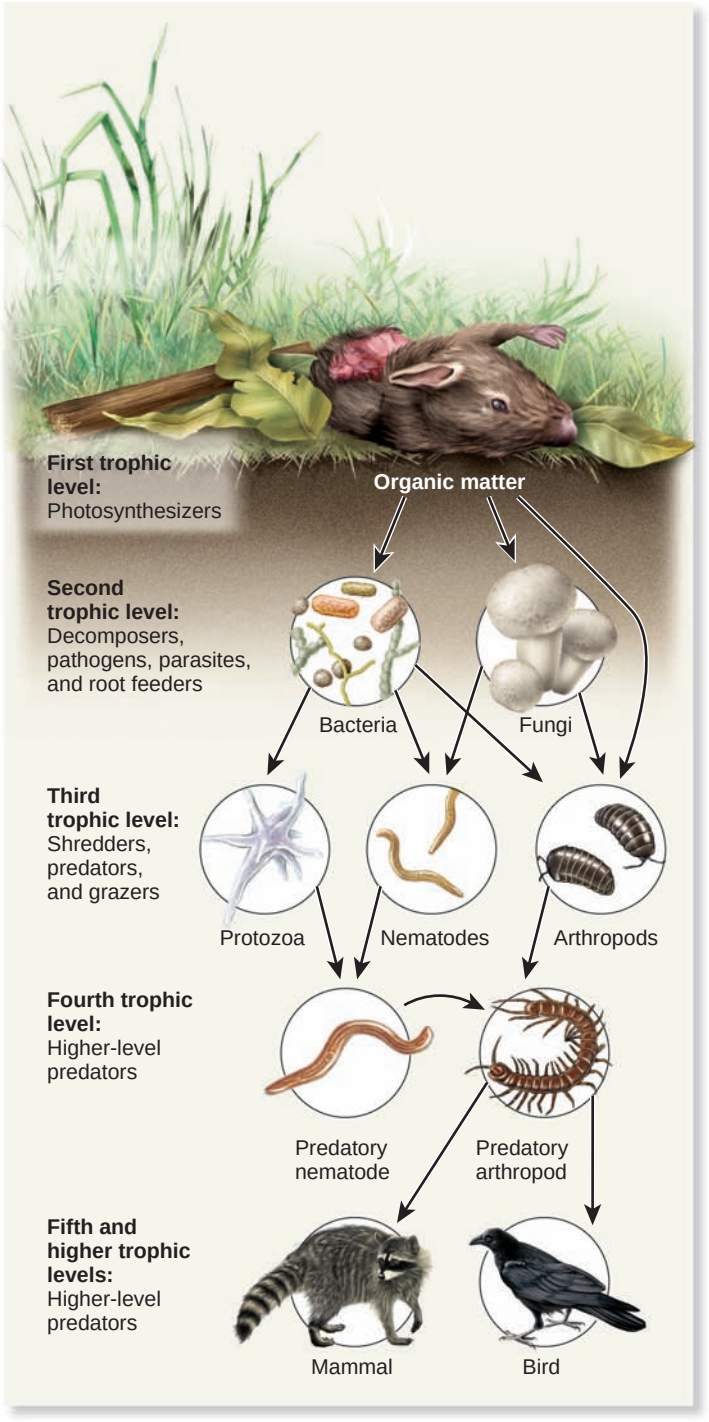

Figure 59.3 **Decomposers (detritivores) feeding on dead plant and animal matter.** Many dead plants and animals are eaten by a variety of decomposers. Here, bacteria and fungi feed on dead animals and rotting plant material. Dead animals, or carrion, may also be fed upon by blowfly larvae, carrion beetles, and other scavengers. These may, in turn, support a variety of predators, including centipedes or larger predators such as mammals and birds, which will also feed on the animal carcass.

Concept check: *At which trophic level do decomposers feed?*

the energy. Detritivores may, in turn, support a community of predators that feed on them. As we noted at the beginning of the chapter, changes in the decomposer community can lead to important changes in nutrient cycling.

The consumption of species between trophic levels is quite varied. For example, many different herbivore species may feed on the same plant species. Also, each species of herbivore may feed on several different plant species. Such branching of food chains also occurs at other trophic levels. For instance, on the African savanna, cheetahs, lions, and hyenas all eat a variety of prey, including wildebeest, impala, and Thompson's gazelle. These, in turn, eat a variety of trees and grasses. It is more correct, then, to draw relationships between these plants and animals not as a simple chain but as a more elaborate interwoven **food web**, in which there are multiple links between species (Figure 59.4).

In Most Food Webs, Chain Lengths Are Short

Let's examine some of the characteristics of food webs in more detail. The concept of chain length refers to the number of links between the trophic levels involved. For example, if a lion feeds on a zebra, and a zebra feeds on grass, the chain length would be two. In many food webs, chain lengths tend to be short, usually less than six levels, even including parasites and detritivores. The main reason why they are short comes from the well-established laws of physics and chemistry that we discussed in Chapter 2. The second law of thermodynamics states that energy conversions are not 100% efficient. In any transfer process, some useful energy, which can do work, is lost, often in the form of heat. This decreases the amount of available energy at higher trophic levels. We can construct energy budgets for food webs that trace energy flow from green plants to tertiary consumers (and if needed beyond) (Figure 59.5). In each trophic level, some energy is lost to maintenance, for example, to maintain body temperature. Because energy transfer between trophic levels is not 100% efficient, energy is lost in the passage from one trophic level to another.

As described next, two ways that ecologists evaluate the efficiency of consumers as energy transformers are production efficiency and trophic-level transfer efficiency.

Production Efficiency **Production efficiency** is defined as the percentage of energy assimilated by an organism that becomes incorporated into new biomass.

$$\text{Production efficiency} = \frac{\text{Net productivity}}{\text{Assimilation}} \times 100$$

Here, net productivity is the energy, stored in biomass, that has accumulated over a given time span, and assimilation is the total amount of energy taken in by an organism over the same time span. Invertebrates generally have high production efficiencies that average about 10–40% (Figure 59.6a). Microorganisms also have relatively high production efficiencies. Vertebrates tend to have lower production efficiencies than invertebrates, because they devote more energy to sustaining

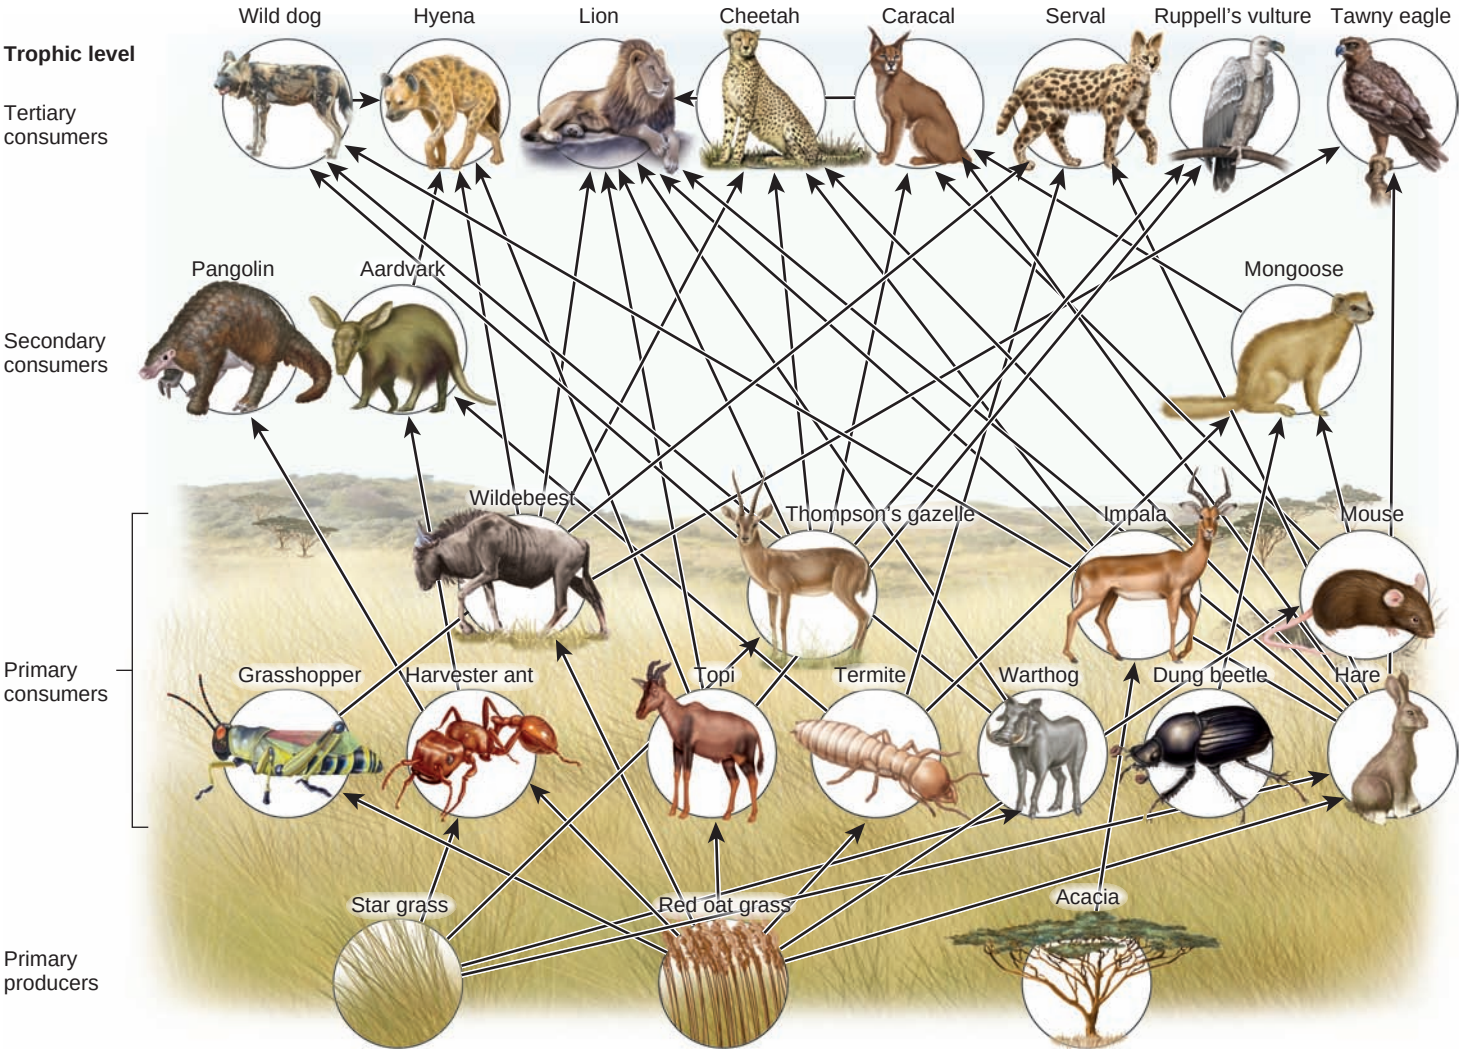

Figure 59.4 **A simplified food web from an African savanna ecosystem.** Each trophic level is occupied by different species. Generally, each species feeds on, or is fed upon by, more than one species.

their metabolism than to new biomass production. Even within vertebrates, much variation occurs. Fishes, which are ectotherms, typically have production efficiencies of around 10%, and birds and mammals, which are endotherms, have production efficiencies in the range of 1–2% (Figure 59.6b). In large part, the difference reflects the energy cost of maintaining a constant body temperature. Production efficiencies are higher in young animals, which are rapidly accruing biomass, than in older animals, which are not. This is the main reason behind the practice of harvesting young animals for meat, at about the time when they first attain adult mass.

One consequence of differing production efficiencies is that sparsely vegetated deserts can support healthy populations of snakes and lizards, whereas mammals might easily starve. The largest living lizard known, the Komodo dragon, eats the equivalent of its own weight every 2 months, whereas a cheetah consumes approximately four times its own weight in the same period.

Trophic-Level Transfer Efficiency The second measure of efficiency of consumers as energy transformers is **trophic-level transfer efficiency**, which is the amount of energy at one trophic level that is acquired by the trophic level above and incorporated into biomass. This provides a way to examine energy flow between trophic levels, not just in an individual species. Trophic level transfer efficiency is calculated as follows:

$$\text{Trophic-level transfer efficiency} = \frac{\text{Production at trophic level } n}{\text{Production at trophic level } n-1} \times 100$$

For example, if there were 14 g/m^2 of zooplankton in a lake (trophic level n) and 100 g/m^2 of phytoplankton production (trophic level $n - 1$), the trophic level efficiency would be 14%. Trophic-level transfer efficiency appears to average around 10%, though there is much variation. In some marine food chains, for example, it can exceed 30%.

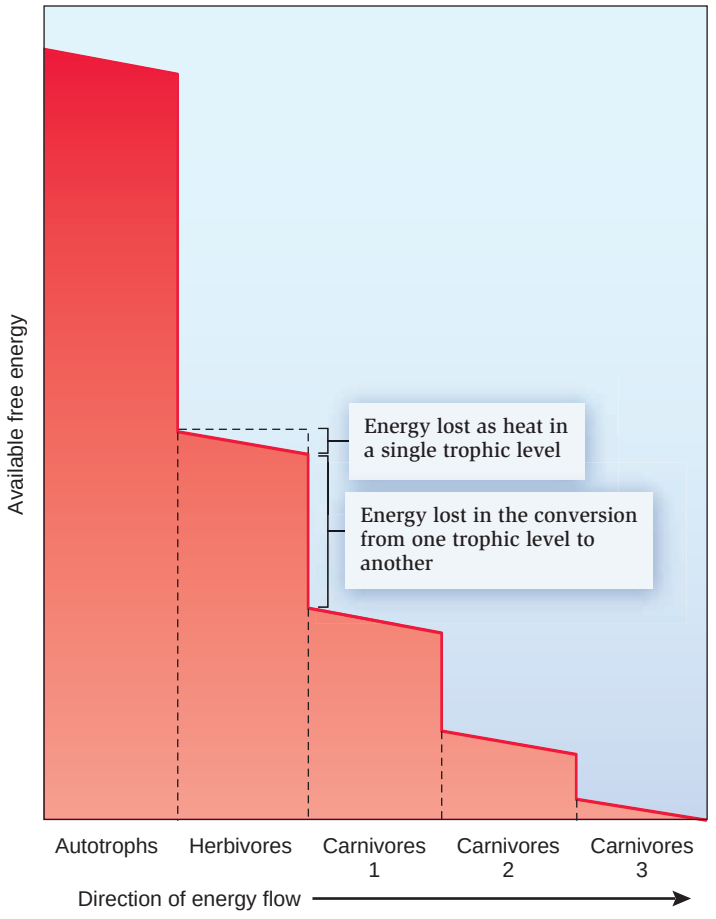

Figure 59.5 Energy flow through a food web.

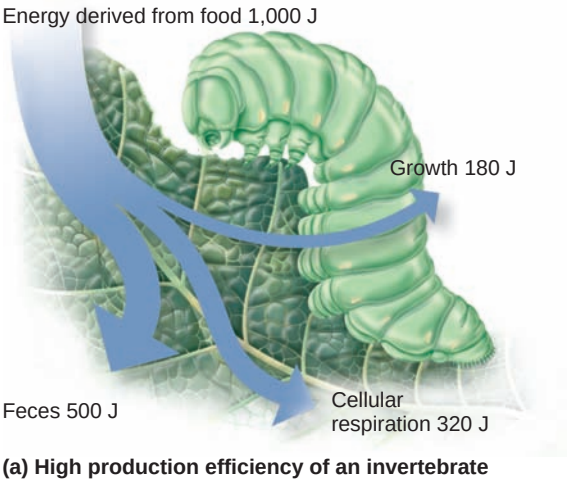
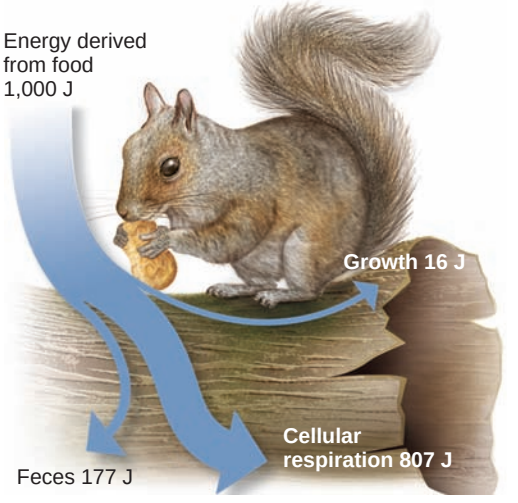
Trophic-level transfer efficiency is generally low for two reasons. First, many organisms cannot digest all their prey. They take only the easily digestible plant leaves or animal tissue such as muscles and guts, leaving the hard wood or energy-rich bones behind. Second, much of the energy assimilated by animals is used in maintenance, so most energy is lost from the system as heat. The 10% average transfer rate of energy from one trophic level to another also necessitates short food webs of no more than four or five levels. Relatively little energy is available for the higher levels.



(a) High production efficiency of an invertebrate



(b) Low production efficiency of a vertebrate

Figure 59.6 **Production efficiencies.** **(a)** This caterpillar, an invertebrate, chews leaves to obtain its energy. If a mouthful of food contains 1,000 joules (J) of energy, about 320 J is used in cellular respiration to fuel metabolic processes (32%), and 500 J (50%) is lost in feces. This leaves about 180 J of the 500g assimilated to be converted into insect biomass, a production efficiency of 36%. **(b)** The production efficiency of this squirrel, a mammal, is much lower.

Concept check: *What is the production efficiency of the squirrel, using the numbers in the figure?*

Eltonian Pyramids Describe the Distribution of Numbers, Biomass, or Energy Between Trophic Levels

Trophic-level transfer efficiencies can be expressed in a graphical form called an Eltonian pyramid, named after the British ecologist Charles Elton. The best-known pyramid, and the one described by Elton in 1927, is the **pyramid of numbers**, in which the number of individuals decreases at each trophic level, with a large number of individuals at the base and fewer individuals at the top. Elton's example was that of a small pond, where the numbers of protozoa may run into the millions and those of *Daphnia*, their predators, number in the hundreds of thousands. Hundreds of beetle larvae may feed on *Daphnia*, and tens of fishes feed on the beetles. Many other examples of this type of pyramid are known. For example, in a grassland, there may be hundreds of individual plants per square meter, dozens of insects that feed on the plants, a few spiders feeding on the insects, and birds that feed on the spiders (Figure 59.7a).

Ecologists have, however, discovered many exceptions to this pyramid. One single producer such as an oak tree can support hundreds of herbivorous beetles, caterpillars, and other primary consumers, which, in turn, may support thousands of predators. This is called an inverted pyramid of numbers (Figure 59.7b).

One way to reconcile this apparent exception is to weigh the organisms in each trophic level, creating a **pyramid of biomass**. For example, an oak tree weighs more than all its herbivores and predators combined. Looking at the biomass at each trophic level rather than at numbers of organisms shows an upright pyramid. In 1957, Howard Odum measured the pyramid of biomass for a freshwater ecosystem, Silver Springs, Florida (Figure 59.7c). Beds of eelgrass (genus *Sagittaria*) and attached algae make up most of the producers. Insects, snails, herbivorous fishes, and turtles eat the producers. Other fishes form the secondary and tertiary consumers. Odum also noted the presence of fungi and bacteria, which were involved in decomposition on all trophic levels.

Even when biomass is used as the measure, inverted pyramids can still occur, albeit rarely. In some marine and lake systems, the biomass of phytoplankton supports a higher biomass of zooplankton (Figure 59.7d). This is possible because the rate of production of phytoplankton biomass is much higher than that of zooplankton, and the small phytoplankton **standing crop** (the total biomass in an ecosystem at any one point in time) processes large amounts of energy.

However, by expressing the pyramid in terms of production rate, it is no longer inverted. The **pyramid of energy**, which shows the rate of energy production rather than standing crop, is never inverted (Figure 59.7e). The laws of thermodynamics ensure that the highest amounts of free energy are found at the lowest trophic levels. Howard Odum's energy pyramid for Silver Springs also shows that large amounts of energy pass through decomposers, despite their relatively small biomass.

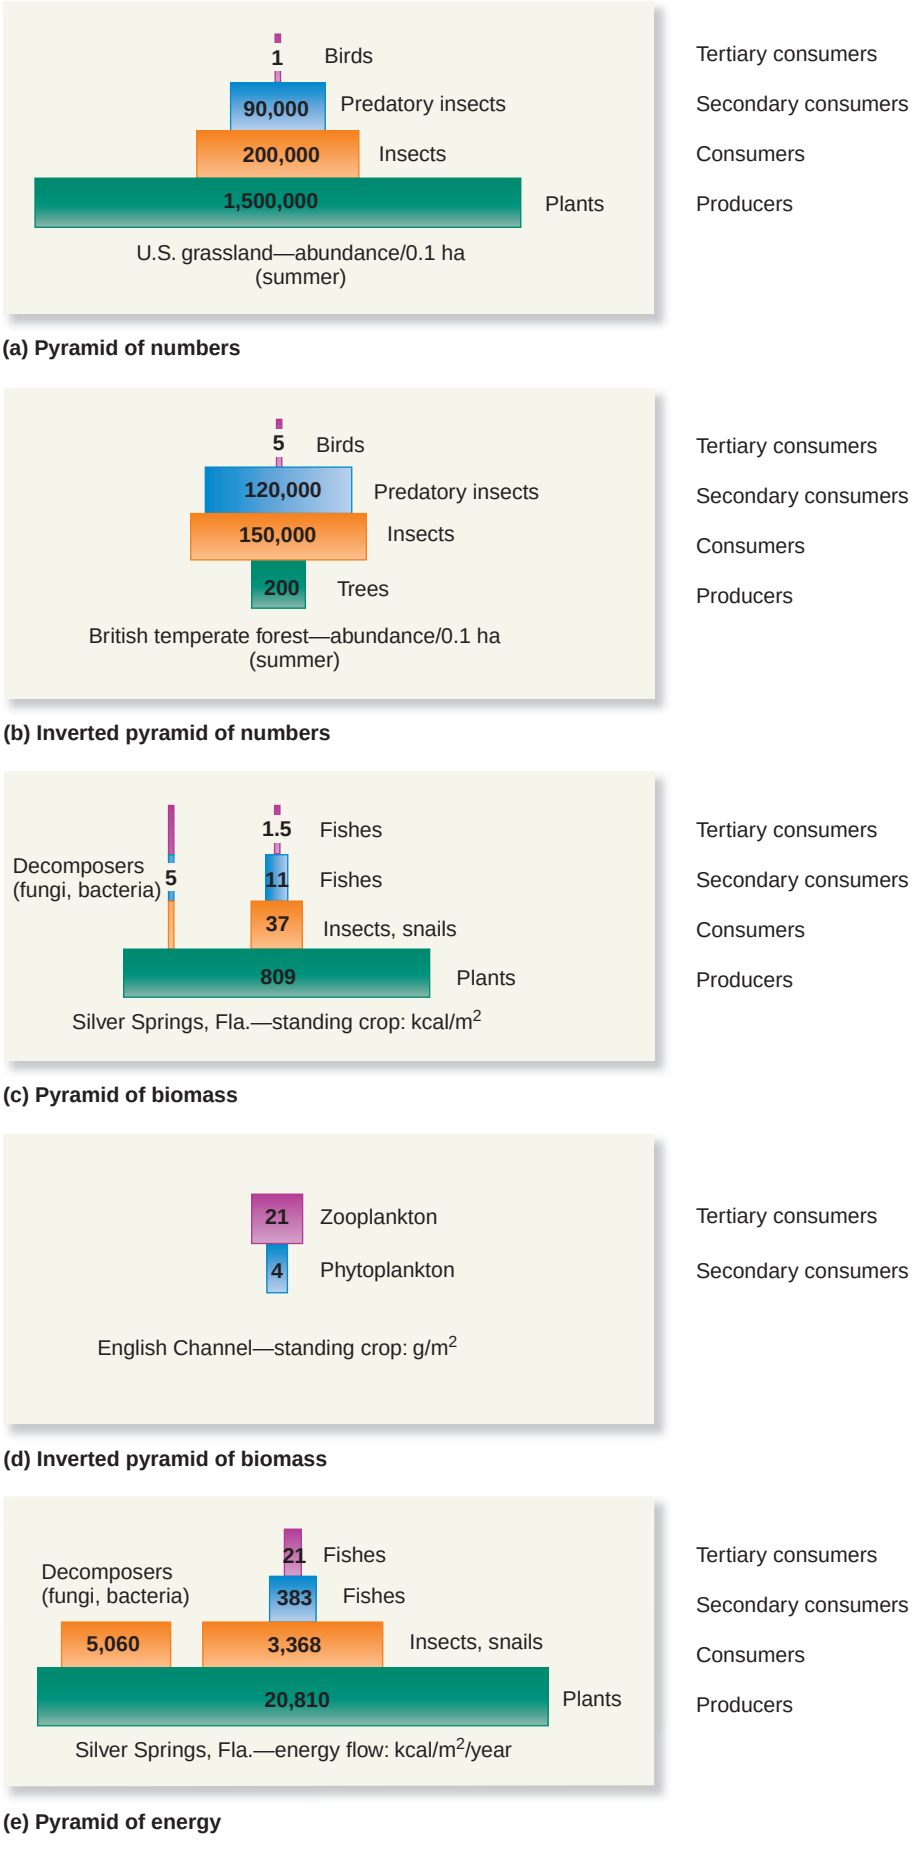


Figure 59.7 Ecological pyramids in food webs. **(a)** In this pyramid of numbers, the abundance of species decreases with increasing trophic level. **(b)** In an inverted pyramid of numbers, the abundance of species increases with increasing trophic level. **(c)** When the amount of biological material decreases with increasing trophic level, the pyramid is termed a pyramid of biomass. Note the presence of decomposers that decompose material at all trophic levels. **(d)** In an inverted pyramid of biomass, biomass increases with increasing trophic level. **(e)** In a pyramid of energy, energy production decreases with increasing tropic level. Note the large energy production of decomposers, despite their small biomass. (After Odum 1971.)

Biomagnification Can Occur in Higher Trophic Levels

Thus far, we have considered how available biomass and energy flow can influence the properties of food chains and webs. An issue that faces organisms is the tendency of certain chemicals to concentrate in higher tropic levels in food chains, a process called **biomagnification**. The passage of DDT in food chains provides a startling example.

Dichlorodiphenyltrichloroethane (DDT) was first synthesized by chemists in 1874. In 1939, its insecticidal properties were recognized by Paul Müller, a Swiss scientist who won a Nobel Prize in 1948 for his discovery and subsequent research on the uses of the chemical. The first important application of DDT was in human health programs during and after World War II, particularly to control mosquito-borne malaria; at that time, its use in agriculture also began. The global production of DDT peaked in 1970, when 175 million kg of the insecticide were manufactured.

DDT has several chemical and physical properties that profoundly influence the nature of its ecological impact. First, DDT is persistent in the environment. It is not rapidly degraded to other, less toxic chemicals by microorganisms or by physical agents such as light and heat. The typical persistence in soil of DDT is about 10 years, which is two to three times longer than the persistence of most other insecticides. Another important characteristic of DDT is its low solubility in water and its high solubility in fats or lipids. In the environment, most lipids are present in living tissue. Therefore, because of its high lipid solubility, DDT tends to concentrate in biological tissues.

Because biomagnification occurs at each step of the food chain, organisms at higher tropic levels can amass especially high concentrations of DDT in their lipids. A typical pattern of biomagnification is illustrated in Figure 59.8, which shows the relative amounts of DDT found in a Lake Michigan food chain. The highest concentration of the insecticide was found in gulls, tertiary consumers that feed on fishes that, in turn, eat small insects. An unanticipated effect of DDT on bird species was its interference with the metabolic process of eggshell formation. The result was thin-shelled eggs that often broke under the weight of incubating birds (Figure 59.9). DDT was responsible for a dramatic decrease in the populations of many birds due to failed reproduction. Relatively high levels of the chemical were also found to be present in some game fishes, which became unfit for human consumption.

Because of growing awareness of the adverse effects of DDT, most industrialized countries, including the U.S., had banned the use of the chemical by the early 1970s. The good news is that following the outlawing of DDT, populations of the most severely affected bird species have recovered. However, had scientists initially possessed a more thorough knowledge of how DDT accumulated in food chains, some of the damage to the bird populations might have been prevented. DDT is still used in some developing countries to kill malaria-carrying mosquitoes, although there has been significant movement toward the use of alternative pest-control technologies to control the disease.

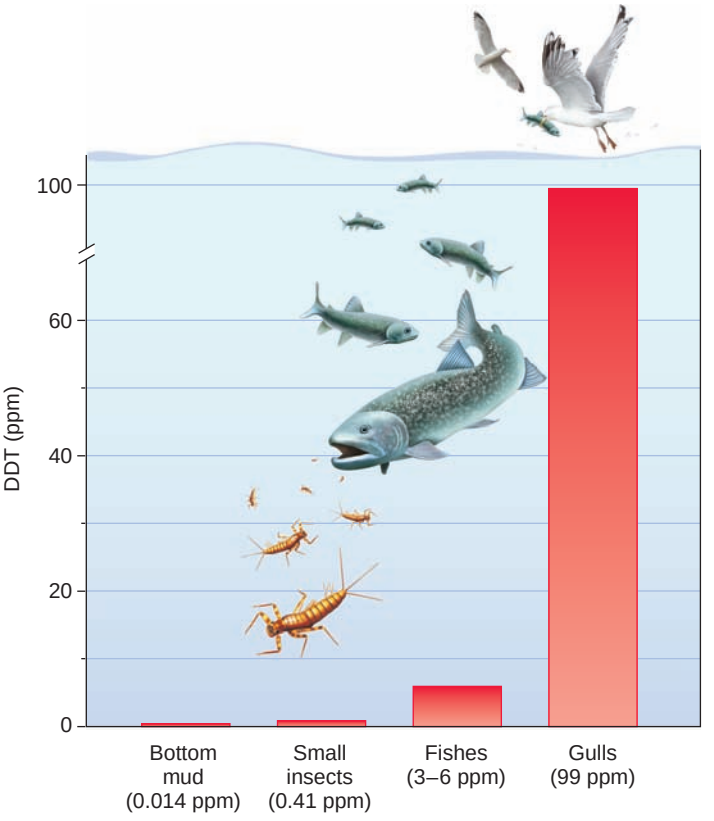

Figure 59.8 Biomagnification in a Lake Michigan food chain. The DDT tissue concentration in gulls, a tertiary consumer, was about 240 times that in the small insects sharing the same environment. The biomagnification of DDT in lipids causes its concentration to increase at each successive link in the food chain.

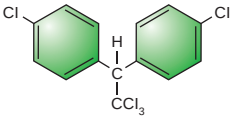

DDT (dichlorodiphenyltrichloroethane)
- Persists in environment
- High solubility in lipids
- Found in high concentrations at higher trophic levels

Figure 59.9 Thinning of eggshells caused by DDT. These ibis eggs are thin-shelled and have been crushed by the incubating adult.

59.2 Biomass Production in Ecosystems

In this section, we will take a closer look at biomass production in ecosystems. Because the bulk of the Earth's biosphere, 99.9% by mass, consists of primary producers, when we measure ecosystem biomass production, we are primarily interested in plants, algae, or cyanobacteria. Because these photosynthetic organisms represent the first, or primary, trophic level, their production is called **gross primary production** (**GPP**). Gross primary production is equivalent to the carbon fixed during photosynthesis. **Net primary production** (**NPP**) is gross primary production minus the energy released during cellular respiration (R) of photosynthetic organisms.

$$NPP = GPP - R$$

Net primary production is thus the amount of energy that is available to primary consumers. Unless otherwise noted, the term primary production will refer to net primary production.

To measure primary production, calories can be used as a common currency, and organisms can be viewed in terms of caloric content. For example, 100 g of rye grass seeds (*Secale cereale*) has a calorific content of about 380 calories, whereas 100 g of lead tree leaves (*Leucaena leucocephala*) has a calorific content of only 68 calories. Energy content is generally measured using dry biomass. Dry weight is used because the bulk of living matter in most species is water, and water content fluctuates widely, often according to wet or dry seasons. Of the dry weight, 95% is made up of carbon compounds, so measuring energy flow in ecosystems is in many ways equivalent to examining the carbon cycle (see Section 59.3). Ecologists often measure NPP in terms of carbon fixed per square meter or per hectare.

Understanding what factors limit primary production is of vital importance if we are to examine ecosystems as energy transformers. Furthermore, by determining these factors, we can understand how primary production varies globally. We can also examine the effects of primary production on **secondary production**, the gain in the biomass of heterotrophs and decomposers.

Primary Production Is Influenced in Terrestrial Ecosystems by Water, Temperature, and Nutrient Availability

In terrestrial systems, water is a major determinant of primary production, and primary production shows an almost linear increase with annual precipitation, at least in arid regions. Likewise, temperature, which affects production primarily by slowing or accelerating plant metabolic rates, is also important. Ecologist Michael Rosenzweig noted that, on a logarithmic scale, evapotranspiration rate could predict the aboveground primary production with good accuracy in North America (Figure 59.10). Recall from Chapter 58 that the evapotranspiration rate measures the amount of water entering the atmosphere from the ground through the process of evaporation from the soil and transpiration of plants, so it is a measure of both temperature and available water. For example, a desert will have a low evapotranspiration rate because water availability is low despite high temperature. Rates of evapotranspiration are maximized when both temperature and moisture are at high levels, as in tropical rain forests.

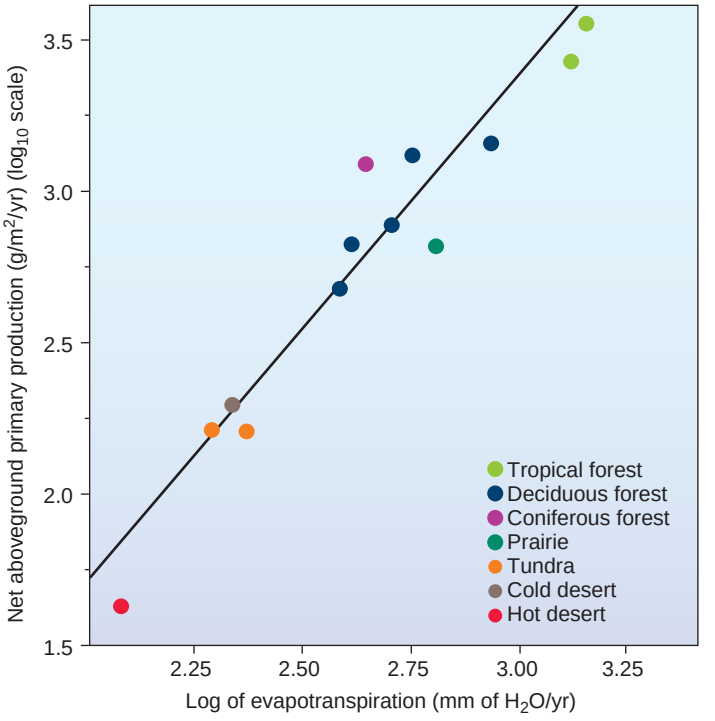

Figure 59.10 Relationship between primary production and the evapotranspiration rate. A positive correlation is observed. Warm, humid environments are ideal for plant growth. Dots represent different ecosystems.

A lack of **nutrients**, key elements in usable form, particularly nitrogen and phosphorus, can also limit primary production in terrestrial ecosystems, as farmers know only too well. Fertilizers are commonly used to boost the production of annual crops.

In 1984, Susan Cargill and Robert Jefferies showed how a lack of both nitrogen and phosphorus was limiting to salt marsh sedges and grasses in subarctic conditions in Hudson Bay, Canada (Figure 59.11). Of the two nutrients, nitrogen was the most limiting; without it, the addition of phosphorus did not increase production. However, once nitrogen was added, phosphorus became the **limiting factor**, that is, the one in shortest supply for growth. Once nitrogen was added and was no longer limiting, the addition of phosphorus increased production. The addition of nitrogen and phosphorus together increased production the most. This result supports a principle known as **Liebig's law of the minimum**, named for Justus von Liebig, a 19th-century German chemist, which states that species biomass or abundance is limited by the scarcest factor. This factor

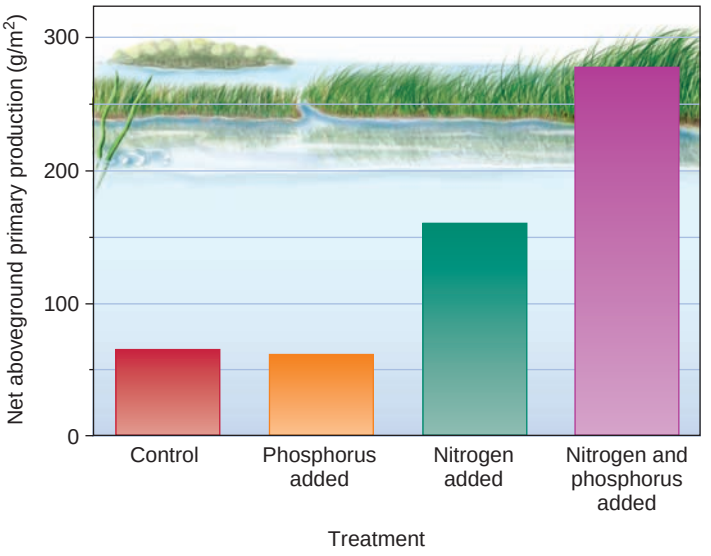

Figure 59.11 **Limitation of primary production by nitrogen and phosphorus.** Net aboveground primary production of a salt marsh sedge (*Carex subspathacea*) in response to nutrient addition. Nitrogen is the limiting factor. After nitrogen is added, phosphorus becomes the limiting factor.

can change, as the Hudson Bay experiment showed. When sufficient nitrogen is available, phosphorus becomes the limiting factor. Once phosphorus becomes abundant, then productivity will be limited by another nutrient.

Primary Production in Aquatic Ecosystems Is Limited Mainly by Light and Nutrient Availability

Of the factors limiting primary production in aquatic ecosystems, the most important are available light and available nutrients. Light is particularly likely to be in short supply because water readily absorbs light. At a depth of 1 m, more than half the solar radiation has been absorbed. By 20 m, only 5–10% of the radiation is left. The decrease in light is what limits the depth of algal growth.

The most important nutrients affecting primary production in aquatic systems are nitrogen and phosphorus, because they occur in very low concentrations. Whereas soil contains about 0.5% nitrogen, seawater contains only 0.00005% nitrogen. Enrichment of the aquatic environment by the addition of nitrogen and phosphorus can result in large, unchecked growths of algae called algal blooms. Such enrichment occurs naturally in areas of upwellings, where cold, deep, nutrient-rich water containing sediment from the ocean floor is brought to the surface by strong currents, resulting in very productive ecosystems and plentiful fishes. Some of the largest areas of upwelling occur in the Antarctic and along the coasts of Peru and California.

Primary Production Is Greatest in Areas of Abundant Warmth and Moisture

Knowing which factors limit primary production helps ecologists understand why the mean net primary production varies across the different biomes on Earth (Table 59.1). In general, primary production is highest in tropical rain forests and decreases progressively toward the poles (Figure 59.12). As we saw in Chapter 58, the productivity hypothesis suggests that greater production by plants results in the latitudinal gradient of species richness. This primary productivity gradient occurs because temperatures decrease toward the poles, and, as we have just learned, temperatures affect primary production greatly. Wetlands also tend to be extremely productive, primarily because water is not limiting and nutrient levels are high. Productivity of the open ocean is very low, falling somewhere between the productivity of deserts and that of the Arctic tundra. Marine production is high on coastal shelves, particularly in upwelling zones. However, the greatest marine production occurs on algal beds and coral reefs, where temperatures are high and water levels are not so deep that light becomes limiting.

Secondary Production Is Generally Limited by Available Primary Production

What factors control secondary production—the productivity of herbivores, carnivores, and decomposers? This is a complex question, but it is generally thought to be limited largely by available primary production. A strong relationship exists between primary production in a variety of ecosystems and the biomass of herbivores (Figure 59.13). This means that more plant biomass, and thus more primary production, leads to an increased biomass of consumers. This is not such a trivial answer as might be assumed; for example, secondary production could be limited by the availability of a particular nutrient or by the presence of natural enemies.

Table 59.1 Net Primary Production for Earth's Ecosystems

Ecosystem type	Mean net primary production (g/m²/yr)
Terrestrial	
Tropical rain forest	2,500
Tropical deciduous forest	1,600
Temperate deciduous forest	1,550
Savanna	1,080
Prairie	750
Cultivated land	610
Taiga	380
Tundra	140
Hot desert	90
Aquatic	
Algal beds and coral reefs	2,500
Wetlands	2,000
Estuaries	1,500
Upwelling zones	500
Continental shelf	360
Lake and stream	250
Open ocean	125

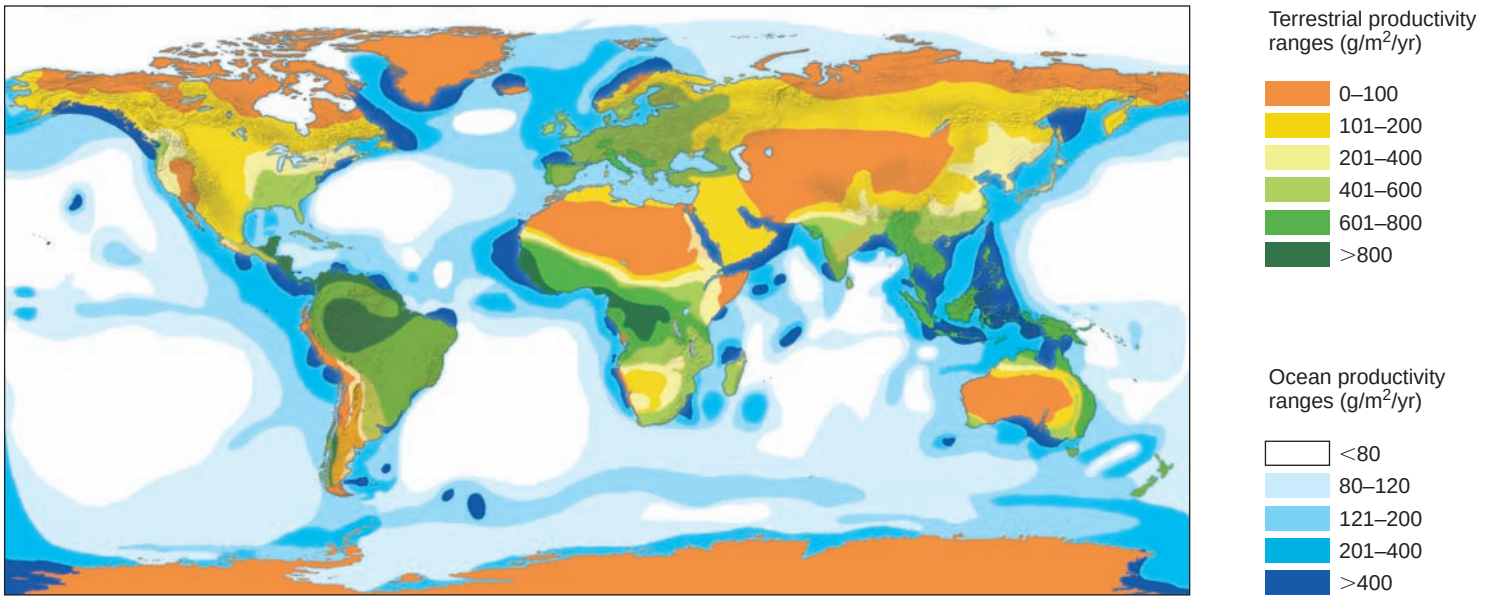

Figure 59.12 **Annual net primary productivity on Earth.** Primary productivity generally increases from the poles to the equator.

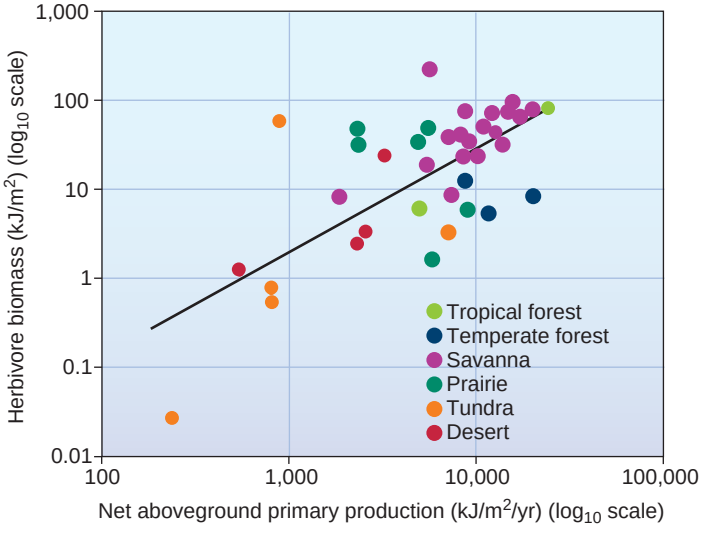

Figure 59.13 **A positive correlation between herbivore biomass and net aboveground primary production.** These data are taken from a variety of case studies from different biomes. Herbivore biomass can be considered a surrogate for secondary production.

Concept check: *What does this relationship imply about the effects of plant secondary metabolites, many of which taste bad and some of which are toxic, on secondary production?*

As we have noted before, trophic-level transfer efficiency averages about 10%. Thus, after one link in the food web, only 1/10 of the energy captured by plants is transferred to herbivores, and after two links in the food web, only 1/100 of the energy fixed by plants goes to carnivores. Thus, secondary production is much smaller than that of primary production. We can see this in the work of John Teal. In 1962, he examined energy flow in a Georgia salt marsh (Figure 59.14). Salt marshes are among the most productive habitats on Earth in terms of the amount of vegetation they produce. In salt marshes, most of the energy from the sun goes to two types of organisms: *Spartina* plants and marine algae. The *Spartina* plants are rooted in the ground, whereas the algae float on the water surface or live on the mud or on *Spartina* leaves at low tide. These photosynthetic organisms absorb about 6% of the sunlight. Most of the plant energy, 77.6%, is used in plant and algal cellular respiration. Of the energy that is accumulated in plant biomass, 22.4%, most dies in place and rots on the muddy ground, to be consumed by bacteria. Bacteria are the major decomposers in this system, followed distantly by nematodes and crabs, which feed on tiny food particles as they sift through the mud. Some of this dead material is also removed from the system (exported) by the tide. The herbivores take very little of the plant production, around 0.8%, eating only a small proportion of the *Spartina* and none of the algae. A fraction of herbivore biomass is then consumed by spiders. Overall, if we view the species in ecosystems as transformers of energy, then plants and algae are by far the most important organisms on the planet, bacteria are next, and animals are a distant third.

59.3 Biogeochemical Cycles

As we have seen, a unit of energy moves through an ecosystem only once, passing through the trophic levels of a food web from producer to consumer and dissipating as heat. In contrast, chemical elements such as carbon or nitrogen are recycled, moving from the physical environment to organisms and back to the environment, where the cycle begins again. Whereas an ecosystem constantly receives energy in the form of light, chemical elements are available in limited amounts and are continually recycled. Because the movements of chemicals through ecosystems involve biological, geological, and chemical

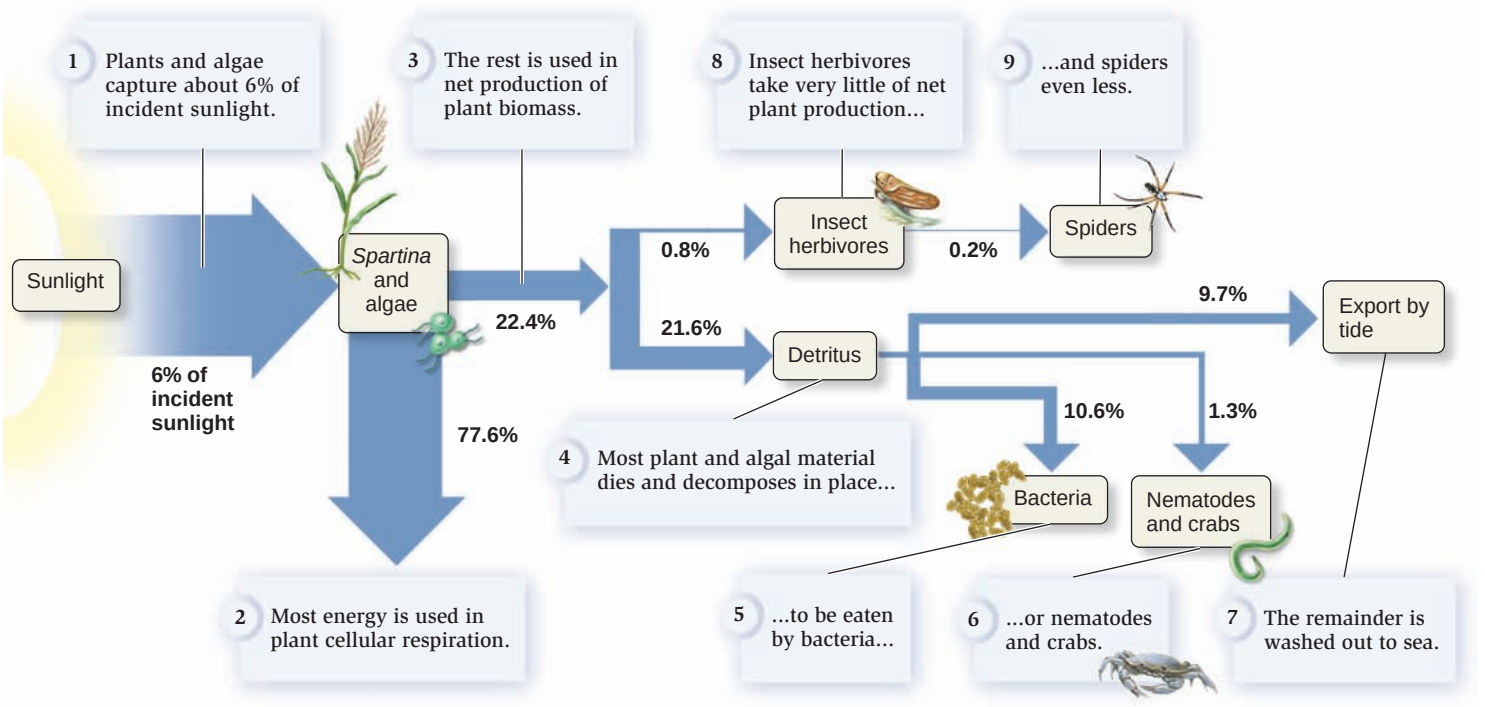

Figure 59.14 **Energy-flow diagram for a Georgia salt marsh.** Numbers represent the percentage of gross primary production that flows into different trophic levels or is used in plant respiration.

transport mechanisms, they are termed biogeochemical cycles. Biological mechanisms involve the absorption of chemicals by living organisms and their subsequent release back into the environment. Geological mechanisms include weathering and erosion of rocks, and elements transported by surface and subsurface drainage. Chemical transport mechanisms include dissolved matter in rain and snow, atmospheric gases, and dust blown by the wind.

In addition to the basic building blocks of hydrogen, oxygen, and carbon, which we discussed in Chapter 2, the elements required in the greatest amounts by living organisms are phosphorus, nitrogen, and sulfur. In this section, we take a detailed look at the cycles of these nutrients. These cycles can be divided into two broad types: local cycles, such as the phosphorus cycle, which involve elements with no atmospheric mechanism for long-distance transfer; and global cycles, which involve an interchange between the atmosphere and the ecosystem. Global nutrient cycles, such as the carbon, nitrogen, and sulfur cycles, unite the Earth and its living organisms into one giant interconnected ecosystem called the **biosphere**. In our discussion of biogeochemical cycles, we will take a particular interest in the alteration of these cycles through human activities that increase the input of chemical elements, such as the burning of fossil fuels.

Phosphorus Cycles Locally Between Geological and Biological Components of Ecosystems

All living organisms require phosphorus, which becomes incorporated into ATP, the compound that provides energy for most metabolic processes. Phosphorus is a key component of other biological molecules such as DNA and RNA, and it is also an essential mineral that in many animals helps maintain a strong, healthy skeleton.

The phosphorus cycle is a relatively simple cycle (Figure 59.15). Phosphorus has no gaseous phase and thus no atmospheric component; that is, it is not moved by wind or rain. As a result, phosphorus tends to cycle only locally. The Earth's crust is the main storehouse for this element. Weathering

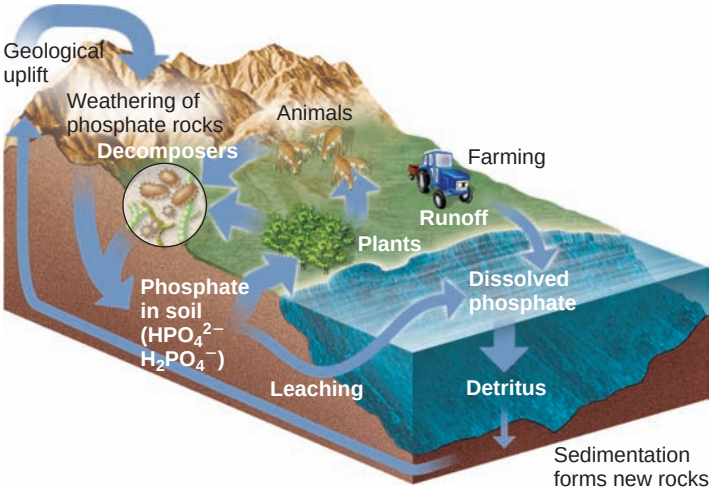

Figure 59.15 **The phosphorus cycle.** Unlike other major biogeochemical cycles, the phosphorus cycle does not have an atmospheric component and thus cycles only locally. The widths of the lines indicate the relative importance of each process.

and erosion of rocks release phosphorus into the soil. Plants have the metabolic means to absorb dissolved ionized forms of phosphorus, the most important of which occurs as phosphate (HPO_4^{2-} or $H_2PO_4^-$). Herbivores obtain their phosphorus only from eating plants, and carnivores obtain it by eating herbivores. When plants and animals excrete wastes or die, the phosphorus becomes available to decomposers, which release it back to the soil.

Leaching and runoff eventually wash much phosphate into aquatic systems, where plants and algae utilize it. Phosphate that is not taken up into the food chain settles to the ocean floor or lake bottom, forming sedimentary rock. Phosphorus can remain locked in sedimentary rock for millions of years, becoming available again through the geological process of uplift.

Plants can take up phosphate so rapidly and efficiently that they often reduce soil concentrations of phosphorus to extremely low levels, so phosphorus becomes a limiting factor, as noted previously (see Figure 59.11). The more phosphorus that is added to an aquatic ecosystem, the more that production of algae and aquatic plants increases. In a pivotal 1974 study, biologist David Schindler showed that an overabundance of phosphorus caused the rapid growth of algae and plants in an experimental lake in Canada (Figure 59.16). What is the consequence of the rapid growth of algae? When the algae die, they sink to the bottom, where bacteria decompose them and consume the dissolved oxygen in the water. Dissolved oxygen concentrations can drop too low for fishes to breathe, causing fish kills. The process by which elevated nutrient levels lead to an overgrowth of algae and the subsequent depletion of water oxygen levels is known as **eutrophication**. Cultural eutrophication refers to the enrichment of water with nutrients derived from human activities, such as fertilizer use and sewage dumping.

Lake Erie became eutrophic in the 1960s due to the fertilizer runoff from farms rich in phosphorus and to the industrial and domestic pollutants released from the many cities along its shores. Fish species such as white fish and lake trout became severely depleted. Based on research such as Schindler's that showed the dramatic effect of phosphorus on a lake system, the U.S. and Canada teamed together to reduce the levels of discharge by 80%, primarily through eliminating phosphorus in laundry detergents and maintaining strict controls on the phosphorus content of wastewater from sewage treatment plants. Fortunately, lake systems have great potential for recovery after phosphorous inputs are reduced, and Lake Erie has experienced fewer algal blooms, clearer water, and more fishes.

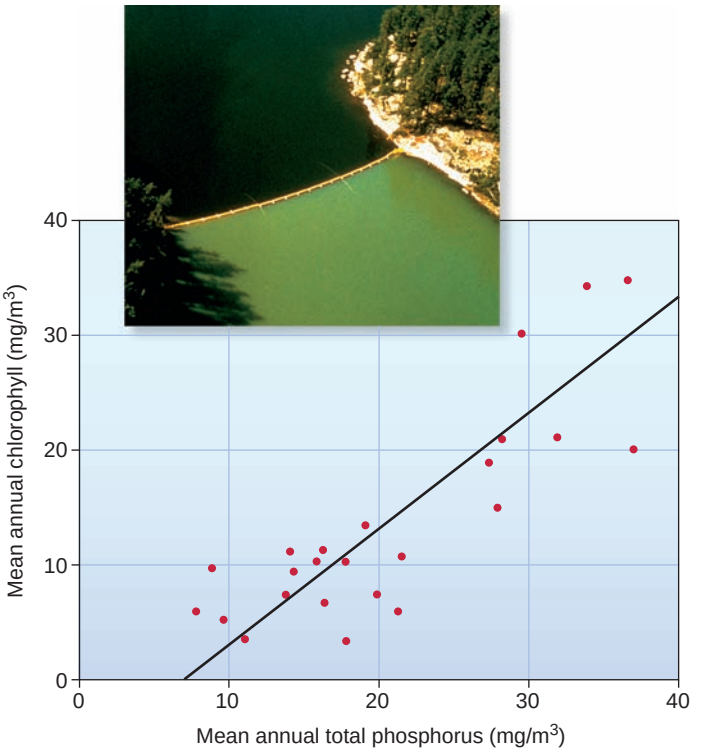

Figure 59.16 The relationship between primary production and total phosphorus concentration. As shown in this graph, primary production (measured by chlorophyll concentration) increases linearly with an increase in phosphorus. Each dot represents a different lake. The aerial photograph shows the contrast in water quality of two basins of an experimental lake in Canada separated by a plastic curtain. Carbon and nitrogen were added to the upper basin, and carbon, nitrogen, and phosphorus were added to the lower basin. The bright green color is from a surface film of algae that resulted from the added phosphorus.

Carbon Cycles Among Biological, Geological, and Atmospheric Pools

The movement of carbon from the atmosphere into organisms and back again is known as the carbon cycle (Figure 59.17). Carbon dioxide is present in the atmosphere at a level of about 380 parts per million (ppm), or about 0.04%. Autotrophs, primarily plants, algae, and cyanobacteria, acquire carbon dioxide from the atmosphere and incorporate it into the organic matter of their own biomass via photosynthesis. Each year, plants, algae, and cyanobacteria remove approximately one-seventh of the CO_2 from the atmosphere. At the same time, respiration and the decomposition of plants recycle a similar amount of carbon back into the atmosphere as CO_2. Much material from primary producers is also transformed into deposits of coal, gas, and oil, which are known as **fossil fuels**. Herbivores can return some carbon dioxide to the atmosphere, eating plants and breathing out CO_2, but the amount flowing through this part of the cycle is minimal. Chemical processes such as diffusion and absorption of CO_2 in and out of oceans also contribute to changes in atmospheric CO_2.

Over time, much carbon is also incorporated into the shells of marine organisms, which eventually form huge limestone deposits on the ocean floor or in terrestrial rocks, where turnover is extremely low. As a result, rocks and fossil fuels contain the largest reserves of carbon. Natural sources of CO_2 such as volcanoes, hot springs, and fires release large amounts of CO_2. In addition, human activities, primarily deforestation and the burning of fossil fuels, are increasingly causing large amounts of CO_2 to enter the atmosphere together with large volumes of particulate matter.

Direct measurements over the past five decades show a steady rise in atmospheric CO_2 (Figure 59.18), a pattern that

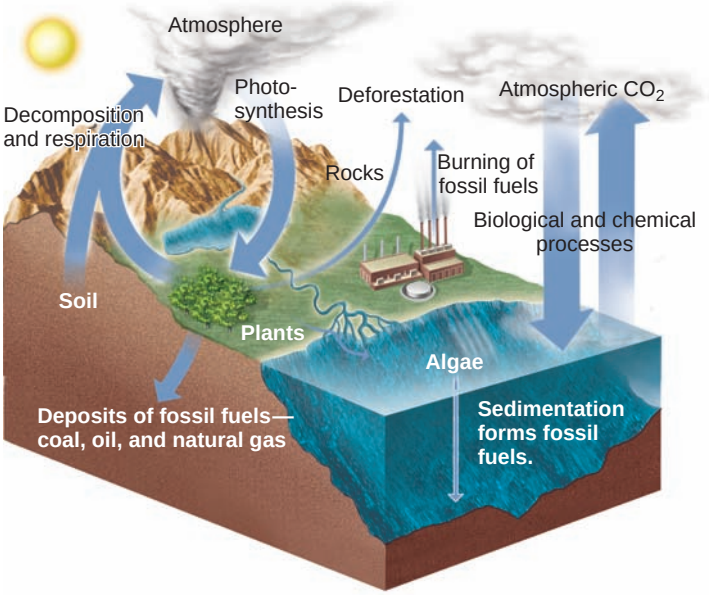

Figure 59.17 **The carbon cycle.** Each year, plants and algae remove about one-seventh of the CO_2 in the atmosphere. Animal respiration is so small it is not represented. The width of the arrows indicates the relative importance of each process.

Concept check: *Where are the greatest stores of global carbon?*

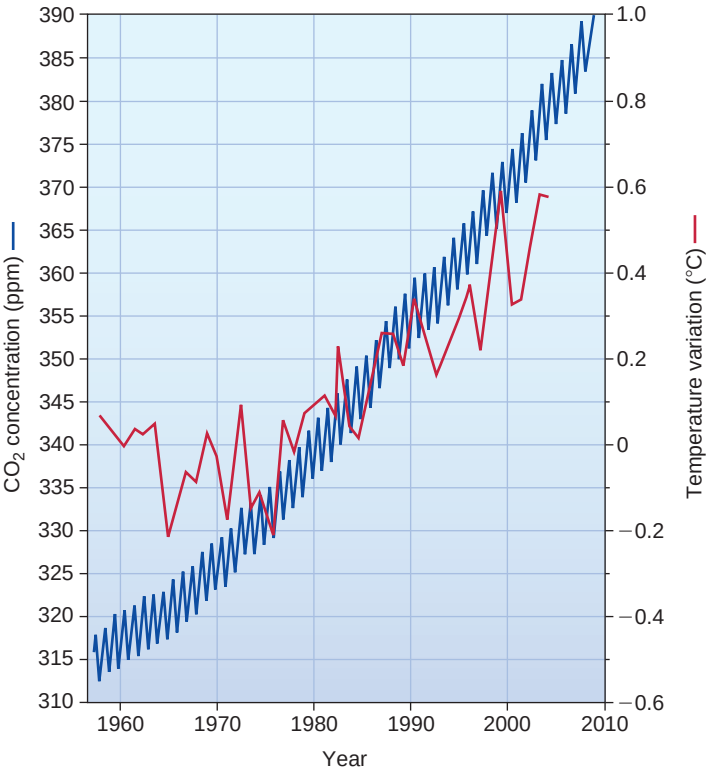

Figure 59.18 **The increase in atmospheric CO_2 levels and temperatures due to the burning of fossil fuels.** From 1958 to 2008, atmospheric CO_2 shows an increase of nearly 20%. In addition, the graph shows a seasonal variation in CO_2. Temperatures are annual deviations from the 1961–1990 average. Measurements were recorded at Mauna Loa Observatory in Hawaii.

Concept check: *Why does the amount of CO_2 fluctuate seasonally in the graph?*

shows no sign of slowing. Because of its increasing concentration in the atmosphere, CO_2 is the most troubling of the greenhouse gases, which are a primary cause of global warming (see Chapter 54). Elevated atmospheric CO_2 has other dramatic environmental effects, boosting plant growth but lowering the amount of herbivory (see Feature Investigation).

The amount of carbon dioxide in the atmosphere shows a seasonal variation, as can be seen in Figure 59.18. Concentrations of atmospheric carbon dioxide are lowest during the Northern Hemisphere's summer and highest during the winter, when photosynthesis is minimal. This phenomenon occurs asynchronously in both of the Earth's hemispheres. Because there is more land in the Northern Hemisphere than in the Southern Hemisphere, and therefore more vegetation, concentrations of atmospheric carbon dioxide are lowest during the Northern Hemisphere's summer. The vegetation has a maximum photosynthetic activity during the summer, reducing the global amount of carbon dioxide. During the Northern Hemisphere's winter, photosynthesis is low, and decomposition is relatively high, causing a global increase in the gas.

Feature Investigation

Stiling and Drake's Experiments with Elevated CO_2 Showed an Increase in Plant Growth but a Decrease in Herbivory

How will forests of the future respond to elevated CO_2? To begin to answer such a question, ecologists ideally would enclose large areas of forests with chambers, increase the CO_2 content within the chambers, and measure the responses. This has proven to be difficult for two reasons. First, it is hard to enclose large trees in chambers, and second, it is expensive to increase CO_2 levels over such a large area. However, in a discovery-based investigation, ecologists Peter Stiling and Bert Drake were able to increase CO_2 levels around small patches of forest at the Kennedy Space Center in Cape Canaveral, Florida. In much of Florida's forests, trees are small, only 3–5 m when mature, because frequent lightning-initiated fires prevent the growth of larger trees. Stiling and Drake teamed up with NASA engineers to create 16 circular, open-topped chambers (Figure 59.19). In eight of these they increased atmospheric CO_2 to double their ambient levels, from 360 ppm to 720 ppm, the

Figure 59.19 The effects of elevated atmospheric CO_2 on insect herbivory.

GOAL To determine the effects of elevated CO_2 on a forest ecosystem; effects on herbivory are highlighted here.

STUDY LOCATION Patches of forest at the Kennedy Space Center in Cape Canaveral, Florida.

	Experimental level	Conceptual level
1 Erect 16 open-top chambers around native vegetation. Increase CO_2 levels from 360 ppm to 720 ppm in half of them.		Expected atmospheric CO_2 level is 720 ppm by end of the 21st century. Open-top chambers allow movement of herbivores in and out of chambers.
2 Conduct a yearly count of numbers of insect herbivores per 200 leaves in each chamber.		
3 Count number of herbivores that died due to nutritional inadequacy. Monitor attack rates on insect herbivores by natural enemies such as predators and parasitoids.		Elevated CO_2 reduces foliar nitrogen, inhibits normal insect development, and prolongs the feeding time of herbivores, allowing natural enemies greater opportunities to attack them.

4 THE DATA

Source of mortality*	Elevated CO_2 (% mortality)	Control (% mortality)
Nutritional inadequacy	10.2	5.0
Predators	2.4	2.0
Parasitoids	10.0	3.2

*Data refer only to mortality of larvae within leaves and do not sum to 100%. Mortality of eggs on leaves, pupae in the soil, and flying adults is unknown.

5 CONCLUSION Elevated CO_2 decreases insect herbivory in a Florida forest.

6 SOURCE Stiling, P., and Cornelissen, T. 2007. How does elevated carbon dioxide (CO_2) affect plant-herbivore interactions? A field experiment and meta-analysis of CO_2-mediated changes on plant chemistry and herbivore performance. *Global Change Biology* 13:1823–1842.

latter of which is the atmospheric level predicted by the end of the 21st century. The experiments were initiated in 1996 and lasted until 2007. Plants produced more biomass in elevated CO_2, because carbon dioxide is limiting to plant growth, but the data revealed much more.

Because the chambers were open-topped, insect herbivores could come and go. Insect herbivores cause the largest amount of herbivory in North American forests, because most vertebrate herbivores cannot access the high foliage. Censuses were conducted of all damaged leaves, but focused on leaves damaged

by leaf miners, the most common type of herbivore at this site. Leaf miners are small moths whose larvae are small enough to burrow between the surfaces of plant leaves and mine tunnels through the leaves.

Densities of damaged leaves, including those damaged by leaf miners, were lower in elevated CO_2 in every year studied. Part of the reason for the decline was that even though plants increased in mass, the existing soil nitrogen was diluted over a greater volume of plant material, so the nitrogen level in leaves decreased. This increased insect mortality by two means. First, poorer leaf quality directly increased insect death because leaf nitrogen levels may have been too low to support the normal development of the leaf miners. Second, lower leaf quality increased the length of time insects had to feed to gain sufficient nitrogen. Increased feeding times, in turn, led to increased exposure to natural enemies, such as predatory spiders and ants, and parasitoids, and top-down mortality also increased (see the data of Figure 59.19). Thus, in a world of elevated CO_2, plant growth may increase, and herbivory could decrease.

Experimental Questions

1. What was the hypothesis of the Stiling and Drake experiment?
2. What was the purpose of increasing the carbon dioxide levels in only half of the chambers in the experiment and not all of the chambers?
3. What were the results of the experiment?

The Nitrogen Cycle Is Strongly Influenced by Biological Processes That Transform Nitrogen into Usable Forms

Nitrogen is an essential component of proteins, nucleic acids, and chlorophyll. Because 78% of the Earth's atmosphere consists of nitrogen gas (N_2), it may seem that nitrogen should not be in short supply for organisms. However, nitrogen is often a limiting factor in ecosystems because N_2 molecules must be broken apart before nitrogen atoms are available to combine with other elements. Because of its triple bond, nitrogen gas is very stable, and only certain bacteria can break it apart into usable forms such as ammonia (NH_3). This process, called nitrogen fixation, is a critical component of the five-part nitrogen cycle (Figure 59.20):

1. A few species of bacteria can accomplish **nitrogen fixation**, that is, convert atmospheric nitrogen (N_2) to forms usable by other organisms. The bacteria that fix nitrogen are fulfilling their own metabolic needs, but in the process, they release excess ammonia (NH_3) or ammonium (NH_4^+), which can be used by some plants. An important group of nitrogen-fixing bacteria are known as rhizobia, which live in nodules on the roots of legumes, including peas, beans, lentils, and peanuts and some woody plants. In more natural systems, such as forests and savannas, nitrogen-fixing bacteria such as *Frankia* form a symbiosis with actinorhizal plants. Cyanobacteria are important nitrogen fixers in aquatic systems.
2. In the process of **nitrification**, soil bacteria convert NH_3 or NH_4^+ to nitrate (NO_3^-), a form of nitrogen commonly used by plants. The bacteria *Nitrosomonas* and *Nitrococcus* first oxidize the forms of ammonia to nitrite (NO_2^-), after which the bacteria *Nitrobacter* converts NO_2^- to NO_3^-.
3. **Assimilation** is the process by which inorganic substances are incorporated into organic molecules. In the nitrogen cycle, organisms assimilate nitrogen by taking up NH_3, NH_4^+, and NO_3^- formed through nitrogen fixation and nitrification and incorporating them into other molecules. Plant roots take up these forms of nitrogen through their roots, and animals assimilate nitrogen from plant tissue.

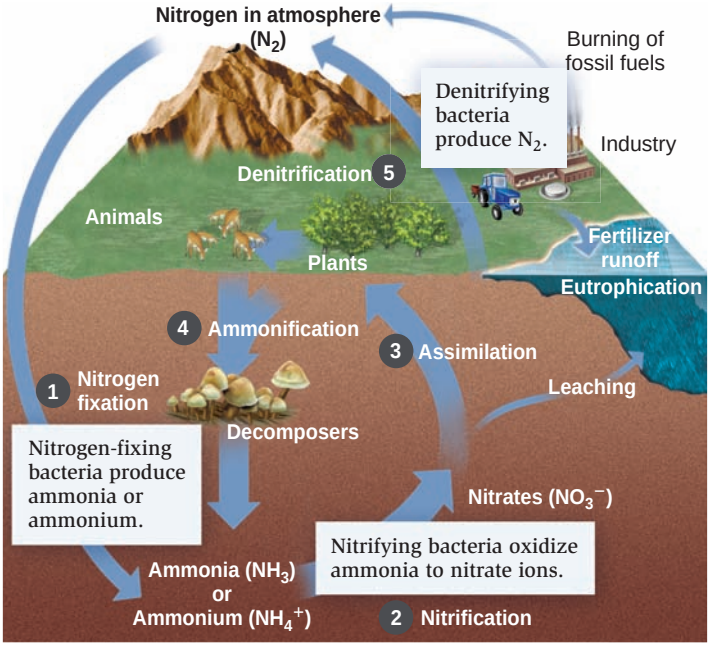

Figure 59.20 The nitrogen cycle. The five main parts of the nitrogen cycle are (1) nitrogen fixation, (2) nitrification, (3) assimilation, (4) ammonification, and (5) denitrification. The recycling of nitrogen from dead plants and animals into the soil and then back into plants is of paramount importance because this is the main pathway for nitrogen to enter the soil. The width of the arrows indicates the relative importance of each process.

4. Ammonia can also be formed in the soil through the decomposition of plants and animals and the release of animal waste. **Ammonification** is the conversion of organic nitrogen to NH_3 and NH_4^+. This process is carried out by bacteria and fungi. Most soils are slightly acidic and, because of an excess of H^+, the NH_3 rapidly gains an additional H^+ to form NH_4^+. Because many soils lack nitrifying bacteria, ammonification is the most common pathway for nitrogen to enter the soil.
5. **Denitrification** is the reduction of nitrate (NO_3^-) to gaseous nitrogen (N_2). Denitrifying bacteria, which are anaerobic and use NO_3^- in their metabolism instead

of oxygen, perform the reverse of their nitrogen-fixing counterparts by delivering nitrogen to the atmosphere. This process delivers only a relatively small amount of nitrogen to the atmosphere.

Human alterations of the nitrogen cycle have approximately doubled the rate of nitrogen input to the cycle. Industrial fixation of nitrogen for the production of fertilizer makes a significant contribution to the pool of nitrogen-containing material in the soils and waters of agricultural regions. One problem is that fertilizer runoff can cause eutrophication of rivers and lakes, and, as the resultant algae die, decomposition by bacteria depletes the oxygen level of the water, resulting in fish die-offs. Excess nitrates in surface or groundwater systems used for drinking water are also a health hazard, particularly for infants. In the body, nitrate is converted to nitrite, which then combines with hemoglobin to form methemoglobin, a type of hemoglobin that does not carry oxygen. In infants, the production of large amounts of nitrites can cause methemoglobinemia, a dangerous condition in which the level of oxygen carried through the body decreases.

Finally, burning fossil fuels releases not only carbon but also nitrogen in the form of nitrogen oxides, which can contribute to air pollution. Nitrous oxides (N_2O) can then react with rainwater to form nitric acid (HNO_3), which contributes to acid rain, decreasing the pH of lakes and streams and increasing fish mortality (see Chapter 54). Although much of the acid rain problem can be traced to the sulfur cycle, nitrogen oxides are also partially to blame.

The dramatic effects of human activities on nutrient cycles in general and the nitrogen cycle in particular were illustrated by a famous long-term study by ecosystem ecologists Gene Likens, Herbert Bormann, and their colleagues at Hubbard Brook Experimental Forest in New Hampshire in the 1960s. Hubbard Brook is a 3,160-hectare reserve that consists of six catchments along a mountain ridge. A catchment is an area of land where all water eventually drains to a single outlet. In Hubbard Brook, each outlet is fitted with a permanent concrete dam that enables researchers to monitor the outflow of water and nutrients (Figure 59.21a). In this large-scale experiment, researchers felled all of the trees in one of the Hubbard Brook catchments (Figure 59.21b). The catchment was then sprayed with herbicides for 3 years to prevent regrowth of vegetation. An untreated catchment was used as a control.

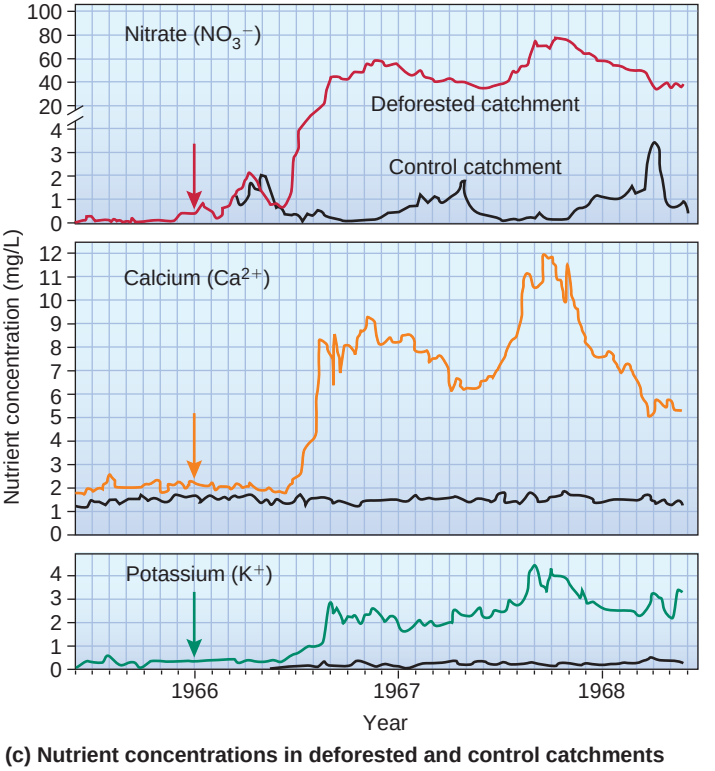
Researchers monitored the concentrations of key nutrients in the flow of water exiting the two catchments for over 3 years. Their results revealed that the overall export of nutrients from the disturbed catchment rose to many times the normal rate (Figure 59.21c). The researchers determined that two phenomena were responsible. First, the enormous reduction in plants reduced water uptake by vegetation and led to 40% more runoff discharged to the streams. This increased outflow caused greater rates of chemical leaching and rock and soil weathering. Second, and more significantly, in the absence of nutrient uptake in spring, when the deciduous trees would have resumed photosynthesis, the inorganic nutrients released by decomposer activity were simply leached in the drainage water. Similar processes operate in the majority of terrestrial ecosystems where clearance of forests is significant.

The Sulfur Cycle Is Heavily Influenced by Human Activities

Most naturally produced sulfur in the atmosphere comes from the gas hydrogen sulfide (H_2S), which is released from volcanic

(a) Hubbard Brook dam and weir

(b) Hubbard Brook Experimental Forest, New Hampshire



(c) Nutrient concentrations in deforested and control catchments

Figure 59.21 The effects of deforestation on nutrient concentrations. **(a)** Concrete dam and weir, which concentrates water flow and permits accurate measurement of discharge rate, used to monitor nutrient flow from a Hubbard Brook catchment. **(b)** Deforested catchment at Hubbard Brook. **(c)** Nutrient concentrations in stream water from the experimentally deforested catchment and a control catchment at Hubbard Brook. The timing of deforestation is indicated by arrows.

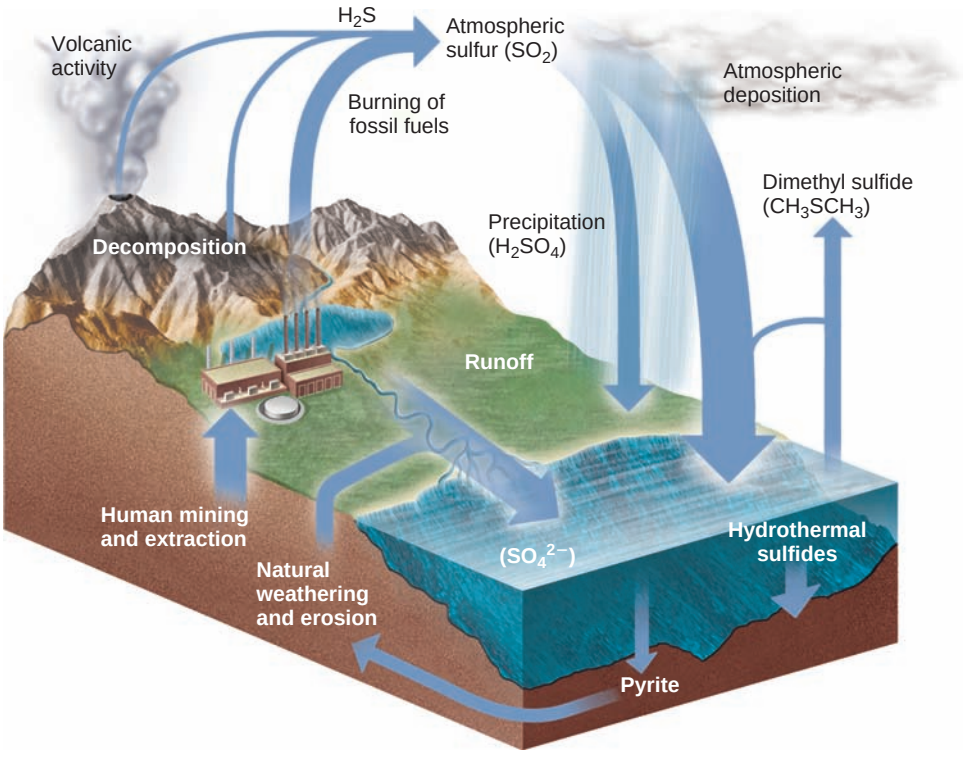


Figure 59.22 The sulfur cycle. This cycle can be dramatically affected by human outputs through the burning of fossil fuels. The width of the arrows indicates the relative importance of each process.

eruptions and during decomposition, especially in wetland environments, where sulfur is very common (Figure 59.22). The H_2S quickly oxidizes into sulfur dioxide (SO_2). Because SO_2 is soluble in water, it returns to Earth as weak sulfuric acid (H_2SO_4), or natural acid rain. H_2SO_4 dissociates into 2 H^+ + SO_4^{2-}, making the pH of natural rainwater slightly acidic, about 5.6 (see also Chapter 54). The sulfate ions, SO_4^{2-}, enter the soil, where sulfate-reducing bacteria may release sulfur as H_2S, or the sulfate may be incorporated by plants into their tissue.

In the presence of iron, sulfur can precipitate as ferrous sulfide, FeS_2, and be incorporated into pyritic rocks. The weathering of rocks and the decomposition of organic matter therefore releases sulfur to solution, which runs through rivers to the sea. Because such rocks commonly overlay coal deposits, mining exposes them to the air and water, resulting in a discharge of sulfuric acid and other sulfur-containing compounds into aquatic ecosystems. Mining has polluted hundreds of kilometers of streams and rivers in mid-Atlantic states such as West Virginia, Kentucky, and Pennsylvania in this way.

Interestingly, certain marine algae and a few salt marsh plants produce relatively large amounts of the sulfurous gas dimethyl sulfide (CH_3SCH_3), commonly abbreviated as DMS. Small DMS particles that diffuse to the atmosphere often form the nuclei around which water vapor can condense and form the water droplets making up clouds. Because of the sheer global extent of the oceans, changes in algal abundance and thus global DMS levels have the potential to alter cloud cover and thus climate. Because of its ability to cool the climate, some researchers are investigating how DMS production might potentially offset global warming.

Human activity involving the combustion of fossil fuels has altered the sulfur cycle more than any of the other nutrient cycles. The burning of coal and oil to provide energy for heating or to fuel electric power stations produces huge amounts of sulfur dioxide (SO_2). This reacts with rain or snow to make human-produced acid rain (see Chapter 54). One of the main differences between human-produced acid rain and natural acid rain is its relative pH. In North America, for example, natural acid rain has a pH of about 5.6, whereas measurements of rain falling in southern Ontario, Canada, in the 1980s showed pH values in the range of 4.1–4.5. Huge areas of the industrial midwest U.S. and Europe were affected by acid rain in the 1950s through the 1980s, but a reduction in the use of high-sulfur coal and the use of scrubbers to prevent sulfur dioxide from passing through smokestacks has reduced the problem in more recent times (Figure 59.23). The combustion of fossil fuel also results in the release of particulate matter into the air. Larger particles are visible as smoke or soot. Recently such particulate matter has been shown to increase heritable mutations (see Genomes & Proteomes).

Genomes & Proteomes Connection

Pollution Can Cause Heritable Mutations

Sulfur dioxide, nitrous oxide, and carbon dioxide are pollutants emitted from the burning of fossil fuels. In addition to these atmospheric gases, the combustion of fossil fuels also results in the release of particulate matter, tiny solid and liquid particles, into the air. Larger particles are visible as smoke or soot. The small particles, when inhaled, can penetrate deeply into the lungs and become distributed throughout the body. Such exposure, whether from transportation sources, factories, power plants, or tobacco smoke, can lead to the formation of lung tumors and induce mutations in somatic cells.

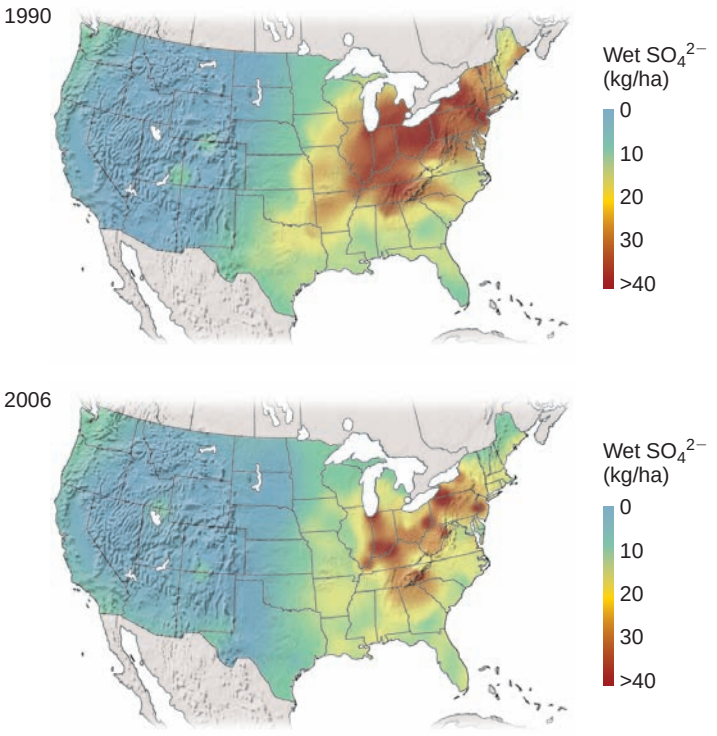

Figure 59.23 **The decrease in acid rain in the U.S. from 1989 to 2006.** Sulfate dissolved in atmospheric water produces acid rain. The data show wet sulfate deposition in kilograms per hectare.

Concept check: Why did relatively high levels of wet sulfate deposition occur in upstate New York in the 1980s when this was not an industrial area?

A study by biologist James Quinn and colleagues in 2004 showed that polluted air can also induce genetic changes in mouse sperm. In the study, the researchers put two groups of mice into separate sheds that were downwind of steel mills in Hamilton, an urban-industrial center of Ontario, Canada. One shed was fitted with high-efficiency particulate air (HEPA) filters, which removed particulate matter from the air, and the other was not. The researchers discovered changes in the size of noncoding DNA sequences in the offspring of the mice in the filterless shed. They concluded that the increased rate of mutations was paternally derived. Offspring of mice from the unfiltered shed inherited twice as many mutations as offspring of mice in the filtered shed. The researchers concluded that the pollutant particles, or some chemical compound associated with them, were responsible for the observed, heritable DNA changes.

What is the mechanism behind these genetic changes? Quinn and colleagues hypothesized that the inhaled pollutants are transported to the liver and metabolized to DNA-reactive compounds. Then they are transported to the testes and finally to the sperm stem cells, where the mutations occurred. The damaged DNA would then be transmitted to first-generation offspring.

The Water Cycle Is Largely a Physical Process of Evaporation and Precipitation

The water cycle, also called the hydrological cycle, differs from the cycles of other nutrients in that very little of the water that cycles through ecosystems is chemically changed by any of the cycle's components (Figure 59.24). It is a physical process, fueled by the sun's energy, rather than a chemical one, because it consists of essentially two phenomena: evaporation and precipitation. Even so, the water cycle has important biological components. Over land, 90% of the water that reaches the atmosphere is moisture that has passed through plants and exited from the leaves via evapotranspiration. Only about 2% of the total volume of Earth's water is found in the bodies of organisms or is held frozen or in the soil. The rest cycles between bodies of water, the atmosphere, and the land.

As we noted in Chapter 54, water is limiting to the abundance of many organisms, including humans. It takes 228 L of water to produce a pound of dry wheat, and 9,500 L of water to support the necessary vegetation to produce a pound of meat. Industry is also a heavy user of water, with goods such as oil, iron, and steel requiring up to 20,000 L of water per ton of product. To increase the amount of available water, humans have interrupted the hydrological cycle in many ways, most prominently through the use of dams to create reservoirs. Such dams, such as those on the Columbia River in Washington State, can greatly interfere with the migration of fishes such as salmon and affect their ability to reproduce and survive. Other activities, such as tapping into underground water supplies, or **aquifers**, for drinking water removes more water than is put back by rainfall and can cause shallow ponds and lakes to dry up and sinkholes to develop.

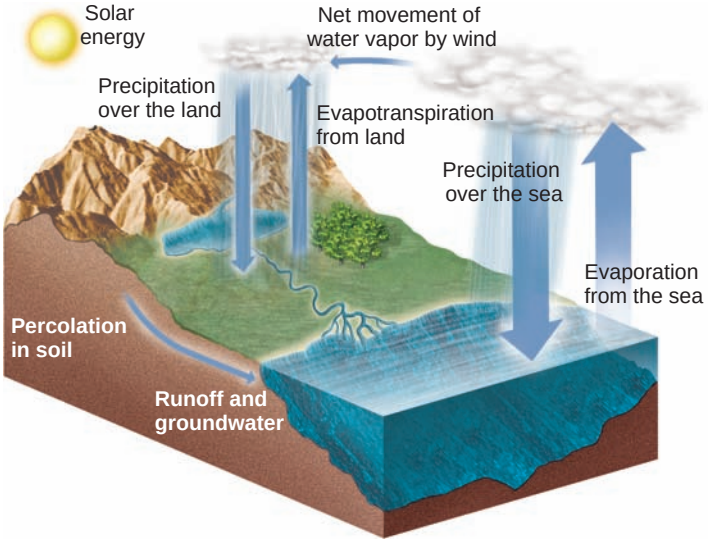

Figure 59.24 **The water cycle.** This cycle is primarily a physical process, not a chemical one. Solar energy drives the water cycle, causing evaporation of water from the ocean and evapotranspiration from the land. This is followed by condensation of water vapor into clouds and precipitation. The width of the arrows indicates the relative importance of each step.

Figure 59.25 Severe erosion following deforestation in Madagascar. After clearing and a few years of farming, the shallow soil can no longer support crops and is susceptible to erosion by rainfall.

Deforestation can also significantly alter the water cycle. When forests are cut down, less moisture is transpired into the atmosphere. This reduces cloud cover and diminishes precipitation, subjecting the area to drought. Reestablishing the forests, which calls for increased water, then becomes nearly impossible. Such a problem has occurred on the island of Madagascar, located off the east coast of Africa. In this country, clearing of the forests for cash crops such as cotton, coffee, and tobacco has been so rapid and extensive that areas devoid of vegetation have appeared (Figure 59.25). In Madagascar, as in so many other areas on Earth, deforestation and other environmental degradations are having an impact on much of the natural habitat. Appropriately, in the following chapter, Chapter 60, we finish our study of ecology in particular, and biology in general, with a discussion of what we gain from ecosystem diversity and how best to conserve the diversity of ecosystems in the future.

Summary of Key Concepts

59.1 Food Webs and Energy Flow

- Ecosystem ecology concerns the movement of energy and materials through organisms and their communities. (Figure 59.1)
- Simple feeding relationships between organisms can be characterized by an unbranched food chain, and each feeding level in the chain is called a trophic level. (Figure 59.2)
- Organisms that obtain energy from light or chemicals are called autotrophs and are the primary producers. Organisms that feed on other organisms are called heterotrophs. Those organisms that feed on primary producers are called primary consumers. Animals that eat plants are also called herbivores. Organisms that feed on primary consumers are called secondary consumers. Animals that eat other animals are called carnivores. Consumers that get their energy from the remains and waste products of organisms are called detritivores or decomposers. (Figure 59.3)
- Food webs are a more complex model of interconnected food chains in which there are multiple links between species. (Figure 59.4)
- Food webs tend to have five or fewer levels. Energy conversions are not 100% efficient, and usable energy is lost within each tropic level and from one trophic level to the next. (Figure 59.5)
- Production efficiency measures the percentage of energy assimilated that becomes incorporated into new biomass. (Figure 59.6)
- Trophic-level transfer efficiency measures the energy available at one trophic level that is acquired by the level above. These efficiencies can be expressed in the form of ecological pyramids, the best known being the pyramid of numbers. (Figure 59.7)
- The increase in the concentration of a substance in living organisms, called biomagnification, can occur at each trophic level of the food web. (Figures 59.8, 59.9)

59.2 Biomass Production in Ecosystems

- Plant production can be measured as gross primary production. Net primary production is gross primary production minus the energy released during respiration via photosynthetic organisms.
- Net primary production in terrestrial ecosystems is limited primarily by temperature and the availability of water and nutrients. Net primary production in aquatic ecosystems is limited mainly by availability of light and nutrients. (Figures 59.10, 59.11)
- Ecosystems differ in their net primary production. (Table 59.1, Figure 59.12)
- Secondary production is limited by available primary production. (Figures 59.13, 59.14)

59.3 Biogeochemical Cycles

- Elements such as phosphorus, carbon, nitrogen, and sulfur recycle from the physical environment to organisms and back in what are called biogeochemical cycles.
- The phosphorus cycle lacks an atmospheric component and thus is a local cycle. An overabundance of phosphorus can cause the overgrowth of algae and subsequent depletion of oxygen levels, called eutrophication. (Figures 59.15, 59.16)
- In the carbon cycle, autotrophs incorporate carbon dioxide from the atmosphere into their biomass; decomposition of

plants and respiration recycles most of this CO_2 back to the atmosphere. Human activities, primarily the burning of fossil fuels, are causing increased amounts of CO_2 to enter the atmosphere. Air pollutants may cause mutations. (Figures 59.17, 59.18)

- Experiments have shown that elevated levels of carbon dioxide result in an increase in plant growth but a decrease in herbivory. (Figure 59.19)
- The nitrogen cycle has five parts: nitrogen fixation, nitrification, assimilation, ammonification, and denitrification. In the nitrogen cycle, atmospheric nitrogen is unavailable for use by most organisms and must be converted to usable forms by certain bacteria. (Figure 59.20)
- The activities of humans, including fertilizer use, fossil fuel use, and deforestation, have dramatically altered the nitrogen cycle. (Figure 59.21)
- Sulfur enters the atmosphere through both natural sources (such as volcanoes and decomposition) and human sources, including the combustion of fossil fuels. Atmospheric sulfur dioxide returns to Earth as weak sulfuric acid (H_2SO_4), commonly called natural acid rain. (Figure 59.22)
- Human-produced acid rain results primarily from the combustion of fossil fuels. (Figure 59.23)
- The water cycle is a physical rather than a chemical process, because it consists of essentially two phenomena: evaporation and precipitation. (Figure 59.24)
- Alteration of the water cycle by deforestation can result in regional climatic changes because a reduction in transpiration causes a decrease in cloud cover and precipitation. (Figure 59.25)

Assess and Discuss

Test Yourself

1. The amount of energy that is fixed during photosynthesis is known as
   a. net primary production.
   b. biomagnification.
   c. trophic-level transfer efficiency.
   d. gross primary production.
   e. production efficiency.
2. Chemoautotrophic bacteria are
   a. primary consumers.
   b. secondary consumers.
   c. tertiary consumers.
   d. primary producers.
   e. decomposers.
3. When considering the average food chain, which of the following statements is true?
   a. Secondary consumers are the most abundant organisms in an ecosystem.
   b. The more lengths in the food chain, the more stable the ecosystem.
   c. Biomass decreases as you move up the food chain.
   d. The trophic level with the highest species abundance is usually the primary producers.
   e. All of the above are true.
4. Which organisms are the most important consumers of energy in a Georgia salt marsh?
   a. *Spartina* grass and algae
   b. insects
   c. spiders
   d. crabs
   e. bacteria
5. Primary production in aquatic systems is limited mainly by
   a. temperature and moisture.
   b. temperature and light.
   c. temperature and nutrients.
   d. light and nutrients.
   e. light and moisture.
6. The net primary production of cultivated land is closest to that of
   a. prairies.
   b. tropical rain forest.
   c. wetlands.
   d. temperate deciduous forest.
   e. lakes and streams.
7. The evapotranspiration rate
   a. can be used as a predictor for primary production.
   b. is increased when temperature decreases.
   c. is not affected by temperature.
   d. is highest in deserts.
   e. can be predicted by measuring only the water content of the soil.
8. Eutrophication is
   a. caused by an overabundance of nitrogen, which leads to an increase in bacteria populations.
   b. caused by an overabundance of nutrients, which leads to an increase in algal populations.
   c. the normal breakdown of algal plants following a pollution event.
   d. normally seen in dry, hot regions of the world.
   e. none of the above.
9. Terrestrial primary producers acquire the carbon necessary for photosynthesis from
   a. decomposing plant material.
   b. carbon monoxide released from the burning of fossil fuels.
   c. carbon dioxide in the atmosphere.
   d. carbon sources in the soil.
   e. both a and d.
10. Nitrogen fixation is the process
    a. that converts organic nitrogen to ammonia.
    b. by which plants and animals take up nitrates.
    c. by which bacteria convert nitrate to gaseous nitrogen.
    d. by which atmospheric nitrogen is converted to ammonia or ammonium ions.
    e. all of the above

Conceptual Questions

1. Define autotrophs and heterotrophs.
2. Explain why chain lengths are short in food webs.
3. What is the major difference among the phosphorous, carbon, and nitrogen cycles?

Collaborative Questions

1. Outline the main trophic levels within a food chain.
2. What might the atmospheric concentration of carbon dioxide be in 2100? What effects might this have on the environment?

Chapter Outline

Biodiversity and Conservation Biology

60

Increased natural enemy diversity increases the suppression of prey. These aphids are attacked by two species of natural enemy, a ladybird beetle larva and a parasitoid, which turns parasitized individuals copper colored and swollen.

Biological control, the control of pests by natural enemies, is seen as a preferable option to chemical control of pests, which leaves chemical residues in the environment. A 2006 study by William Snyder and colleagues showed that an increase in predator biodiversity resulted in greater suppression of insect herbivore populations and a subsequent increase in plant growth. This was important because it was previously thought that strong interspecific competition, predators feeding on other predators, could lead to weaker herbivore control. Snyder's data showed how biological control improved when the natural enemy community included multiple species.

Biological diversity, or **biodiversity**, encompasses the genetic diversity of species, the variety of different species, and the different ecosystems that they form. The field of **conservation biology** uses principles and knowledge from molecular biology, genetics, and ecology to protect the biological diversity of life at each of these three levels. Because it draws from nearly all chapters of this textbook, a discussion of conservation biology is an apt way to conclude our study of biology. In this chapter, we begin by examining the question of why biodiversity should be conserved, and explore how much diversity is needed for ecosystems to function properly. We then survey the main threats to the world's biodiversity. For many species, there are multiple threats from human activities, ranging from habitat loss, overexploitation, and the effects of introduced species to climate change and pollution. Even if species are not exterminated, many may exist only at very small population sizes. We will see how small populations face special problems such as inbreeding, genetic drift, and limited mating, emphasizing the importance of genetics in conservation biology.

Last, we consider what is being done to help conserve the world's endangered biota. This includes identifying global areas rich in species and establishing parks and refuges of the appropriate size, number, and connectivity. We also discuss conservation of particularly important types of species and outline how ecologists have been active in restoring damaged habitats to a more natural condition. We then examine how captive breeding programs have been useful in building up populations of rare species prior to their release back into the wild. Some programs have also used modern genetic techniques such as cloning to help breed and perhaps eventually increase populations of endangered species.

60.1 What Is Biodiversity?

As noted previously, biodiversity can be examined at three levels: genetic diversity, species diversity, and ecosystem diversity. Each level of biodiversity provides valuable benefits to humanity. Genetic diversity consists of the amount of genetic variation that occurs within and between populations. Maintaining genetic variation in the wild relatives of crops may be vital to the continued success of crop-breeding programs. For example, in 1977, Rafael Guzman, a Mexican biologist, discovered a previously unknown wild relative of corn, *Zea diploperennis*, that is resistant to many of the viral diseases that infect domestic corn, *Zea mays*. Genetic engineers believe that this relative has valuable genes that can improve current corn crops. Because corn is the third-largest crop on Earth, the discovery of *Z. diploperennis* may well turn out to be critical to the global food supply.

Figure 60.1 **Ecosystem biodiversity.** This small cemetery in Bureau County, Illinois, contains the remains of a natural prairie ecosystem. Most of the prairie has been plowed under for agriculture.

The second level of biodiversity concerns species diversity, the number and relative abundance of species in a community. Species diversity is an area on which much public attention is focused. In 1973, the U.S. Endangered Species Act was enacted, which was designed to protect both endangered and threatened species. **Endangered species** are those species that are in danger of extinction throughout all or a significant portion of their range. **Threatened species** are those likely to become endangered in the future. Many species are currently threatened. According to the International Union for Conservation of Nature and Natural Resources (IUCN), more than 25% of the fish species that live on coral reefs and 22% of all mammals, 12% of birds, and 31% of amphibians are threatened with extinction.

The last level of biodiversity is ecosystem diversity, the diversity of structure and function within an ecosystem. Conservation at the level of species diversity has largely focused attention on species-rich ecosystems such as tropical forests. Some scientists have argued that other relatively species-poor ecosystems are highly threatened and need to be conserved. In North America, many of the native prairies have been converted to agricultural use, especially in Midwestern states such as Illinois and Iowa. In some counties, remnants of prairie exist only inside cemetery plots, which have been spared from the plow (Figure 60.1).

60.2 Why Conserve Biodiversity?

Biologists Paul Ehrlich and E. O. Wilson have suggested that the loss of biodiversity should be an area of great concern for at least three reasons. First, humans depend on plants, animals, and microorganisms for a wide range of food, medicine, and industrial products. The second reason to preserve biodiversity focuses on preserving the array of essential services provided by ecosystems, such as clean air and water. Finally, they proposed that we have an ethical responsibility to protect what are our only known living companions in the universe. In this section, we examine some of the primary reasons why preserving biodiversity matters, and we explore the link between biodiversity and ecosystem functioning.

The Preservation of Biological Diversity Can Be Justified Based on the Economic and Ecological Values of Diversity as Well as on Ethical Grounds

During the latter half of the 20th century, the reduction of the Earth's biological diversity emerged as a critical issue, one with implications for public policy. A major concern was that loss of plant and animal resources would impair future development of important products and processes in agriculture, medicine, and industry. For example, as previously noted, *Z. diploperennis*, the wild relative of corn discovered in Mexico, is resistant to many corn viruses. Its genes are currently being used to develop virus-resistant types of corn. However, *Z. diploperennis* occurs naturally in only a few small areas of Mexico and could easily have been destroyed by development or cultivation of the land. If we allow such species to go extinct, we may unknowingly threaten the food supply on which much of the world depends.

The pharmaceutical industry is heavily dependent on products made by plants. About 25% of the prescription drugs in the U.S. alone are derived from plants, and the 2006 market value of such drugs was estimated to be $19 billion. Many medicines come from plants found only in tropical rain forests. These include quinine, a drug from the bark of the Cinchona tree (*Cinchona officinalis*) (Figure 60.2), which is used for malaria, and vincristine, a drug derived from rosy periwinkle (*Catharanthus*

Figure 60.2 **The value of biodiversity.** Bark of the Cinchona tree, *Cinchona officinalis*, found only in tropical rain forests, is used to produce quinine, an effective drug against malaria.

roseus), which is a treatment for leukemia and Hodgkin disease. Many plant chemicals of therapeutic importance are likely to be found in the numerous rain forest plant species that have not yet been fully analyzed. The continued destruction of rain forests thus could mean the loss of potential life-saving medical treatments.

On a smaller scale, individual species are valuable for research purposes. The blood of the horseshoe crab (*Limulus polyphemus*) clots when exposed to toxins produced by some bacteria. Pharmaceutical industries use the blood enzyme responsible for this clotting to ensure that their products are free of bacterial contamination. Desert pupfishes, in the genus *Cyprinodon*, found in isolated desert springs in the U.S. Southwest, tolerate salinity twice that of seawater and are valuable models for research on human kidney diseases.

Beyond this, humans benefit enormously from the processes that natural ecosystems provide (Table 60.1). Forests soak up carbon dioxide, maintain soil fertility, and retain water, preventing floods; estuaries provide water filtration and protect rivers and coastal shores from excessive erosion. The loss of biodiversity could disrupt an ecosystem's ability to carry out such functions. Other ecosystem functions include the maintenance of populations of natural predators to regulate pest outbreaks and reservoirs of pollinators to pollinate crops and other plants. As discussed in the chapter opening, scientists continue to discover the benefits of biodiversity to the functioning of communities.

A 1997 paper in the journal *Nature* by economist Robert Constanza and colleagues made an attempt to calculate the monetary value of ecosystems to various economies. They came to the conclusion that, at the time, the world's ecosystems were worth more than $33 trillion a year, nearly twice the gross national product of the world's economies combined ($19 trillion) (Table 60.2). Due to its massive size, open ocean has the greatest total global value of all ecosystems. Another way to view ecosystem value is its dollar value per hectare. From this perspective, shallow aquatic ecosystems, such as estuaries and swamps, are extremely valuable because of their role in nutrient cycling, water supply, and disturbance regulation. They also serve as nurseries for aquatic life. These habitats, once thought of as useless wastelands, are among the ecosystems most endangered by pollution and development.

Arguments can also be made against the loss of biodiversity on ethical grounds. As only one of many species, it has been argued that humans have no right to destroy other species and the environment around us. Philosopher Tom Regan suggests that animals should be treated with respect because they have a life of their own and therefore have value apart from anyone else's interests. Law professor Christopher Stone,

Table 60.1 Examples of the World's Ecosystem Services

Service	Example
Atmospheric gas supply	Regulation of carbon dioxide, ozone, and oxygen levels
Climate regulation	Regulation of carbon dioxide, nitrogen dioxide, and methane levels
Water supply	Irrigation; water for industry
Pollination	Pollination of crops
Biological control	Pest population regulation
Wilderness and refuges	Habitat for wildlife
Food production	Crops; livestock
Raw materials	Fossil fuels; timber
Genetic resources	Medicines; genes for plant resistance
Recreation	Ecotourism; outdoor recreation
Cultural	Aesthetic and educational value
Disturbance regulation	Storm protection; flood control
Waste treatment	Sewage purification
Soil erosion control	Retention of topsoil; reduction of accumulation of sediments in lakes
Nutrient cycling	Nitrogen, phosphorus, carbon, and sulfur cycles

Table 60.2 Valuation of the World's Ecosystem Services

Ecosystem type	Total global value* ($ trillion)	Total value (per ha) ($)	Main ecosystem service
Open ocean	8,381	252	Nutrient cycling
Coastal shelf	4,283	1,610	Nutrient cycling
Estuaries	4,100	22,832	Nutrient cycling
Tropical forest	3,813	2,007	Nutrient cycling/ raw materials
Seagrass and algal beds	3,801	19,004	Nutrient cycling
Swamps	3,231	19,580	Water supply/ disturbance regulation
Lakes and rivers	1,700	8,498	Water supply
Tidal marsh	1,648	9,990	Waste treatment/ disturbance regulation
Grasslands	906	232	Waste treatment/ food production
Temperate forest	894	302	Climate regulation/ waste treatment/ lumber
Coral reefs	375	6,075	Recreational/ disturbance regulation
Cropland	128	92	Food production
Desert	0	0	
Ice and rock	0	0	
Tundra	0	0	
Urban	0	0	
Total	33,260

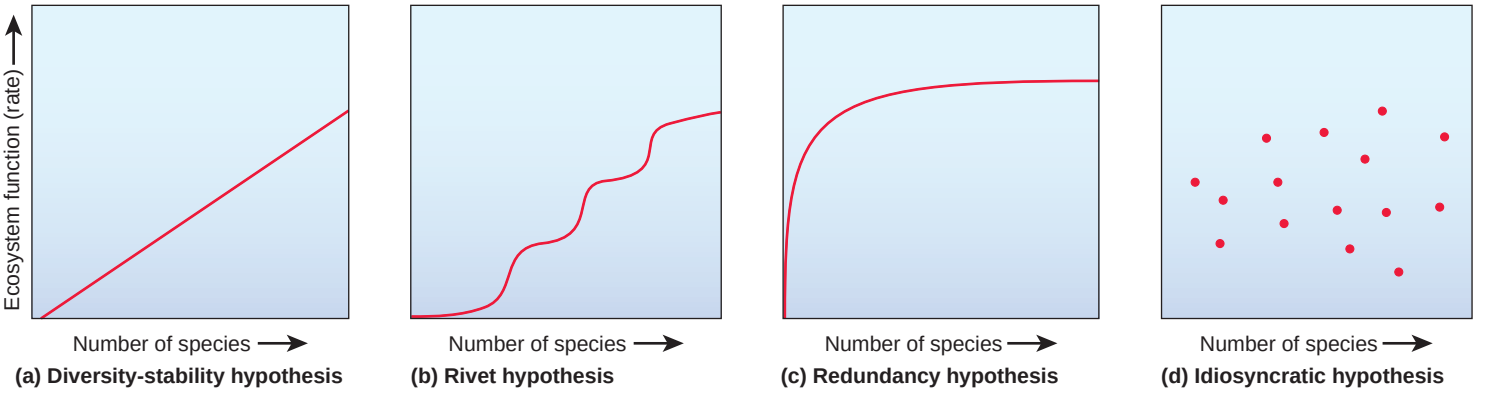

Figure 60.3 **Four models that describe the relationship between ecosystem function and biodiversity.** The relationship is strongest in **(a)** and weakest in **(d)**.

in an influential article titled "Should Trees Have Standing?" has argued that entities such as nonhuman natural objects like trees or lakes should be given legal rights just as corporations are treated as persons for certain purposes. As E. O. Wilson proposed in a 1984 concept known as biophilia, humans have innate attachment with species and natural habitats because of our close association for over millions of years.

How Much Diversity Is Needed for Ecosystems to Function Properly?

Because biodiversity has an impact on the health of ecosystems, ecologists have explored the question of how much diversity is needed for ecosystems to function properly. In doing so, they have described several possible relationships between biodiversity and ecosystem function. Recall that in the 1950s, ecologist Charles Elton proposed in the diversity-stability hypothesis that species-rich communities are more stable than those with fewer species (see Chapter 58). If we use stability as a measure of ecosystem function, Elton's hypothesis suggests a linear correlation between diversity and ecosystem function (Figure 60.3a).

In 1981, ecologists Paul and Anne Ehrlich proposed an alternative called the **rivet hypothesis** (Figure 60.3b). In this model, species are like the rivets on an airplane, with each species playing a small but critical role in keeping the plane (the ecosystem) airborne. The loss of a rivet weakens the plane and causes it to lose a little airworthiness. The loss of a few rivets could probably be tolerated, but the loss of more rivets would prove critical to the airplane's function.

A decade later, Australian ecologist Brian Walker proposed an alternative to this idea, termed the **redundancy hypothesis** (or passenger hypothesis) (Figure 60.3c). According to this hypothesis, most species are more like passengers on a plane—they take up space but do not add to the airworthiness. The species are said to be redundant because they could simply be eliminated or replaced by others with no loss in function. Airworthiness is primarily affected by the activity of a few crucial species, in this case, the pilot or copilot, which are called keystone species (a concept we will discuss in detail later in Section 60.4). In this scenario, species can be lost without affecting ecosystem function as long as species of critical importance remain.

In another alternative, British ecologist John Lawton included the possibility that ecosystem function changes as the number of species increases or decreases but that the amount and direction of change is unpredictable. He called this the idiosyncratic hypothesis (Figure 60.3d).

Determining which model is most correct is very important, as our understanding of the effect of species loss on ecosystem function can greatly affect the way we manage our environment. As we will discuss next, experimental studies have provided data showing that reduced biodiversity does lead to reduced ecosystem functioning.

Feature Investigation

Ecotron Experiments Showed the Relationship Between Biodiversity and Ecosystem Function

In the early 1990s, Shahid Naeem and colleagues used a series of 14 environmental chambers in a facility termed the Ecotron, at Silwood Park, England, to determine how biodiversity affects ecosystem functioning. These chambers contained terrestrial communities that differed only in their level of biodiversity (Figure 60.4). The number of species in each chamber was manipulated to create high-, medium-, and low-diversity ecosystems, each with four trophic levels. The trophic levels consisted of primary producers (annual plants), primary consumers (insects, snails, and slugs), secondary consumers (parasitoids that fed on the herbivores), and decomposers (earthworms and soil insects). The experiment ran for just over 6 months, and species were added only after the trophic level below them was established. For example, parasitoids were not added until herbivores were abundant.

Researchers monitored and analyzed a range of measures of ecosystem function, including community respiration, decomposition, nutrient retention rates, and community productivity. The data of Figure 60.4 focuses only on community productivity. The result was that community productivity, expressed as percent change in vegetation cover (the amount of ground covered by leaves of plants), increased as species richness increased. This occurred because of a greater variety of plant growth forms that could utilize light at different levels of the plant canopy. A larger ground cover also meant a larger plant biomass and greater community productivity, and increased decomposition and nutrient uptake rates. For the first time, ecologists had provided an experimental demonstration that the loss of biodiversity can alter or impair the functioning of an ecosystem.

Experimental Questions

1. What was the goal of Shahid Naeem and colleagues in their experiment at Silwood Park, England?
2. What was the hypothesis tested by the researchers?
3. How did the researchers test for ecosystem functioning?

Figure 60.4 Ecotron experiments comparing species diversity and ecosystem function.

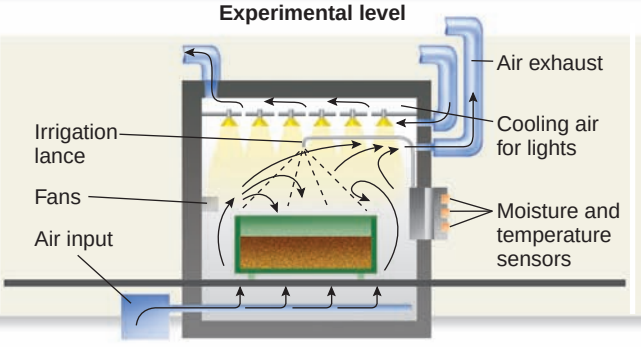
Concept check: *What is one of the dangers in interpreting these results?*

HYPOTHESIS Reduced biodiversity can lead to reduced ecosystem functioning.

STARTING LOCATION Ecotron, a controlled environment facility at the Natural Environment Research Council (NERC) Centre for Population Biology, in Silwood Park, England.

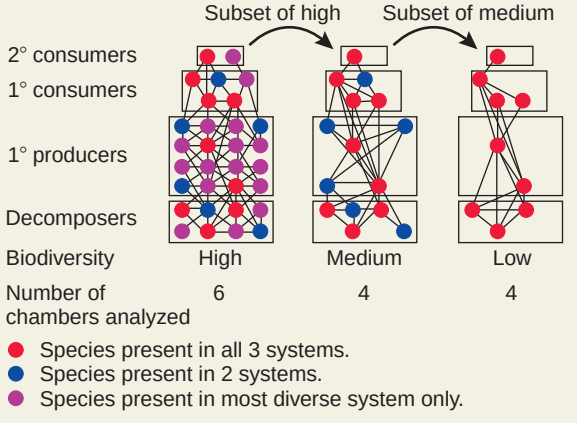
Experimental level | **Conceptual level**

1 Construct 14 identical experimental chambers.



Temperature- and humidity-controlled chambers are used to control environmental conditions and allow identical starting conditions in all chambers.

2 Add different combinations of species to the 14 chambers. The species added were based on 3 types of model communities (food webs), each with 4 trophic levels but with varying degrees of species richness.

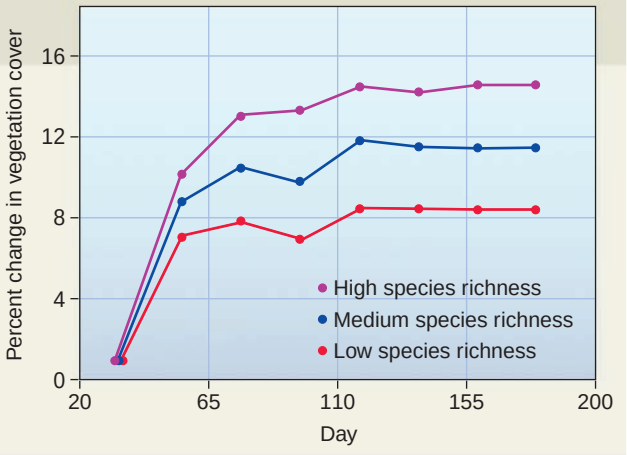


The three diagrams to the left each represent a single chamber. Circles represent species, and lines connecting them represent biotic interactions among the species. Note that each lower-biodiversity community is a subset of its higher-diversity counterpart and that all community types have 4 trophic levels.

3 Measure and analyze a range of processes, including vegetation cover and nutrient uptake.

Measurements help determine how each different type of community functions.

4 THE DATA



Plant productivity is linked to community diversity as measured by the percent change in vegetation cover from initial conditions.

Data reveal that low-diversity communities have lower vegetation cover and thus are less productive than high-diversity communities.

5 CONCLUSION Increases in biodiversity lead to increases in ecosystem function. In this case, increased plant diversity results in greater vegetation cover.

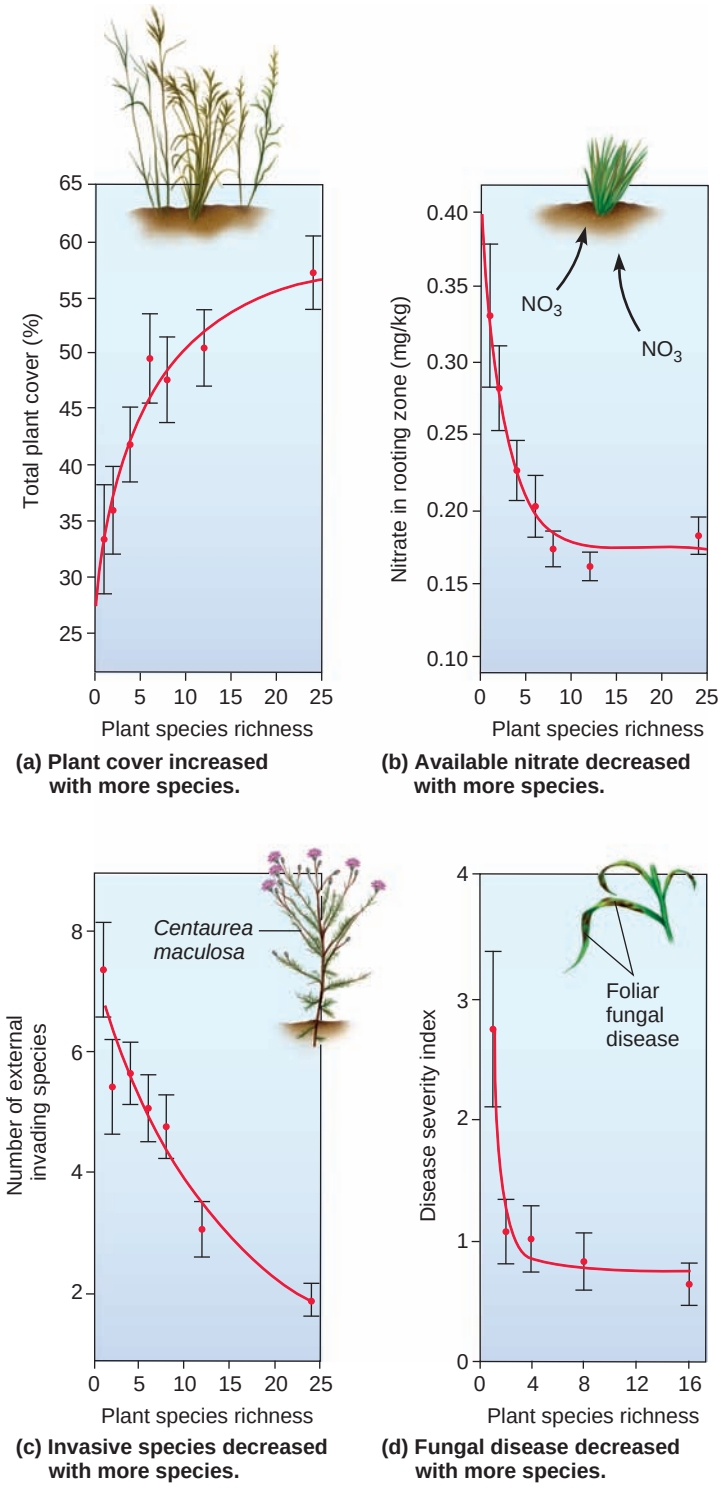
Field Experiments Also Suggest That Biodiversity Is Important for Ecosystem Function

In the mid-1990s, David Tilman and colleagues performed experiments in the field to determine how much biodiversity was necessary for proper ecosystem functioning. Tilman's previous experiments had suggested that species-rich grasslands were more stable; that is, they were more resistant to the ravages of drought and recovered from drought more quickly than species-poor grasslands (refer back to Figure 58.8). In the newer experiments, Tilman's group sowed plots, each 3 m by 3 m and on comparable soils, with seeds of 1, 2, 4, 6, 8, 12, or 24 species of prairie plants. Exactly which species were sown into each plot was determined randomly from a pool of 24 native species. The treatments were replicated 21 times, for a total of 147 plots. The results showed that more-diverse plots had increased productivity and used more nutrients, such as nitrate (NO_3), than less-diverse plots (Figure 60.5a,b). Furthermore, the frequency of invasive plant species (species not originally planted in the plots) decreased with increased plant species richness (Figure 60.5c). In a separate experiment, where plots were planted with 1, 2, 4, 8, or 16 species, Tilman and colleagues showed that increased diversity also reduced the severity of attack by foliar fungal diseases (Figure 60.5d).

Although Tilman's experiments show a relationship between diversity and ecosystem function, they also suggest that most of the advantages of increasing diversity come with the first 5 to 10 species, beyond which adding more species appears to have little to no impact. This supports the redundancy hypothesis (see Figure 60.3c). For example, uptake of nitrogen remains relatively unchanged as the number of species increases beyond 6. This is also observed on a larger scale. The productivity of temperate forests in different continents is roughly the same despite different numbers of tree species present—729 in East Asia, 253 in North America, and 124 in Europe. The presence of more tree species may ensure a supply of "backups" should some of the most-productive species die off from insect attack or disease. This can happen, as was seen in the demise of the American chestnut and elm trees. Diseases devastated both of these species, and their presence in forests dramatically decreased by the mid-20th century (refer back to Figure 57.18). The forests filled in with other species and continued to function as before in terms of nutrient cycling and gas exchange. However, although the forests continued to function without these species, some important changes occurred. For example, the loss of chestnuts deprived bears and other animals of an important source of food and may have affected their reproductive capacity and hence the size of their populations.

60.3 The Causes of Extinction and Loss of Biodiversity

In light of research showing that the loss of species influences ecosystem function, the importance of understanding and preventing species loss takes on particular urgency. Throughout the history of life on Earth, **extinction**—the process by which species die out—has been a natural phenomenon. As we saw in Chapter 22, five major mass extinctions have occurred over the past 500 million years. The average time span of a typical animal or plant species in the fossil record is about 4 million



(a) Plant cover increased with more species.

(b) Available nitrate decreased with more species.

(c) Invasive species decreased with more species.

(d) Fungal disease decreased with more species.

Figure 60.5 Increased species richness improves community function.

years. To calculate the current extinction rate, we could take the total number of species estimated to be alive on Earth at present, around 10 million, and divide it by 4 million, giving an average extinction rate of 2.5 species each year. For the 5,500 species of living mammals, using the same average life span of around 4 million years, we would expect about 1 species to go extinct every 1,000 years. This is termed the background extinction rate. However, it can be argued that the fossil record is heavily biased toward successful, often geographically wide-ranging species, which undoubtedly have a longer than average persistence time. The fossil record is also biased toward vertebrates and marine mollusks, both of which fossilize well because of their hard body parts. If background extinction rates were, say, 10 times higher than the rates perceived from the fossil record, then extinctions among the living mammals today would be expected to occur at a rate of about 1 every 100 years. Because there are twice as many bird species as mammals, the background extinction rate for birds would be 2 species every 100 years.

However, the extinction rate for species in recent times has been far higher than this. In the past 100 years, approximately 20 species of mammals and over 40 species of birds went extinct (Figure 60.6). The rates of species extinctions on islands in the past confirm the dramatic effects of human activity. The Polynesians, who colonized Hawaii in the 4th and 5th centuries, appear to have been responsible for the extinction of half of the 100 or so species of endemic land birds in the period between their arrival and that of the Europeans in the late 18th century. A similar impact was felt in New Zealand, which was colonized by settlers some 500 years later than Hawaii. In New Zealand, an entire avian megafauna, consisting of huge land birds, was exterminated over the course of a century, probably through

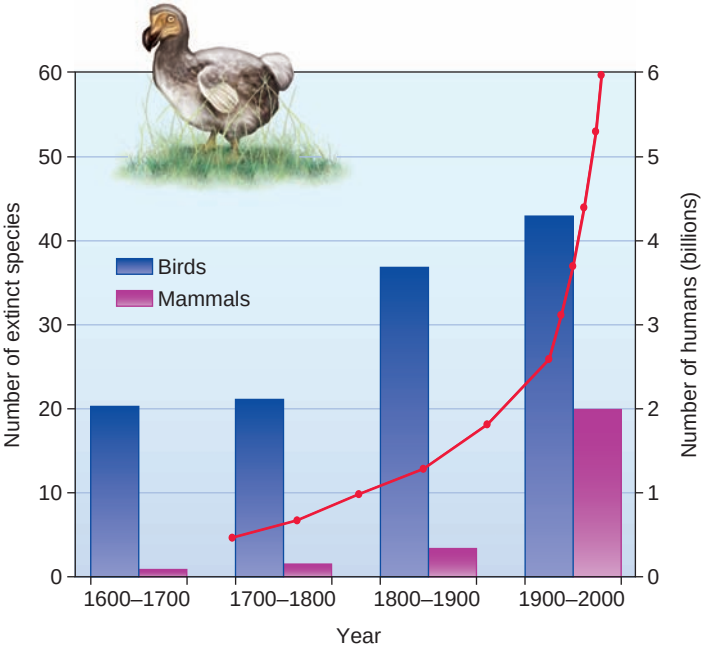


Figure 60.6 **Animal extinctions since the 17th century in relation to human population growth.** Increasing numbers of known extinctions in birds and mammals are concurrent with exponential increases in the global human population. These data suggest that as human numbers increase, more and more species will go extinct.

Concept check: *Why might the increasing human population result in an increase in the extinction rate of other species?*

a combination of hunting and large-scale habitat destruction through burning.

The term **biodiversity crisis** is often used to describe this elevated loss of species. Many scientists believe that the rate of loss is higher now than during most of geological history, and most suggest that the growth in the human population has led to the increase in the number of extinctions of other species. Most scientists believe that we are in the middle of a sixth mass extinction.

To understand the process of extinction in more modern times, ecologists need to examine the role of human activities and their environmental consequences. In this section, we examine why species have gone extinct in the past and look at the factors that are currently threatening species with extinction.

The Main Threats to Species Are Human-Induced

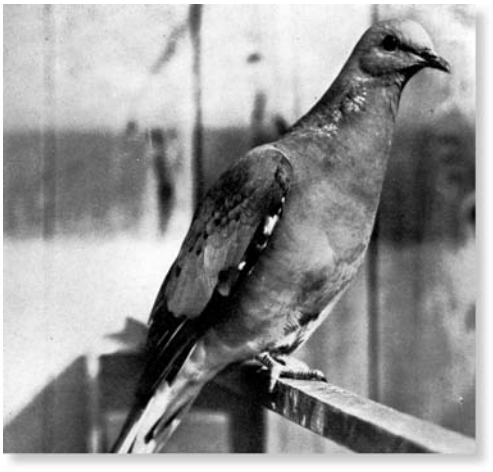
Although all causes of extinctions are not known, introduced species, direct exploitation, and habitat destruction have been identified as the most important human-induced threats. In addition, climate change is increasingly being viewed as a significant threat to species.

Introduced Species **Introduced species** are those species moved by humans from a native location to another location. Most often the species are transported for agricultural purposes or as sources of timber, meat, or wool. Others, such as plants, insects, or marine organisms, are unintentionally transported in the cargo of ships or planes. Regardless of their method of introduction, some introduced species become **invasive species**, spreading and outcompeting native species for space and resources.

We can categorize the interactions between introduced and native species into competition, predation, and disease. Competition can eliminate local populations and cause huge reductions in the densities of native species, but it has not yet been clearly shown to exterminate entire species. On the other hand, many recorded cases of extinction have been due to predation. Introduced predators such as rats, cats, and mongooses have accounted for at least 43% of recorded extinctions of birds on islands. Lighthouse keepers' cats have annihilated populations of ground-nesting birds on small islands around the world. The brown tree snake, which was accidentally introduced onto the island of Guam, has decimated the country's native bird populations (refer back to Figure 57.12). Parasitism and disease carried by introduced organisms have also been important in causing extinctions. Avian malaria in Hawaii, spread by introduced mosquito species, is believed to have contributed to the demise of up to 50% of native Hawaiian birds (Figure 60.7a).

Direct Exploitation Direct exploitation, particularly the hunting of animals, has been the cause of many extinctions in the past. Two remarkable North American bird species, the passenger pigeon and the Carolina parakeet, were hunted to extinction by the early 20th century. The passenger pigeon (*Ectopistes migratorius*) was once the most common bird in North America, probably accounting for over 40% of the entire bird population (Figure 60.7b). Their total population size was estimated to be over 1 billion birds. It may seem improbable that the most common bird on the continent could be hunted to extinction for its meat, but that is just what happened! The flocking behavior of the birds made them relatively easy targets for hunters, who used special firearms to harvest the birds in quantity. In 1876, in Michigan alone, over 1.6 million birds were killed and sent to markets in the eastern U.S. The Carolina parakeet (*Conuropsis*

(a) Introduced species



(b) Direct exploitation

(c) Habitat destruction

Figure 60.7 **Causes of extinction.** **(a)** Many Hawaiian honeycreepers such as this Ou, *Psittirostra psittacea,* were exterminated by avian malaria from introduced mosquito species. **(b)** The passenger pigeon, which may have once been among the most abundant bird species on Earth, was hunted to extinction for its meat. **(c)** The ivory-billed woodpecker, the third-largest woodpecker in the world, was long thought to be extinct in the southeastern U.S. because of habitat destruction, but a possible sighting occurred in 2004. This nestling was photographed in Louisiana in 1938.

carolinensis), the only species of parrot native to the eastern U.S., was similarly hunted to extinction by the early 1900s.

Many whale species were driven to the brink of extinction prior to a moratorium on commercial whaling issued in 1988 (refer back to Figure 57.13). Steller's sea cow (*Hydrodamalis gigas*), a 9-meter-long manatee-like mammal, was hunted to extinction in the Bering Strait only 27 years after its discovery by humans in 1740. A poignant example of human excess in hunting was the dodo (*Raphus cucullatus*), a flightless bird native only to the island of Mauritius that had no known predators. A combination of overexploitation and introduced species led to its extinction within 200 years of the arrival of humans. Sailors hunted it for its meat, and the rats, pigs, and monkeys brought to the island by humans destroyed the dodo's eggs and chicks in their ground nests.

Habitat Destruction Habitat destruction through **deforestation**, the conversion of forested areas to nonforested land, has historically been a prime cause of the extinction of species. About one-third of the world's land surface is covered with forests, and much of this area is at risk of deforestation through human activities such as development, farming, animal grazing, or logging. Although tropical forests are probably the most threatened forest type, with rates of deforestation in Africa, South America, and Asia varying between 0.6% and 0.9% per year, the destruction of forests is a global phenomenon. The ivory-billed woodpecker (*Campephilus principalis*), the largest woodpecker in North America and an inhabitant of wetlands and forests of the southeastern U.S., was widely assumed to have gone extinct in the 1950s due to destruction of its habitat by heavy logging (Figure 60.7c). In 2004, the woodpecker was purportedly sighted in the Big Woods area of eastern Arkansas, though this has not been confirmed despite concerted efforts.

Deforestation is not the only form of habitat destruction. The scouring of land to plant agricultural crops can create soil erosion, increased flooding, declining soil fertility, silting of the rivers, and desertification. The average area of land under cultivation worldwide averages about 11%, with an additional 24% given over to rangeland; however, this amount varies tremendously between regions. For example, Europe uses 28% of its land for crops and pasturelands, with the result that many of its native species went extinct long ago. Wetlands also have been drained for agricultural purposes. Others have been filled in for urban or industrial development. In the U.S., as much as 90% of the freshwater marshes and 50% of the estuarine marshes have disappeared. Urbanization, the development of cities on previously natural or agricultural areas, is the most human-dominated and fastest-growing type of land use worldwide and devastates the land more severely than practically any other form of habitat degradation.

Climate Change As mentioned at the beginning of Chapter 54, human-induced climate change, or global warming, has been implicated in the dramatic decrease in the population sizes of frog species in Central and South America. We also noted that the distribution of trees would also change as climate zones shifted. Unfortunately, such shifts would occur faster than many plants could migrate via seed dispersal. Indeed, a recent study of six biodiversity-rich regions employed computer models to simulate the movement of species' ranges in response to changing climate conditions. The models predicted that unless greenhouse gas emissions are cut drastically, climate change will cause 15–37% of the species in those regions to go extinct by the year 2050.

Other ecological properties of species, not just range limits, may change with global warming, including population densities and the timing of events, called phenology, such as flowering, egg laying, or migration. In 2003, Terry Root and colleagues examined the phenologies of 694 species over the past 30 years. Over an average decade, the estimated mean number of days changed in spring phenology was 5.1 days earlier. For example, the North American common murre (*Uria aalge*) bred, on average, 24 days earlier per decade, and Fowler's toad (*Bufo fowleri*) bred 6.3 days earlier. Potentially more critical than the absolute change in phenology is the possible disruption of timing between associated species such as herbivores and host plants or predators and prey. All is well if the phenologies of all species are sped up by global warming. However, limited evidence suggests that this is not the case. Only 11 systems have been examined in detail, but in 7 of them, interacting species responded differently enough to temperature changes to put them more out of synchrony than they were earlier. For example, in the Colorado Rockies, yellow-bellied marmots (*Marmota flaviventris*) now emerge from hibernation 23 days earlier than they did in 1975, changing the relative phenology of the marmots with their food plants.

Small Populations Are Threatened by the Loss of Genetic Diversity

Even if habitats are not destroyed, many become fragmented, leading to the development of small, isolated populations. Such populations are more vulnerable to the loss of genetic diversity resulting from three factors: inbreeding, genetic drift, and limited mating.

Inbreeding **Inbreeding**, which is mating among genetically related relatives, is more likely to take place in nature when population size becomes very small and there are a limited number of potential mates to choose from (see Chapter 24). In many species, the health and survival of offspring declines as populations become more inbred. This phenomenon was shown as long ago as the 19th century. Litter size in inbred rats declined from 7.5 in 1887 to 3.2 in 1892. Furthermore, during the same time span, the level of nonproductive matings, those where no offspring were born, rose from 2% to 50%. Generally, the more inbred the population, the more severe these types of problems become.

One of the most striking examples of the effects of inbreeding in conservation biology involves the greater prairie chicken (*Tympanuchus cupido*). The male birds have a spectacular mating display that involves inflating the bright orange air sacs on

their throat, stomping their feet, and spreading their tail feathers. The prairies of the Midwest were once home to millions of these birds, but as the prairies were converted to farmland, the range and population sizes of the bird shrank dramatically. The population of prairie chickens in Illinois decreased from 25,000 in 1933 to less than 50 in 1989. At that point, according to studies by Ronald Westemeier and colleagues, only 10 to 12 males existed. Because of the decreasing numbers of males, inbreeding in the population had increased. This was reflected in the steady reduction in the hatching success of eggs (Figure 60.8). The prairie chicken population had entered a downward spiral toward extinction from which it could not naturally recover, a phenomenon called an **extinction vortex**. In the early 1990s, conservation biologists began trapping prairie chickens in Kansas and Nebraska, where populations remained larger and more genetically diverse, and moved them to Illinois, bringing an infusion of new genetic material into the population. This transfer resulted in a rebounding of the egg-hatching success rate to over 90% by 1993.

Genetic Drift In small populations, there is a greater chance that some individuals will fail to mate successfully purely by chance. For example, finding a mate may be increasingly difficult as population size decreases. The decline in the reproduction and survival of individuals in small populations is known as the **Allee effect**, after ecologist W. C. Allee, who first described it. If an individual that fails to mate possesses a rare gene, that genetic information will not be passed on to the next generation, resulting in a loss of genetic diversity from the population. As noted in Chapter 24, **genetic drift** refers to the random change in allele frequencies attributable to chance. Because the likelihood of an allele being represented in just one or a few individuals is higher in small populations than in large populations, small, isolated populations are particularly vulnerable to this type of reduction in genetic diversity. Such isolated populations will lose a percentage of their original diversity over time, approximately at the rate of $1/(2N)$ per generation, where N = population size. This has a greater effect in smaller versus larger populations:

If $N = 500$, then $\frac{1}{2N} = 1/1{,}000 = 0.001$, or 0.1% genetic diversity lost per generation

If $N = 50$, then $\frac{1}{2N} = 1/100 = 0.01$, or 1.0% genetic diversity lost per generation

Due to genetic drift, a population of 500 will lose only 0.1% of its genetic diversity in a generation, whereas a population of 50 will lose 1%. Such losses become magnified over many generations. After 20 generations, the population of 500 will lose 2% of its original genetic variation, but the population of 50 will lose about 20%! For organisms that breed annually, this would mean a substantial loss in genetic variation over 20 years. Once again, this effect becomes more severe as the population size decreases.

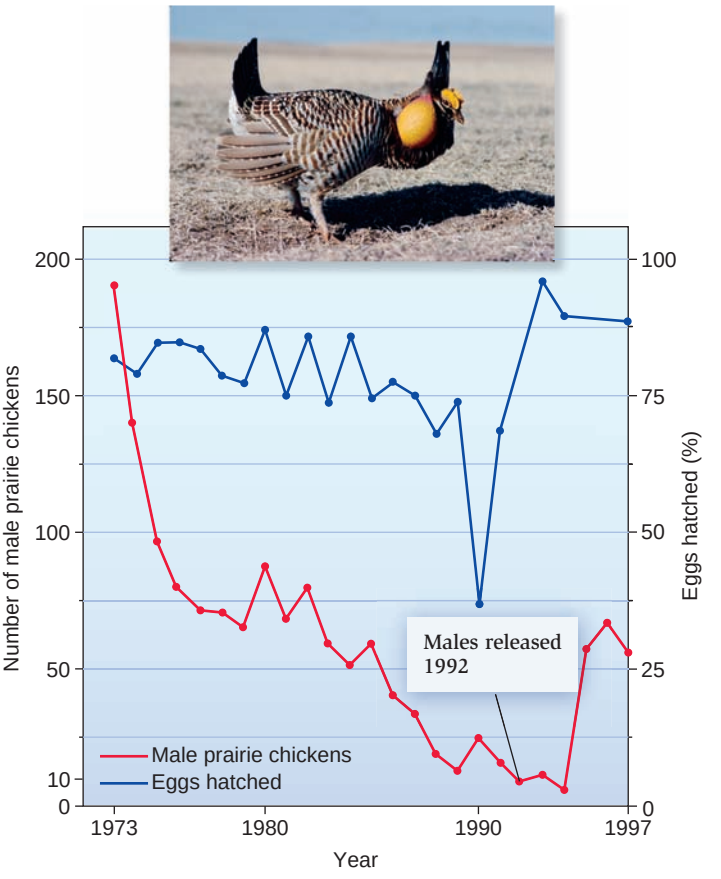


Figure 60.8 **Changes in the abundance and egg-hatching success rate of prairie chickens.** As the number of males decreased, inbreeding increased, resulting in a decrease in fertility, as indicated by a reduced egg-hatching rate. An influx of males in the early 1990s increased the egg-hatching success rate dramatically.

Concept check: *Is the fitness of all organisms decreased by inbreeding?*

As with inbreeding, the effects of genetic drift can be countered by immigration of individuals into a population. Even relatively low immigration rates of about one immigrant per generation (or one individual moved from one population to another) can be sufficient to counter genetic drift in a population of 100 individuals.

Limited Mating In many populations, the **effective population size**, the number of individuals that contribute genes to future populations, may be smaller than the number of individuals in the population, particularly in animals with a harem mating structure in which only a few dominant males breed. For example, dominant elephant seal bulls control harems of females, and a few males command all the matings (refer back to Figure 55.22). If a population consists of breeding males and breeding females, the effective population size is given by

Effective population size (N_e) = $\frac{4N_mN_f}{N_m + N_f}$

(N_m: Number of breeding males; N_f: Number of breeding females)

In a population of 500, a 50:50 sex ratio, and all individuals breeding, $N_e = (4 \times 250 \times 250)/(250 + 250) = 500$, or 100% of the actual population size. However, if 10 males breed with 250 females, $N_e = (4 \times 10 \times 250)/(10 + 250) = 38.5$, or 8% of the actual population size.

Knowledge of effective population size is vital to ensuring the success of conservation projects. One notable project in the U.S. involved planning the sizes of reserves designed to protect grizzly bear populations in the contiguous 48 states. The grizzly bear (*Ursus arctos*) has declined in numbers from an estimated 100,000 in 1800 to less than 1,000 at present. The range of the species is now less than 1% of its historical range and is restricted to six separate populations in four states (**Figure 60.9**). Research by biologist Fred Allendorf has indicated that the effective population size of grizzly populations is generally only about 25% of the actual population size because not all bears breed. Thus, even fairly large, isolated populations, such as the 200 bears in Yellowstone National Park, are vulnerable to the harmful effects of loss of genetic variation because the effective population size may be as small as 50 individuals.

Figure 60.9 **Past and current ranges of the grizzly bear.** The range of the grizzly bear is currently less than 1% of its historical range. The current range in the continental U.S. has contracted to just six populations in four states, as the population size has shrunk from 100,000 before the West was settled to about 1,000 today.

Concept check: *If 500 male and 500 female grizzlies exist today, but only 25% of the males breed, what is the effective population size?*

Allendorf and his colleagues proposed that an exchange of grizzly bears between populations or zoo collections would help tremendously in promoting genetic variation. Even an exchange of two bears per generation between populations would greatly reduce the loss of genetic variation.

60.4 Conservation Strategies

In their efforts to maintain the diversity of life on Earth, conservation biologists are currently active on many fronts and employ many strategies. We begin this section by discussing how conservation biologists identify the global habitats richest in species. Next, we explore the concept of nature reserves and consider questions such as how large conservation areas should be and how far apart they should be situated. These questions are within the realm of landscape ecology, which studies the spatial arrangement of communities and ecosystems in a geographic area. Next we discuss how conservation efforts often focus on certain species that can have a disproportionate impact on their ecosystem. We will also examine the field of restoration ecology, focusing on how wildlife habitats can be established from degraded areas and how captive breeding programs have been used to reestablish populations of threatened species in the wild. We conclude by returning to the theme of genomes and proteomes to show how modern molecular techniques of cloning can contribute to the fight to save critically endangered species.

Habitat Conservation Focuses on Identifying Countries Rich in Species, Areas Rich in Endemics, or Representative Habitats

Conservation biologists often must make decisions regarding which habitats should be protected. Many conservation efforts have focused on saving habitats in so-called megadiversity countries, because they often have the greatest number of species. However, more recent strategies have promoted preservation of certain key areas with the highest levels of unique species or the preservation of representative areas of all types of habitat, even relatively species-poor areas.

Megadiversity Countries One method of targeting areas for conservation is to identify those countries with the greatest numbers of species, the **megadiversity countries**. Using the number of plants, vertebrates, and selected groups of insects as criteria, biologist Russell Mittermeier and colleagues have determined that just 17 countries are home to nearly 70% of all known species. Brazil, Indonesia, and Colombia top the list, followed by Australia, Peru, Mexico, Madagascar, China, and nine other countries. The megadiversity country approach suggests that conservation efforts should be focused on the most biologically rich countries. However, although megadiversity areas may contain the most species, they do not necessarily contain the most unique species. The mammal species list for

Peru is 344, and for Ecuador, it is 271; of these, however, 208 species are common to both.

Areas Rich in Endemic Species Another method of setting conservation priorities, one adopted by the organization Conservation International, takes into account the number of species that are **endemic**, or found only in a particular place or region and nowhere else. This approach suggests that conservationists focus their efforts on geographic **hot spots**. To qualify as a hot spot, a region must meet two criteria: It must contain at least 1,500 species of vascular plants as endemics and have lost at least 70% of its original habitat. Vascular plants were chosen as the primary group of organisms to determine whether or not an area qualifies as a hot spot, mainly because most other terrestrial organisms depend on them to some extent.

Conservationists Norman Myers, Russell Mittermeier, and colleagues identified 34 hot spots that together occupy a mere 2.3% of the Earth's surface but contain 150,000 endemic plant species, or 50% of the world's total (Figure 60.10). Of these areas, the Tropical Andes and Sundaland (the region including Malaysia, Indonesia, and surrounding islands) have the most endemic plant species (Table 60.3). This approach proposes that protecting geographic hot spots will prevent the extinction of a larger number of endemic species than would protecting areas of a similar size elsewhere. The main argument against using hot spots as the criterion for targeting conservation efforts is that the areas richest in endemics—tropical rain forests—would receive the majority of attention and funding, perhaps at the expense of protecting other areas.

Representative Habitats In a third approach to prioritizing areas for conservation, scientists have recently argued that we need to conserve representatives of all major habitats. An example is the Pampas region of South America, which is arguably the most threatened habitat on the continent because of conversion of its natural grasslands to ranch land and agriculture. The Pampas does not compare well in richness or endemics to the rain forests, but it is a unique area that without preservation could disappear (Figure 60.11). By selecting habitats that are most distinct from those already preserved, many areas that are threatened but not biologically rich may be preserved in addition to the less immediately threatened, but richer, tropical forests.

Ecologists are divided as to which is the best way to identify areas for habitat conservation. Perhaps the best approach might be one that creates a "portfolio" of areas to conserve, containing some areas of high species richness, others with large numbers of endemic species, and some with various habitat types.

The Theory and Practice of Reserve Design Incorporate Principles of Island Biogeography and Landscape Ecology

After identifying areas to preserve, conservationists must determine the size, arrangement, and management of the protected land. Among the questions conservationists address is whether one large reserve is preferable to an equivalent area composed of smaller reserves. Ecologists also need to determine whether parks should be close together or far apart and whether they

Figure 60.10 **Location of major biodiversity hot spots around the world.** Hot spots have high numbers of endemic species.

Table 60.3 Numbers of Endemic Species Present in the Top 10 Hot Spots of the World, Ranked by the Numbers of Endemic Plants

Rank	Hot spot	Plants	Birds	Mammals	Reptiles	Amphibians	Freshwater fishes
1	Tropical Andes	15,000	584	75	275	664	131
2	Sundaland	15,000	146	173	244	172	350
3	Mediterranean Basin	11,700	32	25	77	27	63
4	Madagascar	11,600	183	144	367	226	97
5	Brazil's Atlantic Forest	8,000	148	71	94	286	133
6	Indo-Burma	7,000	73	73	204	139	553
7	Caribbean	6,550	167	41	468	164	65
8	Cape Floristic Province	6,210	6	4	22	16	14
9	Philippines	6,091	185	102	160	74	67
10	Brazil's Cerrado	4,400	16	14	33	26	200

should be connected by strips of suitable habitat to allow the movement of plants and animals between them. Conservationists also need to consider that park design is often contingent on economic factors. Let's examine some of the many issues that conservationists address in the creation and management of protected land.

The Role of Island Biogeography In our exploration of the equilibrium model of island biogeography (see Chapter 58), we noted that wildlife reserves and sanctuaries are, in essence, islands in a sea of human-altered land. Seen this way, the tenets of the equilibrium model of island biogeography can be applied not only to a body of land surrounded by water but also to nature reserves. One question for conservationists is how large a protected area should be (Figure 60.12a). According to island biogeography, the number of species should increase with increasing area (the species-area effect). Thus, the larger the area, the greater the number of species would be protected. In addition, larger parks have other benefits. For example, they are beneficial for organisms that require large spaces, including migrating species and species with extensive territories, such as lions and tigers.

A related question is whether it is preferable to protect one single, large reserve or several smaller ones (Figure 60.12b). This is called the **SLOSS debate** (for single large or several small). Proponents of the single, large reserve claim that a larger reserve is better able to preserve more and larger populations than an equal area divided into small areas. According to island biogeography, a larger block of habitat should support more species than several smaller blocks.

However, many empirical studies suggest that multiple small sites of equivalent area will contain more species, because a series of small sites is more likely to contain a broader variety of habitats than one large site. Looking at a variety of sites, researchers Jim Quinn and Susan Harrison concluded that animal life was richer in collections of small parks than in a smaller number of larger parks. In their study, having more habitat types outweighed the effect of area on biodiversity. In addition, another benefit of a series of smaller parks is a reduction of extinction risk by a single event such as a wildfire or the spread of disease.

Figure 60.11 **The pampas, Argentina.** This habitat is not rich in species but is threatened due to conversion to ranch land and agricultural land.

Landscape Ecology Landscape ecology is a subdiscipline of ecology that examines the spatial arrangement of communities and ecosystems in a geographic area. In the design of nature reserves, one question that needs to be addressed is how close to situate reserves to each other, such as whether to place three or four small reserves close to each other or farther apart. A similar question is whether to have a linear or a cluster arrangement of small reserves. Island biogeography suggests that if an area must be fragmented, the sites should be as close as possible

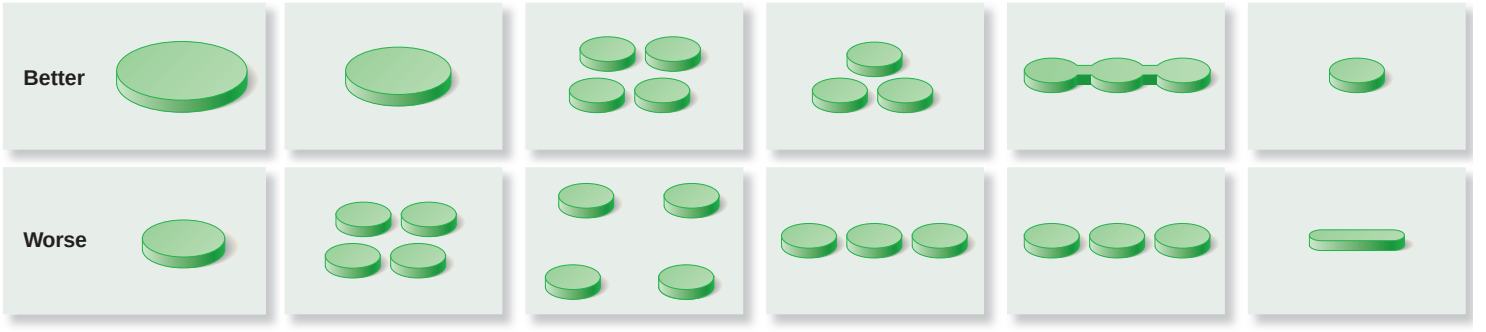

Figure 60.12 **The theoretical design of nature reserves.** **(a)** A larger reserve will hold more species and have low extinction rates. **(b)** A given area should be fragmented into as few pieces as possible. **(c)** If an area must be fragmented, the pieces should be as close as possible to permit dispersal. **(d)** To enhance dispersal, a cluster of fragments is preferable to a linear arrangement. **(e)** Maintaining or creating corridors between fragments may also enhance dispersal. **(f)** Circular-shaped areas will minimize the amount of edge effects.

Concept check: *What are some of the potential risks in connecting areas via habitat corridors?*

to permit dispersal (Figure 60.12c,d). In practice, however, having small sites far apart may preserve more species than having them close together, because once again, distant sites are likely to incorporate slightly different habitats and species.

Landscape ecologists have also suggested that small reserves should be linked together by biotic corridors, or **movement corridors**, which are thin strips of land that may permit the movement of species between patches (Figure 60.12e). Such corridors ideally facilitate movements of organisms that are vulnerable to predation outside of their natural habitat or that have poor powers of dispersal between habitat patches. In this way, if a disaster befalls a population in one small reserve, immigrants from neighboring populations can more easily recolonize it. This avoids the need for humans to physically move new plants or animals into an area.

Several types of habitat function as corridors, including hedgerows in Europe, which facilitate movement and dispersal of species between forest fragments (Figure 60.13). In China, corridors of habitat have been established to link small, adjacent populations of giant pandas. Riparian habitats, vegetated corridors bordering watercourses, are thought to help facilitate movement of species between habitats. In Florida, debate continues about whether to establish new populations of the Florida panther in refuges in both central and north Florida and whether to have these populations connect with the current population in south Florida via riparian movement corridors. In theory, this would lessen the threat of extinction of the Florida panther via inbreeding or a catastrophic event, such as a hurricane. However, disadvantages are associated with movement corridors. First, corridors also can facilitate the spread of disease, invasive species, and fire between small reserves. Second, it is not yet clear if species, such as female Florida panthers, would actually use such corridors.

Finally, parks are often designed to minimize **edge effects**, the special physical conditions that exist at the boundaries or edges of ecosystems. Habitat edges, particularly those between natural habitats such as forests and developed land, are often different in physical characteristics from the habitat core. For example, the center of a forest is shaded by trees and has less wind and light than the forest edge, which is unprotected. Many forest-adapted species therefore shy away from forest edges and prefer forest centers. Because the amount of edge is minimized, circular parks are generally preferable to oblong parks (Figure 60.12f).

Figure 60.13 **Habitat corridors.**

Concept check: *Why would these European hedgerows act as habitat corridors?*

Economic Considerations in Conservation Although the principles of island biogeography theory and landscape ecology are useful in illuminating conservation issues, in reality, there

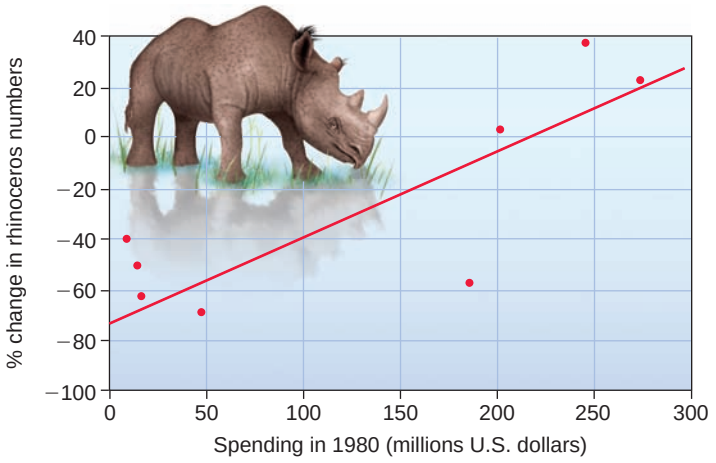

Figure 60.14 **The economics of conservation.** A positive relationship is seen between the percent change in the number of black rhinoceros and conservation spending in various African countries between 1980 and 1984.

is often little choice as to the location, size, shape, and extent of nature reserves. Management practicalities, such as costs of acquisition and maintenance, and politics often override ecological considerations, especially in developing countries, where costs for large reserves may be relatively high. Economic considerations often enter into the choice of which areas to preserve. Typically, many countries protect areas in those regions that are the least economically valuable rather than choosing areas to ensure a balanced representation of the country's biota. In the U.S., most national parks have been chosen for their scenic beauty, not because they preserve the richest habitat for wildlife.

When designing nature reserves, countries should also consider how to finance their management. Interestingly, the amount of money spent to protect nature reserves may better determine species extinction rates than reserve size. According to island biogeography theory, large areas minimize the risk of extinctions because they contain sizable populations. In Africa, several parks, such as Serengeti and Selous in Tanzania, Tsavo in Kenya, and Luangwa in Zambia, are large enough to fulfill this theoretical ideal. However, in the 1980s, populations of black rhinoceroses and elephants declined dramatically within these areas because of poaching. A larger park is also more difficult to patrol. Research has shown that the rates of decline of rhinos and elephants, largely a result of poaching, have been related directly to conservation efforts and spending (Figure 60.14). Populations of the remaining black rhinos, lowland gorillas, and pygmy chimpanzees in Africa, and the vicuna, a llama-like animal in South America, have all shown the greatest stabilization in areas that have been heavily patrolled and where economic resources have been concentrated.

The Single-Species Approach Focuses Conservation Efforts on Particular Types of Species

Much public awareness of the biodiversity crisis results from efforts to preserve individual species that are at risk of extinction. The single-species approach to conservation focuses on saving species that are deemed particularly important. As with habitat conservation, there are different approaches to identifying ecologically important species to focus effort on, such as indicator, umbrella, flagship, or keystone species, as well as phylogenetically distinct taxa.

Indicator Species Some conservation biologists have suggested that certain organisms can be used as **indicator species**, those species whose status provides information on the overall health of an ecosystem. Corals are good indicators of marine processes such as siltation, the accumulation of sediments transported by water. Because siltation reduces the availability of light, the abundance of many marine organisms decreases in such situations, with corals among the first to display a decline in health. Coral bleaching is also an indicator of climate change. A proliferation of the dark variety of the peppered moth (*Biston betularia*) has been shown to be a good indicator of air pollution. The darker-colored moths flourish because predators are less able to detect them on trees darkened by soot. Polar bears (*Ursus maritimus*) are thought to be an indicator species for global climate change (Figure 60.15a). Scientists believe that global warming is causing the ice in the Arctic to melt earlier in the spring than in the past. Because polar bears rely on the

(a) Indicator species: Polar bear

(b) Umbrella species: Northern spotted owl

(c) Flagship species: Florida panther

Figure 60.15 **Indicator, umbrella, and flagship species.** **(a)** Polar bears have been called an indicator species of global climate change. **(b)** The Northern spotted owl is considered an umbrella species for the old-growth forest in the Pacific Northwest. **(c)** The Florida panther has become a flagship species for Florida.

ice to hunt for seals, the earlier breakup of the ice is leaving the bears less time to feed and build the fat that enables them to sustain themselves and their young. A U.S. Geological survey concluded that future reduction of arctic ice could result in a loss of two-thirds of the world's polar bear population within 50 years. In May 2008, polar bears were listed as a threatened species under the U.S. Endangered Species Act (ESA).

Umbrella Species **Umbrella species** are species whose habitat requirements are so large that protecting them would protect many other species existing in the same habitat. The Northern spotted owl (*Strix occidentalis*) of the Pacific Northwest is considered to be an important umbrella species (Figure 60.15b). A pair of birds needs at least 800 hectares of old-growth forest for survival and reproduction, so maintaining healthy owl populations is thought to help ensure survival of many other forest-dwelling species. In the southeast area of the U.S., the red-cockaded woodpecker (*Picoides borealis*) is often seen as the equivalent of the spotted owl, because it requires large tracks of old-growth long-leaf pine (*Pinus palustris*), including old diseased trees in which it can excavate its nests. Some species, such as *Zea diploperennis*, which we discussed at the beginning of the chapter, fall into this category. For example, to protect *Z. diploperennis* in its natural environment, the state of Jalisco in Mexico bought the land where it grows and established a nature reserve and research facility there.

Flagship Species In the past, conservation resources were often allocated to a **flagship species**, a single large or instantly recognizable species. Such species were typically chosen because they were attractive and thus more readily engendered support from the public for their conservation. The concept of the flagship species, typically a charismatic vertebrate such as the American buffalo (*Bison bison*), has often been used to raise awareness for conservation in general. The giant panda (*Ailuropoda melanoleuca*) is the World Wildlife Fund's emblem for endangered species, and the Florida panther (*Puma concolor*) has become a symbol of the state's conservation campaign (Figure 60.15c).

Keystone Species A different, perhaps more effective conservation strategy focuses on **keystone species**, species within a community that have a role out of proportion to their abundance or biomass. The beaver, a relatively small animal, can completely alter the composition of a community by building a dam and flooding an entire river valley (Figure 60.16). The resultant lake may become a home to fish species, wildfowl, and aquatic vegetation. A decline in the number of beavers could have serious ramifications for the remaining community members, promoting fish die-offs, waterfowl loss, and the death of vegetation adapted to waterlogged soil.

In the southeastern U.S., gopher tortoises can be regarded as keystone species because the burrows they create provide homes for an array of other animals, including mice, opossums, frogs, snakes, and insects. Many of these creatures depend on the gopher tortoise burrows and would be unable to survive without them. Gopher tortoises and some other keystone species, including beavers, are also called **ecosystem engineers**, because they create, modify, and maintain habitats. African elephants act as ecosystem engineers through their browsing activity, destroying small trees and shrubs and changing woodland habitats into grasslands.

Figure 60.16 **Keystone species.** The American beaver creates large dams across streams, and the resultant lakes provide habitats for a great diversity of species.

Tropical ecologist John Terborgh considers palm nuts and figs to be keystone species because they produce fruit during otherwise fruitless times of the year and are thus critical resources for tropical forest fruit-eating animals, including primates, rodents, and many birds. Together, these fruit eaters account for as much as three-quarters of the tropical forest animal biomass. Without the fruit trees, wholesale extinction of these animals could occur. Note that a keystone species is not the same as a **dominant species**, one that has a large effect in a community because of its abundance or high biomass. For example, *Spartina* cordgrass is a dominant species in a salt marsh because of its large biomass, but it is not a keystone species.

Few studies have analyzed the community importance of keystone species, and no set criteria have been established for designating a keystone species. Nevertheless, such species do seem to affect species diversity. The conservation community is eager to identify keystone species, because by managing a keystone species, they may also ensure the survival of many other species in the ecosystem. This supports the concept of the redundancy hypothesis that we talked about earlier in Section 60.2.

Restoration Ecology Attempts to Rehabilitate Degraded Ecosystems and Populations

Restoration ecology is the full or partial repair or replacement of biological habitats and/or their populations that have been degraded or destroyed. It can focus on restoring or rehabilitating a habitat, or it can involve attempting to return species to the wild following captive breeding. Following opencast mining for coal or phosphate, huge tracts of disturbed land must be replenished with topsoil, and a large number of species such as grasses, shrubs, and trees must be replanted. Aquatic habitats

can be restored by reducing human impacts and replanting vegetation. In Florida, seagrass beds damaged by boat propellers are closed off to motorboats and the area replanted.

Habitat Restoration The three basic approaches to habitat restoration are complete restoration, rehabilitation, and ecosystem replacement. In complete restoration, conservationists attempt to return a habitat to its condition prior to the disturbance. Under the leadership of Aldo Leopold, the University of Wisconsin pioneered the restoration of prairie habitats as early as 1935, converting agricultural land back to species-rich prairies (Figure 60.17a). The second approach aims to return the habitat to something similar to, but a little less than, full restoration, a goal called rehabilitation. In Florida, phosphate mining involves removing a layer of topsoil or "overburden," mining the phosphate-rich layers, returning the overburden, and replanting the area. Exotic species such as cogongrass (*Imperata cylindrica*), an invasive Southeast Asian species, often invade these disturbed areas, and the biodiversity of the restored habitat is usually not comparable to that of unmined areas (Figure 60.17b). The third approach, termed replacement, makes no attempt to restore what was originally present but instead replaces the original ecosystem with a different one. The replacement could be an ecosystem that is simpler but more productive, as when deciduous forest is replaced after mining by grassland to be used for public recreation.

Although any of these approaches can be employed in the habitat restoration process, complete restoration is not always the desired endpoint. In some cases, full restoration is appropriate, but there are also many cases where restoration is so difficult or expensive as to be impractical. Ecosystem replacement is particularly sensible for land that has been significantly damaged by past activities. It would be nearly impossible to re-create the original landscape of an area that was mined for stone or gravel. In these situations, however, wetlands or lakes may be created in the open pits (Figure 60.17c).

Bioremediation Restoration can also involve **bioremediation**, the use of living organisms, usually microbes or plants, to detoxify polluted habitats such as dump sites or oil spills. Some bacteria can detoxify contaminants, while certain plants can accumulate toxins in their tissues and are then harvested, removing the poison from the system. As we noted in Chapter 20, biologists have used microbes in the degradation of sewage for over 100 years. More recently, as we saw in Chapter 27, the bacteria *Geobacter sulfurreducens* has been used to treat borrow pits contaminated with uranium.

In 1975, a leak from a military fuel storage facility released 80,000 gallons of jet fuel into the sandy soil at Hanahan, South Carolina. Soon the groundwater contained toxic chemicals such as benzene. By the 1980s, it was found that naturally occurring microorganisms in the soil were actively consuming many of these toxic compounds and converting them into carbon dioxide. In 1992, nutrients were delivered in pipes to the contaminated soils to speed up the action of the natural microbial community. By the end of 1993, contamination had been reduced by 75%. The increasing interest in bacterial genomes is providing opportunities for understanding the genetic and molecular bases of degradation of organic pollutants. Many novel biochemical reactions have been discovered.

Heavy metals such as cadmium or lead are not readily absorbed by microorganisms. Phytoremediation, the treatment of environmental problems through the use of plants, is valuable in these cases. Plants absorb contaminants in the root system and store them in root biomass or transport them to stems and leaves. After harvest, a lower level of soil contamination will remain. Several growth/harvest cycles may be needed to achieve cleanup. Sunflower (*Helianthus annuus*) may be used to extract arsenic and uranium from soils. Pennycress (*Thalsphi caenilescens*) is an accumulator of zinc and cadmium, and lead may be removed by Indian mustard (*Brassica juncea*) and ragweed (*Ambrosia artemisifolia*). Some polychlorinated biphenyls (PCBs) have been removed by transgenic plants containing genes for bacterial enzymes.

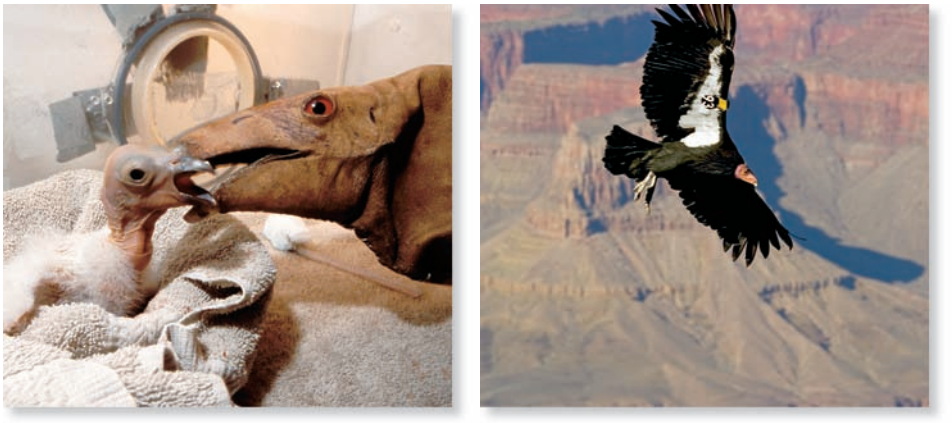
Captive Breeding Captive breeding, the propagation of animals and plants outside their natural habitat to produce stock for subsequent release into the wild, has proved valuable in

(a) Complete restoration

(b) Rehabilitation

(c) Ecosystem replacement

Figure 60.17 **Habitat restoration.** **(a)** The University of Wisconsin pioneered the practice of complete restoration of agricultural land to native prairies. **(b)** In Florida, phosphate mines are so degraded that complete restoration is not possible. After topsoil is replaced, some exotic species such as cogongrass often invade, allowing only habitat rehabilitation. **(c)** These old open-pit mines in Middlesex, England, have been converted to valuable freshwater habitats, replacing the wooded area that was originally present.



(a) A condor chick being fed using a puppet (b) A released captive-bred condor

Figure 60.18 Captive breeding programs. The California condor, the largest bird in the U.S., with a wingspan of nearly 3 m, has been bred in captivity in California. **(a)** A researcher at the San Diego Wild Animal Park feeds a chick with a puppet so that the birds will not become habituated to the presence of humans. **(b)** This captive-bred condor soars over the Grand Canyon. Note the tag on the underside of its wing.

reestablishing breeding populations following extinction or near extinction. Zoos, aquariums, and botanical gardens often play a key role in captive breeding, propagating species that are highly threatened in the wild. They also play an important role in public education about the loss of biodiversity and the use of restoration programs.

Several classic programs illustrate the value of captive breeding and reintroduction. The peregrine falcon (*Falco peregrinus*) became extinct in nearly all of the eastern U.S. by the mid-1960s, a decline that was linked to the effects of DDT (refer back to Figure 59.9). In 1970, Tom Cade gathered falcons from other parts of the country to start a captive breeding program at Cornell University. Since then, the program has released thousands of birds into the wild, and in 1999, the peregrine falcon was removed from the Endangered Species List. A captive breeding program is also helping save the California condor (*Gymnogyps californicus*) from extinction. In the 1980s, there were only 22 known birds, some in captivity and some in the wild. Scientists made the decision to capture the remaining wild birds in order to protect and breed them (Figure 60.18a). By 2008, the captive population numbered 152 individuals, and 147 birds were living in the wild, 80 in California and 67 in Arizona (Figure 60.18b). A milestone was reached in 2002, when a pair of captive-reared California condors bred in the wild.

Because the number of individuals in any captive breeding program is initially small, care must be exercised to avoid inbreeding. Matings are usually carefully arranged to maximize resultant genetic variation in offspring. The use of genetic engineering to clone endangered species is a new area that may eventually help bolster populations of captive-bred species.

Genomes & Proteomes Connection

Can Cloning Save Endangered Species?

In 1997, Ian Wilmut and colleagues at Scotland's Roslin Institute announced to the world that they had cloned a now-famous sheep, Dolly, from mammary cells of an adult ewe (see Chapter 20). Since then, interest has arisen among conservation biologists about whether the same technology might be used to save species on the verge of extinction. Scientists were encouraged that in January 2001, an Iowa farm cow called Bessie gave birth to a cloned Asian gaur (*Bos gaurus*), an endangered species. The gaur, an oxlike animal native to the jungles of India and Burma, was cloned from a single skin cell taken from a dead animal. To clone the gaur, scientists removed the nucleus from a cow's egg and replaced it with a nucleus from the gaur's cell. The treated egg was then placed into the cow's womb. Unfortunately, the gaur died from dysentery 2 days after birth, although scientists believe this was unrelated to the cloning procedure. In 2003, another type of endangered wild cattle, the Javan banteng (*Bos javanicus*), was successfully cloned (Figure 60.19). In 2005, clones of the African wildcat (*Felis libyca*) successfully produced wildcat kittens. This is the first time that clones of a wild species have bred.

Despite the promise of cloning, a number of issues remain unresolved:

1. Scientists would have to develop an intimate knowledge of different species' reproductive cycles. For sheep and cows, this was routine, based on the vast experience in breeding these species, but eggs of different species, even if they could be harvested, often require different nutritive media in laboratory cultures.
2. Because it is desirable to leave natural mothers available for breeding, scientists will have to identify surrogate females of similar but more common species that can carry the fetus to term.
3. Some argue that cloning does not address the root causes of species loss, such as habitat fragmentation or poaching, and that resources would be better spent elsewhere, for example, in preserving the remaining habitat of endangered species.
4. Cloning might not be able to increase the genetic variability of the population. However, if it were possible to use cells from deceased animals, for example, from their hair or feathers, these clones could theoretically reintroduce lost genes back into the population.

Many biologists believe that while cloning may have a role in conservation, it is only part of the solution and that we should address what made the species go extinct before attempting to restore it.

Figure 60.19 **Cloning an endangered species.** In 2004, this 8-month-old cloned Javan banteng made its public debut at the San Diego Zoo.

Conservation is clearly a matter of great importance, and a failure to value and protect our natural resources adequately could be a grave mistake. Some authors, most recently the ecologist and geographer Jared Diamond, have investigated why many societies of the past—including Angkor Wat, Easter Island, and the Mayans—collapsed or vanished, leaving behind monumental ruins. Diamond has concluded that the collapse of these societies occurred partly because people inadvertently destroyed the ecological resources on which their societies depended. Modern nations such as Rwanda face similar issues. The country's population density is the highest in Africa, and it has a limited amount of land that can be used for growing crops. By the late 1980s, the need to feed a growing population led to the wholesale clearing of Rwanda's forests and wetlands, with the result that little additional land was available to farm. Increased population pressure, along with food shortages fueled by environmental scarcity, were likely contributing factors in igniting the genocide of 1994.

As we've seen throughout this textbook, an understanding of biology is vital to comprehend and help solve many of society's problems. Within this large field, genomics and proteomics may have a huge potential for improving people's lives and society at large. These disciplines offer the opportunity to unlock new diagnoses and treatments for diseases, to improve nutrition and food production, and even to help us restore biological diversity.

Summary of Key Concepts

60.1 What Is Biodiversity?

- Biodiversity represents diversity at three levels: genetic diversity, species diversity, and ecosystem diversity.
- Conservation biology uses knowledge from molecular biology, genetics, and ecology to protect the biological diversity of life. (Figure 60.1)

60.2 Why Conserve Biodiversity?

- The preservation of biodiversity has been justified because of its economic value, because of the value of ecosystem services, and on ethical grounds. (Tables 60.1, 60.2, Figure 60.2)
- Four models exist that describe the relationship between biodiversity and ecosystem function: diversity-stability, rivet, redundancy, and idiosyncratic. (Figure 60.3)
- Experiments both in the laboratory and in the field have shown that increased biodiversity results in increased ecosystem function. (Figures 60.4, 60.5)

60.3 The Causes of Extinction and Loss of Biodiversity

- Extinction—the process by which species die out—has been a natural phenomenon throughout the history of life on Earth. Extinction rates in recent times, however, have been much higher than in the past, a phenomenon called the biodiversity crisis. (Figure 60.6)
- The main causes of extinctions have been and continue to be introduced species, direct exploitation, and habitat destruction. (Figure 60.7)
- Reduced population size can lead to a reduction of genetic diversity through inbreeding, genetic drift, and limited mating, which reduces effective population size.
- Inbreeding, mating among genetically related relatives, can lead to a reduction in fertility. (Figure 60.8)
- Knowledge of a species' effective population size is vital to ensure the success of conservation projects. (Figure 60.9)

60.4 Conservation Strategies

- Habitat conservation strategies commonly target megadiversity countries, countries with the largest number of species; biodiversity hot spots, areas with the largest number of endemic species, those unique to the area; and representative habitats, areas that represent the major habitats. (Figures 60.10, 60.11, Table 60.3)
- Conservation biologists employ many strategies in protecting biodiversity. Principles of the equilibrium model of island biogeography and landscape ecology are used in the theory and practice of park reserve design to determine, for example, whether the park should take the form of one single or several small reserves. (Figures 60.12, 60.13)
- Economic considerations also play an important role in reserve creation, and it has been shown that conservation spending is positively related to population size. (Figure 60.14)
- The single-species approach focuses conservation efforts on indicator species, umbrella species, flagship species, and keystone species. Indicator species are species whose status can provide information on the overall health of an ecosystem. Umbrella species are species whose habitat requirements are so large that preserving them would also preserve many other species. Flagship species are usually charismatic or instantly recognizable species. Keystone species have an effect out of proportion to their abundance. (Figures 60.15, 60.16)
- Restoration ecology seeks to repair or replace populations and their habitats. Three basic approaches to habitat restoration

are complete restoration, rehabilitation, and ecosystem replacement. (Figure 60.17)

- Captive breeding is the propagation of animals outside their natural habitat. Several programs have illustrated the success of captive breeding and reintroduction to the wild, including those for California condors. (Figure 60.18)
- Cloning of endangered species has been accomplished on a very small scale and despite its limitations may have a role in conservation biology. (Figure 60.19)

Assess and Discuss

Test Yourself

1. Which of the following statements best describes an endangered species?
   a. a species that is likely to become extinct in a portion of its range
   b. a species that has disappeared in a particular community but is present in other natural environments
   c. a species that is extinct
   d. a species that is in danger of becoming extinct throughout all or a significant portion of its range
   e. both b and d
2. Biological diversity is important and should be preserved because
   a. food, medicines, and industrial products are all benefits of biodiversity.
   b. ecosystems provide valuable services to us in many ways.
   c. many species can be used as valuable research tools.
   d. we have an ethical responsibility to protect our environment.
   e. all of the above are correct.
3. The research conducted by Tilman and colleagues demonstrated that
   a. as diversity increases, productivity increases.
   b. as diversity decreases, productivity increases.
   c. areas with higher diversity demonstrate less efficient use of nutrients.
   d. species-richness increases lead to an increase in invasive species.
   e. increased diversity results in increased susceptibility to disease.
4. Approximately what percentage of genetic variation remains in a population of 25 individuals after three generations?
   a. 98 c. 94 e. 84
   b. 96 d. 92
5. What is the effective population size of an island population of parrots of 30 males and 30 females, where only 10 of the males breed?
   a. 10 c. 30 e. 60
   b. 20 d. 40
6. Saving endangered habitats, such as the Argentine pampas, focuses on
   a. saving genetic diversity.
   b. saving keystone species.
   c. conservation in a megadiversity country.
   d. preserving an area rich in endemic species.
   e. preservation of a representative habitat.
7. Geographic hotspots are those areas rich in
   a. species. d. biodiversity.
   b. habitats. e. endemic species.
   c. rare species.
8. A new canine distemper pathogen that decimates a population of black-footed ferrets is known as a(n):
   a. keystone species. d. umbrella species.
   b. dominant species. e. flagship species.
   c. indicator species.
9. Small strips of land that connect and allow organisms to move between small patches of natural habitat are called
   a. biological conduits. d. migration pathways.
   b. edge effects. e. landscape breaks.
   c. movement corridors.
10. Bioremediation is
    a. a process that restores a disturbed habitat to its original state.
    b. a process that uses microbes or plants to detoxify contaminated habitats.
    c. the legislation requiring rehabilitation of a disturbed habitat.
    d. a process of capturing all of the living individuals of a species for breeding purposes.
    e. the process of removing tissue from a dead organism in the hopes of cloning it.

Conceptual Questions

1. What are the three levels at which biodiversity can be examined?
2. Which types of species are most vulnerable to extinction?
3. Distinguish between an umbrella species, a flagship species, and a keystone species.

Collaborative Questions

1. Discuss several causes of species extinction.
2. You are called upon to design a park to maximize biodiversity in a tropical country. What are your recommendations?

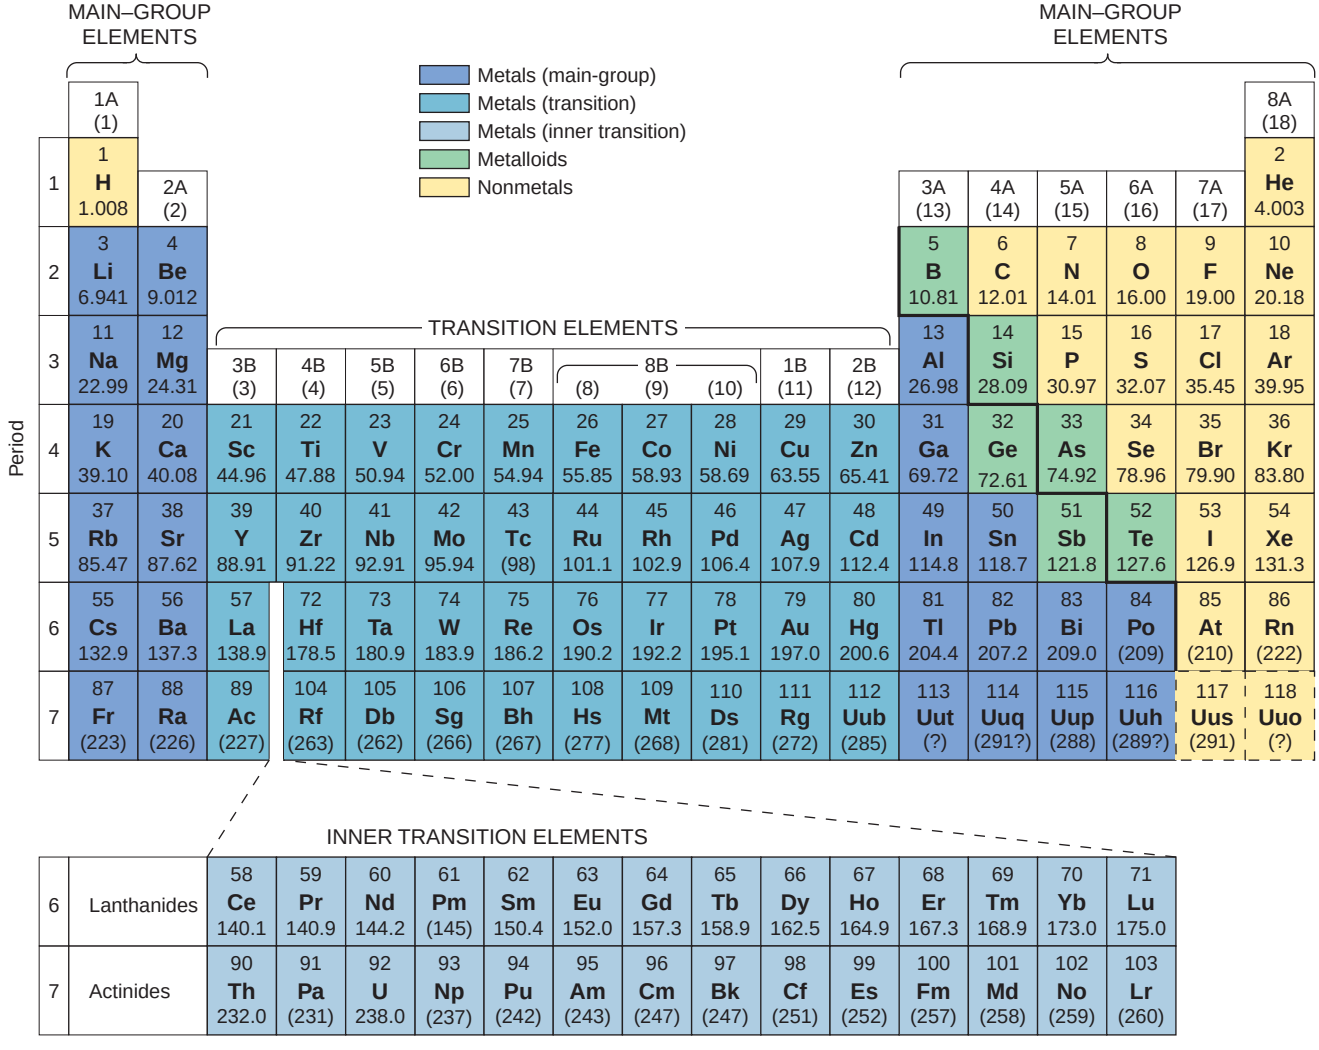
APPENDIX A

Periodic Table of the Elements



The complete Periodic Table of the Elements. Group numbers are different in some cases from those presented in Figure 2.5, because of the inclusion of transition elements. In some cases, the average atomic mass has been rounded to one or two decimal places, and in others only an estimate is given in parentheses due to the short-lived nature or rarity of those elements. The symbols and names of elements 112–118 are temporary until the chemical characteristics of these elements become better defined. Element 117 is currently not confirmed as a true element, and little is known about element 118. The International Union of Pure and Applied Chemistry (IUPAC) has recently proposed adopting the name copernicium (Cp) for element 112 in honor of scientist and astronomer Nicolaus Copernicus.

Appendix B

Answer Key

Answers to Collaborative Questions can be found on the website.

Chapter 1

Concept Checks

Figure 1.4 It benefits humans in many different ways. Discoveries in biology are important in the fields of medicine, research, agriculture, biotechnology, and many other disciplines. Most of the medicines we take were developed by biologists.

Figure 1.6 It would be at the population level.

Figure 1.8 In monkeys, the tail has been modified to grasp onto things, such as tree branches. In skunks, the tail is modified with a bright stripe; the tail can stick up and act as a warning signal to potential predators. In cattle, the tail has long hairs and is used to swat insects. Many more examples are possible.

Figure 1.9 Natural selection is the process that causes evolution to happen.

Figure 1.11 A tree of life suggests that all living organisms evolved from a single ancestor by vertical evolution with mutation. A web of life assumes that both vertical evolution with mutation and horizontal gene transfer were important mechanisms in the evolution of new species.

Figure 1.13 Taxonomy helps us to appreciate the unity and diversity of life. Organisms that are closely related evolutionarily are placed in smaller groups.

Figure 1.14 The genome stores the information to make an organism's proteins. In and of itself, the genome is merely DNA. The traits of cells and organisms are largely determined by the structures and functions of the hundreds or thousands of different proteins they make.

Figure 1.17 Discovery-based science does not require a preconceived hypothesis in order to carry out an experiment.

Figure 1.18 A researcher can compare the results in the experimental group and control group to determine if a single variable is causing a particular outcome in the experimental group.

Figure 1.19 After the *CF* gene was identified by discovery-based science, researchers realized that the *CF* gene was similar to other genes that encoded proteins that were already known to be transporters. This provided an important clue that the *CF* gene also encodes a transporter protein.

Feature Investigation Questions

1. In discovery-based science, a researcher does not need to have a preconceived hypothesis. Experimentation is conducted in the hope that it may have practical applications or may provide new information that will lead to a hypothesis. By comparison, hypothesis testing occurs when a researcher forms a hypothesis that makes certain predictions. Experiments are conducted to see if those predictions are correct. In this way, the hypothesis may be accepted or rejected.
2. This strategy may be described as a five-stage process:
    1. Observations are made regarding natural phenomena.
    2. These observations lead to a hypothesis that tries to explain the phenomena. A useful hypothesis is one that is testable because it makes specific predictions.
    3. Experimentation is conducted to determine if the predictions are correct.
    4. The data from the experiment are analyzed.
    5. The hypothesis is accepted or rejected.
3. In an ideal experiment, the control and experimental groups differ by only one factor. Biologists apply statistical analyses to their data to determine if the control and experimental groups are likely to be different from each other because of the single variable that is different between the two groups. This provides an objective way to accept or reject a hypothesis.

Test Yourself

1. d 2. a 3. c 4. c 5. d 6. b 7. d 8. d 9. a 10. b

Conceptual Questions

1. Cells and organization—All living organisms consist of cells; organisms maintain an internal order that is separated from the environment.
    - Energy use and metabolism—All living organisms acquire energy from the environment and use that energy to maintain their internal order. An organism's chemical reactions are collectively known as metabolism.
    - Response to environmental changes—Living organisms respond to environmental changes. These responses are adaptations.
    - Regulation and homeostasis—Living organisms maintain relatively stable internal conditions, homeostasis.
    - Growth and development—Growth produces more or larger cells; development produces organisms with a defined set of characteristics.
    - Reproduction—To sustain life, organisms must produce others like themselves; the genetic material maintains continuity over the generations.
    - Biological evolution—Populations of organisms change over the course of many generations.
2. The unity among different species occurs because modern species have evolved from a group of related ancestors. Some of the traits in those ancestors are also found in modern species and thereby unites them. The diversity is due to the variety of environments on the Earth. Each species has evolved to occupy its own unique environment. For every species, many traits are evolutionary adaptations to survival in a specific environment. For this reason, evolution also promotes diversity.
3. Domains and kingdoms are very diverse, being composed of hundreds of thousands or even millions of different species. The least-diverse groups are genera and species. A species is composed of just one type of organism, and a genus is typically composed of several or several dozen different species, though some genera are quite large.

Chapter 2

Concept Checks

Figure 2.4 An energy shell is a region outside the nucleus of an atom occupied by electrons of a given energy level. More than one orbital can be found within an electron shell. An orbital may be spherical or dumbbell-shaped and contains up to two electrons.

Figure 2.9 The octet rule states that atoms are stable when they have eight electrons in their outermost shell. Oxygen has six electrons in its outer shell. When two oxygen atoms share two pairs of electrons, each atom has eight electrons in its outer shell, at least part of the time.

Figure 2.11 Strand separation requires energy, because the DNA strands are held together by a large number of hydrogen bonds. Although each hydrogen bond is weak, collectively the vast number of such bonds in a molecule of DNA adds up to a considerable strength.

Figure 2.17 The oil would be in the center of the soap micelles.

Figure 2.19 Due to the colligative properties of water, the solutes in blood lower its freezing point. Human blood, for example, freezes at a temperature that is about half a degree Celsius lower than that of pure water.

Figure 2.21 It is 10^{-6} M. Because $[H^+][OH^-]$ always equals 10^{-14} M, if $[H^+] = 10^{-8}$ M (i.e., pH 8.0), then $[OH^-]$ must be 10^{-6} M.

Feature Investigation Questions

1. Scientists were aware that atoms contained charged particles. Many believed that the positive charges and mass were evenly distributed throughout the atom.
2. Rutherford was testing the hypothesis that atoms are composed of positive charges evenly distributed throughout the atom. Based on this model of the structure of the atom, alpha particles, which are positively charged nuclei of helium atoms, should be deflected as they pass through the foil, due to the presence of positive charges spread throughout the gold foil.
3. Instead of detecting slight deflection of most alpha particles as they passed through the gold foil, the majority, 98%, of the alpha particles passed directly through the gold foil without deflection. A much smaller percentage either deflected or bounced back from the gold foil. Rutherford suggested that since most of the alpha particles passed unimpeded through the gold foil, most of the volume of atoms is empty space. Rutherford also proposed that the bouncing back of some of the alpha particles indicated that most of the positively charged particles were concentrated in a compact area. These results were counter to the hypothesized model.

Test Yourself

1. b 2. b 3. b 4. d 5. e 6. e 7. e 8. c 9. e 10. b

Conceptual Questions

1. Covalent bonds are bonds in which atoms share electrons. A hydrogen bond is a weak polar covalent bond that forms when a hydrogen atom from one polar molecule becomes electrically attracted to an electronegative atom. A nonpolar covalent bond is one between two atoms of similar electronegativities, such as two carbon atoms. The van der Waal forces are temporary, weak bonds, resulting from random electrical forces generated by the changing distributions of electrons in the outer shells of nearby atoms. The strong attraction between two oppositely charged atoms forms an ionic bond.
2. Hydrophobic: "Water-fearing"—molecules that are not attracted to water molecules. Hydrophilic: "Water-loving"—generally, ions and molecules that contain polar covalent bonds will dissolve in water and are said to be hydrophilic.
3. Within limits, bonds within molecules can rotate and thereby change the shape of a molecule. This is important because it is the shape of a molecule that determines, in part, the ability of that molecule to interact with other molecules. Also, when two molecules do interact through such forces as hydrogen bonds, the shape of one or both molecules may change as a consequence. The change in shape is often part of the mechanism by which signals are sent within and between cells.

Chapter 3

Concept Checks

Figure 3.1 Due to the fact that he had earlier purified urea from urine and then formed urea crystals, he already knew what urea crystals looked like. As seen in this figure, they are quite distinctive looking. Therefore, when he reacted ammonia and cyanic acid and got a compound that formed crystals, the distinctive look of the crystals made him realize that he had synthesized urea.

Figure 3.6 One reason is that the binding of a molecule to an enzyme depends on the spatial arrangements of the atoms in that molecule. Enantiomers have different spatial relationships that are mirror images of each other. Therefore, one may bind very tightly to an enzyme while the other may not be recognized at all.

Figure 3.7 Recall from Figure 3.5 that the reverse of a dehydration reaction is called a hydrolysis reaction, in which a molecule of water is added to the molecule being broken down, resulting in the formation of monomers.

Figure 3.11 Hydrogenation is adding hydrogens to double-bonded carbon atoms, changing them from unsaturated to saturated. This causes them to be solid at room temperature.

Figure 3.12 The phospholipids would be oriented such that their polar regions dissolved in the water layer and the nonpolar regions dissolved in the oil. Thus, the phospholipids would form a layer at the interface between the water and oil.

Figure 3.15 71; one less than the number of amino acids in the polypeptide

Figure 3.19 If the primary structure of Protein 1 were altered in some way, this would, in turn, most likely alter the secondary and tertiary structures of Protein 1. Therefore, it is possible that the precise fit between Proteins 1 and 2 would be lost and that the two proteins would lose the ability to interact.

Figure 3.24 Yes. The opposite strand must be the mirror image of the first strand, because pairs can form only between A and T, and G and C. For instance, if a portion of the first strand is AATGCA, the opposite strand along that region would be TTACGT.

Feature Investigation Questions

1. Many scientists assumed that protein folding was directed by some cellular factor, meaning some other molecule in the cytoplasm, and therefore, protein folding could not occur spontaneously. Others assumed that protein folding was determined somehow by the ribosome, because this organelle is primarily responsible for synthesizing proteins.
2. Anfinsen was testing the hypothesis that the information necessary for determining the three-dimensional shape of a protein is contained within the protein itself. In other words, the chemical characteristics of the amino acids that make up a protein will determine the three-dimensional shape.
3. The urea disrupts hydrogen bonds and ionic interactions that are necessary for protein folding. The mercaptoethanol disrupted the S—S bonds that also form between certain amino acids of the same polypeptide chains. Both substances essentially allow the polypeptide chain to unfold, disrupting the three-dimensional shape. Anfinsen removed the urea and mercaptoethanol from the protein solution by size-exclusion chromatography. After removing the urea and mercaptoethanol, Anfinsen discovered that the protein refolded into its proper three-dimensional shape and became functional again. This was important because the solution contained only the protein and lacked any other cellular material that could possibly assist in protein folding. This demonstrated that the protein could refold into the functional conformation.

Test Yourself

1. b 2. b 3. e 4. b 5. c 6. b 7. b 8. d 9. b 10. b

Conceptual Questions

1. Isomers are two structures with an identical molecular formula but with different structures and arrangements of atoms within the molecule. There are two major types of isomers: structural and stereoisomers. Because many chemical reactions in biology depend upon the actions of enzymes, which are often highly specific for the spatial arrangement of atoms in a molecule, one isomer of a pair may have biological functions, and the other may not.
2. a. Carbohydrates—energy storage and structural support
   b. Lipids—energy storage and components of cellular membranes
   c. Proteins—many functions, including enzymes, defense, transport, structure, contraction
   d. Nucleic acids—information storage, gene expression
3. Saturated fatty acids are saturated with hydrogen and have only single (C—C) bonds, whereas unsaturated fatty acids have one or more double (C═C) bonds. The double bonds in unsaturated fatty acids alters their shape, resulting in a kink in the structure. Saturated fatty acids are unkinked and are better able to stack tightly together. Fats containing saturated fatty acids have a higher melting point than those containing mostly unsaturated fatty acids; consequently, saturated fats tend to be solids at room temperatures, and unsaturated fatty acids are usually liquids at room temperature.

Chapter 4

Concept Checks

Figure 4.1 You would use transmission electron microscopy. The other methods do not have good enough resolution.

Figure 4.3 The primary advantage is that it gives an image of the 3-D surface of a material.

Figure 4.6 They have different proteomes.

Figure 4.7 Centrioles: Not found in plant cells; their role is not entirely clear, but they are found in the centrosome, which is where microtubules are anchored.

Chloroplasts: Not found in animal cells; function in photosynthesis.

Cell wall: Not found in animal cells; important in cell shape.

Figure 4.12 Both dynein and microtubules are anchored in place. Using ATP as a source of energy, dynein tugs on microtubules. Because the microtubules are anchored, they bend in response to the force exerted by dynein.

Figure 4.15 The nuclear lamina organizes the nuclear envelope and also helps to organize/anchor the chromosomes. The nuclear matrix is inside the nucleus and helps to organize the chromosomes into chromosome territories.

Figure 4.18 The protein begins its synthesis in the cytosol and then is further synthesized into the ER. It travels via vesicles to the *cis*-, *medial*-, and *trans*-Golgi and then is secreted.

Figure 4.22 Of these three choices, membrane transport is probably the most important because it regulates which molecules can enter the cell and participate in metabolism and which products of metabolism are exported from the cell. Cell signaling may affect metabolism, but its overall effect is probably less important than membrane transport.

Figure 4.24 It increases the surface area where ATP synthesis takes place and thereby makes it possible to increase the amount of ATP synthesis.

Figure 4.27 Bacteria and mitochondria are similar in size; they both have circular chromosomes; they both divide by binary fission; and they both make ATP. Bacterial chromosomes are larger, and they make all of their cellular proteins. Mitochondria chromosomes are smaller, and they import most of their proteins from the cytosol.

Figure 4.29 The signal sequence of an ER protein is recognized by SRP, which halts translation. The emerging protein and its ribosome are then transferred to the ER membrane, where translation resumes.

Figure 4.31 If chaperone proteins were not found in the cytosol, the mitochondrial matrix protein would start to fold, which might prevent it from being able to pass through the channel in the outer and inner mitochondrial membrane. Normally, a protein is threaded through this channel in an unfolded state.

Feature Investigation Questions

1. In a pulse-chase experiment, radioactive material is provided to cells. This is referred to as the pulse, or single administration of the radioactive material to the cells. After a few minutes, a large amount of nonradioactive material is provided to the cells to remove or "chase away" any of the remaining radioactive material.

   The researchers were attempting to determine the movement of proteins through the different compartments of a cell. Radioactive amino acids were used to label the proteins and enable the researchers to visualize where the proteins were at different times.
2. Pancreatic cells produce large numbers of proteins that are secreted from the cell. The number and final location of the proteins would allow the researchers an ideal system for studying protein movement through the cell.
3. Using electron microscopy, the researchers found that the proteins, indicated by radioactivity, were first found in the endoplasmic reticulum of the cells. Later the radioactivity moved to the Golgi and then into vesicles near the plasma membrane.

   The researchers were able to conclude that secreted proteins moved through several cellular compartments before they were secreted from the cell. Also, the movement of proteins through these compartments was not random but followed a particular pathway: ER, Golgi, secretory vesicles, plasma membrane, and, finally, secreted.

Test Yourself

1. d 2. d 3. b 4. c 5. e 6. a 7. e 8. e 9. a It would go there first, because targeting to the ER occurs cotranslationally. 10. c It is true they carry out metabolism, but so do eukaryotic cells.

Conceptual Questions

1. There are a lot of possibilities. The interactions between a motor protein (dynein) and cytoskeletal filaments (microtubules) cause a flagellum to bend. The interaction between v-snares and t-snares causes a vesicle to fuse with the correct target membrane.
2. If the motor is bound to a cargo and the motor can walk along a filament that is fixed in place, this will cause the movement of the cargo when the motor is activated. If the motor is fixed in place and the filament is free to move, this will cause the filament to move when the motor is activated. If both the motor and filament are fixed in place, the activation of the motor will cause the filament to bend.
3. The Golgi apparatus performs three overlapping functions: (1) processing of proteins and lipids, (2) protein sorting, and (3) secretion.

Chapter 5

Concept Checks

Figure 5.3 More double bonds and shorter fatty acyl tails make the membrane more fluid. Changing the cholesterol concentration can also affect fluidity, but that depends on the starting level of cholesterol. If cholesterol was at a level that maximized stability, increasing the cholesterol concentration would probably increase fluidity.

Figure 5.4 The low temperature prevents lateral diffusion of membrane proteins. Therefore, after fusion, all of the mouse proteins would stay on one side of the fused cell, and all of the human proteins would remain on the other.

Figure 5.6 In animal cells, the glycocalyx primarily plays a protective function. It protects proteins in the plasma membrane.

Figure 5.7 Probably not. The hydrophobic tails of both leaflets touch each other, so the heavy metal would probably show a single, thick dark line. Osmium tetroxide shows two parallel lines because it labels the polar head groups, which are separated by the hydrophobic interior of the membrane.

Figure 5.8 Lipids are transferred to the other leaflet of the ER via enzymes called flippases.

Figure 5.9 The most common way for a transmembrane segment to form is that it contains a stretch (about 20) of amino acids that mostly have hydrophobic (nonpolar) side chains.

Figure 5.12 Leucine would more readily cross a membrane because its side chain is nonpolar. The side chain of lysine is positively charged.

Figure 5.13 Although both of these molecules penetrate the bilayer fairly quickly, methanol has a polar —OH group and therefore crosses a bilayer more slowly than methane.

Figure 5.16 Water will move from outside to inside, from the hypotonic medium into the hypertonic medium.

Figure 5.18 Freshwater protists live in a hypotonic environment, which causes them to continually take in water. To avoid bursting, they use contractile vacuoles that regularly expel the water. Note that such protists lack a cell wall.

Figure 5.21 The purpose of gating is to regulate the function of channels.

Figure 5.25 The Na^+/K^+-ATPase could reach the point where the protein was covalently phosphorylated and Na^+ was released on the outside. At that stage, the reaction would stop, because it needs K^+ to proceed through the rest of the cycle.

Figure 5.26 The protein coat is needed for the membrane to bud from its site and form a vesicle.

Feature Investigation Questions

1. Most cells allow movement of water across the cell membrane by passive diffusion. However, it was noted that certain cell types had a much higher rate of water movement, indicating that something different was occurring in these cells.
2. The researchers identified water channels by characterizing proteins that are present in red blood cells and kidney cells but not other types of cells. Red blood cells and kidney cells have a faster rate of water movement across the membrane than other cell types. These cells are more likely to have water channels. By identifying proteins that are found in both of these types of cells but not in other cells, the researchers were identifying possible candidate proteins that function as water channels. In addition, CHIP28 had a structure that resembled other known channel proteins.

   Agre and his associates experimentally created multiple copies of the gene that produces the CHIP28 protein and then artificially transcribed

the genes to produce many mRNAs. The mRNAs were injected into frog oocytes where they could be translated to make the CHIP28 proteins. After altering the frog oocytes by introducing the CHIP28 mRNAs, they compared the rate of water transport in the altered oocytes versus normal frog oocytes. This procedure allowed them to introduce the candidate protein to a cell type that normally does not have the protein present.

3. After artificially introducing the candidate protein into the frog oocytes, the researchers found that the experimental oocytes took up water at a much faster rate in a hypotonic solution as compared to the control oocytes. The results indicated that the presence of the CHIP28 protein did increase water transport into cells.

Test Yourself

1. c 2. c 3. b 4. d 5. b 6. e 7. d 8. e 9. e 10. c

Conceptual Questions

1. See Figure 5.1 for the type of drawing you should have made. The membrane is considered a mosaic of lipid, protein, and carbohydrate molecules. The membrane exhibits properties that resemble a fluid because lipids and proteins can move relative to each other within the membrane.
2. Integral membrane proteins can contain transmembrane segments that cross the membrane, or they may contain lipid anchors. Peripheral membrane proteins are noncovalently bound to integral membrane proteins or to the polar heads of phospholipids.
3. A solute would touch the tails of the phospholipids in the process of diffusion. For facilitated diffusion and active transport, it would avoid touching the tails because it would be moving through a protein. For exocytosis and endocytosis, the membrane vesicles fuse with the plasma membrane, and the solute never really crosses through a membrane.

Chapter 6

Concept Checks

Figure 6.2 The solution of dissolved Na^+ and Cl^- has more entropy. A salt crystal is very ordered, whereas the ions in solution are much more disordered.

Figure 6.3 The negative ΔG value tells that the direction will proceed from reactants to products. It does not tell us anything about the rate.

Figure 6.4 It speeds up the rate. When the activation energy is lower, it takes less time for reactants to reach a transition state where a chemical reaction can occur. It does not affect the direction of a reaction.

Figure 6.5 The activation energy is lowered during the second step when the substrates undergo induced fit.

Figure 6.6 At a substrate concentration of 0.5 mM, enzyme A would have a higher velocity. Enzyme A would be very near its V_{max}, whereas enzyme B would be well below its V_{max}.

Figure 6.11 The oxidized form is NAD^+.

Figure 6.12 The breakdown of ADP would have an adverse effect. Usually, ATP is made by the covalent attachment of pre-existing phosphate and ADP. If there was insufficient ADP, a cell would have to make more ADP to make ATP. This would take a lot of energy.

Figure 6.13 The metabolic pathway would not be controlled by feedback inhibition. This may result in an overaccumulation of the product of the pathway.

Figure 6.15 Protein degradation eliminates proteins that are worn out, misfolded, or no longer needed by the cell. Such proteins could interfere with normal cell function. In addition, the recycling of amino acids saves the cell energy.

Feature Investigation Questions

1. RNase P has both a protein and RNA subunit. To determine which subunit has catalytic function, it was necessary to purify them individually and then see which one is able to cleave ptRNA.
2. The experimental strategy was to incubate RNase P or subunits of RNase P with ptRNA and then run a gel to determine if ptRNA had been cleaved to a mature tRNA and a 5′ fragment. The control without protein was to determine if the RNA alone could catalyze the cleavage. The control without RNA was to determine if some other factor in the experiment (e.g., Mg^{2+} or protein) was able to cleave the ptRNA.
3. The critical results occurred when the researchers incubated the purified RNA subunit at high Mg^{2+} concentrations with the ptRNA. Under these conditions, the ptRNA was cleaved. These results indicate that the RNA subunit has catalytic activity. A high Mg^{2+} concentration is needed to keep it catalytically active in the absence of a protein subunit.

Test Yourself

1. d 2. e 3. b 4. d 5. a 6. c 7. b 8. c 9. e 10. a

Conceptual Questions

1. Exergonic reactions are spontaneous. They proceed in a particular direction. An exergonic reaction could be slow or fast. By comparison, an endergonic reaction is not spontaneous. It will not proceed in a particular direction unless free energy is supplied. An endergonic reaction can be fast or slow.
2. During feedback inhibition, the product of a metabolic pathway binds to an allosteric site on an enzyme that acts earlier in the pathway. The product inhibits this enzyme and thereby prevents the overaccumulation of the product.
3. Recycling of amino acids and nucleotides is important because it conserves a great deal of energy. Cells don't have to remake these building blocks, which would require a large amount of energy. Eukaryotes primarily use the proteasome to recycle proteins.

Chapter 7

Concept Checks

Figure 7.1 Most of the NADH is oxidized to make ATP during oxidative phosphorylation.

Figure 7.2 The first phase is named the energy investment phase because some ATP is used up. The second phase is called the cleavage phase because a 6-carbon molecule is broken down into two 3-carbon molecules. The energy liberation phase is so named because NADH and ATP are made.

Figure 7.3 The molecules that donate phosphates are 1,3-bisphosphoglycerate and phosphoenolpyruvate.

Figure 7.5 For each acetyl group that is oxidized, the main products are 2 CO_2, 3 NADH, 1 $FADH_2$, and 1 GTP.

Figure 7.7 It is called cytochrome oxidase because it removes electrons from (oxidizes) cytochrome *c*. Another possible name would be oxygen reductase because it reduces oxygen.

Figure 7.9 No. The role of the electron transport chain is to make an H^+ electrochemical gradient. It is the H^+ electrochemical gradient that drives ATP synthase. If the H^+ electrochemical is made another way, such as by bacteriorhodopsin, the ATP synthase still makes ATP.

Figure 7.10 The gamma subunit turns clockwise, when viewed from the intermembrane space. The β subunit in the back right is in conformation 3 and the one on the left is in conformation 1.

Figure 7.12 Tumors often become hypoxic and therefore have trouble making ATP via oxidative phosphorylation. Being able to carry out a higher level of glycolysis, which doesn't require oxygen, allows them to make ATP even if they're hypoxic.

Figure 7.13 The advantage is that the cell can use the same enzymes to metabolize different kinds of organic molecules. This saves the cell energy because it is costly to make a lot of different enzymes, which are composed of proteins.

Figure 7.16 Depending on the species, almost any part of a plant may contain anthocyanins. They are most common in fruits, vegetables, and flowers, but they may also be found in stems and even in leaves. For example, the red color found in many leaves in the autumn is due, in part, to anthocyanins.

Figure 7.17 Animals that eat this plant and ingest atropine become very sick and may die. Any animal that eats deadly nightshade and survives would be unlikely to eat it a second time.

Figure 7.19 The advantage of making streptomycin is that it kills other bacterial species in the soil that might compete with *S. griseus* for the same resources.

Feature Investigation Questions

1. The researchers attached an actin filament to the γ subunit of ATP synthase. The actin filament was fluorescently labeled so the researchers could determine if the actin filament moved when viewed under the fluorescence microscope.
2. When functioning in the hydrolysis of ATP, the actin filament was seen to rotate. The actin filament was attached to the γ subunit of ATP synthase. The rotational movement of the filament was the result of the rotational movement of the enzyme. In the control experiment, no ATP was added to stimulate enzyme activity. In the absence of ATP, no movement was observed.
3. No, the observation of counterclockwise rotation is the opposite of what would be expected inside the mitochondria. During the experiment, the enzyme was not functioning in ATP synthesis but instead was running backwards and hydrolyzing ATP.

Test Yourself

1. a 2. d 3. b 4. b 5. b 6. d 7. d 8. b 9. e 10. e

Conceptual Questions

1. The purpose of the electron transport chain is to pump H^+ across the inner mitochondrial membrane to establish a H^+ electrochemical gradient. When the H^+ flows back across the membrane through ATP synthase, ATP is synthesized.
2. The movement of H^+ through the *c* subunits causes the γ subunit to rotate. As it rotates, it sequentially alters the conformation of the subunits, where ATP is made. This causes: (1) ADP and P_i to bind with moderate affinity, (2) ADP and P_i to bind very tightly such that ATP is made, and (3) ATP to be released.
3. There are two main reasons. First, NADH can be toxic at high levels because it haphazardly donates electrons and may generate free radicals. Second, the oxidation of NADH to NAD^+ is necessary to keep glycolysis running so that ATP can be made.

Chapter 8

Concept Checks

Figure 8.1 Both heterotrophs and autotrophs carry out cellular respiration.

Figure 8.3 The Calvin cycle can occur in the dark as long as there is sufficient CO_2, ATP, and NADPH.

Figure 8.4 Gamma rays have higher energy than radio waves.

Figure 8.5 To drop down to a lower orbital at a lower energy level, an electron could release energy in the form of heat, release energy in the form of light, or transfer energy to another electron by resonance energy transfer.

Figure 8.7 By having different pigment molecules, plants can absorb a wider range of wavelengths of light.

Figure 8.8 ATP and NADPH are made in the stroma. O_2 is made in the thylakoid lumen.

Figure 8.9 Noncyclic electron flow produces equal amounts of ATP and NADPH. However, plants usually need more ATP than NADPH. Cyclic photophosphorylation allows plants to make just ATP and thereby increases the relative amount of ATP.

Figure 8.10 Because these two proteins are homologous, this means that the genes that encode them were derived from the same ancestral gene. Therefore, the amino acid sequences of these two proteins are expected to be very similar, though not identical to each other. Because the amino acid sequence of a protein determines its structure, two proteins with similar amino acid sequences would be expected to have similar structures.

Figure 8.12 The answer is five. It catalyzes the following electron transfers.

1. H_2O to tyrosine (Tyr).
2. Tyr to P680.
3. P680 to pheophytin (Pp).
4. Pp to Q_A.
5. Q_A to Q_B.

Figure 8.13 No. The enhancement effect occurs because the flashes activate both photosystem II and photosystem I. Light at 700 nm is needed to activate P700 in photosystem I.

Figure 8.14 An electron has its highest amount of energy just after it has been boosted by light in PSI.

Figure 8.15 NADPH reduces organic molecules and makes them more able to form C—C and C—H bonds.

Figure 8.18 The arrangement of cells in C_4 plants makes the level of CO_2 high and the level of O_2 low in the bundle sheath cells.

Figure 8.19 When there is plenty of moisture and it is not too hot, C_3 plants are more efficient. However, under hot and dry conditions, C_4 and CAM plants have the advantage because they lose less water and avoid photorespiration.

Feature Investigation Questions

1. The researchers were attempting to determine the biochemical pathway of the process of carbohydrate synthesis in plants. The researchers wanted to identify different molecules produced in plants over time to determine the steps of the biochemical pathway.
2. The purpose for using ^{14}C was to label the different carbon molecules produced during the biochemical pathway. The researchers could "follow" the carbon molecules from CO_2 that were incorporated into the organic molecules during photosynthesis. The radioactive isotope provided the researchers with a method of labeling the different molecules.

   The purpose of the experiment was to determine the steps in the biochemical pathway of photosynthesis. By examining samples from different times after the introduction of the labeled carbon source, the researchers would be able to determine which molecules were produced first and, thus, products of the earlier steps of the pathway versus products of later steps of the pathway.

   The researchers used two-dimensional paper chromatography to separate the different molecules from each other. Afterwards, the different molecules were identified by different chemical methods. The text describes the method of comparing two-dimensional paper chromatography results of unknown molecules to known molecules and identifying the unknown with the known molecule it matched.
3. The researchers were able to determine the biochemical process that plants use to incorporate CO_2 into organic molecules. The researchers were able to identify the biochemical steps and the molecules produced at these steps in what is now called the Calvin cycle.

Test Yourself

1. c 2. c 3. c 4. a 5. b 6. b 7. c 8. b 9. e 10. c

Conceptual Questions

1. The two stages of photosynthesis are the light reactions and the Calvin cycle. The key products of the light reactions are ATP, NADPH, and O_2. The key product of the Calvin cycle is carbohydrate. The initial product is G3P, which is used to make sugars and other organic molecules.
2. NADPH is used during the reduction phase of the Calvin cycle. It donates its electrons to 1,3 BPG.
3. After one pigment molecule absorbs energy, resonance energy transfer allows that energy to be transferred among many pigment molecules, eventually reaching the reaction center. If resonance energy transfer did not occur, the light energy would have to be absorbed directly by the pigment in the reaction center, which is either P680 or P700. In contrast, the light-harvesting complex is composed of many pigment molecules of different types (chlorophylls and carotenoids), which can absorb light at different wavelengths and transfer that energy to the reaction center. The light-harvesting complex makes it easier for plants to absorb light energy.

Chapter 9

Concept Checks

Figure 9.1 It is glucose.

Figure 9.2 Auxin causes cells to elongate. Therefore, cells on the nonilluminated side grow faster, causing the plant to bend toward the light.

Figure 9.3 Endocrine signals are more likely to exist for a longer period of time. This is necessary because endocrine signals called hormones travel relatively long distances to reach their target cells. Therefore, the hormone must exist long enough to reach its target cells.

Figure 9.4 The effect of a signaling molecule is to cause a cellular response. Most signaling molecules do not enter the cell. Therefore, to exert an effect, they must alter the conformation of a receptor protein, which, in turn, stimulates an intracellular signal transduction pathway that leads to a cellular response.

Figure 9.6 Phosphorylation of a protein via a kinase involves ATP hydrolysis, which is an exergonic reaction. The energy from this reaction usually alters the conformation of the phosphorylated protein and thereby influences its function. Phosphorylation is used to regulate protein function.

Figure 9.7 The α subunit has to hydrolyze its GTP to GDP. This changes the conformation of the α subunit so that it can reassociate with the β/γ subunits.

Figure 9.10 The GTP-bound form of Ras is active and promotes cell division. To turn the pathway off, Ras hydrolyzes GTP to GDP. If this cannot occur due to a mutation, the pathway will be continuously on, and uncontrolled cell division will result.

Figure 9.12 The signal transduction pathway begins with the G protein and ends with protein kinase A being activated. The cellular response involves the phosphorylation of target proteins. The phosphorylation of target proteins will change their function in some way, which is how the cell is responding.

Figure 9.13 Depending on the protein involved, phosphorylation can activate or inhibit protein function. Phosphorylation of phosphorylase kinase and glycogen phosphorylase activates their function, whereas it inhibits glycogen synthase.

Figure 9.14 Signal amplification allows a single signaling molecule to affect many proteins within a cell and thereby amplify a cellular response.

Figure 9.20 The initiator caspase is part of the death-inducing signaling complex. It is directly activated when a cell receives a death signal. The initiator caspase then activates the executioner caspases, which degrade various cellular proteins and thereby cause the destruction of the cell.

Feature Investigation Questions

1. Compared to control rats, those injected with prednisolone alone would be expected to have a decrease in the number of cells because it suppresses ACTH synthesis. Therefore, apoptosis would be higher. By comparison, prednisolone + ACTH would have a normal number of cells because the addition of ACTH would compensate for effects of prednisolone. ACTH alone would be expected to have a greater number of cells; apoptosis would be inhibited.
2. Yes, when injected with ACTH, prednisolone probably inhibited the ability of the rats to make their own ACTH. Even so, they were given ACTH by injection, so they didn't need to make their own ACTH to prevent apoptosis.
3. The lowest level of apoptosis would occur in the ACTH alone group, because they could make their own ACTH plus they were given ACTH. With such high levels of ACTH, they probably had the lowest level of apoptosis; it was already known that ACTH promotes cell division.

Test Yourself

1. d 2. c 3. d 4. e 5. a 6. d 7. e 8. e 9. e 10. b

Conceptual Questions

1. Cells need to respond to a changing environment, and cells need to communicate with each other.
2. In the first stage, a signaling molecule binds to a receptor, causing receptor activation. In the second stage, one type of signal is transduced or converted to a different signal inside the cell. In the third stage, the cell responds in some way to the signal, possibly by altering the activity of enzymes, structural proteins, or transcription factors. When the estrogen receptor is activated, the second stage, signal transduction, is not needed because the estrogen receptor is an intracellular receptor that directly activates the transcription of genes to elicit a cellular response.
3. If apoptosis did not occur, embryonic development would not occur properly, and adults would not maintain a correct number of cells. Also, cells that are worn out, infected by viruses or intracellular bacteria, or have the potential to cause cancer, would not be eliminated. In mammals, the immune system would not function properly because apoptosis is needed to eliminate B and T cells that are ineffective or potentially damaging to the body.

Chapter 10

Concept Checks

Figure 10.1 The four functions of the ECM in animals are strength, structural support, organization, and cell signaling.

Figure 10.2 The extension sequences of procollagen prevent fibers from forming intracellularly.

Figure 10.3 The proteins would become more linear, and the fiber would come apart.

Figure 10.4 GAGs are highly negatively charged molecules that tend to attract positively charged ions and water. Their high water content gives GAGs a gel-like character, which makes them difficult to compress.

Figure 10.5 Because the secondary cell wall is usually rigid, it prevents cell growth. If it were made too soon, it might prevent a cell from attaining its proper size.

Figure 10.7 Adherens junctions and desmosomes are cell-to-cell junctions, whereas hemidesomosomes and focal adhesions are cell-to-ECM junctions.

Figure 10.9 Tight junctions in your skin prevent harmful things like toxins and viruses from entering your body. They also prevent materials like nutrients from leaking out of your body.

Figure 10.10 As opposed to the results shown in Figure 10.10, the dye would be in the side of the cell layer facing the intestinal tract. You would see dye up to the tight junction on this side of the cells, but not on the side of the tight junction facing the blood.

Figure 10.13 Middle lamellae are similar to anchoring junctions and desmosomes in that they all function in cell-to-cell adhesion. However, their structures are quite different. Middle lamellae are composed primarily of carbohydrates that involve linkages between negatively charged carbohydrates and divalent cations. By comparison, anchoring junctions and desmosomes hold cells together via proteins such as cadherins and integrins.

Figure 10.15 Connective tissue would have the most extensive ECM.

Figure 10.16 Dermal tissue would be found on the surfaces of leaves, stems, and roots.

Figure 10.19 Simple epithelium and epidermis are one cell layer thick, whereas stratified epithelium and periderm are several cell layers thick.

Figure 10.21 Both ground tissue in plants and connective tissue in animals are important in supporting the organism. These tissues have a large amount of ECM that provides structural support.

Feature Investigation Questions

1. The purpose of this study was to determine the sizes of molecules that can move through gap junctions from one cell to another.
2. The researchers used fluorescent dyes to visibly monitor the movement of material from one cell to an adjacent cell through the gap junctions. First, single layers of rat liver cells were cultured. Next, fluorescent dyes with molecules of various masses were injected into particular cells. The researchers then used fluorescence microscopy to determine whether or not the dyes were transferred from one cell to the next.
3. The researchers found that molecules of masses less than 1,000 daltons could pass through the gap junction channels. Molecules of masses larger than 1,000 daltons could not pass through the gap junctions. Further experimentation revealed variation in gap junction channel size of different cell types. However, the upper limit of the gap junction channel size was determined to usually be around 1,000 daltons.

Test Yourself

1. e 2. c 3. b 4. e 5. e 6. d 7. e 8. d 9. e 10. a

Conceptual Questions

1. The primary cell wall is synthesized first between the two newly made daughter cells. It is relatively thin and allows cells to expand and grow. The secondary cell wall is made in layers by the deposition of cellulose fibrils and other components. In many cell types, it is relatively thick.
2. Cadherins and integrins are both membrane proteins that function as cell adhesion molecules. They also can function in cell signaling. Cadherins bind one cell to another cell, whereas integrins bind a cell to

the extracellular matrix. Cadherins require calcium ions to function, but integrins do not.

3. To create tissues and organs, cells must undergo six basic processes that influence their shape, arrangement, and number:
   - Cell division—Many cells are needed to make tissues and organs. These arise via cell division.
   - Cell growth—After a cell divides, it needs to grow to reach its correct size.
   - Differentiation—Due to the expression of different genes, cells can differentiate into specialized cells based on what cells are needed at that particular time in the tissue or organ.
   - Migration—During embryonic development in animals, cells migrate to their appropriate position within the body. This event doesn't occur in plants.
   - Apoptosis—Apoptosis is also known as programmed cell death. During development, organs and tissues need to be shaped to form their correct structure. For example, during the development of fingers and toes, the cells between the digits must be removed. This cell removal is done through the process of apoptosis.
   - Cell connections—For tissues and organs to work properly, the cells must be held together in a specific arrangement. This is achieved through the different types of cell-to-cell connections.

Chapter 11

Concept Checks

Figure 11.1 Yes, they would be resistant to killing. These bacteria are derived from the type R bacteria, so they would have this trait. In addition, they have become type S because they obtained genetic material from the dead type S bacteria.

Figure 11.4 ^{35}S was used to label phage proteins, whereas ^{32}P was used to label phage DNA.

Figure 11.6 Cytosine is found in both DNA and RNA.

Figure 11.7 The phosphate is attached to the number 5′ carbon in a single nucleotide. In a DNA strand, it is attached to both the 5′ carbon and 3′ carbon.

Figure 11.8 A phosphoester bond is a single covalent bond between a phosphorus atom and an oxygen atom. A phosphodiester linkage involves two phosphoester bonds. This linkage occurs along the backbone of DNA and RNA strands.

Figure 11.10 Because it is antiparallel and obeys the AT/GC rule, it would be 3′–CTAAGCAAG–5′.

Figure 11.13 It would be 1/8 half-heavy and 7/8 light.

Figure 11.17 The oxygen in a new phosphoester bond comes from the sugar.

Figure 11.19 The lagging strand is made discontinuously in the direction opposite to the movement of the replication fork.

Figure 11.20 When primase is synthesizing a primer in the lagging strand, it moves from left to right in this figure. After it is done making a primer, it needs to hop to the opening of the replication fork to make a new primer. This movement is from right to left in this figure.

Figure 11.22 Telomerase uses a short strand of RNA as template to make the DNA repeat sequence.

Figure 11.25 Proteins hold the bottoms of the loops in place.

Figure 11.26 Proteins that compact the radial loop domains are primarily responsible for the X shape.

Feature Investigation Questions

1. Previous studies had indicated that mixing different strains could lead to transformation or the changing of a strain into a different one. Griffith had shown that mixing heat-killed type S with living type R would result in the transformation of the type R to type S. Though mutations could cause the changing of the identity of certain strains, the type R to type S transformation was not due to mutation but was more likely due to the transmission of a biochemical substance between the two strains. Griffith recognized this and referred to the biochemical substance as the "transformation principle." If Avery, MacCleod, and McCarty could determine the biochemical identity of this "transformation principle," they could identify the genetic material for this organism.
2. A DNA extract contains DNA that has been purified from a sample of cells.
3. The researchers could not verify that the DNA extract was completely pure and did not have small amounts of contaminating molecules, such as proteins and RNA. The researchers were able to treat the extract with enzymes to remove proteins (using protease), RNA (using RNase), or DNA (using DNase). Removing the proteins or RNA did not alter the transformation of the type R to type S strains. Only the enzymatic removal of DNA disrupted the transformation, indicating that DNA is the genetic material.

Test Yourself

1. a 2. b 3. d 4. d 5. b 6. c 7. b 8. d 9. d 10. c

Conceptual Questions

1. The genetic material must contain the information necessary to construct an entire organism. The genetic material must be accurately copied and transmitted from parent to offspring and from cell to cell during cell division in multicellular organisms. The genetic material must contain variation that can account for the known variation within each species and among different species.

   Griffith discovered something called the transformation principle, and his experiments showed the existence of biochemical genetic information. In addition, he showed that this genetic information can move from one individual to another of the same species. In his experiments, Griffith took heat-killed type S bacteria and mixed them with living type R bacteria and injected them into a live mouse, which died after the injection. By themselves, these two strains would not kill the mouse, but when they were put together, the genetic information from the heat-killed type S bacteria was transferred into the living type R bacteria, thus transforming the type R bacteria into type S.
2. In the case of the Hershey and Chase experiment, a radioactive isotope of sulfur was used to label the protein in the viral protein coat. The DNA was labeled using a radioactive isotope of phosphorus. This was an ideal way of labeling the different components, because sulfur is found in proteins but not DNA, and phosphorus is found in DNA but not proteins. By labeling the two candidate molecules with the radioactive isotopes, Hershey and Chase could determine the genetic material by seeing which isotope entered the bacterial cells.
3. Two long chains of nucleotides are coiled around a central axis forming a helix. The two chains run in opposite directions or are antiparallel. Hydrogen bonds between the bases in opposite strands stabilize the structure. Adenine always pairs with thymine, and cytosine always pairs with guanine. The width of the double helix is relatively constant. One complete turn of the double helix is composed of 10 base pairs.

Chapter 12

Concept Checks

Figure 12.1 A person with two defective copies of phenylalanine hydroxylase would have phenylketonuria.

Figure 12.2 The ability to convert ornithine into citrulline is missing.

Figure 12.3 The usual direction of flow of genetic information is from DNA to RNA to protein, though exceptions occur.

Figure 12.4 If a terminator was removed, transcription would occur beyond the normal stopping point. Eventually, RNA polymerase would encounter a terminator from an adjacent gene, and transcription would end.

Figure 12.10 The ends of structural genes do not have a poly T region that acts as a template for the synthesis of a poly A tail. Instead, the poly A tail is added after the pre-mRNA is made by an enzyme that attaches many adenine nucleotides in a row.

Figure 12.11 A structural gene would still be transcribed into RNA if the start codon was missing. However, it would not be translated properly into a polypeptide.

Figure 12.12 It would bind to a 5′–UGG–3′codon, and it would carry tryptophan.

Figure 12.14 The function of the anticodon in tRNA is to recognize a codon in an mRNA.

Figure 12.15 The attachment of an amino acid to a tRNA is an endergonic reaction. ATP provides the energy to catalyze this reaction.

Figure 12.17 Each mammal is closely related to the other mammals, and *E. coli* and *S. marcescens* are also closely related. The mammals are relatively distantly related to the bacterial species.

Figure 12.19 A region near the 5′ end of the mRNA is complementary to a region of rRNA in the small subunit. These complementary regions hydrogen-bond with each other to promote the binding of the mRNA to the small ribosomal subunit.

Feature Investigation Questions

1. A triplet mimics mRNA because it can cause a specific tRNA to bind to the ribosome. This was useful to Nirenberg and Leder because it allowed them to correlate the binding of a tRNA carrying a specific amino acid with a triplet sequence.
2. The researchers were attempting to match codons with appropriate amino acids. By labeling one amino acid in each of the 20 tubes for each codon, the researchers were able to identify the correct relationship by detecting which tube resulted in radioactivity on the filter.
3. The AUG triplet would have shown radioactivity in the methionine test tube. Even though AUG acts as the start codon, it also codes for the amino acid methionine. The other three codons act as stop codons and do not code for an amino acid. In these cases, the researchers would not have found radioactivity trapped on filters.

Test Yourself

1. b 2. d 3. d 4. b 5. c 6. e 7. d 8. d 9. d 10. b

Conceptual Questions

1. Beadle and Tatum had the insight from their studies that a single gene controlled the synthesis of a single enzyme. In later years, it became apparent that genes code for all proteins and that some proteins consist of more than one polypeptide chain. So the modern statement is one gene codes for each polypeptide.

   Confirmation of their hypothesis came from studies involving arginine biosynthesis. Biochemists had already established that particular enzymes are involved in a pathway to produce arginine. Intermediates in this pathway are ornithine and citrulline. Mutants in single genes disrupted the ability of cells to catalyze just one reaction in this pathway, thereby suggesting that a single gene encodes a single enzyme.
2. Each of these 20 enzymes catalyzes the attachment of a specific amino acid to a specific tRNA molecule.
3. It would be complementary to the 5′–CCA–3′ codon. This tRNA should carry proline.

Chapter 13

Concept Checks

Figure 13.1 The advantage is energy savings. The bacterium saves energy by making these proteins only when they are needed for lactose uptake and breakdown.

Figure 13.2 Gene regulation causes each cell type to express its own unique set of proteins, which, in turn, are largely responsible for the morphologies and functions of cells.

Figure 13.3 The embryonic and fetal forms of hemoglobin have a higher affinity for oxygen. This allows the embryo and fetus to obtain oxygen from their mother's bloodstream.

Figure 13.6 The *lacZ, lacY,* and *lacA* genes are under the control of the *lac* promoter.

Figure 13.7 Negative control refers to the action of a repressor protein, which inhibits transcription when it binds to the DNA. Inducible refers to the action of a small effector molecule. When it is present, it promotes transcription.

Figure 13.11 In this case, the repressor keeps the *lac* operon turned off unless lactose is present in the environment. The activator allows the bacterium to choose between glucose and lactose.

Figure 13.12 Both proteins are similar in that they repress transcription. They prevent RNA polymerase from transcribing the operons. They are different with regard to the effects of their small effector molecules. For the lac repressor, the binding of allolactose causes a conformational change that prevents the repressor from binding to its operator site. In contrast, the binding of tryptophan to the trp repressor allows it to bind to its operator site. Another difference is that the lac repressor binds to the DNA sequence found in the *lac* operator site, whereas the trp repressor recognizes a different DNA sequence that is found in the *trp* operator site.

Figure 13.16 When an activator interacts with mediator, it causes RNA polymerase to proceed to the elongation phase of transcription.

Figure 13.17 The common state of euchromatin, the 30-nm fiber, is too compact to be transcribed. This level of compaction must be loosened up so that transcription can occur.

Figure 13.18 Some histone modifications may promote a loosening of chromatin structure, whereas others cause the chromatin to become more compact.

Figure 13.19 The gene could not be activated in the presence of glucocorticoid hormone.

Figure 13.20 The advantage of alternative splicing is that it allows a single gene to encode two or more polypeptides. This enables organisms to have smaller genomes, which is more efficient and easier to package into a cell.

Figure 13.22 When iron levels rise in the cell, the iron binds to IRP and removes it from the mRNA that encodes ferritin. This results in the rapid translation of ferritin protein, which can store excess iron. Unfortunately, ferritin storage does have limits, so iron poisoning can occur if too much is ingested.

Feature Investigation Questions

1. The first observation was the identification of rare bacterial strains that had constitutive expression of the *lac* operon. Normally, the genes are expressed only when lactose is present. These mutant strains expressed the genes all the time. The researchers also observed that some of these strains had mutations in the *lacI* gene. These two observations were key to the development of hypotheses explaining the relationship between the *lacI* gene and the regulation of the *lac* operon.
2. The correct hypothesis is that the *lacI* gene encodes a repressor protein that inhibits the operon.
3. The researchers used an F′ factor to introduce the wild-type *lacI* gene into the cell. In this case, the cells that contained the F′ factor had both a mutant copy of the gene and a normal copy of the gene. By creating a merozygote with an F′ factor with a normal copy of the *lacI* gene, regulation of the *lac* operon was restored. The researchers concluded that the normal *lacI* gene produced adequate amounts of a diffusible protein that could interact with the operator on the chromosomal DNA as well as the F′ factor DNA and regulate transcription.

Test Yourself

1. d 2. b 3. c 4. c 5. c 6. d 7. c 8. c 9. d 10. c

Conceptual Questions

1. In an inducible operon, the presence of a small effector molecule causes transcription to occur. In repressible operons, a small effector molecule inhibits transcription. The effects of these small molecules are mediated through regulatory proteins that bind to the DNA. Repressible operons usually encode anabolic enzymes, and inducible operons encode catabolic enzymes.
2. a. regulatory protein; b. small effector molecule; c. segment of DNA; d. small effector molecule; and e. regulatory protein
3. The addition of methyl groups to CpG islands, especially near the promoters of eukaryotic genes, may prevent an activator from binding to an enhancer element or may convert chromatin from an open to a closed conformation.

Chapter 14

Concept Checks

Figure 14.1 At neutral pH, glutamic acid is negatively charged. Perhaps the negative charges repel each other and prevent hemoglobin proteins from aggregating into fiber-like structures.

Figure 14.3 Only germ-line cells give rise to gametes (sperm or egg cells). A somatic cell cannot give rise to a gamete and therefore cannot be passed to offspring.

Figure 14.4 This is a mutation in a somatic cell, so it cannot be transmitted to an offspring.

Figure 14.6 A thymine dimer is harmful because it can cause errors in DNA replication.

Figure 14.7 If we divide 44 by 2 million, the rate is 2.2×10^{-5}.

Figure 14.8 UvrC and UvrD are responsible for removing the damaged DNA. UvrC makes cuts on both sides of the damage, and then UvrD removes the damaged region.

Figure 14.9 The sun has UV rays and other harmful radiation that could damage the DNA. This person has a defect in the nucleotide excision repair pathway. Therefore, his DNA is more likely to suffer mutations, which cause growths on the skin.

Figure 14.11 Growth factors turn on a signaling pathway that ultimately leads to cell division.

Figure 14.14 The type of cancer associated with this fusion is leukemia, which is a cancer of blood cells. The gene fusion produces a chimeric gene that is expressed in blood cells because it has the *bcr* promoter. The abnormal fusion protein promotes cancer in these cells.

Figure 14.15 Checkpoints prevent cell division if a genetic abnormality is detected. This helps to properly maintain the genome, thereby minimizing the possibility that a cell harboring a mutation will divide to produce two daughter cells.

Figure 14.16 Cancer would not occur if both copies of the *Rb* gene and both copies of the *E2F* gene were rendered inactive due to mutations. An active copy of the *E2F* gene is needed to promote cell division.

Figure 14.18 Translocations could create oncogenes as in the *bcr/abl* fusion example found in the Philadelphia chromosome. Chromosome loss could result in the loss of tumor suppressor genes. Increases in chromosome number could contribute to cancer if the extra chromosomes carry proto-oncogenes.

Feature Investigation Questions

1. Some individuals believed that heritable traits may be altered by physiological events. This suggests that mutations may be stimulated by certain needs of the organism. Others believed that mutations were random. If a mutation had a beneficial effect that improved survival and/reproductive success, these mutations would be maintained in the population through natural selection.
2. The Lederbergs were testing the hypothesis that mutations are random events. By subjecting the bacteria to some type of environmental stress, the bacteriophage, the researchers would be able to see if the stress induced mutations or if mutations occurred randomly.
3. When looking at the number and location of colonies that were resistant to viral infection, the pattern was consistent among the secondary plates. This indicates that the mutation that allowed the colonies to be resistant to viral infection occurred on the master plate. The secondary plates introduced the selective agent that allowed the resistant bacteria colonies to survive and reproduce while the other colonies were destroyed. Thus, mutations occurred randomly in the absence of any selective agent.

Test Yourself

1. c 2. d 3. d 4. e 5. d 6. b 7. b 8. b 9. c 10. e

Conceptual Questions

1. Random mutations are more likely to be harmful than beneficial. The genes within each species have evolved to work properly. They have functional promoters, coding sequences, terminators, and so on, that allow the genes to be expressed. Mutations are more likely to disrupt these sequences. For example, mutations within the coding sequence may produce early stop codons, frameshift mutations, and missense mutations that result in a nonfunctional polypeptide. On rare occasions, however, mutations are beneficial; they may produce a gene that is expressed better than the original gene or produce a polypeptide that functions better.
2. A spontaneous mutation originates within a living cell. It may be due to spontaneous changes in nucleotide structure, errors in DNA replication, or products of normal metabolism that may alter the structure of DNA. The causes of induced mutations originate from outside the cell. They may be physical agents, such as UV light or X-rays, or chemicals that act as mutagens. Both spontaneous and induced mutations may cause a harmful phenotype such as a cancer. In many cases, induced mutations are avoidable if the individual can prevent exposure to the environmental agent that acts as a mutagen.
3. The effects of mutations are cumulative. If one mutation occurs in a cell, this mutation will be passed to the daughter cells. If a mutation occurs in the daughter cell, now there will be two mutations. These two mutations will be passed to the next generation of daughter cells, and so forth. The accumulation of many mutations eventually kills the cells. That is why mutagens are more effective at killing dividing cells compared to nondividing cells. It is because the number of mutations accumulates to a lethal level.

   There are two main side effects to this treatment. First, some normal (noncancerous) cells of the body, particularly skin cells and intestinal cells, are actively dividing. These cells are also killed by chemotherapy and radiation therapy. Second, it is possible that the therapy may produce mutations that will cause noncancerous cells to become cancerous. For these reasons, there is a maximal dose of chemotherapy or radiation therapy that is recommended.

Chapter 15

Concept Checks

Figure 15.1 Chromosomes are readily seen when they are compacted in a dividing cell. By adding such a drug, you increase the percentage of cells that are actively dividing.

Figure 15.2 Interphase consists of the G_1, S, and G_2 phases of the cell cycle.

Figure 15.3 You would find 92 chromatids in a human cell at metaphase. These are attached to form 46 pairs of sister chromatids.

Figure 15.4 Checkpoint proteins monitor conditions and prevent cell division if the conditions are not appropriate. They also sense if there is DNA damage, incompletely replicated chromosomes, and chromosomes not attached to the spindle. If such abnormalities are detected, cell division is halted. This maintains the integrity of the genome.

Figure 15.7 As shown in the inset, each object is a pair of sister chromatids.

Figure 15.8 The astral microtubules, which extend away from the chromosomes, are important for positioning the spindle apparatus within the cell. The polar microtubules project into the region between the two poles. Polar microtubules that overlap with each other play a role in the separation of the two poles. Kinetochore microtubules are attached to kinetochores at the centromeres and are needed to sort the chromosomes.

Figure 15.9 The mother cell (in G_1 phase) and the daughter cells have the same chromosome composition. They are genetically identical.

Figure 15.10 Micrographs showing cytokinesis in animal and plant cells.

Cytokinesis in both animal and plant cells separates a mother cell into two daughter cells. In animal cells, cytokinesis involves the formation of a cleavage furrow, which constricts like a drawstring to separate the cells. In plants, the two daughter cells are separated by the formation of a cell plate, which forms a cell wall between the two daughter cells.

Figure 15.14 The mother cell is diploid with two sets of chromosomes, whereas the four resulting cells are haploid with one set of chromosomes.

Figure 15.15 The reason for meiosis in animals is to produce gametes. These gametes combine during fertilization to produce a diploid organism. Following fertilization, the purpose of mitosis is to produce a multicellular organism.

Figure 15.17 Inversions and the translocations shown here do not affect the total amount of genetic material.

Feature Investigation Questions

1. Researchers had demonstrated that the binding of progesterone to receptors in oocytes caused the cells to progress from the G_2 phase of the cell cycle to mitosis. It appeared that progesterone acted as a signaling molecule for the progression through the cell cycle.
2. The researchers proposed that progesterone acted as a signaling molecule that led to the synthesis of molecules that cause the cell to progress through the cell cycle. These changes led to the maturation of the oocyte.

   To test their hypothesis, donor eggs were exposed to progesterone for either 2 or 12 hours. Control donor oocytes were not exposed to

progesterone. Cytosol from each treatment was then transferred to recipient oocytes. The researchers recorded whether or not the recipient oocytes underwent maturation.

3. The oocytes that were exposed to the progesterone for only 2 hours did not induce maturation in the recipient oocytes, whereas the oocytes that were exposed to progesterone for 12 hours did induce maturation in the recipient oocytes. The researchers suggested that a time span greater than 2 hours is needed to accumulate the proteins that are necessary to promote maturation.

Test Yourself

1. b 2. e 3. b 4. e 5. c 6. a 7. c 8. d 9. b 10. c

Conceptual Questions

1. In diploid species, chromosomes are present in pairs, one from each parent, and contain similar gene arrangements. Such chromosomes are homologous. When DNA is replicated, two identical copies are created, and these are sister chromatids.
2. There are four copies. A karyotype shows homologous chromosomes that come in pairs. Each member of the pair has replicated to form a pair of sister chromatids. Therefore, four copies of each gene are present. See the inset to Figure 15.1.
3. Two cells would have five chromosomes (one copy of each chromosome plus an extra copy of chromosome 3), and the other two cells would have only three chromosomes because they would be missing a chromosome (chromosome 3).

Chapter 16

Concept Checks

Figure 16.2 Having blue eyes is a variant (also called a trait). A character is a more general term, which in this case would refer to eye color.

Figure 16.4 In this procedure, stamens are removed from the purple flower to prevent self-fertilization.

Figure 16.5 The reason why offspring of the F_1 generation exhibit only one variant of each character is because one trait is dominant over the other.

Figure 16.6 The ratio of alleles (*T* to *t*) is 1:1. The reason why the phenotypic ratio is 3:1 is because *T* is dominant to *t*.

Figure 16.7 It was *Pp*. To produce white offspring, which are *pp,* the original plant had to have at least one copy of the *p* allele. Because it had purple flowers, it also had to have one copy of the *P* allele. So, its genotype must be *Pp.*

Figure 16.8 If the linked hypothesis had been correct, the ratio would have been 3 round, yellow : 1 wrinkled, green.

Figure 16.10 The word segregate means that alleles are separated into different places. In this case, the alleles are segregated into different cells during the process of meiosis. Alleles are located on chromosomes. A diploid cell has two copies of each allele. During meiosis, a diploid cell divides twice to produce four haploid cells that each have only one copy of an allele.

Figure 16.11 There would be four possible ways of aligning the chromosomes, and eight different types of gametes (*ABC*, *abc*, *ABc*, *abC*, *Abc*, *aBC*, *AbC*, *aBc*) could be produced.

Figure 16.12 No. If two parents are affected with the disease, they must be homozygous for the mutant allele if it's recessive. Two homozygous parents would have to produce all affected offspring. If they don't, then the inheritance pattern is not recessive.

Figure 16.13 When all affected offspring have at least one affected parent, this suggests a dominant pattern of inheritance.

Figure 16.14 The person would be a female. In mammals, the presence of the Y chromosome causes maleness. Therefore, without a Y chromosome, a person with a single X chromosome would develop into a female.

Figure 16.18 The mother is *Bb,* and the father is *bb.* Both of these parents would not be bald. The son is *Bb* and is bald because *B* is dominant in males.

Figure 16.19 No. You need a genetically homogenous population to study the norm of reaction. A wild population of squirrels is not genetically homogenous, so it could not be used.

Feature Investigation Questions

1. Morgan was testing the hypothesis of use and disuse. This hypothesis suggests that if a structure is not used, over time, it will diminish and/or disappear. In Morgan's experiments, originally he was testing to see if flies reared in the dark would lose some level of eye development.
2. When the F_1 individuals were crossed, only male F_2 offspring expressed the white eye color. At this time, Morgan was aware of sex chromosome differences between male and female flies. He realized that since males only possess one copy of X-linked genes, this would explain why only F_2 males exhibited the recessive trait.
3. In a cross between a white-eyed male and a female that is heterozygous for the white and red alleles, 1/2 of the female offspring would have white eyes. Also, a cross between a white-eyed male and a white-eyed female would yield all offspring with white eyes.

Test Yourself

1. c 2. b Mendel's law of segregation refers to the separation of the two alleles into separate cells. Meiosis is the cellular division process that produces haploid cells. During the first meiotic division, a diploid cell divides to produce haploid cells. This is the phase in which the two alleles segregate, or separate, from each other. 3. d 4. c 5. e 6. d 7. d 8. d 9. d 10. c

Conceptual Questions

1. If two affected parents had an unaffected offspring, that would rule out recessive inheritance. If two unaffected parents had an affected offspring, that would rule out dominant inheritance. However, it should be noted that this answer assumes that no new mutations are happening. In rare cases, a new mutation could cause or alter these results. For recessive inheritance, two affected parents could have an unaffected offspring if the offspring had a new mutation that converted the recessive allele to the dominant allele. Similarly for dominant inheritance, two unaffected parents could have an affected offspring if the offspring inherited a new mutation that was dominant. Note: New mutations are expected to be relatively rare.
2. The individual probabilities are as follows: $AA = 0.25$; $bb = 0.5$; $CC = 0.5$; and $Dd = 0.5$. These are determined by making small Punnett squares. We use the product rule to calculate the probability of $AAbbCCDd = (0.25)(0.5)(0.5)(0.5) = 0.03125$, or 3.125%.
3. Because males are hemizygous, they may display a recessive trait that is masked by the dominant allele in a heterozygous female. It only takes one recessive allele for the male to display the trait.

Chapter 17

Concept Checks

Figure 17.1 The recessive allele is the result of a loss-of-function mutation. In a *Ccpp* individual, the enzyme encoded by the *P* gene is defective.

Figure 17.2 The pigmentation phenotype displays a continuous distribution because it is polygenic and because environmental variation has a big impact. This creates genotypes that result in a range of phenotypes that overlap.

Figure 17.4 Crossing over occurred during oogenesis in the heterozygous female of the F_1 generation to produce the recombinant offspring of the F_2 generation.

Figure 17.5 One strategy would be to begin with two true-breeding parental strains: *alal dpdp* and al^+al^+ dp^+dp^+ and cross them together to get F_1 heterozygotes al^+al dp^+dp. Then testcross female F_1 heterozygotes to male *alal dpdp* homozygotes. In the F_2 generation, the recombinant offspring would be al^+al *dpdp* and *alal* dp^+dp, and the nonrecombinants would be al^+al dp^+dp, and *alal dpdp.*

Figure 17.6 The evolutionary origin of these organelles is an ancient endosymbiotic relationship. Mitochondria are derived from purple bacteria, and chloroplasts are derived from cyanobacteria.

Figure 17.7 The gene is located in the chloroplast DNA. In this species, chloroplasts are transmitted from parent to offspring via eggs but not via sperm.

Figure 17.9 The Barr body is much more compact than the other X chromosome in the cell. This compaction prevents most of the genes on the Barr body from being expressed.

Figure 17.10 On rare occasions, a cat can be XXY. Because it carries a Y chromosome, it will be a male. If it is heterozygous for the orange and black coat-color alleles that are X-linked, it will be a calico male.

Figure 17.11 Only the male genes are transcriptionally active in the offspring. In this case, half the offspring would be normal, and half would be dwarf. The dwarf offspring would have inherited the *Igf-2* allele from their father.

Figure 17.14 Its mother must be *dd*. The genotype of the mother determines the phenotype of the offspring. A *dd* mother produces offspring that coil to the left.

Figure 17.15 A haploid egg that carries a *D* allele cannot produce an offspring that coils to the left. Such an egg would have to come from a mother that carried at least one *D* allele. The nurse cells would supply this egg with the *D* gene product, and the offspring would coil to the right because the *D* gene product is dominant. On the other hand, an egg that carries the *d* allele could possibly produce an offspring that coils to the right. Such an egg could be from a mother that is *Dd*. The nurse cells from such a mother would supply the egg with both gene products. Because the *D* gene product is dominant, such an offspring would coil to the right.

Feature Investigation Questions

1. Bateson and Punnett were testing the hypothesis that the gene pairs that influence flower color and pollen shape would assort independently of each other. The two traits were expected to show a pattern consistent with Mendel's law of independent assortment.
2. The expected results were a phenotypic ratio of 9:3:3:1. The researchers expected 9/16 of the offspring would have purple flowers and long pollen, 3/16 of the offspring would have purple flowers and round pollen, 3/16 of the offspring would have red flowers and long pollen, and 1/16 of the offspring would have red flowers and round pollen.
3. Though all four of the expected phenotype groups were seen, they were not in the predicted ratio of 9:3:3:1. The number of individuals with the phenotypes found in the parental generation (purple flowers and long pollen or red flowers and round pollen) was much higher than expected. Bateson and Punnett suggested that the gene controlling flower color was somehow coupled with the gene that controls pollen shape. This would explain why these traits did not always assort independently.

Test Yourself

1. d 2. c 3. d 4. c 5. d 6. b 7. a 8. d 9. a 10. a

Conceptual Questions

1. The correct answer is 6%. Individuals that are *Aabb* are recombinants that occurred as a result of crossing over. Because the genes are 12 map units apart, we expect that 12% will be recombinants. However, there are two types of recombinants: *Aabb* and *aaBb*, which would occur in equal amounts. Therefore, we expect 6% to be *Aabb*.
2. This may happen due to X inactivation. As a matter of bad luck, a female embryo may preferentially inactivate the X chromosome carrying the normal allele in the embryonic cells that will give rise to the eyes. If the X chromosome carrying the color-blind allele is preferentially expressed, one or both eyes may show color blindness to some degree.
3. The mother is *Nn*; the father and offspring could be any genotype. The mother has a small head, so her mother must have been *nn*. Because the mother with the small head also had offspring with normal heads, she also must carry the *N* allele. Therefore, the mother must be *Nn*.

Chapter 18

Concept Checks

Figure 18.3 Viruses vary with regard to their structure and their genomes. Genome variation is described in Table 18.1.

Figure 18.5 The advantage of the lytic cycle is that the virus can make many copies of itself and proliferate. However, sometimes the growth conditions may not be favorable to make new viruses. The advantage of the lysogenic cycle is that the virus can remain latent until conditions become favorable to make new viruses.

Figure 18.8 Here are four possible effects of a drug: 1. A drug could specifically recognize the PrP^{Sc} conformation and prevent it from binding to PrP^{C}. 2. It could convert PrP^{Sc} back to PrP^{C}. 3. It could recognize PrP^{C} and prevent the binding of PrP^{Sc}. 4. It could bind to PrP^{C} and stabilize its conformation, thereby preventing PrP^{Sc} from changing it to the abnormal conformation. You may also think of other interesting possibilities.

Figure 18.9 There appears to be three nucleoids in the bacterial cell to the far right.

Figure 18.11 The loop domains are held in place by proteins that bind to the DNA at the bases of the loops. The proteins also bind to each other.

Figure 18.12 Bacterial chromosomes and plasmids are similar in that they typically contain circular DNA molecules. However, bacterial chromosomes are usually much longer than plasmids and carry many more genes. Also, bacterial chromosomes tend to be more compacted due to the formation of loop domains and supercoiling.

Figure 18.13 16 hours is the same as 32 doublings. So, $2^{32} = 4{,}294{,}967{,}296$. (The actual number would be much less because the cells would deplete the growth media and grow more slowly than the maximal rate.)

Figure 18.16 Yes. The two strains would have mixed together, allowing them to conjugate. Therefore, there would have been colonies on the plates.

Figure 18.17 During conjugation, only one strand of the DNA from an F factor is transferred from the donor to the recipient cell. The single-stranded DNA in both cells is then used as a template to create double-stranded F factor DNA in both cells.

Figure 18.19 Transduction is not a normal part of the phage life cycle. It is a mistake in which a piece of the bacterial chromosome is packaged into a phage coat and is then transferred to another bacterial cell.

Feature Investigation Questions

1. Lederberg and Tatum were testing the hypothesis that genetic material could be transferred from one bacterial strain to another.
2. The experimental growth medium lacked particular amino acids and biotin. The mutant strains were unable to synthesize these particular amino acids or biotin. Therefore, they were unable to grow due to the lack of the necessary nutrients. The two strains used in the experiment each lacked the ability to make two essential nutrients necessary for growth. The appearance of colonies growing on the experimental growth medium indicated that some bacterial cells had acquired the normal genes for the two mutations they carried. By acquiring these normal genes, the ability to synthesize the essential nutrients was restored.
3. Bernard Davis placed samples of the two bacterial strains in different arms of a U-tube. A filter allowed the free movement of the liquid in which the bacterial cells were suspended, but prevented the actual contact between the bacterial cells. After incubating the strains in this environment, Davis found that genetic transfer did not take place. He concluded that physical contact between cells of the two strains was required for genetic transfer.

Test Yourself

1. c 2. e 3. c 4. b 5. e 6. a 7. d 8. d 9. b 10. c

Conceptual Questions

1. Viruses are similar to living cells in that they contain a genetic material that provides a blueprint to make new viruses. However, viruses are not composed of cells, and by themselves, they do not carry out metabolism, use energy, maintain homeostasis, or even reproduce. A virus or its genetic material must be taken up by a living cell to replicate.
2. Conjugation—The process involves a direct physical contact between two bacterial cells in which a donor cell transfers a strand of DNA to a recipient cell.
   - Transformation—This occurs when a living bacteria takes up genetic information that has been released from a dead bacteria.
   - Transduction—When a virus infects a donor cell, it incorporates a fragment of bacterial chromosomal DNA into a newly made virus particle. The virus then transfers this fragment of DNA to a recipient cell.
   - Horizontal gene transfer is the transfer of genes from another organism without being the offspring of that organism. These acquired genes sometimes increase survival and therefore may have an evolutionary advantage. Such genes may even promote the formation of new species. From a medical perspective, an important example of horizontal gene transfer is when one bacterium acquires

antibiotic resistance from another bacterium and then itself becomes resistant to that antibiotic. This phenomenon is making it increasingly difficult to treat a wide variety of bacterial diseases.

3. If neither cell has a selective growth advantage, we would expect that the F^+ cells would eventually overrun the population. This is because a mating starts with an F^+ and F^- cell and ends with two F^+ cells. Therefore, F^+ cells can convert F^- cells into F^+ cells, but the opposite cannot occur.

Chapter 19

Concept Checks

Figure 19.1 Model organisms are studied by many different researchers so they can compare their results and determine scientific principles that apply more broadly to other species.

Figure 19.3 Cell division and cell migration are common in the earliest stages of development, whereas cell differentiation and apoptosis are more common as tissues and organs start to form.

Figure 19.4 If apoptosis did not occur, the fingers would be webbed.

Figure 19.5 During development, positional information may a cause a cell to respond in one of four ways: cell division, cell migration, cell differentiation, and cell death.

Figure 19.6 Cell division and migration would be the most prevalent in the early phases of development, such as phase 1 and 2.

Figure 19.8 The larva would have anterior structures at both ends and would lack posterior structures such as a spiracle.

Figure 19.9 The Bicoid protein functions as a transcription factor. Its function is highest in the anterior end of the zygote.

Figure 19.11 There are 15 pink stripes in this embryo. Each stripe corresponds to a portion of the 15 segments in the embryo.

Figure 19.14 The last abdominal segment would have legs!

Figure 19.18 Stem cells can divide, and they can differentiate into specific cell types.

Figure 19.20 Hematopoietic stem cells are multipotent.

Figure 19.23 Most stem cells in plants are found in meristems, which are located at the tips of roots and shoots.

Figure 19.24 The pattern would be sepal, petal, stamen, stamen.

Feature Investigation Questions

1. The researchers were interested in the factors that cause cells to differentiate. For this particular study, the researchers were attempting to identify genes involved in the differentiation of muscle cells.
2. Using genetic technology, the researcher compared the gene expression in cells that could differentiate into muscle cells to the gene expression in cells that could not differentiate into muscle cells. Though many genes were expressed in both, the researchers were able to isolate three genes that were expressed in muscle cell lines that were not expressed in the nonmuscle cell lines.
3. Again, using genetic technology, each of the candidate genes was introduced into a cell that normally did not give rise to skeletal muscle. This procedure was used to test whether or not these genes played a key role in muscle cell differentiation. If the genetically engineered cell gave rise to muscle cells, the researchers would have evidence that a particular candidate gene was involved in muscle cell differentiation. Of the three candidate genes, only one was shown to be involved in muscle cell differentiation. When the *MyoD* gene was expressed in fibroblasts, these cells differentiated into skeletal muscle cells.

Test Yourself

1. c 2. d 3. e 4. b 5. c 6. e 7. a 8. a 9. b 10. d

Conceptual Questions

1. a. This would be consistent with a defect in a segmentation gene, such as a gap gene.

   b. This would be consistent with a mutation in a homeotic gene because the characteristics of a particular segment have been changed.
2. Both types of genes encode transcription factors that bind to the DNA and regulate the expression of other genes. The effects of *Hox* genes are to determine the characteristics of certain regions of the body, whereas the *myoD* gene is cell specific—it causes a cell to become a skeletal muscle cell.
3. In plants, there are organized groups of cells that are very active with respect to cell division and producing stem cells. These areas are called meristems. At these areas, cells divide and retain the ability to differentiate into several different types of cells. In plants, there are two major places where these meristems are found. First, meristem tissue found in the roots is called the root meristem, which gives rise to the roots and tissue associated with the roots. The second is the shoot meristem, which produces all of the aerial parts of the plant, such as stems, leaves and flowers.

Chapter 20

Concept Checks

Figure 20.2 No. A recombinant vector has been made, but it has not been cloned. In other words, many copies of the recombinant vector have not been made yet.

Figure 20.3 The insertion of chromosomal DNA into the vector disrupts the *lacZ* gene and thereby prevents the expression of β-galactosidase. The functionality of *lacZ* can be determined by providing the growth medium with a colorless compound, X-Gal, which is cleaved by β-galactosidase into a blue dye. Bacterial colonies containing recircularized vectors will form blue colonies, whereas colonies containing recombinant vectors carrying a segment of chromosomal DNA will be white.

Figure 20.5 The 600 bp piece would be closer to the bottom. Smaller pieces travel faster through the gel.

Figure 20.6 The primers are complementary to sequences at each end of the DNA region to be amplified.

Figure 20.7 It means that part of their inserts are exactly the same, but other regions are not.

Figure 20.8 If a dideoxynucleotide ddNTP is added to a growing DNA strand, the strand can no longer grow because the 3′—OH group, the site of attachment for the next nucleotide, is missing.

Figure 20.9 A fluorescent spot identifies a cDNA that is complementary to a particular DNA sequence. Because the cDNA was generated from mRNA, this technique identifies a gene that has been transcribed in a particular cell type under a given set of conditions.

Figure 20.10 The reason why the A and B chains are made as fusion proteins is because the A and B chains are rapidly degraded when expressed in bacterial cells by themselves. The fusion proteins, however, are not.

Figure 20.12 Only the T DNA within the Ti plasmid is transferred to a plant cell.

Figure 20.14 Not all of Dolly's DNA came from a mammary cell. Her mitochondrial DNA came from the oocyte donor.

Figure 20.15 The bands match suspect 2.

Feature Investigation Questions

1. Gene therapy is the introduction of cloned genes into living cells to correct genetic mutations. The hope is that the cloned genes will correct or restore the normal gene function and thereby eliminate the clinical effects of the disease.

   ADA deficiency is a recessive genetic disorder in which an enzyme, adenosine deaminase, is not functional. The absence of this enzyme causes a buildup of deoxyadenosine, which is toxic to lymphocytes. When lymphocytes are destroyed, a person's immune system begins to fail, leading to a severe combined immunodeficiency disease, or SCID.
2. The researchers introduced normal copies of the ADA gene into lymphocytes, restoring normal cell metabolism. The researchers isolated lymphocytes from the patient and used a viral vector to introduce the gene into the lymphocytes. These lymphocytes were then reintroduced back into the patient.
3. Following several rounds of treatment with gene therapy, researchers were able to document continued production of the correct enzyme by the lymphocytes over the course of 4 years. However, because the

patients were also receiving other forms of treatment, it was not possible to determine if the gene therapy reduced the negative effects of the genetic disease.

Test Yourself

1. e 2. d 3. b 4. b 5. b 6. c 7. d 8. c 9. e 10. e

Conceptual Questions

1. The restriction enzyme cuts the plasmid at a specific site, leaving sticky ends. The gene of interest, cut with the same enzyme, will have complementary sticky ends that allow hydrogen bonding between the gene of interest and the plasmid. The connections are then made permanent, using DNA ligase that connects the DNA backbones.
2. A ddNTP is missing an oxygen at the 3′ position. These prevents the further growth of a DNA strand and thereby causes chain termination.
3. A mouse model is a strain of mice that carries a mutation that is analogous to a mutation that causes a human disease. Such mice exhibit disease symptoms resembling those found in humans. These mice can be used as model organisms to study a human disease. Such mice models have also been used to test the effects of various therapies in the treatment of human diseases.

Chapter 21

Concept Checks

Figure 21.2 One reason is that more complex species tend to have more genes. A second reason is that species vary with regard to the amount of repetitive DNA that is found in their genome.

Figure 21.3 The answer is a matter of opinion. Many people find it surprising that the vast majority of DNA is not part of genes or the coding region of genes.

Figure 21.5 For DNA transposons, inverted repeats are recognized by transposase, which cleaves the DNA and inserts the transposon into a new location.

Figure 21.6 Retroelements. A single retroelement can be transcribed into multiple copies of RNA, which can be converted to DNA by reverse transcriptase, and inserted into multiple sites in the genome.

Figure 21.8 The overall advantage is specialization. When multiple copies of a gene are found in the genome, each copy can become specialized to suit the needs of particular cell types or particular stages of development.

Figure 21.9 Differential gene regulation. Genes that encode metabolic enzymes are highly expressed in liver cells, whereas those same genes are expressed in lower amounts in muscle cells. Conversely, genes that encode cytoskeletal and motor proteins are highly expressed in muscle cells, but less so in liver cells.

Figure 21.10 Reversible post-translation covalent modifications provide a way to modulate protein function. Certain types can turn off protein function, whereas others can turn on protein function. These modifications provide a rapid way for a cell to control protein function.

Figure 21.11 The two main advantages of having a computer program translate a genetic sequence is that it's faster and probably more accurate.

Figure 21.12 It is possible for orthologs to have exactly the same DNA sequence if neither of them has accumulated any new mutations that would cause their sequences to become different. This is likely only for closely related species that have diverged relatively recently from each other.

Feature Investigation Questions

1. The goal of the experiment was to sequence the entire genome of *Haemophilus influenzae.* By conducting this experiment, the researchers would have information about genome size and the types of genes the bacterium has.
2. One strategy requires mapping the genome prior to sequencing. After mapping is completed, each region of the genome is then sequenced. The shotgun approach does not require mapping of the genome prior to sequencing. Instead, many fragments are randomly sequenced.

   The advantage of the shotgun approach is the speed at which the sequencing can be conducted because the researchers do not have to spend time mapping the genome first. The disadvantage is that because the researchers are sequencing random fragments, some fragments may be sequenced more than necessary.
3. The researchers were successful in sequencing the entire genome of the bacterium. The genome size was determined to be 1,830,137 base pairs, with a predicted 1,743 structural genes. The researchers were also able to predict the function of many of these genes. More importantly, the results were the first complete genomic sequence of a living organism.

Test Yourself

1. c 2. e 3. a 4. c 5. e 6. b 7. b 8. d 9. c 10. c

Conceptual Questions

1. a. yes

   b. No, it's only one chromosome in the nuclear genome.

   c. yes

   d. yes
2. The two main reasons why the proteomes of eukaryote species are usually much larger than their genomes are alternative splicing and post-translational covalent modifications. During alternative splicing, a pre-mRNA is spliced in two or more different ways to yield two or more different polypeptides. Post-translational covalent modifications can affect protein structure in a variety of ways, including proteolytic processing; disulfide bond formation; the attachment of prosthetic group, sugars, or lipids; phosphorylation; acetylation; and methylation.
3. Because they are derived from the same ancestral gene, homologous genes usually carry out similar or identical functions. In many cases, the first way to identify the function of a newly determined gene sequence is to find a homologous gene whose function is already known.

Chapter 22

Concept Checks

Figure 22.2 Organic molecules form the chemical foundation for the structure and function of living organisms. Modern organisms can synthesize organic molecules. However, to explain how life got started, biologists need to explain how organic molecules were made prior to the existence of living cells.

Figure 22.3 These vents release hot gaseous substances from the interior of the Earth. Organic molecules can form in the temperature gradient between the extremely hot vent water and the cold water that surrounds the vent.

Figure 22.4 A liposome is more similar to real cells, which are surrounded by a membrane that is composed of a phospholipid bilayer.

Figure 22.5 Certain chemicals, such as RNA molecules, may have properties that provide advantages and therefore cause them to increase in number compared to other molecules.

Figure 22.7 In a sedimentary rock formation, the layer at the bottom is usually the oldest.

Figure 22.8 For this time frame, you would analyze the relative amounts of the rubidium-87 and strontium-87 isotopes.

Figure 22.12 In part (a) at the top, the two cells are associating with each other, but one cell is not inside of the other cell, as in part (b).

Figure 22.13 The number of cells increases, and parts (c) and (d) have two cell types (somatic and reproductive). When comparing (c) and (d), the number of somatic cells increases relative to the number of reproductive cells.

Figure 22.14 Most animal species exhibit bilateral symmetry, including fruit flies, fishes, and humans.

Feature Investigation Questions

1. Chemical selection occurs when a particular chemical in a mixture has advantageous properties that allow it to increase in number compared to the other chemicals in the mixture. Bartel and Szostak hypothesized that variation in the catalytic abilities of RNA molecules would allow for chemical selection in the laboratory. Bartel and Szostak proposed to select for RNA molecules with higher catalytic abilities.
2. The short RNA molecules allowed the researchers to physically separate the mixture of longer RNA molecules based on catalytic properties. Long RNA molecules with catalytic abilities would covalently bond

with the short RNA molecules. The short RNA molecules had a specific region that caused them to be attracted to column beads in the experimental apparatus. The long RNA molecules that did not have catalytic abilities passed through the column and therefore could be separated from the ones that had catalytic activity and became bound to the column beads.

3. The researchers found that with each round of selection, the enzymatic activity of the selected pool of RNA molecules increased. These results provided evidence that chemical selection could improve the functional characteristics of a group of molecules. Much of the explanation of the evolution of life on Earth is theoretical, meaning it is based on scientific principles but has not been experimentally verified. Researchers are attempting to develop laboratory experiments that test the explanations of the evolution of life. The experiment conducted by Bartel and Szostak provided experimental data to support the hypothesis of chemical selection as a possible mechanism for the early evolutionary process that led to living cells.

Test Yourself

1. b 2. e 3. b 4. c 5. e 6. a 7. d 8. c 9. b 10. d

Conceptual Questions

1. Nucleotides and amino acids were produced prior to the existence of cells.

   Nucleotides and amino acids became polymerized to form DNA, RNA, and proteins.

   Polymers became enclosed in membranes.

   Polymers enclosed in membranes evolved cellular properties.

2. The relative ages of fossils can be determined by the locations in sedimentary rock formation. Older fossils are found in lower layers. A common way to determine the ages of fossils is via radioisotope dating, which is often conducted on igneous rock in the vicinity of the fossil. A radioisotope is an unstable isotope of an element that decays spontaneously, releasing radiation at a constant rate. The half-life is the length of time required for a radioisotope to decay to exactly one-half of its initial value. To determine the age of a rock (and that of a nearby fossil), scientists can measure the amount of a given radioisotope as well as the amount of the decay product.

3. The Cambrian period lasted from 543 million years ago to 490 million years ago. The Cambrian explosion was an abrupt increase on a geological scale in the diversity of animal species. During the Cambrian period, all of the existing major types of marine invertebrates arose as well as many other major animal groups. The basic body types of all modern animal species are based on body types that arose during the Cambrian.

Chapter 23

Concept Checks

Figure 23.2 A single organism does not evolve. Populations may evolve from one generation to the next.

Figure 23.7 Due to a changing global climate, the island fox became isolated from the mainland species. Over time, natural selection resulted in adaptations for the population on the island and eventually resulted in a new species with characteristics that are somewhat different from the mainland species.

Figure 23.8 Many answers are possible. One example is the wing of a bird and the wing of a bat.

Figure 23.11 The relative sizes of traits are changing. For example, in dogs, the lengths of legs, body size, etc., are quite different. Artificial selection is often aimed at changing the relative sizes of body parts.

Figure 23.13 Rhesus and green monkeys = 0, Congo puffer fish and European flounder = 2, and Rhesus monkey and Congo puffer fish = 10. Pairs that are closely related evolutionarily have fewer differences than do pairs that are more distantly related.

Figure 23.14 Orthologs have similar gene sequences because they are derived from the same ancestral gene. The sequences are not identical because after the species diverged, each one accumulated different random mutations that changed their sequences.

Figure 23.15 It creates multifunctional proteins that may have new properties that can be acted upon by natural selection.

Figure 23.17 Humans have one large chromosome 2, but this chromosome is divided into two separate chromosomes in the other three species. In chromosome 3, the banding patterns among humans, chimpanzees, and gorillas are very similar, but the orangutan has a large inversion that flips the arrangement of bands in the centromeric region.

Feature Investigation Questions

1. The island has a moderate level of isolation but is located near enough to the mainland to have some migrants. The island is an undisturbed habitat, so the researchers would not have to consider the effects of human activity on the study. Finally, the island had an existing population of ground finches that would serve as the study organism over many generations.

2. First, the researchers were able to show that beak depth is a genetic trait that has variation in the population. Second, the depth of the beak is an indicator of the types of seeds the birds can eat. The birds with larger beaks can eat larger and drier seeds; therefore, changes in the types of seeds available could act as a selective force on the bird population.

   During the study period, there were annual changes in rainfall. This had an impact on the seed sizes produced by the plants on the island. In the drier year, fewer small seeds were produced, so the birds would have to eat larger, drier seeds.

3. The researchers found that following the drought in 1978, the average beak depth in the finch population increased. This indicated that birds with larger beaks were better able to adapt to the environmental changes due to the drought and produce more offspring. This is direct evidence of the phenomenon of natural selection.

Test Yourself

1. d 2. d 3. b 4. b 5. b 6. d 7. c 8. b 9. d 10. e

Conceptual Questions

1. Some random mutations result in a phenotype with greater reproductive success. If so, natural selection results in a greater proportion of such individuals in succeeding generations. These individuals are more likely to survive and reproduce, which means they have evolved to be better adapted to their environment.

2. The process of convergent evolution produces two different species from different lineages that show similar characteristics because they occupy similar environments. An example is the long snout and tongue of both the giant anteater, found in South America, and the echidna, found in Australia. This enables these animals to feed on ants, but the two structures evolved independently. These observations support the idea that evolution results in adaptations to particular environments.

3. Homologous structures are two or more structures that are similar because they are derived from a common ancestor. An example is the same set of bones that is found in the human arm, turtle arm, bat wing, and whale flipper. The forearms in these species have been modified to perform different functions. This supports the idea that all of these animals evolved from a common ancestor.

Chapter 24

Concept Checks

Figure 24.2 If C^R is 0.4, then C^W must be 0.6, because the allele frequencies add up to 1.0. The heterozygote ($2pq$) equals $2(0.4)(0.6)$, which equals 0.48, or 48%.

Figure 24.3 Over the short run, alleles that confer better fitness would be favored and increase in frequency, perhaps enhancing diversity. Over the long run, however, an allele that confers high fitness in the homozygous state may become monomorphic, thereby reducing genetic diversity.

Figure 24.4 Stabilizing selection eliminates alleles that give phenotypes that deviate significantly from the average phenotype. For this reason, it tends to decrease genetic diversity.

Figure 24.6 If malaria was eradicated, there would be no selective advantage for the heterozygote. The H^S allele would eventually be eliminated

because the H^SH^S homozygote has a lower fitness. Directional selection would occur.

Figure 24.7 This is likely to be a form of intersexual selection. Such traits are likely to be involved in mate choice.

Figure 24.11 The bottleneck effect decreases genetic diversity. This may eliminate adaptations that promote survival and reproductive success. Therefore, the bottleneck effect makes it more difficult for a population to survive.

Figure 24.12 There are several possibilities. Two examples would be changing the DNA sequence within an intron or changing the DNA sequencing in a chromosomal region where a gene is not found.

Figure 24.13 Gene flow tends to make the allele frequencies in neighboring populations more similar to each other. It also promotes genetic diversity by introducing new alleles into populations.

Figure 24.14 Inbreeding favors homozygotes. If a homozygote has a higher Darwinian fitness, inbreeding would accelerate the prevalence of the allele in the population. Alternatively, if a homozygote has a lower fitness, inbreeding would accelerate the elimination of the allele from the population.

Feature Investigation Questions

1. The two species of cichlids used in the experiment are distinguishable by coloration, and the researchers were testing the hypothesis that the females make mate choices based on this variable.
2. Individual females were placed in tanks that contained one male from each species. The males were held in small glass tanks to limit their movement but allowed the female to see each of the males. The researchers recorded the courtship behavior between the female and males and the number of positive encounters between the female and each of the different males. This procedure was conducted under normal lighting and under monochromatic lighting that obscured the coloration differences between the two species. Comparing the behavior of the females under normal light conditions and monochromatic light conditions allowed the researchers to determine the importance of coloration in mate choice.
3. The researchers found that the female was more likely to select a mate from her own species in normal light conditions. However, under monochromatic light conditions, the species-specific mate choice was not observed. Females were as likely to choose males of the other species as they were males of their own species. This indicated that coloration is an important factor in mate choice in these species of fish.

Test Yourself

1. d 2. c 3. c 4. e 5. b 6. c 7. b 8. d 9. b 10. a

Conceptual Questions

1. The frequency of the disease is a genotype frequency because it represents individuals with the disease. If we let q^2 represent the genotype frequency, then q equals the square root of 0.04, which is 0.2. If $q = 0.2$, then $p = 1 - q$, which is 0.8. The frequency of heterozygous carriers is $2pq$, which is $2(0.8)(0.2) = 0.32$, or 32%.
2. Directional selection—This is when natural selection favors an extreme phenotype that makes the organism better suited to survive and reproduce in its environment. As a result, the extreme phenotype will become predominant in the population. This can occur either through new mutation or through a prolonged environmental change. In addition to selecting for a certain phenotype, the opposite end of the extreme is removed from the gene pool.
   - Stabilizing selection—In this type of selection, natural selection favors individuals with intermediate phenotypes, whereas organisms with extreme phenotypes are less likely to reproduce. This selection tends to prevent major changes in the phenotypes of populations.
   - Disruptive selection—This type of selection favors both extremes and removes the intermediate phenotype. It is also known as diversifying selection.
   - Balancing selection—This type of selection results in a balanced polymorphism in which two or more alleles are stably maintained in a population. Examples include heterozygote advantage, as in the sickle-cell allele, and negative frequency-dependent selection, as in certain prey.
   - Sexual selection—This is a type of natural selection that is directly aimed at reproductive success. It can occur by any of the previous four mechanisms. Male coloration in African cichlids is an example.
3. The founder effect occurs when a small group of individuals separates from a larger population and establishes a colony in a new location. Genetic drift can occur for two reasons. First, the founding population, which is relatively small, may have less genetic variation and different allele frequencies than the larger, original population from which it was derived. Second, as a matter of chance, the allele frequencies in the founding population will drift substantially while the population is small.

Chapter 25

Concept Checks

Figure 25.1 There are a lot of possibilities. Certain grass species look quite similar. Elephant species look very similar. And so on.

Figure 25.3 Temporal isolation is an example of a prezygotic isolating mechanism. Because the species breed at different times of the year, hybrid zygotes are not formed between the two species.

Figure 25.5 Hybrid sterility is a type of postzygotic isolating mechanism. A hybrid forms between the two species, but it is sterile.

Figure 25.7 The Hawaiian Islands have many different ecological niches that can be occupied by birds. The first founding bird inhabitants evolved to occupy those niches and thereby evolved into many different species.

Figure 25.11 The offspring would inherit 16 chromosomes from *G. tetrahit*, and from the hybrid, it would inherit anywhere from 8 to 16. So the answer is 24 to 32. The hybrid parent would always pass the 8 chromosomes that are found in pairs. With regard to the 8 chromosomes not found in pairs, it could pass 0 to 8 of them.

Figure 25.12 The insects on different host plants would tend to breed with each other, and natural selection would favor the development of traits that are an advantage for feeding on that host. Over time, the accumulation of genetic changes may lead to reproductive isolation between the populations of insects.

Figure 25.14 If the *Gremlin* gene was underexpressed, this would cause less Gremlin protein to be produced. Because Gremlin protein inhibits apoptosis, more cell death would occur, and the result would probably be smaller feet, and maybe they would not be webbed.

Figure 25.15 By comparing the number of *Hox* genes in many different animal species, a general trend is observed that animals with more complex body structures have a greater number of *Hox* genes.

Figure 25.17 The tip of the mouse's tail would have a mouse eye!

Feature Investigation Questions

1. Podos hypothesized that the morphological changes in the beak would also affect the birds' songs. A bird's song is an important component for mate choice. If changes in the beak alter the song of the bird, this would impact reproductive ability. Podos suggested that changes in the beak morphology could thus lead to reproductive isolation among the birds.
2. Podos first caught male birds in the field and collected data on beak size. The birds were banded for identification and released. Later, the banded birds' songs were recorded and analyzed for range of frequencies and trill rates. The results were then compared to similar data from other species of birds to determine if beak size constrained the frequency range and trill rate of the song.
3. The results of the study did indicate that natural selection on beak size due to changes in diet could lead to changes in song. Considering the importance of bird song to mate choice, the changes in the song could also lead to reproductive isolation.

   The phrase "by-product of adaptation" refers to changes in the phenotype that are not directly acted on by natural selection. In the case of the Galápagos finches, the changes in beak size were directly related to diet; however, as a consequence of that selection, the song pattern was also altered. The change in song pattern was a by-product.

Test Yourself

1. b 2. b 3. e 4. d 5. c 6. a 7. b 8. d 9. c 10. c

Conceptual Questions

1. Prezygotic isolating mechanisms prevent the formation of the zygote. An example is mechanical isolation, the incompatibility of genitalia. Postzygotic isolating mechanisms act after the formation of the zygote.

An example is inviability of the hybrid that is formed. (Other examples shown in Figure 25.2 would also be correct.) Postzygotic mechanisms are more costly because some energy is spent in the formation of a zygote and its subsequent growth.

2. The concept of gradualism suggests that each new species evolves continuously over long spans of time (Figure 25.13a). The principal idea is that large phenotypic differences that produce new species are due to the accumulation of many small genetic changes. According to the punctuated equilibrium model, species exist relatively unchanged for many generations. During this period, the species is in equilibrium with its environment. These long periods of equilibrium are punctuated by relatively short periods during which evolution occurs at a far more rapid rate. This rapid evolution is caused by relatively few genetic changes.
3. One example involves the *Hox* genes, which control morphological features along the anteroposterior axis in animals. An increase in the number of *Hox* genes during evolution is associated with an increase in body complexity and may have spawned many different animal species.

Chapter 26

Concept Checks

Figure 26.2 A phylum is broader than a family.

Figure 26.3 Yes. They can have many common ancestors, depending on how far back you go in the tree. For example, dogs and cats have a common ancestor that gave rise to mammals, and an older common ancestor that gave rise to vertebrates. The most recent common ancestor is the point at which two species diverged from each other.

Figure 26.4 An order is a smaller taxa that would have a more recent common ancestor.

Figure 26.9 A hinged jaw is the character common to the salmon, lizard, and rabbit, but not to the lamprey.

Figure 26.10 Changing the second G to an A is common to species A, B, and C, but not to species G.

Figure 26.12 The pair with a 3% difference would have an older common ancestor. A higher difference (3% compared to 1%) has occurred because the common ancestor is older and there has been more time to accumulate mutations.

Figure 26.13 Gorillas and humans would be expected to have fewer genetic differences because their common ancestor (named C) is more recent than that of orangutans and gorillas, which is ancestor B.

Figure 26.15 The kiwis are found in New Zealand. Even so, the kiwis are more closely related to Australian and African flightless birds than they are to the moas, which were found in New Zealand.

Figure 26.16 Monophyletic groups are based on the concept that a particular group of species descended from a common ancestor. When horizontal gene transfer occurs, not all of the genes in a species were inherited from the common ancestor, so this muddles the concept of monophyletic groups.

Feature Investigation Questions

1. Molecular paleontology is the sequencing and analysis of DNA obtained from extinct species. Tissue samples from specimens of extinct species may contain DNA molecules that can be extracted, amplified, and sequenced. The DNA sequences can then be compared to living species to study evolutionary relationships between modern and extinct species.

   The researchers extracted DNA from tissue samples of moas, extinct flightless birds that lived in New Zealand. The DNA sequences from the moas were compared to the DNA sequences of modern species of flightless birds to determine the evolutionary relationships of this particular group of organisms.
2. The researchers compared the DNA sequences of the extinct moas and modern kiwis of New Zealand to the emu and cassowary of Australia and New Guinea, the ostrich of Africa, and rheas of South America. All of the birds are flightless birds. With the birds selected, the researchers could look for similarities between birds over a large geographic area.
3. The sequences were very similar among the different species of flightless birds. Interestingly, the sequences of the kiwis of New Zealand were more similar to those of the modern species of flightless birds found on other land masses than they were to those of the moas found in New Zealand.

   The researchers constructed a new evolutionary tree that suggests that kiwis are more closely related to the emu, cassowary, and ostrich. Also, based on the results of this study, the researchers suggested that New Zealand was colonized twice by ancestors of flightless birds. The first ancestor gave rise to the now-extinct moas. The second ancestor gave rise to the kiwis.

Test Yourself

1. c 2. d 3. e 4. d 5. b 6. d 7. b 8. b 9. c 10. e

Conceptual Questions

1. The scientific name of every species has two parts, which are the genus name and the species epithet. The genus name is always capitalized, whereas the species name is not. Both names are italicized. An example is *Canis lupus.*
2. Morphological analysis focuses on morphological features of extinct and modern species. Many traits are analyzed to obtain a comprehensive picture of two species' relatedness. Convergent evolution leads to similar traits that arise independently in different species as they adapt to similar environments. Convergent evolution can, therefore, cause errors if a researcher assumes that a particular trait arose only once and that all species having the trait have the same common ancestor.
3. If neutral mutations occur at a relatively constant rate, they act as a molecular clock on which to measure evolutionary time. Genetic diversity between species that is due to neutral mutation gives an estimate of the time elapsed since the last common ancestor. A molecular clock can provide a timescale to a phylogenetic tree.

Chapter 27

Concept Checks

Figure 27.2 The red color arises from rhodopsins, pigment-protein complexes located in the cell membranes of the halophytic archaea growing abundantly in these salty ponds.

Figure 27.5 The cell will tend to float because it is full of intact gas vesicles.

Figure 27.11 The fluorescence staining process may be faster but requires the use of a fluorescence microscope, which is more expensive and complex than a simple compound microscope. The Gram stain can be assessed with a simple compound microscope of the type often found in biology class laboratories.

Figure 27.12 The motion of the stiff filament of a prokaryotic flagellum is more like that of a propeller shaft than the flexible arms of a human swimmer.

Figure 27.14 Cells having pili tend to move with a twitching or gliding motion.

Figure 27.15 When DNA sequencing studies show that samples contain many uncultured bacterial species, the fluorescence method is preferred, though it requires the use of a fluorescence microscope. Under such conditions, the culture method will give an underestimate of bacterial numbers. But when the goal is to estimate numbers of bacteria whose culture preferences are known, the culture method may provide good estimates.

Figure 27.16 Endospores allow bacterial cells to survive treatments and environmental conditions that would kill ordinary cells.

Figure 27.18 The transition point for both genes occurs around dusk.

Figure 27.19 Structural similarities to bacterial flagella and pili indicate that these types of attack systems evolved from these structures.

Feature Investigation Questions

1. *Deinococcus radiodurans* has the ability to survive levels of ionizing radiation that would kill most other organisms, and for periods of time that are not tolerated by other organisms. Investigators wanted to know why *D. radiodurans* was so resistant to radiation.
2. Daly and associates suggested that cellular levels of manganese ion might play a role in radiation resistance.
3. Bacteria that had been grown on media containing higher levels of manganese ion were better able to resist radiation than those grown on media containing lower levels of manganese ion.

Test Yourself

1. c 2. b 3. c 4. e 5. a 6. a 7. b 8. e 9. d 10. d

Conceptual Questions

1. Small cell size and simple division processes allow many bacteria to divide much more rapidly than eukaryotes. This helps to explain why food can spoil so quickly and why infections can spread very rapidly within the body. Other factors also influence these rates.
2. Pathogen populations naturally display genetic variation in their susceptibility to antibiotics. When such populations are exposed to antibiotics, even if initially only a few cells are resistant, the numbers of resistant cells will eventually increase and could come to dominate natural populations.
3. Humans. Only when humans pollute natural waters with high levels of fertilizers originating from sewage effluent or crop field runoff are cyanobacterial populations able to grow large enough to produce harmful blooms.

Chapter 28

Concept Checks

Figure 28.1 Diatoms are algal protists, meaning that they are typically photosynthetic and produce organic compounds. These organic compounds can be digested and respired as food by heterotrophic protists.

Figure 28.6 After particles are ingested via feeding grooves, particles are enclosed by membrane vesicles and then digested by enzymes.

Figure 28.7 The intestinal parasite *Giardia lamblia* is transmitted from one person to another via fecal wastes, whereas the urogenital parasite *Trichomonas vaginalis* can be transmitted by sexual activity.

Figure 28.14 The nucleomorph encodes some of the materials needed for plastid function.

Figure 28.16 The sail-like portions of the dinoflagellate cell wall help keep the cells afloat.

Figure 28.17 Flagellar hairs function like oars, helping to pull cells through the water.

Figure 28.18 Kelps are harvested for the production of industrially useful materials. In addition, they nurture fishes and other wildlife of economic importance.

Figure 28.21 Genes that encode cell adhesion and extracellular matrix proteins are likely essential to modern choanoflagellates' ability to attach to surfaces, where they feed. Similar proteins are involved in the formation of multicellular tissues in animals. Evolutionary biologists would say that ancient choanoflagellates were preadapted for the later evolution of multicellular tissues in early animals.

Figure 28.24 Cysts allow protists to survive conditions that are not suitable for growth. One such condition would be the dry or cold environment outside a parasitic protist's warm, moist host tissues.

Figure 28.29 Gametes of *Plasmodium falciparum* undergo fusion to produce zygotes while in the mosquito host.

Feature Investigation Questions

1. One strain had earlier been reported to be toxic to fishes, while the other had been reported to be nontoxic, a difference that could be attributed to differing experimental conditions. The investigators wanted to determine the degree of toxicity of the two strains when grown under the same conditions.
2. Producing toxins requires considerable ATP and other resources, so many organisms produce such compounds only when needed. In the case of *Pfiesteria shumwayae,* this might be when a major food source, fish, was present, but not when they fed primarily upon algal cells. The investigators needed to know if this dinoflagellate produces toxin even when feeding on algae alone (which would not require toxin production) or only when exposed to fishes.
3. The team knew that fishermen and scientists had suffered amnesia and other neurological impairments when they were near water containing large populations of the genus *Pfiesteria.* These observations suggested that the toxin was volatile or suspended in water droplets that people could inhale. As a precaution, they used the biohazard containment system to avoid personal harm. The use of biohazard containment systems is generally recommended for scientists who work with hazardous or potentially hazardous biological materials.

Test Yourself

1. c 2. a 3. b 4. b 5. e 6. b 7. e 8. d 9. b 10. c

Conceptual Questions

1. Protists are amazingly diverse, reflecting the occurrence of extensive adaptive radiation after the origin of eukaryotic cells, widespread occurrence of endosymbiosis, and adaptation to many types of moist habitats, including the tissues of animals and plants. As a result of this extensive diversity, protists cannot be classified into a single kingdom or phylum.
2. Several protists, including the apicomplexans *Cryptosporidium parvum* and *Plasmodium falciparum* and the kinetoplastids *Leishmania major* and *Trypanosoma brucei,* cause many cases of illness around the world, but few treatments are available, and organisms often evolve drug resistance. Genomic data allow researchers to identify metabolic features of these parasites that are not present in humans and are therefore good targets for development of new drugs. An example is provided by metabolic pathways of the apicoplast, a reduced plastid that is present in cells of the genus *Plasmodium.* Because the apicoplast plays essential metabolic roles in the protist but is absent from humans, drugs that disable apicoplast metabolism would kill the parasite without harming the human host.
3. Most protist cells cannot survive outside moist environments, but cysts have tough walls and dormant cytoplasm that allow them to persist in habitats that are unfavorable for growth. While cysts play important roles in the asexual reproduction and survival of many protists, they also allow protist parasites such as *Entamoeba histolytica* (the cause of amoebic dysentery) to spread to human hosts who consume food or water that have been contaminated with cysts. Widespread contamination can sicken thousands of people at a time.

Chapter 29

Concept Checks

Figure 29.3 Liverworts grow very close to surfaces such as soil or tree trunks. Raising their sporophytes off the surface helps to disperse spores into air currents.

Figure 29.4 Wind speed varies, so if the moss released all the spores at the same time into a weak air current, the spores would not travel very far and might have to compete with the parent plant for scarce resources. By releasing spores gradually, some spores may enter strong gusts of wind that carry them long distances, reducing competition with the parent.

Figure 29.8 Larger sporophytes are able to capture more resources for use in producing larger numbers of progeny and therefore have greater fitness than do smaller sporophytes.

Figure 29.14 The capacity to produce both wood and seeds are key features of lignophytes.

Figure 29.16 The polyester cutin found in cuticle, sporopollenin on spore walls, and lignin on water-conducting tracheids of vascular tissues are resistant to decay and thus help plants fossilize.

Figure 29.17 During the Carboniferous (Coal Age), atmospheric oxygen levels reached historic high levels that were able to supply the large needs of giant insects, which obtain oxygen by diffusion.

Figure 29.20 Increase in the surface area of placental transfer cells provides room for increased numbers of transport proteins. The greater the number of transport proteins per cell, the more rapidly solutes can be transferred from one cell to another.

Figure 29.22 Because the veins of fern leaves reflect the vascular systems of branched stem systems, you might infer that leaves evolved from more highly branched stem systems would be more-densely veined, that is, have more-veins per unit area than fern leaves.

Figure 29.23 Although some angiosperm seeds, such as those of corn and coconut, contain abundant endosperm, many angiosperm embryos consume most or all of the nutritive endosperm during their development.

Figure 29.25 Because the lacy integument of *Runcaria* does not completely enclose the megasporangium, it probably did not function to protect the megasporangium before fertilization nor as an effective seed coat after

fertilization, as do the integuments of modern seed plants. However, the lacy integument of *Runcaria* might have retained the megasporangium on the parent sporophyte during the period of time when nutrients flowed from parent to developing ovule and seed. That function would prevent megasporangia from dropping off the parent plant before fertilization occurred, allow the parent plant to provide nutrients needed during embryo development, and allow seeds time to absorb and store more nutrients from the parent. Such a function would illustrate how one mutation having a positive reproductive benefit can lay the foundation for subsequent mutations that confer additional fitness. *Runcaria* illustrates a first step in the multistage evolutionary process that gave rise to modern seeds.

Feature Investigation Questions

1. The experimental goals were to determine the rate at which organic molecules produced by gametophyte photosynthesis were able to move into sporophytes and to investigate the effect of sporophyte size on the amount of organic molecules transferred from the gametophyte.
2. The investigators shaded sporophytes with black glass covers to ensure that all of the radioactive organic molecules detected in sporophytes at the end of the experiment came originally from the gametophyte.
3. The investigators measured the amount of radioactivity in gametophytes and sporophytes, and in sporophytes of different sizes. These measurements indicated the relative amounts of labeled organic compounds that were present in different plant tissues.

Test Yourself

1. c 2. d 3. d 4. e 5. b 6. a 7. c 8. e 9. c 10. b

Conceptual Questions

1. Charophycean algae, particularly the complex genera *Chara* and *Coleochaete*, share many features of structure, reproduction, and biochemistry with land plants. Examples include cell division similarities and plasmodesmata and sexual reproduction by means of flagellate sperm and eggs.
2. Bryophytes are well adapted for sexual reproduction when water is available for fertilization. Their green gametophytes efficiently transfer nutrients to developing embryos, enhancing their growth into sporophytes. Their sporophytes are able to produce many genetically diverse spores as the result of meiosis and effectively disperse these spores by means of wind.
3. Vascular tissues allow tracheophytes to effectively conduct water from roots to stems and to leaves. Waxy cuticle helps prevent loss of water by evaporation through plant surfaces. Stomata allow plants to achieve gas exchange under moist conditions and help them avoid losing excess water under arid conditions.

Chapter 30

Concept Checks

Figure 30.3 People should not eat cycad seeds and other plant parts because they typically contain toxic compounds.

Figure 30.4 The nitrogen-fixing cyanobacteria that often occur within the coralloid roots of cycads are photosynthetic organisms that require light. If coralloid roots occurred underground, symbiotic cyanobacteria would not receive enough light to survive.

Figure 30.9 In the dry or cold conditions in which conifers live, air bubbles may form in tracheids; these air bubbles can interfere with water flow if they spread from one tracheid to another. When such bubbles form, the torus seals off connections to other tracheids, thereby helping to maintain water flow.

Figure 30.10 Ways in which conifer leaves are adapted to resist water loss include low surface area/volume needle- or scale-shape, thick surface coating of waxy cuticle, and stomata that are sunken into the leaf and are therefore less exposed to drying winds.

Figure 30.12 Wide vessels are commonly present in the water transport tissues of angiosperms and much less commonly in other plants. The vessels occasionally found in nonangiosperms are thought to have evolved independently from those of angiosperms.

Figure 30.20 A large, showy perianth would not be useful to grass plants because they are wind pollinated; such a perianth would interfere with pollination in grasses. By not producing a showy perianth, grasses increase the chances of successful pollination and save resources that would otherwise be consumed during perianth development.

Figure 30.24 The flower characteristics of *Brighhamia insignis* shown in this figure (white color and deep, narrow nectar tubes) are consistent with pollination by a moth (see Table 30.1).

Figure 30.26 Importantly, ears of modern *Zea mays* do not readily shatter when the fruits are mature, as do those of teosinte. This feature fosters human ability to harvest the fruits.

Feature Investigation Questions

1. The investigators obtained many samples from around the world because they wanted to increase their chances of finding as many species as possible.
2. The researchers grew plants in a greenhouse under consistent environmental conditions because they wanted to reduce possible impact of environmental variation on the ratio of cannabinoids produced.
3. Although cannabinoids are produced in glandular hairs that cover the plant surface, these compounds are most abundant on leaves near the flowers. Collecting such leaves reduces the chances that compounds might be missed by the analysis.

Test Yourself

1. d 2. a 3. e 4. e 5. b 6. d 7. e 8. c 9. d 10. e

Conceptual Questions

1. Humans should generally not consume food products made from cycads because these plants typically produce toxins that protect against herbivory. At least some cycads harbor cyanobacterial symbionts that are known to produce an unusual amino acid (BMAA) that is associated with dementia in humans.
2. Apple, strawberry, and cherry plants coevolved with animals that use the fleshy, sweet portion of the fruits as food and excrete the seeds, thereby dispersing them. Humans have sensory systems similar to those of the target animals and likewise are attracted by the same colors, odors, and tastes.
3. A sunflower is not a single flower, but rather is an inflorescence, a group of flowers.

Chapter 31

Concept Checks

Figure 31.3 Fungal hyphae growing into a substrate having much higher solute concentration will tend to lose cell water to the substrate, a process that could inhibit fungal growth. This process explains how salting or drying foods helps to protect them from fungal degradation and thus are common preservation techniques.

Figure 31.6 You might filter the air entering the patient's room and limit the entry of visitors and materials that could introduce fungal spores from the outside environment.

Figure 31.8 Early-diverging fungi that are adapted to live and reproduce in the water would not display the reproductive features shown.

Figure 31.11 The toxin amanitin could kill eukaryotic cells by interfering with transcription, thus stopping gene expression.

Figure 31.16 Compounds that interfere with the function of histidine kinase would not harm humans (because we lack such proteins) but would prevent dimorphic fungi from producing the yeast form that spreads so readily in the body by means of budding.

Figure 31.18 Modern AM (arbuscular mycorrhizal fungi), also known as Glomeromycota, do not occur separately from plant hosts, as far as is known.

Figure 31.19 Ectomycorrhizal fungi provide their plant partners with water and minerals absorbed from a much larger area of soil than plant roots can exploit on their own.

Figure 31.22 Lichens do not necessarily contain the same algae as the soredia from which the lichens develop, because lichens often switch algal partners.

Feature Investigation Questions

1. Plants growing on soils up to 65°C would be expected to have fungal endophytes that aid in heat stress tolerance.
2. The investigators cured some of their *C. protuberata* cultures of an associated virus; then they compared the survival of plants infected with fungal endophytes that had virus versus endophytes lacking virus under conditions of heat stress. Only plants having fungal endophytes that possessed the virus were able to survive growth on soils of high temperature.
3. The fungus *C. protuberata* might be used to confer heat stress tolerance to crop plants, as the investigators demonstrated in tomato.

Test Yourself

1. c 2. b 3. e 4. b 5. a 6. d 7. e 8. b 9. e 10. a

Conceptual Questions

1. Fungi are like animals in being heterotrophic, having absorptive nutrition, and storing surplus organic compounds in their cells as glycogen. Fungi are like plants in having rigid cell walls and reproducing by means of walled spores that are dispersed by wind, water, or animals.
2. Toxic or hallucinogenic compounds likely help to protect the fungi from organisms that would consume them.
3. Some fungi partner with algae or cyanobacteria to form lichens. Some fungi associate with plant roots to form mycorrhizae. Some fungi grow as endophytes within the bodies of plants. In all cases, the heterotrophic fungi receive photosynthetic products from the autotrophic partner.

Chapter 32

Concept Checks

Figure 32.2 Simple choanoflagellates are single-celled organisms. Only later, when such organisms become colonial and groups of cells acquire specialized functions, as in sponges, can we consider them early animals.

Figure 32.5 The coelom functions as a hydrostatic skeleton, which aids in movement. This feature permitted increased burrowing activity and contributed to the development of a profusion of wormlike body shapes.

Figure 32.10 Molecular analysis splits the protostomes into two distinct clades—the Lophotrochozoa and the Ecdysozoa—whereas the traditional phylogeny does not.

Figure 32.11 The sister group to the deuterostomes is the protostomes, but in the body plan phylogeny, the sister group is a more loosely defined part of the protostomes, the coelomate protostomes, including mollusks, annelids, and arthropods.

Figure 32.12 The main members of the Ecdysozoa are the arthropods (insects, spiders, and crustaceans) and the nematodes.

Feature Investigation Questions

1. The researchers sequenced the complete gene that encodes small subunit rRNA from a variety of representative taxa of animals to determine their phylogenetic relationships, particularly the relationships of arthropods to other animal taxa.
2. The results indicated a monophyletic clade containing arthropods and nematodes, plus several other smaller phyla. This clade was called the Ecdysozoa. The results of this study indicated that nematodes were more closely related to the arthropods than previously believed.
3. The fruit fly, *Drosophila melanogaster,* and the nematode, *Caenorhabditis elegans,* have been widely studied to understand early development. Under the traditional phylogeny, these two species were not considered to be closely related, so similarities in development were assumed to have arisen early in animal evolution. With the closer relationship indicated by this study, these similarities may have evolved after the divergence of the Ecdysozoan clade. This puts into question the applicability of studies of these organisms to the understanding of human biology.

Test Yourself

1. b 2. c 3. e 4. c 5. c 6. e 7. d 8. d 9. b 10. e

Conceptual Questions

1. (1) Absence or existence of different tissue types. (2) Type of body symmetry. (3) Presence or absence of a true body cavity. (4) Patterns of embryonic development.
2. Radially symmetric animals can be divided equally by a longitudinal plane passing through the central axis. Bilaterally symmetric animals can be divided along a vertical plane at the midline to create two halves; thus, a bilateral animal has a left side and a right side, which are mirror images.
3. Sea urchins are deuterostomes. Deuterostomes have indeterminate cleavage, and all cells have the ability to develop into a complete embryo. Humans are also deuterostomes, so sea urchin embryos can be used as a model for human development.

Chapter 33

Concept Checks

Figure 33.2 Sponges aren't eaten by other organisms because they produce toxic chemicals and contain needle-like silica spicules that are hard to digest.

Figure 33.4 The dominant life stages are jellyfish: medusa; sea anemone: polyp; Portuguese man-of-war: polyp (in a large floating colony).

Figure 33.7 Having no specialized respiratory or circulatory system, flatworms obtain oxygen by diffusion. A flattened shape ensures no cells are too far from the body surface.

Figure 33.11 (1) A ciliary feeding device, and (2) a respiratory device are the two main functions of the lophophore.

Figure 33.12 Technically, most mollusks pump hemolymph into vessels and then into tissues. The hemolymph collects in open, fluid-filled cavities called sinuses, which flow into the gills and then back to the heart. This is known as an open circulatory system. Only closed circulatory systems pump blood, as occurs in the cephalopods.

Figure 33.17 Some advantages of segmentation are organ duplication, minimization of body distortion during movement, and specialization of some segments.

Figure 33.20 Other parasitic nematodes in humans are roundworms, *Ascaris lumbricoides;* hookworms, *Necator americanus;* and pinworms, *Enterobius vermicularis.*

Figure 33.25 All arachnids have a body consisting of two tagmata: a cephalothorax and an abdomen. Insects have three tagmata: a head, thorax, and abdomen.

Figure 33.27 Two key insect adaptations are the development of wings and an exoskeleton that reduced water loss and aided in the colonization of land.

Figure 33.33 In embryonic development, deuterostomes have radial cleavage, indeterminate cleavage, and the blastopore becomes the anus. (In protostomes, cleavage is spiral and determinate, and the blastopore becomes the mouth.)

Figure 33.34 Two unique features of an echinoderm are an internal skeleton of calcified plates and a water vascular system.

Feature Investigation Questions

1. The researchers tested the hypothesis that an octopus can learn by observing the behavior of another octopus.
2. The results indicated that the observer learned by watching the training of the other octopus. The observer was much more likely to choose the same color ball that the demonstrator was trained to attack. These results seem to support the hypothesis that octopuses can learn by observing the behavior of others.
3. The untrained octopuses had no prior exposure to the demonstrators. The results indicated that these octopuses were as likely to attack the white ball as the red ball. No preference for either color was indicated. The untrained octopuses acted as a control. This is an important factor to ensure the results from the trials using observers indicate response to learning and not an existing preference for a certain color.

Test Yourself

1. b 2. d 3. d 4. d 5. b 6. c 7. b 8. a 9. c 10. a

Conceptual Questions

1. The five main feeding methods used by animals are (1) suspension feeding, (2) decomposition, (3) herbivory, (4) predation, and (5) parasitism. Suspension feeding is usually used to filter out food particles from the water column. A great many phyla are filter feeders, including sponges, rotifers, lophophorates, some mollusks and echinoderms and tunicates. Decomposers usually feed on dead material such as animal carcasses or dead leaves. For example, many fly and beetle larvae feed on dead animals, and earthworms consume dead leaves from the surface of the Earth. Earthworms and crabs also sift through soil or mud, eating the substrate and digesting the soil-dwelling bacteria, protists, and dead organic material. Herbivores eat plants or algae and are especially common in the arthropoda. Adult moths and butterflies also consume nectar. Snails are also common plant feeders. Predators feed on other animals, killing their prey, and may be active hunters or sit-and-wait predators. Many scorpions and spiders actively pursue their prey, whereas web-spinning spiders ambush their prey using webs. Parasites also feed on other animals but do not normally kill their hosts. Endoparasites live inside their hosts and include flukes, tapeworms, and nematodes. Ectoparasites live on the outside of their hosts and include ticks and lice.
2. The nematocyst is a powerful capsule with an inverted coiled and barbed thread that functions to immobilize small prey so they can be passed to the mouth and ingested. It is a unique and characteristic feature of the cnidarians.
3. Complete metamorphosis has four stages: egg, larva, pupa, and adult. The larval stage is often spent in an entirely different habitat from that of the adult, and larval and adult forms utilize different food sources. Incomplete metamorphosis has only three stages: egg, nymph, and adult. Young insects, called nymphs, look like miniature adults when they hatch from their eggs.

Chapter 34

Concept Checks

Figure 34.1 Vertebrates (but not invertebrates) usually possess a (1) notochord; (2) dorsal hollow nerve chord; (3) pharyngeal slits; (4) postanal tail, exhibited by all chordates; (5) cranium; (6) neural crest, exhibited by all craniates; (7) vertebral column; (8) endoskeleton of cartilage or bone; and (9) diversity of internal organs.

Figure 34.2 The hagfish is not a true fish because it does not possess vertebrae.

Figure 34.7 Ray-finned fishes (but not sharks) have a (1) bony skeleton; (2) mucus-covered skin; (3) swim bladder; and (4) operculum covering the gills.

Figure 34.11 The advantages to animals that moved onto land included an oxygen-rich environment and a bonanza of food in the form of terrestrial plants and the insects that fed on them.

Figure 34.14 No. Caecilians and some salamanders give birth to live young.

Figure 34.15 Besides the amniotic egg, other critical innovations in amniotes are thoracic breathing; internal fertilization; a thicker, less permeable skin; and more efficient kidneys.

Figure 34.18 Both classes have four-chambered hearts and care for their young.

Figure 34.21 Adaptations in birds to reduce body weight for flight include a lightweight skull; reduction of organ size; and a reduction of organs outside of breeding season. Also female birds have one ovary and relatively few eggs, and no urinary bladder.

Figure 34.28 Defining features of primates are grasping hands; eyes situated on the front of the head to facilitate binocular vision; a large brain; and digits with flat nails instead of claws.

Feature Investigation Questions

1. The researchers were interested in determining the method in which *Hox* genes controlled limb development.
2. The researchers bred mice that were homozygous for certain mutations in specific *Hox* genes. This allowed the researchers to determine the function of individual genes.
3. The researchers found that homozygous mutants would develop limbs of shorter lengths compared to the wild-type mice. The reduced length was due to the lack of development of particular bones in the limb, specifically, the radius, ulna, and some carpels. These results indicated that simple mutations in a few genes could lead to dramatic changes in limb development.

Test Yourself

1. e 2. d 3. a 4. d 5. d 6. c 7. c 8. a 9. c 10. d

Conceptual Questions

1. Both taxa have external limbs that move when the attached muscles contract or relax. The difference is that arthropods have external skeletons with the muscles attached internally, whereas vertebrates have internal skeletons with the muscles attached externally.
2. The sensors of the lateral line pick up pressure waves and send nervous signals to the brain. The operculum is a protective flap that covers the gills.
3. 1. The amnion, the innermost membrane, protects the developing embryo in a fluid-filled sac.
   2. The yolk sac provides a stockpile of nutrients.
   3. The allantois functions as a disposal sac for metabolic wastes.
   4. The chorion allows gas exchange between the embryo and the surrounding air.

Chapter 35

Concept Checks

Figure 35.3 Because organ systems are defined as structures that are composed of more than one organ, roots lack organ systems.

Figure 35.5 As in the case of shoots, the capacity to divide the root into two equal pieces by means of a line drawn from the circular edges through the center would indicate that a root has superficial radial symmetry. In order to determine that an organ has radial symmetry at the cellular level, you would have to compare the microscopic views of randomly chosen, wedge-shaped pieces of cross-slices. If the structure of the wedges is similar, the organ has radial symmetry at the microscopic level.

Figure 35.8 Locating stomata on the darker and cooler lower leaf surface helps reduce water loss from the leaf.

Figure 35.12 A twig having five sets of bud scale scars is likely to be approximately 6 years old.

Figure 35.17 Cactus stems are green and photosynthetic, playing the role served by the leaves of most plants.

Figure 35.22 A woody stem builds up a thicker layer of wood than inner bark in part because older tracheids and vessel element walls are not lost during shedding of bark, which is the case for secondary phloem. In addition, plants typically produce a greater volume of xylem than phloem tissue per year, in part because vessel elements are relatively wide. A large volume of water-conducting tissue helps plants maintain a large amount of internal water.

Figure 35.26 Lateral roots are produced from internal meristematic tissue because roots do not produce axillary buds like those from which shoot branches develop. Internal production of branch roots helps to prevent them from shearing off as the root tip grows through abrasive soil.

Feature Investigation Questions

1. The advantages of using natural plants include the opportunity to avoid influencing plants with unnatural environmental factors, such as artificial light, and the exposure of all experimental plants to similar growth conditions. In addition, the investigators studied the leaves of some large trees, which would be hard to accommodate in a greenhouse.
2. Pinnately veined leaves were splinted to prevent their breaking, since they were cut at the single main vein, which has both support and conducting functions.
3. Sack and associates measured leaf water conduction at two or more places on each leaf because the effect of cutting a vein might have affected some portions of leaves more than others.

Test Yourself

1. d 2. c 3. b 4. a 5. c 6. a 7. d 8. e 9. 6 10. d

Conceptual Questions

1. If overall plant architecture were bilaterally symmetrical, plants would be shaped like higher animals, with a distinct front (ventral surface) and back (dorsal surface). By comparison to radially symmetrical organisms, bilaterally symmetrical plants would have reduced ability to deploy branches and leaves in a way that would fill available lighted space and would thus not be able to take optimal photosynthetic advantage of their habitats.
2. If leaves were generally radially symmetrical (shaped like spheres or cylinders), leaves would not have maximal ability to absorb sunlight, and they would not be able to optimally disperse excess heat from their surfaces.
3. Although tall herbaceous plants exist (palms and bamboo are examples), the additional support and water-conducting capacity that are provided by secondary xylem allow woody plants to grow tall.

Chapter 36

Concept Checks

Figure 36.4 Auxin efflux carriers could be located on the upper sides of root cells, thereby allowing auxin to move upward in roots.

Figure 36.6 Once a callus has been established from a single plant having desirable characteristics using plant tissue culture, the callus can be divided into many small calluses. A grower could transfer these to separate containers having the appropriate hormone mixtures to induce root and shoot growth, then transplant the young plant clones to soil. This would allow the grower to produce many identical plants.

Figure 36.9 The triple response that dicot seedlings show in response to internally produced ethylene allows them to protect the delicate apical meristem from damage as the seedling emerges through the soil.

Figure 36.10 The active conformation of phytochrome absorbs far-red light. Such absorption causes the active conformation of phytochrome to change to the inactive conformation and to move out of the nucleus and into the cytosol.

Figure 36.11 The inactive conformation of phytochrome would absorb the red portion of sunlight, thereby converting phytochrome into the active conformation.

Figure 36.12 Exposing plants to brief periods of darkness during the daytime will have no effect on flowering because flowering is determined by night length.

Figure 36.14 Yes, just as shoots exhibit negative gravitropism in upward growth, roots are capable of using negative phototropism to grow downward, because light decreases with depth in the soil.

Figure 36.16 In some plants, aerenchyma development is genetically determined and occurs even in the absence of flooding. In other cases, aerenchyma develops only under flooding conditions as a result of controlled cell death.

Figure 36.17 Predators are more likely to be able to find their prey if the latter are concentrated and exposed while feeding on plants. Plants benefit when predation removes herbivores, a process that lessens damage to plants.

Figure 36.19 Similar suites of protective plant hormones, such as jasmonic acid, are used in both types of defenses.

Feature Investigation Questions

1. The following experiment by Briggs falsified the hypothesis that light destroys auxin:
2. Hypothetically, auxin enhances the rate at which cell membrane proton pumps acidify the plant cell wall, thereby allowing cells to extend. Although the evidence for acid effects on cell wall extension is strong, the molecular basis of possible auxin effects on proton pumps is not as yet clear.
3. A small number of seedling tips could display atypical responses for a variety of reasons. The investigators actually performed the experiment with many replicate seedling tips (coleoptiles), in order to gain confidence that the responses are general.

Test Yourself

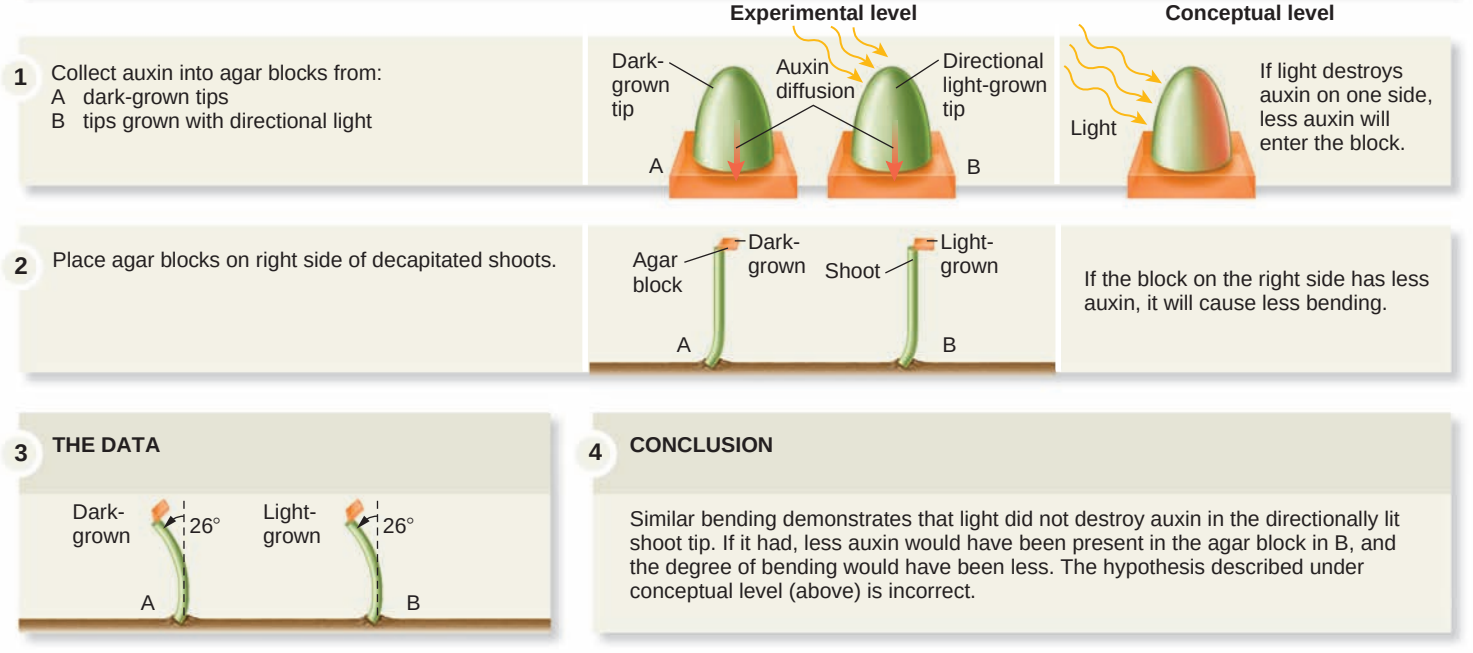
(b) Briggs experiment 1

HYPOTHESIS Light destroys auxin on lit side of shoot tips, causing unequal auxin distribution. Unlit side should grow more than lit side.

STARTING MATERIALS Corn seedlings.



Conceptual Questions

1. Behavior is defined as the responses of living things to a stimulus. Therefore, because plants display many kinds of responses to diverse stimuli, they display behavior.
2. Many kinds of disease-causing bacteria and fungi occur in nature, and these organisms evolve very quickly, producing diverse elicitors. Thus, plants must maintain a stock of resistance genes, each having many alleles.
3. Talking implies a conversation with "listeners" who detect a message and respond to it. Thus, plants that exude volatile compounds that attract enemies of herbivores could be interpreted as "talking" to those enemies. The message is "Hey, you guys, there's food for you over here." In addition, research has revealed that some plants near those under attack respond to volatile compounds by building up defenses. "Talking" to other plants does not enhance the "talker's" fitness. But the ability to "listen" enhances the "listener's" fitness, because it can take preemptive actions to prevent attack.

Chapter 37

Concept Checks

Figure 37.4 Plants adapted to deep shade may have green and photosynthetic plastids in their epidermal cells, whereas the epidermal cells of most plants have plastids that lack chlorophyll.

Figure 37.5 Plastids that occur in a cluster near the nucleus would have more rubisco than plastids at the periphery.

Figure 37.6 Chlorosis is not always a sign of iron deficiency; it can be a deficiency symptom for several mineral nutrients, including zinc in corn.

Figure 37.10 Mineral leaching occurs more readily from sandy soils than from clay soils.

Figure 37.11 Tropical soils are often acidic, as are those of higher latitude regions that are impacted by acid rain resulting from air pollution.

Figure 37.12 The list could include chlorophyll, carotenoids, ATP, NADP, rubisco, and many other enzymes.

Figure 37.13 Soil crusts containing nitrogen-fixing cyanobacteria increase soil fertility, fostering the growth of larger plants that stabilize soils against erosion and provide forage for animals.

Figure 37.14 Oxygen, which makes up 21% of Earth's present atmosphere, can bind to the active site of nitrogenase, thereby inactivating it.

Figure 37.16 Acidic conditions cause soil aluminum ions to become more mobile and thus to enter plants more easily. Hydrangea stores aluminum ions in the cell vacuole, a protective adaptation that prevents aluminum from damaging other cell components. The aluminum causes pigments that are also located in the vacuoles of sepals to change from pink to blue.

Feature Investigation Questions

1. During this period of time, the amount of phosphorus in plant tissues had significantly decreased, but plant growth had not yet been affected. Thus, a monitoring system based on gene expression changes occurring during this time would allow farmers time to apply fertilizer in order to prevent crop losses resulting from nutrient deficiency.
2. *SDQ1* expression is induced by phosphorus deficiency. This gene fosters replacement of plastid phospholipids with sulfur-containing lipids, thereby reducing the plant's phosphorus requirement.
3. They used genetic engineering techniques to place a reporter gene under the control of the *SQD1* promoter, so that when *SQD1* was expressed, the reporter gene was expressed also. After growing plants in nutrient solutions containing various levels of phosphorus, they removed sample leaves and treated them with a compound that turns blue when the reporter gene is expressed. When they saw blue leaves, the investigators could infer (1) that the plants from which those leaves had been taken were beginning to experience phosphorus deficiency, and (2) that application of fertilizer at this point could prevent damage to the plants.

Test Yourself

1. e 2. a 3. c 4. b 5. e 6. c 7. d 8. d 9. a 10. b

Conceptual Questions

1. Agricultural experts are concerned that adding excess fertilizer to crop fields increases the costs of crop production. Ecologists are concerned that excess fertilizers will wash from crop fields into natural waters and cause harmful overgrowths of cyanobacteria, algae, and aquatic plants. Methods for closely monitoring crop nutrient needs so that only the appropriate amount of fertilizer is applied would help to allay both groups' concerns.
2. Boron deficiency induces the expression of a gene that encodes a membrane transporter protein that moves boron from living root cells into root xylem for transport throughout the plant. This action helps to reduce boron deficiency in plant tissues. When plants are exposed to too much boron, the transporter protein is removed from root cell membranes, with the result that boron cannot move into the xylem and the rest of the plant. This action protects the plant from boron toxicity.
3. Use Figure 37.10 as a reference. A first arrow could be drawn from a root to rhizobia in the soil, and the arrow labeled "flavonoids." A second arrow could be drawn from rhizobia to roots and labeled "Nod factors." A third arrow from rhizobia to roots could be labeled "infection proteins." A fourth arrow from roots to rhizobia could be labeled "nodulins" and the resulting nodule environmental conditions, which influence the formation of bacteroids. A fifth arrow could represent the flow of fixed nitrogen from bacterioids to plant. A sixth arrow could represent the flow of organic compounds from plant to bacteroids.

Chapter 38

Concept Checks

Figure 38.5 When placed in pure water, a turgid cell having a water potential of 1.0 will lose water, because 1 is greater than 0. When placed in pure water, a plasmolyzed cell having a water potential of −1.0 MPa will gain water. When placed in pure water, a flaccid cell having a water potential of −0.5 MPa will gain water. This is because water moves from a region of higher water potential to a region of lower water potential, and 0 is greater than −0.5.

Figure 38.8 In most plants, most Al^{3+} will remain in the roots, because the ions can move through outer root tissues but cannot cross the endodermis. However, some aluminum may be able to get into root vascular tissues by seeping into root tips where the endodermis has not yet formed or at places where the endodermis has been broken by the emergence of branch roots. These processes, together with the fact that aluminum ions are very abundant in soils, explain why plant tissues may contain some aluminum even though it is not a plant nutrient.

Figure 38.11 You would likely see stained rings or helical ribbons extending up the insides of the long walls of extensible tracheids. You would not see staining at the ends of tracheids, where they connect to form cell files.

Figure 38.12 The large perforations in vessel element end walls allow an air bubble to extend from one element to another, thereby clogging vessels and preventing water flow through them. In contrast, the much smaller pores in the end walls of tracheids do not allow water to flow as efficiently as it does through vessels, but these smaller pores also retard the movement of air bubbles. As a result, air bubbles are confined to a single tracheid where they do little harm.

Figure 38.13 Root pressure can help to reverse embolism, thereby aiding water flow through xylem.

Figure 38.16 The evaporation of water has a powerful cooling effect because it disperses heat so effectively. Water has the highest heat of vaporization of any known liquid.

Figure 38.17 You could model a stomatal guard cell with an elongate balloon by partially inflating it, then attaching thick tape along one side to represent thickened inner walls and circles of string or thin tape to represent radial cellulose, then adding more air to the balloon. The balloon should curve as it expands, just as a guard cell does when the stomatal pore opens. Two such balloons could be used to model both guard cells and the stomatal pore.

Figure 38.19 In its desert habitat, times of drought and contrasting availability of water sufficient to support the development and photosynthetic function of leaves do not occur at predictable times, as is the case for

temperate forests. For this reason, ocotillo leaf abscission is not amenable to the evolution of genetic mechanisms that allow leaf drop to be precisely timed in anticipation of the onset of drought.

Figure 38.25 You could note the relatively few genes that are plotted along the middle left side of the triangle, then try to localize the encoded proteins within the tissues of very young stem tissue, using microscopy.

Feature Investigation Questions

1. This design allowed investigators to compensate for variation among plants, which might have influenced the results had they used separate plants for experiments and controls.
2. Transpiration! Water evaporating from the surfaces of leaves exerted a tension on the water column of the xylem, pulling sap and water through it.
3. The effects of ions on sap flow rates did not directly depend on a biological process, so xylem sap of the same ionic concentration moved through dead plants at the same rate as in living plants.

Test Yourself

1. c 2. b 3. e 4. d 5. a 6. d 7. d 8. e 9. a 10. c

Conceptual Questions

1. In the case of plant fertilizers, more is not better, because the ion concentration of overfertilized soil may become so high as to draw water from plant cells. In this case, the cells would be bathed in a hypertonic solution and would likely lose water to the solution. If plant cells lose too much water, they will die.
2. When the natural vegetation is removed, transpiration stops, so water is not transported from the ground to the atmosphere, where it may be an important contributor to local rainfall. Extensive removal of plants actually changes local climates in ways that reduce agricultural productivity and human survival.
3. You cannot assume that an ocotillo plant lacking leaves is dead, because this plant responds to drought by shedding its leaves, and living plants can produce new leaves when the drought stress is relieved. However, if the ocotillo plants do not produce new leaves after normal rainstorms, you might suspect that they have died.

Chapter 39

Concept Checks

Figure 39.2 Because gametophytes are haploid, they lack the potential for allele variation at each gene locus that is present in diploid sporophytes. Hence, gametophytes are more vulnerable to environmental stresses. By living within the diploid tissues of flowers, flowering plant gametophytes are protected to some extent, and the plant does not lose its gamete-producing life cycle stage.

Figure 39.3 Some flowers lack some of the major flower parts.

Figure 39.4 By clustering its stamens around the pistil, the hibiscus flower increases the chance that a pollinator will both pick up pollen and deliver pollen from another hibiscus flower on the same trip.

Figure 39.7 The absence of showy petals often correlates with wind pollination, because large petals would interfere with the shedding of pollen in the wind.

Figure 39.10 The rim flowers of *Gerbera* inflorescences have bilateral symmetry, conferred by expression of a *CYCLOIDEA*-like gene. Rim flowers also possess showy petals that attract pollinators, but lack pollen-producing stamens. By contrast, central flowers display radial symmetry, lack showy petals, and possess pollen-producing stamens.

Figure 39.11 The maximum number of cells in a mature male gametophyte of a flowering plant is three: a tube cell and two sperm cells.

Figure 39.12 Female gametophytes are not photosynthetic and cannot produce their own food. Enclosed within ovules, female gametophytes lack direct access to the outside environment. Carpels contain veins of vascular tissue that bring nutrients from sporophytic tissue to ovules.

Figure 39.17 An embryo in which the TOPLESS genes were nonfunctional would have two roots and no shoots.

Figure 39.18 During their maturation, the cotyledons of eudicot seeds absorb the nutrients originally present in endosperm.

Feature Investigation Questions

1. Plant gametes, particularly egg cells, are produced by microscopic gametophytes enclosed by sporophytic flower tissues and were thus difficult to isolate.
2. The investigators used a pulse of electricity to stimulate cell fusion. This process is similar to electroporation, the use of electrical discharges to cause small pores to appear in the membranes of cells prior to their transformation during genetic engineering.
3. Investigators obtained egg cells and sperm cells from parents that differed in the color of stigmas and stigma hairs. They demonstrated that progeny plants were hybrids that had stigmas that were colored the same as one parent and stigma hairs that were colored the same as the other parent.

Test Yourself

1. a 2. b 3. d 4. b 5. d 6. e 7. b 8. c 9. d 10. c

Conceptual Questions

1. Pollen grains are vulnerable to mechanical damage and microbial attack during the journey through the air from the anthers of a flower to a stigma. Sporopollenin is an extremely tough polymer that helps to protect pollen cells from these dangers. The function of the beautiful sculptured patterns of sporopollenin on pollen surfaces is unclear.
2. The embryos within seeds are vulnerable to mechanical damage and microbial attack after they are dispersed. Seed coats protect embryos from these dangers and also help to prevent seeds from germinating until conditions are favorable for seedling survival and growth.
3. Flower diversity is an evolutionary response to diverse pollination circumstances. For example, plants such as oak and corn that are wind-pollinated produce flowers having a poorly developed perianth. If such wind-pollinated flowers had large, showy perianths, they would get in the way of pollen dispersal or acquisition. On the other hand, flowers that are pollinated by animals often have diverse shapes and attractive petals of differing colors or fragrances that have coevolved with different types of animal pollinators.

Chapter 40

Concept Checks

Figure 40.2 Locomotion is the movement of an animal's body from one place to another. This is achieved by the actions of skeletal muscle. However, smooth muscle contraction promotes movement of internal structures, like those of the digestive system, and contraction of cardiac muscle causes movement (beating) of the heart.

Figure 40.6 No. The brain, for example, does not contain muscle tissue (although the blood vessels supplying the brain do contain smooth muscle).

Figure 40.7 Blood, including plasma and blood cells, would leak out of the blood vessel into the interstitial space. The fluid level of the bloodstream would decrease, and that of the interstitial space near the site of the injury would increase. Eventually the blood that entered the interstitial space would be degraded by enzymes, resulting in the characteristic skin appearance of a bruise. If the injury were very severe, the fluid level in the blood could decrease to a point where the various tissues and organs of the body would not receive sufficient nutrients and oxygen to function normally.

Figure 40.8 A decrease in intracellular fluid volume, like that shown in the cell in this figure, would result in an increase in intracellular solute concentration (likewise, an increase in intracellular fluid volume would decrease intracellular solute concentrations). This may have drastic consequences on cell function. For example, some solutes, like Ca^{2+} and certain other ions, are toxic to cells at high concentrations.

Figure 40.10 Surface area is important to any living organism that needs to exchange materials with the environment. A good example of a high surface area/volume ratio is that of most tree leaves. This makes leaves ideally suited for such processes as light absorption (required for photosynthesis; see Chapter 8) and the exchange of gases and water with the environment.

Figure 40.12 No, not necessarily. Body temperature, for example, is maintained at different set points in birds and mammals. Other vertebrates and most invertebrates do not have temperature set points; their body temperature simply conforms close to that of the environment. As another example, a

giraffe has a set point for blood pressure that is higher than that of a human being, because a giraffe's circulatory system must generate enough pressure to pump blood up its long neck.

Figure 40.15 In nature, an animal such as a horse would have the same type of responses shown here if threatened by a predator. Upon sensing the presence of the predator, the horse's respiratory and circulatory systems would begin increasing their activities in preparation for the possibility that the horse might have to flee or defend itself. This would occur even before the horse began to flee.

Feature Investigation Questions

1. Pavlov studied feedforward regulation of saliva production that occurs in hungry dogs even before they receive food. He hypothesized that the feedforward response could be conditioned to other, nonrelevant stimuli such as sounds, as long as the sounds were presented simultaneously with food.
2. Pavlov remained outside the room where the dog was housed when the conditioning stimulus—a metronome—was started. In addition, the room was carefully sealed to prevent any other stimuli, including smells, sights, and sounds, from interfering with the conditioning response.
3. He measured the amount of saliva secreted by salivary glands in the dog's mouth by collecting the saliva through a tube and funnel, and then recording the number of drops. He discovered that once a dog had become conditioned to hearing the sound of the metronome whenever presented with food, the sound itself was sufficient to stimulate the feedforward response of salivation. This experiment revealed that feedforward processes could be modulated by experience and learning.

Test Yourself

1. d 2. c 3. d 4. b 5. c 6. c 7. d 8. b 9. d 10. e

Conceptual Questions

1. Anatomy is the study of structure (form), and physiology is the study of function. For example, an anatomist might be interested in the arrangement of cells and tissues in an organ such as the heart, while a physiologist might be interested in the mechanisms by which heart cells contract to produce a heartbeat.
2. Structure and function are related in that the function of a given organ, for example, depends in part on the organ's size, shape, and cellular and tissue arrangement. Clues about a physical structure's function can often be obtained by examining the structure's form. For example, the extensive surface area of a moth's antennae suggests that the antennae are important in detecting the presence of airborne chemicals. Likewise, any structure that contains a large surface area for its volume is likely involved in some aspect of signal detection, cell-cell communication, or transport of materials within the animal or between the animal and the environment. Surface area increases by a power of 2, and volume increases by a power of 3 as an object enlarges; this means that in order to greatly increase surface area of a structure such as an antenna, without occupying enormous volumes, specializations must be present (such as folds) to package the structure in a small space.
3. Homeostasis is the ability of animals to maintain a stable internal environment by adjusting physiological processes, despite changes in the external environment. Examples include maintenance of salt and water balance, pH of body fluids, and body temperature. Some animals conform to their external environment to achieve homeostasis, but others regulate their internal environment themselves.

Chapter 41

Concept Checks

Figure 41.1 This is an example of a feedforward response, most famously demonstrated by the conditioning experiments of Ivan Pavlov. In this case, the peripheral and central nervous systems interact to prepare the hyena for feeding.

Figure 41.4 Many reflexes, such as the knee-jerk reflex, cannot be prevented once started. Others, however, can be controlled to an extent. Open your eyes widely and gently touch your eyelashes. A reflex that protects your eye will tend to make you close your eyelid. However, you can overcome this reflex with a bit of difficulty if you need to, for example, when you are putting in contact lenses.

Figure 41.5 The squid axon is not coated in myelin sheaths. This is another feature of the squid giant axon that makes it a convenient model for conducting in vitro experiments such as the one depicted in this figure.

Figure 41.7 Yes, the flow of K^+ down its chemical gradient does create an electrical gradient because K^+ is electrically charged. The net flow of K^+ will stop when the chemical gradient balances the electrical gradient. This occurs at the equilibrium potential.

Figure 41.10 When the K^+ channels open (at 1 msec), the Na^+ channels would still be opened, so the part of the curve that slopes downward would not occur as rapidly, and perhaps the cell would not be able to restore its resting potential.

Figure 41.12 The action potential can move faster down an axon. This is especially important for long axons, such as those that carry signals from the spinal cord to distant muscles.

Figure 41.14 In the absence of such enzymes, neurotransmitters would remain in the synapse for too long, and the postsynaptic cell could become overstimulated. In addition, the ability of the postsynaptic cell to respond to multiple, discrete inputs from the presynaptic cell would be compromised.

Feature Investigation Questions

1. Loewi was aware that electrical stimulation of the vagus nerve associated with heart muscle would slow down the rate of heart contractions in a frog. Also, he knew that electrical stimulation of other nerves associated with the frog heart produced opposite results. If the effects of the different nerves on heart muscle were mediated directly by electrical activity only, the heart muscle cells would have no way to distinguish between stimulatory and inhibitory signals. Loewi hypothesized that nerves released chemicals onto heart muscle cells and that it was these different chemicals that produced the varied effects on the heart.
2. Loewi placed two hearts in separate chambers, one heart with its vagus nerve intact and the other with its vagus nerve removed. He electrically stimulated the vagus nerve of the first heart, then removed some of the saline solution surrounding the heart and transferred it to the second heart. He then observed whether or not the second heart responded as if its vagus nerve had been intact and had been stimulated.
3. When fluid from the saline solution around the stimulated heart was added to the saline solution of the second, unstimulated heart, the rate of contraction in the second heart was decreased just as if its own vagus nerve had been intact and was stimulated. This suggested that chemicals were released into the saline solution of the first heart following the electrical stimulation of its vagus nerve, and that it was these chemicals that caused the cardiac muscle to slow its rate of contraction. The results did support Loewi's hypothesis.

Test Yourself

1. c 2. d 3. e 4. e 5. b 6. d 7. b 8. e 9. a 10. e

Conceptual Questions

1. Neurons are highly specialized, electrically excitable cells that communicate with another cell of its kind and with other types of cells by electrical or chemical signals.

   Glia are cells that surround the neurons; they are a major class of cells in nervous systems that perform various functions.

   Schwann cells are glial cells that form myelin around axons in the peripheral nervous system.
2. In a graded potential, a weak stimulus causes a small change in the membrane potential while a strong stimulus produces a greater change. Graded potentials occur along the dendrites and cell body. If a graded potential reaches the threshold potential at the axon hillock, this results in an action potential. This is a change in the membrane potential that is of a constant value and is propagated from the axon hillock to the axon terminal.
3. An increase in extracellular Na^+ concentration would slightly depolarize neurons, thereby changing the resting membrane potential. This effect would be minimal, however, because the resting membrane is not very permeable to Na^+. However, the shape of the action potentials in such neurons would be a little steeper, and the peak a little higher, because the electrochemical gradient favoring Na^+ entry into the cell through voltage-gated channels would be greater.

Chapter 42

Concept Checks

Figure 42.4 Not necessarily. Brain mass is not the sole determinant of intelligence or the ability to perform complex tasks. The degree of folding of the cerebral cortex is also important.

Figure 42.6 A spinal nerve is composed of both afferent and efferent neurons.

Figure 42.7 The major symptom experienced by patients undergoing a lumbar puncture is headache, in part because the brain is no longer cushioned adequately by CSF. Within 24–48 hours, however, the CSF is replenished to normal levels.

Figure 42.9 Damage to the cerebellum would result in loss of balance and a lack of fine motor control, such as picking up fine objects or making graceful, smooth movements.

Figure 42.12 It was in her right hand.

Figure 42.15 Thinking requires energy! Even daydreaming requires energy; imagine how much energy the brain uses when you concentrate for 60 minutes on a difficult exam. In fact, you just expended energy thinking about this question!

Feature Investigation Questions

1. Gaser and Schlaug hypothesized that repeated exposure to musical training would increase the size of certain areas of the brain associated with motor, auditory, and visual skills. All three skills are commonly used in reading and performing musical pieces.
2. The researchers used MRI to examine the areas of the brain associated with motor, auditory, and visual skills in three groups of individuals: professional musicians, amateur musicians, and nonmusicians. The researchers found that certain areas of the brain were larger in the professional musicians compared to the other groups, and larger in the amateur musicians compared to the nonmusicians.
3. Schmithorst and Holland found that, when exposed to music, certain regions of the brains of musicians were activated differently compared to nonmusicians. This study supports the hypothesis that there is a difference in the brains of musicians compared to nonmusicians.

   The experiment conducted by Gaser and Schlaug compared the size of certain regions of the brain among professional musicians, amateur musicians, and nonmusicians. Schmithorst and Holland, however, were also able to detect functional differences between musicians and nonmusicians.

Test Yourself

1. b 2. a 3. e 4. c 5. c 6. b 7. e 8. b 9. a 10. d

Conceptual Questions

1. All animals with nervous systems have reflexes, which allow rapid behavioral responses to changes in the environment. When a cnidarian senses a tactile stimulus, its nerve net responds immediately and the animal reflexively contracts nearly all of its muscles, making the animal a smaller target. This behavior protects the animal from predators. When you hear a loud, unexpected, and frightening sound (such as a firecracker), you hunch your shoulders and slightly lower your head; this reflex protects you from danger by minimizing exposure of your neck and head to danger. Dilation of the pupils of the eyes in darkness, and constriction of the pupils in bright light, are reflexes that help us see in the dark and protect our retinas in bright light. Reflexes are particularly adaptive because they occur rapidly, typically with very few synapses involved, and without the need for conscious thought.
2. White matter consists of the myelinated axons that are bundled together in large tracts in the central nervous system and which connect different CNS regions. The lipid-rich myelin gives the tracts a whitish appearance. It is distinguished from gray matter, which are the cell bodies, dendrites, and some unmyelinated axons of neurons in the CNS.
3. The sympathetic division is responsible for rapidly activating "fight-or-flight" systems that provide beneficial responses to stress or danger. For example, activation of the sympathetic division results in increased heart rate, increased breathing rate, and increased energy production.

   The parasympathetic system is involved in "rest-or-digest" processes that stimulate digestion of food, slow the heart rate, and decrease energy production.

Chapter 43

Concept Checks

Figure 43.1 The term sensory receptor refers to a type of cell that can respond to a specific type of stimulus. The term membrane receptor refers to a protein within a cell membrane that binds a ligand and thereby generates signals that initiate a cellular response.

Figure 43.3 To think about what types of touch you are aware of, let's take the example of sitting in a chair reading this textbook while holding it on your lap. You are aware of the constant weight of the book, the brush of the pages on your fingertips as you turn a page, a gentle breeze that may be circulating in your environment, the deep pressure from regularly adjusting your posture in your chair, an itch you may have on your skin, and the heat or cold of the room. Even a simple exercise such as this one is filled with stimuli of numerous types and durations.

Figure 43.11 This orientation permits animals to detect circular or angular movement of the head in three different planes. The fluid in a canal that is oriented in the same plane as the plane of movement will respond maximally to the movement. For example, the canal that is oriented horizontally would respond greatest to horizontal movements, while the other two canals would not. Overall, by comparing the signals from the three canals, the brain can interpret the motion in three dimensions.

Figure 43.18 The discs of photoreceptors are an example of increasing surface area without greatly expanding the volume of a structure. The greater surface area allows for more rhodopsin molecules per photoreceptor and thus a greater likelihood of capturing even low levels of light.

Figure 43.19 Because red-green color blindness is a sex-linked recessive gene, males require only a single defective allele on an X chromosome, whereas females require two defective alleles, one on each X chromosome.

Figure 43.27 Salt is a vital nutrient needed to maintain plasma membrane potentials and fluid balance in animals' bodies. Sugar provides glucose and other monosaccharides, important energy-yielding compounds. Sour (acidic) foods, like citrus fruits, provide nutrients and important antioxidants (vitamin C, for example) that protect against disease. Bitter substances are often toxic, and their bad taste discourages animals from eating them.

Feature Investigation Questions

1. One possibility is that many different types of odor molecules might bind to one or just a few types of receptor proteins, with the brain responding differently depending on the number or distribution of the activated receptors. The second hypothesis is that organisms can make a large number of receptor proteins, each type binding a particular odor molecule or group of odor molecules. According to this hypothesis, it is the *type* of receptor protein, and not the number or distribution of receptors, that is important for olfactory sensing.

   The researchers extracted RNA molecules from the olfactory receptor cells of the nasal epithelium. They then used this RNA to identify genes that encoded G-protein-coupled receptor proteins.
2. In their study, they identified 18 different genes that encoded different G-protein-coupled receptor proteins.
3. The results of the experiment conducted by Buck and Axel support the hypothesis that animals discriminate between different odors based on having a variety of receptor proteins that recognize different odor molecules. Current research suggests that each olfactory receptor cell has a single type of receptor protein that is specific to particular odor molecules. Because most odors are due to multiple chemicals that activate many different types of odor receptor proteins, the brain detects odors based on the combination of the activated receptor proteins. Odor seems to be discriminated by many olfactory receptor proteins, which are in the membrane of separate olfactory receptor cells.

Test Yourself

1. d 2. d 3. a 4. c 5. e 6. d 7. b 8. b 9. d 10. b

Conceptual Questions

1. Sensory transduction—The process by which incoming stimuli are converted into neural signals. An example would be the signals generated in the retina when a photon of light strikes a photoreceptor.

   Perception—An awareness of the sensations that are experienced. An example would be an awareness of what a particular visual image is.

2. The organ of Corti contains the hair cells and sensory neurons that initiate signaling. The hair cells sit on top of the basilar membrane, and their stereocilia are embedded in the tectorial membrane at the top of the organ of Corti. Pressure waves of different frequencies cause the basilar membrane to vibrate at particular sites. This bends the stereocilia of hair cells back and forth, sending oscillating signals to the sensory neurons. Consequently, the sensory neurons send intermittent action potentials to the CNS via the auditory nerve. Hair cells at the end of the basilar membrane closest to the oval window respond to high-pitched sounds, and lower-pitched sounds trigger hair cell movement further along the basilar membrane.
3. Animals that have both eyes located at the front of the head facing forward have a large degree of binocular vision, because the overlapping images coming into both eyes are processed together to form one perception. Binocular vision provides excellent depth perception. Predators depend on binocular vision to locate prey precisely. In contrast, animals with eyes toward the side of the head have reduced binocular vision, but a wide visual field, which allows them to see a wide area at one time. Most prey animals benefit from a wide visual field, which allows them to detect the presence of predators even, in some cases, if a predator is behind the prey.

Chapter 44

Concept Checks

Figure 44.1 Yes. In addition to not having a requirement to shed their skeletons periodically, animals with endoskeletons can use their skin as an efficient means of heat transfer (and, to an extent in amphibians, water transfer). In addition, the body surface of such animals is often a highly sensitive sensory organ.

Figure 44.3 If a tendon is torn, its ability to link a muscle to bone is reduced or lost. Therefore, when a muscle such as the one shown in this illustration contracts, it will not be able to move the bone to which the tendon has become dislodged.

Figure 44.8 The ATP concentration in cells becomes depleted after death, because oxygen and nutrients are not being provided to cells. Consequently, the cross-bridge cycle becomes locked before Step 3. Without ATP, the cross-bridges cannot dissociate until many hours later, when the muscle tissue sufficiently decomposes.

Figure 44.11 Na^+ enters the muscle cell because all cells have an electrochemical gradient for Na^+ that favors diffusion of Na^+ from extracellular to intracellular fluid (see Chapter 41). This is because cells have a negative membrane potential and because Na^+ concentrations are higher in the extracellular fluid. The acetylcholine receptor on skeletal muscle cells is also a ligand-gated ion channel; when acetylcholine binds the receptor, it induces a shape change that opens the channel. This allows the entry of Na^+ into the cell.

Figure 44.14 No. The data are expressed as "per kg"; this means that when normalized to a standard body mass (1 kg), the amount of energy expended for any type of locomotion by a small animal tends to be greater than that of a larger animal. However, these are *relative* values. For example, the *absolute* amount of energy expended by a tiny minnow is much less than that of a large tuna over any given distance.

Feature Investigation Questions

1. PPAR-δ is a nuclear receptor that regulates the expression of genes that enable cells to more efficiently burn fat instead of glucose for energy.
2. Evans suggested that if PPAR-δ were highly activated in mice, the mice would lose weight because of the high level of fat metabolism.
3. They developed transgenic mice with highly activated PPAR-δ. Then they fed the transgenic mice and a strain of normal mice high-fat diets. They then compared the weights of the two strains of mice to determine if the change in PPAR-δ activity affected weight. The weights of the transgenic mice were considerably lower than those of the normal mice. These results supported the hypothesis that highly activated PPAR-δ would lead to lower weight gain due to fat metabolism. Interestingly, the researchers also discovered that the transgenic mice could perform prolonged exercise for a much longer time than the normal mice. The muscle tissue of the transgenic mice was more specialized for long-term exercise.

Test Yourself

1. c 2. e 3. d 4. c 5. e 6. c 7. a 8. e 9. c 10. e

Conceptual Questions

1. Locomotion is the ability of an animal to move from place to place. Examples include swimming, walking or running, jumping, flying, crawling, and sliding.
2. Exoskeletons are on the outside of an animal's body, and endoskeletons are inside the body. Both function in support and protection, but only exoskeletons protect an animal's outer surface. Exoskeletons must be shed when an animal grows, whereas endoskeletons grow with an animal.
3. a. The cycle begins with the binding of an energized myosin cross-bridge to an actin molecule on a thin filament.
   b. The cross-bridge moves, and the thin filaments slide past the thick filaments.
   c. The ATP binds to myosin, causing the cross-bridge to detach.
   d. The ATP bound to myosin is hydrolyzed by ATPase, re-forming the energized state of myosin.

Chapter 45

Concept Checks

Figure 45.4 After a large blood meal, the body mass of a flying blood-sucking animal increases sufficiently as to make it nearly impossible to fly. The problem is solved, however, by a unique adaptation that allows such animals to concentrate the nutrients from blood and excrete most of the water portion of blood as soon as they begin eating. By the time the meal is finished, much of the water they consumed has already been excreted.

Figure 45.7 Sauropod dinosaurs were herbivores that probably contained a gizzard-type stomach in which stones helped to grind coarse vegetation. Such stones would have become smooth after months or even years of rumbling around in the gizzard. Some of these sauropods are known to have lacked the sort of grinding teeth characteristic of modern mammalian herbivores, and thus a gizzard would have aided in their digestion much as it does in modern birds.

Figure 45.10 By having bile stored in a gallbladder, bile can be released precisely when needed in response to a meal; this is particularly useful for animals that consume large or infrequent meals. In the absence of a gallbladder, bile flows into the intestine continuously and cannot be increased to match the amount or timing of food intake.

Figure 45.11 Secondary active transport requires energy provided by ATP. Thus, absorption of nutrients by this mechanism is an energy-requiring event, and some portion of an animal's regular nutrient consumption is used to provide the energy required to absorb the nutrients.

Figure 45.13 CCK inhibits stomach activity. This is an example of negative feedback. The arrival of chyme in the small intestine stimulates CCK, which promotes digestion as shown in the figure. At the same time, CCK inhibits contraction of the smooth muscles of the stomach so that the entry of chyme into the small intestine is slowed down. This allows time for controlled digestion and absorption of nutrients in the intestine, without the intestine becoming overfilled with chyme. Simultaneously, CCK inhibits acid production by the stomach so that the pH of the intestine does not become dangerously low before bicarbonate ions are able to neutralize it.

Feature Investigation Questions

1. The researchers severed the nerves that connected to the small intestine in a dog. Following the removal of the nerves, the researchers introduced an acidic solution directly into the intestine of the dog. The introduction of the acid into the intestine caused pancreatic secretion. This suggested that non-neural factors must have mediated communication between the digestive tract and the secretory cells of the pancreas.
2. Other researchers were not convinced that all the nerves were dissected from the intestine, because of the technical difficulty in performing such a procedure. To provide more conclusive evidence of other regulatory factors that were produced by the intestine, the researchers conducted a second experiment. First, they dissected a portion of a small intestine from a dog, treated it with acid, ground it up to produce a mash, and then filtered the mash to obtain an extract. The extract—which was expected to contain any secretions of the intestine that occurred following acid exposure—was then injected into the circulatory system of a second dog. The results indicated that the second dog had pancreatic secretion following the injection.

3. The results suggested that factors were secreted by the small intestine following exposure of the intestine to acid, as would occur when chyme enters the intestine from the stomach. These factors probably reached the pancreas through the bloodstream. The researchers called these factors hormones. Thus, the digestive system was regulated not only by the nervous system, but also by chemical secretions, and different parts of the digestive system were able to communicate with each other via hormones.

Test Yourself

1. d 2. e 3. e 4. b 5. c 6. b 7. d 8. c 9. a 10. e

Conceptual Questions

1. Digestion is the breakdown of large molecules into smaller ones by the action of enzymes and acid. Absorption is the transport of digested molecules and small molecules that do not require digestion, across the epithelial cells of the alimentary canal and from there into the extracellular fluid of an animal.
2. Carnivores eat live animal flesh and/or fluids or may scavenge dead animals. Carnivores' teeth are adapted for seizing, grasping, piercing, biting, slicing, tearing, or holding prey; they generally do not chew their food extensively, but may chew to facilitate swallowing. Herbivores have powerful jaw muscles and large, broad molars for grinding tough, fibrous plant material; they may also have incisors adapted for nipping grass or other vegetation. Simply examining the type of teeth an animal has is often sufficient to determine whether that animal eats vegetation, animals, or both.
3. The crop is a dilation of the esophagus, which stores and softens food. The gizzard contains swallowed pebbles that help pulverize food. Both of these functions are adaptations that assist digestion in birds, who do not have teeth and therefore do not chew food. Humans, like many animals, can chew food before swallowing.

Chapter 46

Concept Checks

Figure 46.3 The time required for the vesicles to move to the plasma membrane and fuse with it is much shorter than the time required for new GLUTs to be synthesized by activation of GLUT genes. Thus, the action of insulin on cells is very quick, because the GLUTs are already synthesized.

Figure 46.4 The glycerol and fatty acids used to make glucose are the breakdown products of triglycerides that were stored in adipose tissue during the absorptive period. The amino acids used to make glucose are derived from the breakdown of protein in muscle and other tissue.

Figure 46.6 Even though the goose was resting, sampling the air from the mask would be only a rough estimate of BMR. That is because the artificial setting and the placement of the mask would be enough of a stimulus to affect the activity and behavior of the goose and thereby increase its metabolism.

Figure 46.7 As shown in Figure 46.7, for humans exercise is a voluntary activity. In nature, however, "exercise" is often a component of the fight-or-flight reaction, such as when an animal attempts to escape danger. During such times, digestion and absorption of food are less important than providing as much blood flow, oxygen, and nutrients as possible to skeletal muscle. The gut, therefore, temporarily reduces its activity and requires less blood flow.

Figure 46.8 Nearly all animals today show a similar relationship between body mass and metabolic rate, and there is no reason why it should not always have been true. Thus, the tiny 1-foot-tall ancestral horse *Eohippus* most likely had a higher BMR than do today's larger horses.

Figure 46.11 Humans are homeothermic endotherms. We maintain our body temperature within a very narrow range, and we supply our own body heat.

Feature Investigation Questions

1. Scientists were interested in knowing why animals seemed to regulate their body mass around a particular level, even though many animals experience changes in food supply throughout the year. This seemed to indicate that a mechanism existed within the body that monitored when fuel stores were higher or lower than normal, and that initiated changes in behavior and metabolism to compensate.
2. Coleman hypothesized that communication regarding energy status must take place between the brain and the rest of the body. He suggested that chemical signals were transported through the blood from outside the brain to feeding or satiety centers within the brain, where they regulated appetite and thus regulated body weight. He tested this by linking the blood circulations of normal mice and genetically obese mice and then monitoring the mice for changes in body weight.
3. In most cases, the obese mice lost weight and ate less during the experimental procedure. This confirmed that something in the bloodstream of the wild-type mice was regulating body weight but was missing in the obese mice. When the unknown factor crossed into the bloodstream of the obese mice, it caused them to lose weight. In another group of parabiosed mice, however, the wild-type mice lost weight, but the obese mice did not. Coleman concluded that these obese mice were not able to respond to the chemical signal that regulates body weight, even though they made the signal themselves and it was active in their parabiosed wild-type partners.

Test Yourself

1. c 2. a 3. d 4. c 5. a 6. e 7. e 8. c 9. c 10. e

Conceptual Questions

1. Insulin acts on adipose and skeletal muscle cells to facilitate the diffusion of glucose from extracellular fluid into the cell cytosol. This is accomplished by increasing the translocation of glucose-transporter (GLUT) proteins from the cytosol to sites within the plasma membrane of insulin-sensitive cells. Insulin also inhibits glycogenolysis and gluconeogenesis in the liver, which decreases the amount of glucose secreted into the blood by the liver. Insulin is required for glucose transport because like many other polar molecules, glucose cannot move across the lipid bilayer of a plasma membrane by simple diffusion. The inhibitory effects of insulin on liver function help to ensure that liver glycogen stores will be spared for the postabsorptive period.
2. Appetite is controlled by a satiety center in the brain that receives signals from the stretched stomach and intestines after a meal. When digestion and absorption are complete, the stomach and intestines return to their original size, and the brain no longer senses that an animal feels "full." In addition, appetite is controlled by leptin, a hormone secreted by adipose cells in direct proportion to the amount of fat stored in an animal's body. When leptin levels in the blood are high, appetite is suppressed. When leptin levels are low, as occurs when an animal is losing weight, appetite is increased. The presence of a hormone that is released into the blood in proportion to fat mass in the body allows the brain to monitor the amount of energy stored in the body. A decrease in the concentration of leptin in the blood, for example, is the mechanism that communicates to the brain that fat stores are lower than normal. This initiates the sensation of hunger, which encourages an animal to seek food.
3. Countercurrent heat exchange is a mechanism for retaining body heat. As warm blood travels through arteries down a bird's leg, for example, heat moves by conduction from the artery to adjacent veins carrying cooler blood in the other direction, toward the heart. By the time the arterial blood reaches the tip of the leg, its temperature has dropped considerably, reducing the amount of heat loss to the environment, while the heat is returned to the body's core via the warmed veins.

Chapter 47

Concept Checks

Figure 47.2 Open circulatory systems evolved prior to closed systems. However, this does not mean that open systems are in some way inferior to closed circulatory systems. It is better to think of open systems as being ideally suited to the needs of those animals that have them. Arthropods are an incredibly successful order of animals, with the greatest number of species, and inhabiting virtually every ecological niche on the planet. Clearly, their type of circulatory system has not prevented arthropods from achieving their great success.

Figure 47.4 Keeping oxygenated and deoxygenated blood fully separate allows the arterial blood of birds and mammals to provide the maximum amount of oxygen to tissues. This means that those tissues can achieve higher metabolisms and be more active at all times.

Figure 47.6 Each hemoglobin molecule contains four subunits, each of which has an iron atom at its core. Each iron binds one oxygen molecule (O_2); therefore, a total of eight oxygen atoms can bind to one hemoglobin molecule.

Figure 47.11 Body fluids, both extracellular and intracellular, contain large amounts of charged ions, which are capable of conducting electricity. The slight electric currents generated by the beating heart muscle cells are conducted through the surrounding body fluids by the movements of ions in those fluids. This is recorded by the surface electrodes and amplified by the recording machine.

Figure 47.14 When the animal is active, the arterioles of its leg muscle would dilate, bringing more blood and, consequently, nutrients and oxygen to the active muscle tissue.

Figure 47.17 The valves open toward the heart. When the head is upright, the valves are open, and blood drains from the head to the right atrium by gravity. When the giraffe lowers its head to drink, however, gravity would prevent the venous blood from reaching the heart; instead, blood would pool in the head and could raise pressure in the head and brain. The valves in the neck veins work the same way as those in the legs of other animals, helping to propel blood against gravity to the heart.

Figure 47.20 Baroreceptors are mechanoreceptors. Like all mechanoreceptors (e.g., those in distensible or deformable structures such as the urinary bladder and stomach), their ion channels are opened by physical deformation or stretching of the plasma membrane. They are, therefore, mechanically gated ion channels.

Feature Investigation Questions

1. Furchgott noted that acetylcholine had different effects on the rabbit aorta depending on the manner in which the aorta was isolated and prepared. When applied to flattened strips of the aorta, acetylcholine caused contraction of the aorta smooth muscle; however, when applied to circular rings of the aorta, acetylcholine caused relaxation. Furchgott suggested that the difference was due to the absence of the endothelial layer of tissue in the flattened strips of aorta.
2. Furchgott hypothesized that acetylcholine stimulated the endothelial cells to secrete a substance that functioned as a vasodilator, causing the muscle layer to relax. Furchgott performed several experiments to test his hypothesis. He compared the effects of acetylcholine on circular rings of aorta that either had the endothelial layer intact or experimentally removed. The results of this experiment demonstrated that when the endothelial layer was present, relaxation occurred in the presence of acetylcholine. Removal of the endothelial layer, however, resulted in contraction of muscle in the presence of acetylcholine. In a second experiment, a strip of the aorta with the endothelial layer removed was put in contact with a strip of aorta with an intact endothelial layer. When this "sandwiched" treatment was exposed to acetylcholine, both muscle layers relaxed.
3. Furchgott concluded that the endothelial layer produced a vasodilator in the presence of acetylcholine. The vasodilator diffused from the intact strip of muscle to the denuded strip and caused the muscle layer to relax.

Test Yourself

1. b 2. a 3. c 4. b 5. a 6. d 7. c 8. d 9. c 10. d

Conceptual Questions

1. The three main components of a circulatory system are (1) blood or hemolymph, an internal body fluid containing dissolved solutes; (2) blood vessels, a system of hollow tubes within the body through which blood travels; and (3) one or more hearts, muscular structures that pump blood through the blood vessels.
2. ***Closed circulatory system***—In a closed circulatory system, the blood and interstitial fluid are contained within tubes called blood vessels and are transported by a pump called the heart. All of the nutrients and oxygen that tissues require are delivered directly to them by the blood vessels. Advantages of closed circulatory systems are that different parts of an animal's body can receive blood flow in proportion to that body part's metabolic requirements at any given time. Due to its efficiency, a closed circulatory system allows organisms to become larger.

   Open circulatory system—In an open circulatory system, the organs are bathed in hemolymph that ebbs and flows into and out of the heart(s) and body cavity, rather than blood being directed to all cells. Like a closed circulatory system, there are a pump and blood vessels, but these two structures are less developed and less complex compared to a closed circulatory system. Partly as a result, organisms such as mollusks and arthropods are generally limited to being relatively small, although exceptions do exist.
3. The cardiac cycle can be divided into two phases. The first is diastole, during which the ventricles fill with blood coming from the atria through the open AV valves. This is followed by systole, the contraction of the ventricles that ejects blood through the open semilunar valves. Valves must be one-directional because if, for example, the AV valves opened in both directions, then blood would flow from the ventricles into the atria whenever the ventricles contracted. This would reduce the amount of blood flowing into the arteries, and consequently, cardiac output and blood pressure would decrease to dangerously low levels.

Chapter 48

Concept Checks

Figure 48.2 Regardless of whether the atmosphere is measured on Mt. Everest or at sea level, the percentage of gas molecules that are oxygen remains close to 21%. However, the pressure exerted by those gas molecules decreases as one ascends in elevation.

Figure 48.3 If a lungless salamander were to dry out, its capacity for gas exchange would be greatly reduced. Gases diffuse into and out of the body of the salamander by dissolving in the moist fluid layer on the skin.

Figure 48.5 Imagine holding several thin sheets of a wet substance, such as paper. If you wave them in the air, what happens? The sheets stick to one another because of surface tension and other properties of moist surfaces. This is what happens to the lamellae in gills when they are in air. When the lamellae stick to each other, this reduces the surface area available for gas exchange, and the fish suffocates.

Figure 48.7 There are probably several factors that limit insect body size, but the respiratory system most likely is one such factor. If an insect grew to the size of a human, for example, the trachea and tracheoles would be so large and extensive that there would be little room for any other internal organs in the body! Also, the mass of the animal's body and the forces generated during locomotion would probably collapse the tracheoles. Finally, diffusion of oxygen from the surface of the body to the deepest regions of a human-sized insect would take far too long to support the metabolic demands of internal structures.

Figure 48.12 Because fishes have the most efficient means of extracting oxygen from their environment, one might conclude that this is an adaptation to cope with low environmental oxygen. Based on that logic, you would conclude that the oxygen content of water was less than that of air, which is indeed correct.

Figure 48.15 The waters off the coast of Antarctica are extremely cold, rarely warmer than 0.30°C. As we saw earlier in this chapter, more oxygen dissolves in cold water than in warm water, and therefore icefish have the potential to obtain more oxygen across their gills. Cold temperatures also decrease the metabolic rate of the animals, because all chemical reactions slow down at low temperature. Thus, the oxygen demands of icefish are lower than those of warm-water fish. Several other adaptations have evolved to enable these animals to live without hemoglobin. Large gills with exceptionally high surface area facilitate diffusion of oxygen into the animal's blood. In addition, cardiovascular adaptations evolved to help increase the total amount of oxygen in the blood and its ability to be pumped to all body tissues. For example, icefish have larger blood volumes and a larger heart than warm-water fish of a similar size. Also, the absence of red blood cells makes the blood less viscous (makes it "thinner") and therefore easier to pump through the body.

Figure 48.16 An increase in the blood concentration of HCO_3^- would favor the reaction $HCO_3^- + H^+ \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$. This would reduce the hydrogen ion concentration of the blood, thereby raising the pH; the CO_2 formed as a result would be exhaled. These changes would shift the hemoglobin curve to the left of the usual position.

Feature Investigation Questions

1. The study conducted by Schmidt-Neilsen intended to determine the route of air through the avian respiratory system. This would provide a better understanding of the functions of the air sacs and the process of gas exchange in birds.

2. The first experiment by Schmidt-Neilsen compared the composition of air between the posterior and anterior air sacs. Oxygen content was high in the posterior sacs but low in the anterior sacs. Carbon dioxide levels, however, were low in the posterior sacs but high in the anterior sacs. The researchers concluded that when inhaled, the air moves first to the posterior sacs; then to the lungs where oxygen diffuses into the blood and carbon dioxide diffuses into the lungs; and, finally, to the anterior sacs before being exhaled.
3. The second experiment by Schmidt-Neilsen was conducted to verify the pathway of air through the respiratory system of the bird. In this experiment, the researcher monitored oxygen levels by surgically implanting oxygen probes in the anterior and posterior air sacs. The bird was fitted with a face mask and allowed to take one breath of pure oxygen. The researcher was then able to track the movement of this oxygen through the respiratory tract. Schmidt-Neilsen concluded that it takes two complete breaths for air to move from the environment through the lungs and back out again to the environment. The two breaths are required to move the air from the posterior air sacs through the lungs and, finally, to the anterior air sacs before exiting the body.

Test Yourself

1. a 2. e 3. c 4. c 5. a 6. b 7. e 8. e 9. d 10. b

Conceptual Questions

1. Countercurrent exchange maximizes the amount of oxygen that can be obtained from the water in fishes. Oxygenated water flows across the lamellae of a fish gill in the opposite direction in which deoxygenated blood flows through the capillaries of the lamellae. In this way, a diffusion gradient for oxygen is maintained along the entire length of the lamellae, facilitating diffusion of oxygen even when much of it has already entered the blood.
2. The avian respiratory system is unique among vertebrates in that it is supplemented with air sacs, which do not participate in gas exchange. They do, however, create a unidirectional flow of air through the respiratory system. Air enters the trachea and flows into the two bronchi and then into a series of sacs and parallel tubes called parabronchi, which comprise the avian lungs. Air moves through the system in two cycles. In the first inhalation, air flows into the posterior air sacs. On exhalation, air exits the posterior air sacs and flows through the parabronchi from the back to the front of the lungs. During the next inhalation, air flows from the anterior area of the lungs into the anterior air sacs, which serve as a holding chamber, while fresh air enters the posterior sacs again. The efficiency of this avian flow-through system is a major reason why birds can fly at altitudes with extremely low atmospheric pressure and, consequently, low partial pressures of oxygen.
3. Animals that live at high altitudes face the special challenge of obtaining oxygen where the atmospheric pressure is low. When atmospheric pressure is low, the partial pressure of oxygen in the air is also low. This means that there is less of a driving force for the diffusion of oxygen from the air into the body of the animal. Several adaptations have arisen that help animals cope with such habitats. For example, many high-altitude animals have more red blood cells and have hemoglobin with a higher affinity for oxygen than that of sea-level animals. This means their hemoglobin can bind oxygen even at the low partial pressures of high altitudes and thereby saturate their blood with oxygen. In addition, such animals generally have larger hearts and lungs for their body size than animals that live at lower altitudes. Animals that move to high altitude show increases in the number of red blood cells in their circulation and in respiratory rates. The number of capillaries in skeletal muscle increases to facilitate oxygen diffusion into the muscle cells. Myoglobin content of muscle cells also increases, expanding the reservoir of oxygen in the cytosol.

Chapter 49

Concept Checks

Figure 49.1 No, obligatory exchanges must always occur, but animals can minimize obligatory losses through modifications in behavior. For example, terrestrial animals that seek shade on a hot, sunny day reduce evaporative water loss. As another example, reducing activity minimizes water loss due to respiration.

Figure 49.4 Humans cannot survive by drinking seawater because we do not possess specialized salt glands to rid ourselves of the excess sodium and other ions ingested with seawater. The human kidneys cannot eliminate that much salt. The high blood levels of sodium and other ions would cause changes in cellular membrane potentials, disrupting vital functions of electrically excitable tissue such as cardiac muscle and nerve tissue.

Figure 49.6 Secretion of substances into excretory organ tubules is advantageous because it increases the amount of a substance that gets removed from the body by the excretory organs. This is important, because many substances that get secreted are potentially toxic. Filtration, though efficient, is limited by the volume of fluid that can leave the capillaries and enter the excretory tubule.

Figure 49.12 A brush border composed of microvilli is also present along the epithelial cell layer of the vertebrate small intestine (see Chapter 45). In the intestine, the brush border serves to increase the absorption of nutrients. In both the intestine and the proximal tubule of nephrons, therefore, a brush border provides extensive surface area for the transport of substances between a lumen and the epithelial cells (and from there to extracellular fluid).

Figure 49.14 Epithelial cells like those in the kidney tubules can distribute proteins between the luminal and basolateral sides of the plasma membrane. In this way, the Na^+/K^+-ATPase pumps that are stimulated by aldosterone are present and active only on one side of the cell, the basolateral surfaces. If the pumps were activated on the luminal surface of the cell, aldosterone would not be able to promote reabsorption of Na^+ and water, because Na^+ would also be transported from the cell into the tubule lumen.

Feature Investigation Questions

1. Symptoms of prolonged, heavy exercise include fatigue, muscle cramps, and even occasionally seizures. Fatigue results from the reduction in blood flow to muscles and other organs. Muscle cramps and seizures are the results of imbalances in plasma electrolyte levels. Cade and his colleagues hypothesized that maintaining proper water and electrolyte levels would prevent these problems, and that if water and electrolyte levels were maintained, athletic performance should not decrease as rapidly with prolonged exercise.
2. To test their hypothesis, the researchers created a drink that would restore the correct proportions of lost water and electrolytes within the athletes. If the athletes consumed the drink during exercise, they should not experience as much fatigue or muscle cramping, and thus their performance should be enhanced compared to a control group of athletes that drank only water.
3. The performance of a group of exercising athletes given the electrolyte-containing drink was better than that of the control group that drank only water during exercise. This could be attributed to the replacement of normal electrolyte levels by the drink.

Test Yourself

1. e 2. e 3. d 4. c 5. a 6. c 7. e 8. d 9. a 10. b

Conceptual Questions

1. Nitrogenous wastes are the breakdown products of the metabolism of proteins and nucleic acids. They consist of ammonia, ammonium ions, urea, and uric acid. The predominant type of waste excreted depends in part on an animal's environment. For example, aquatic animals typically excrete ammonia and ammonium ions, whereas many terrestrial animals excrete primarily urea and uric acid. Urea and uric acid are less toxic than the other types but require energy to be synthesized. Urea and uric acid also result in less water excreted, an adaptation that is especially useful for organisms that must conserve water, such as many terrestrial species.
2. Salt glands contain a network of secretory tubules that actively transport NaCl from the extracellular fluid into the tubule lumen. This solution then moves through a central duct and to the outside environment through pores in the nose, around the eyes, and in other locations. The ability to remove salt from body fluids is an adaptation for many marine reptiles and birds, which do not have ready access to fresh water and would otherwise run the risk of having very high levels of salts in their blood and other body fluids.
3. In filtration, an organ acts like a sieve or filter, removing some of the water and its small solutes from the blood, interstitial fluid, or

hemolymph, while retaining blood cells and large solutes such as proteins. Reabsorption is the process whereby epithelial cells of an excretory organ recapture useful solutes that were filtered. Secretion is the process whereby epithelial cells of an excretory organ transport unneeded or harmful solutes from the blood to the excretory tubules for elimination. Some substances such as glucose and amino acids are reabsorbed but not secreted, while some other substances such as toxic compounds are not reabsorbed and are secreted. Still other substances, namely proteins, are not filtered at all.

Chapter 50

Concept Checks

Figure 50.4 When dopamine is secreted from an axon terminal into a synapse where it diffuses to a postsynaptic cell, it is considered a neurotransmitter. When it is secreted from an axon terminal into the extracellular fluid, from where it diffuses into the blood, it is considered a hormone.

Figure 50.7 In addition to the pancreas, certain other organs in an animal's body may contain both exocrine and endocrine tissue or cells. For example, you learned in Chapters 45 and 46 that the vertebrate alimentary canal is composed of several types of secretory cells. Some of these cells release hormones into the blood that regulate the activities of the pancreas and other structures, such as the gallbladder. Other cells of the alimentary canal secrete exocrine products such as acids or mucus into the gut lumen that directly aid in digestion or act as a protective coating, respectively.

Figure 50.10 Not all mammals use the energy of sunlight to synthesize vitamin D. There are many animals, such as those that inhabit caves or that are strictly nocturnal, that rarely are exposed to sunlight. Some of these animals get their vitamin D from dietary sources. How others maintain calcium balance without dietary or sunlight-derived active vitamin D remains uncertain.

Figure 50.12 Sodium and potassium ion balance is of vital importance for most animals because of the critical role these ions play in nervous system and muscle function. It is more the rule than the exception that such important physiological variables are under multiple layers of control. This grants a high degree of fine-tuning capability such that these ions—and other similarly important molecules—rarely exceed or fall below the normal range of concentrations for a given animal.

Figure 50.13 The great height of the twin on the left in Figure 50.13 clearly indicates that his condition arose prior to puberty. The enlarged bones further suggest that the disease continued for a time after puberty, when further linear bone growth was no longer possible.

Figure 50.15 Because 20-hydroxyecdysone is a steroid hormone, you would predict that its receptor would be intracellular. All steroid hormones interact with receptors located either in the cytosol or, more commonly, in the nucleus. The hormone : receptor complex then acts to promote or inhibit transcription of one or more genes. The receptor for 20-hydroxyecdysone is indeed found in cell nuclei.

Feature Investigation Questions

1. Banting and Best based their procedure on a medical condition that results when pancreatic ducts are blocked. The exocrine cells will deteriorate in a pancreas that has obstructed ducts; however, the islet cells are not affected. The researchers proposed to experimentally replicate the condition to isolate the cells suspected of secreting the glucose-lowering factor. From these cells, they assumed they would be able to extract the substance of interest without contamination or degradation due to exocrine products.
2. The extracts obtained by Banting and Best did contain insulin, the glucose-lowering factor, but were of low strength and purity. Collip developed a procedure to obtain a more purified extract with higher concentrations of insulin.
3. The researchers chose to use bovine pancreases as their starting material for preparing the extracts. Because of the large size of these animals and their availability at local slaughterhouses, the researchers were able to obtain great yields of insulin. Second, Collip developed a highly sensitive assay for monitoring changes in blood glucose levels after injection of insulin. This allowed the researchers to better estimate how much insulin was in a preparation and how much was necessary to give to a patient.

Test Yourself

1. b 2. e 3. b 4. e 5. b 6. e 7. c 8. d 9. b 10. d

Conceptual Questions

1. Leptin acts in the hypothalamus to reduce appetite and increase metabolic rate. Because adipose tissue is typically the most important and abundant source of stored energy in an animal's body, the ability to relay information to the appetite and metabolism centers of the brain about the amount of available adipose tissue is a major benefit. In this way, the brain's centers can indirectly monitor the minute-to-minute energy status in the body. A decrease in leptin, for example, would indicate that a decrease in adipose tissue existed—as might occur during a fast. Removal of the leptin signal would cause appetite to increase and metabolism to decrease, thereby conserving energy. The presence of an appetite and the subjective sensations associated with hunger is a motivation that drives an animal to seek food at the expense of other activities, such as seeking shelter, finding a mate, and so on.
2. Insulin acts to lower blood glucose concentrations, for example, after a meal, whereas glucagon elevates blood glucose, for example, during fasting. Insulin acts by stimulating the insertion of glucose transporter proteins into the cell membrane of muscle and fat cells. Glucagon acts by stimulating glycogenolysis in the liver. If a high dose of glucagon were injected into an animal, including humans, the blood concentration of glucagon would increase rapidly. This would stimulate increased glycogenolysis, resulting in blood glucose concentrations that were above normal.
3. Type 1 DM is characterized by insufficient production of insulin due to the immune system destroying the insulin-producing cells of the pancreas. In type 2 DM, insulin is still produced by the pancreas, but adipose and muscle cells do not respond normally to insulin.

Chapter 51

Concept Checks

Figure 51.4 Aquatic environments in which the water is stagnant or only gently moving, as shown in this figure, are generally best for external fertilization. Fast-moving bodies of water reduce the likelihood of a sperm contacting an egg and increase the chances that gametes will be washed away in the current. Many river-dwelling fishes lay eggs in gently moving streams, and many marine fishes do so in relatively shallow waters.

Figure 51.7 The elevated testosterone levels would inhibit LH and FSH production through negative feedback. This would result in reduced spermatogenesis and possibly even infertility (an inability to produce sufficient sperm to cause a pregnancy).

Figure 51.10 FSH and LH concentrations do not surge in males, but instead remain fairly steady, because the testes do not show cyclical activity. Sperm production in males is constant throughout life after puberty.

Figure 51.11 In addition to its other functions, the placenta must serve the function of the lungs for the fetus, because its real lungs are not breathing air during this time. Arteries always carry blood away from the heart; veins carry blood to the heart. Consequently, blood leaving the heart of the fetus and traveling through arteries to the placenta is deoxygenated. As blood leaves the placenta and returns to the heart, the blood has become oxygenated as oxygen diffuses from the maternal blood into fetal blood. That oxygenated blood then gets pumped from the fetal heart through other arteries to the rest of the fetus' body.

Figure 51.14 Pregnancy and subsequent lactation require considerable energy and, therefore, nutrient ingestion. Consuming the placenta provides the female with a rich source of protein and other important nutrients.

Feature Investigation Questions

1. Using *Daphnia*, Paland and Lynch compared the accumulation of mitochondrial mutations between sexually reproducing populations and asexually reproducing populations.
2. The results—that sexually reproducing populations had a lower rate of deleterious mutations compared to asexually reproducing populations—indicate that sexual reproduction does decrease the accumulation of deleterious mutations, at least in this species.

3. Sexual reproduction allows for mixing of the different alleles of genes with each generation, thereby increasing genetic variation within the population. This could prevent the accumulation of deleterious alleles in the population.

Test Yourself

1. d 2. c 3. e 4. a 5. b 6. c 7. b 8. c 9. b 10. c

Conceptual Questions

1. In viviparity, most of embryonic development occurs within the mother, and the animal is born alive, as occurs in most mammals. If all or most of embryonic development occurs outside the mother and the embryo depends exclusively on yolk from an egg for nourishment, the process is called oviparity; this occurs in most vertebrates and in insects. In ovoviviparity, which occurs in some reptiles, sharks and some invertebrates, fertilized eggs covered with a very thin shell hatch inside the mother's body, but the offspring receive no nourishment from the mother. Humans are viviparous. An advantage of viviparity is that the embryo and fetus develop in a protected environment.
2. Sexual reproduction requires that males and females of a species produce different gametes and that these gametes come into contact with each other. This requires males and females to expend energy to locate mates. It also may require specialized organs for copulation and in some cases requires the production of very large numbers of gametes to increase the likelihood that the eggs are fertilized. These costs are outweighed by the genetic diversity afforded by sexual reproduction.
3. Cells of the hypothalamus produce two important hormones that regulate reproduction. GnRH stimulates the anterior pituitary gland to release two gonadotropic hormones, LH and FSH. These two hormones regulate the production of gonadal hormones and development of gametes in both sexes. In addition, increased secretion of GnRH contributes to the initiation of puberty. The hypothalamus also produces oxytocin, a hormone that is stored in the posterior pituitary gland and that acts to stimulate milk release during lactation. Finally, changes in neuroendocrine activity in the hypothalamus are linked to seasonal changes in day length and therefore contribute to seasonal breeding in certain mammals.

Chapter 52

Concept Checks

Figure 52.1 The process by which a tadpole develops into an adult frog is called metamorphosis. This process is widespread in animals and occurs in many arthropods, certain fishes, numerous marine invertebrates such as gastropods, and amphibia.

Figure 52.5 No, all vertebrates do not use internal fertilization. External fertilization is common in fishes and amphibia; these animals lay unfertilized eggs, over which males deposit sperm (see Chapter 51).

Figure 52.14 Different concentrations of a signaling protein can exert different effects on cells when, for example, different cells express different isoforms of a plasma membrane receptor for the protein. If one cell expresses a high-affinity receptor and another cell a low-affinity receptor, the two cells would respond to the signaling protein at different concentrations. Likewise, the different receptors may be linked with different second messenger molecules generated within the cell. These messengers, such as camp and Ca^{2+}, may have different effects on cell function.

Feature Investigation Questions

1. Knowing the genes expressed in this region of a developing embryo would provide important information about the control of the patterning of embryonic tissues and structures.
2. Harland and colleagues tested the hypothesis that cells within the Spemann organizer expressed certain genes important in the development of dorsal structures, such as the notochord.
3. The scientists used a procedure called expression cloning. In this process, they isolated the various mRNAs that were present in the tissue of the dorsal lip of the embryo. After purifying these mRNAs, they produced a cDNA library. This library contained all the genes expressed in the particular tissue at that particular time of development. The scientists then transcribed the different genes in the cDNA library into mRNAs and injected these into UV-damaged eggs, which were subsequently fertilized. UV-damaged fertilized eggs fail to develop dorsal structures. The scientists were interested in any mRNA that "rescued" the developing embryo and restored some level of normal development. One protein, noggin, was found to rescue the embryos and acted as a morphogen.

Test Yourself

1. a 2. c 3. c 4. d 5. b 6. c 7. b 8. e 9. e 10. e

Conceptual Questions

1. Embryonic development is the process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts. Cell differentiation is the process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes. Growth is the enlargement of an embryo, as cells divide and/or enlarge.
2. The timing of the final development of an embryo's organs is typically linked with the requirement for that organ's function. In mammals, for example, the heart is required early in development to pump blood through the embryonic and fetal circulation, thereby delivering nutrients and removing wastes. Fully functional lungs, however, are not required until the animal is born and begins breathing air for the first time.
3. Autonomous specification results from the asymmetrical distribution of intracellular proteins and mRNAs during the cleavage events of embryonic development. The resulting daughter cells will contain different amounts of these cytoplasmic determinants, and this will direct these cells into different developmental fates. Conditional specification results from the interactions of proteins on the extracellular surface of the cell membranes of different cells or from proteins secreted from one cell and acting on another cell. This type of specification determines where a cell ends up within the embryo and what type of cell develops.

Chapter 53

Concept Checks

Figure 53.2 Although swelling is one of the most obvious manifestations of inflammation, it has no significant adaptive value of its own. It is a consequence of fluid leaking out of blood vessels into the interstitial space. It can, however, contribute to pain sensations, because the buildup of fluid may cause distortion of connective tissue structures such as tendons and ligaments. Pain, while obviously unpleasant, is an important signal that alerts many animals to the injury and serves as a reminder to protect the injured site.

Figure 53.3 Recall from Chapter 47 that as blood circulates, a portion of the plasma—the fluid part of blood—exits venules and capillaries and enters the interstitial fluid. Most of the plasma is reabsorbed back into the capillaries, but a portion gets left behind. That excess fluid is drained away by lymph vessels and becomes lymph. Without lymph vessels, fluid would accumulate outside of the blood, in the interstitial fluid.

Figure 53.12 Because an animal may encounter the same type of pathogen many times during its life, having a secondary immune response means that future infections will be fought off much more efficiently.

Figure 53.13 Although social insects live in colonies that may reach enormous numbers of individuals, many other insect species inhabit densely populated colonies, as do many species of vertebrates. The free-tailed bat *Tamarind brasiliensis,* for example, lives in caves that contain as many as 10–20 million individuals! It is highly likely that all such species have evolved immune defense mechanisms that enable them to ward off infections that might devastate the entire population.

Feature Investigation Questions

1. Termites produce and line their nests with antimicrobial secretions that reduce the probability that an infection can spread. Termites also practice social grooming that removes foreign objects and possible pathogens from nest mates. Sick or dead termites are also removed from the nest, thus decreasing the likelihood of disease transmission.
2. The researchers tested the hypothesis that social interaction among termites promotes disease resistance. That is, termites that had contact with nest mates that had previously been exposed to a pathogen were

subsequently less likely to become infected with that pathogen than termites that lacked prior contact with nest mates. The researchers regarded this as social immunity.

3. The researchers formed two groups of termites. The experimental group was exposed to a microbial pathogen, whereas the control group was not. After 1 week, the control group was divided into two groups. One control subgroup was introduced to the group of termites previously exposed to the pathogen, whereas the other control subgroup was kept isolated from the exposed termites. Finally, the researchers challenged both groups with a lethal concentration of the same microbial pathogen. The researchers then evaluated the effect of social interaction on survival. The results indicated that the termites that previously had been introduced to the exposed termites had higher survival rates compared to the control group that was not introduced to exposed termites. The researchers concluded that the interaction with the exposed termites allowed the control termites to acquire immunity to the microbial pathogen.

Test Yourself

1. e 2. b 3. c 4. c 5. a 6. d 7. b 8. a 9. d 10. b

Conceptual Questions

1. Nonspecific immunity is present at birth and is found in all animals. These defenses recognize general, conserved features common to a wide array of pathogens and include external barriers, such as the skin, and internal defenses involving phagocytes and other cells. Specific immunity develops *after* an animal has been exposed to a *particular* antigen. The responses include humoral and cell-mediated defenses. Specific immunity appears to be largely restricted to vertebrates. Unlike nonspecific immunity, in specific immunity, the response to an antigen is greatly increased if an animal is exposed to that antigen again at some future time.
2. Cytotoxic T cells are "attack" cells that are responsible for cell-mediated immunity. Once activated, they migrate to the location of their targets, bind to the targets by combining with an antigen on them, and directly kill the targets via secreted chemicals.
3. Each immunoglobulin molecule is Y shaped and composed of four interlinked polypeptide chains: two long heavy chains and two short light chains. The chains within the Y have complex looplike structures due to disulfide bonds within and between the chains. This accounts for the characteristic tertiary (three-dimensional) structure of immunoglobulins. At one region of immunoglobulins, the amino acid sequence is highly variable; this accounts for the specificity of binding of immunoglobulins to particular antigens.

Chapter 54

Concept Checks

Figure 54.5 Higher predation would occur where locust numbers are highest. This means that predators would be responding to an increase in prey density by eating more individuals.

Figure 54.7 Cold water suppresses the ability of the coral-building organisms to secrete their calcium carbonate shell.

Figure 54.10 In some areas when fire is prevented, fuel, in the form of old leaves and branches, can accumulate. When a fire eventually occurs, it can be so large and hot that it destroys everything in its path, even reaching high into the tree canopy.

Figure 54.17 Acid soils are low in essential plant and animal nutrients such as calcium and nitrogen and are lethal to some soil microorganisms that are important in decomposition and nutrient cycling.

Figure 54.19 This occurs because increasing cloudiness and rain at the tropics maintain fairly constant temperatures across a wide latitudinal range.

Figure 54.24 Soil conditions can also influence biome type. Nutrient-poor soils, for example, may support vegetation different than that of the surrounding area.

Feature Investigation Questions

1. Most believe that invasive species succeed in new environments due to the lack of natural enemies and that diseases and predators present in the original environment controlled the growth of the population. When these organisms are introduced into a novel environment, the natural enemies are usually absent. This allows for an unchecked increase in the population of the invasive species.
2. Callaway and Aschehoug were able to demonstrate through a controlled experiment that the presence of *Centaurea,* an invasive species, reduced the biomass of three other native species of grasses by releasing allelochemicals. Similar experiments using species of grasses that are found in the native region of *Centaurea* indicate that these species have evolved defenses against the allelochemicals.
3. The activated charcoal helps to remove the allelochemical from the soil. The researchers conducted this experiment to provide further evidence that the chemical released by the *Centaurea* was reducing the biomass of the native Montana grasses. With the removal of the chemicals by the addition of the charcoal, the researchers showed an increase in biomass of the native Montana grasses compared to the experiments lacking the charcoal.

Test Yourself

1. b 2. e 3. a 4. b 5. a 6. a 7. d 8. d 9. a 10. a

Conceptual Questions

1. Mountains are cooler than valleys because of adiabatic cooling. Air at higher altitudes expands because of decreased pressure. As it expands, air cools, at a rate of 10°C for every 1,000 m in elevation. As a result, mountain tops can be much cooler than the plains or valleys that surround them.
2. Solar radiation in the form of short-wave energy passes through the atmosphere to heat the Earth's surface. This energy is then radiated back to the atmosphere in the form of infrared radiation. Much of this radiation is absorbed by atmospheric gases and reradiated toward Earth, causing an increase in temperature.
3. Florida is a peninsula that is surrounded by the Atlantic Ocean and the Gulf of Mexico. Differential heating between the land and the sea creates onshore sea breezes on both the east and west coasts. These breezes often drift across the whole peninsula, bringing heavy rain.

Chapter 55

Concept Checks

Figure 55.3 In classical conditioning, an involuntary response comes to be associated with a stimulus that did not originally elicit the response, as with Pavlov's dogs salivating at the sound of a metronome.

Figure 55.5 The ability to sing the same distinctive song must be considered innate behavior because the cuckoo has had no opportunity to learn its song from its parents.

Figure 55.7 Tinbergen manipulated pinecones, but not all digger wasp nests are surrounded by pinecones. You could manipulate branches, twigs, stones, and leaves to determine the necessary size and dimensions of objects that digger wasps use as landmarks.

Figure 55.8 This is an unusual example because the return trip involves several different generations to complete: One generation overwinters in Mexico, but these individuals lay eggs and die on the return journey, and their offspring continue the return trip.

Figure 55.14 The individuals in the center of the group are less likely to be attacked than those on the edge of the group. This is referred to as the geometry of the selfish herd.

Figure 55.16 Because of the genetic benefit, the answer is nine cousins. Consider Hamilton's rule, expressed in the formula $rB > C$. Using cousins, $B = 9$, $r = 0.125$, and $C = 1$, and $1.125 > 1$. Using sisters, $B = 2$, $r = 0.5$, and $C = 1$. Because rB would not be greater than C, there would be no net genetic benefit in self-sacrifice.

Figure 55.17 All the larvae in the group are likely to be the progeny of one egg mass from one adult female moth. The death of the one caterpillar teaches a predator to avoid the pattern and benefits the caterpillar's close kin.

Figure 55.21 Because sperm are cheaper to produce than eggs, males try to maximize their fitness through attracting multiple females, whereas female fitness is maximized by choosing a mate with good genetic quality and par-

enting skills. Colorful plumage and elaborate adornments are thus signals of the male's overall health.

Figure 55.22 The males aren't careful because it is likely the pups were fathered in the previous year by a different male. Being a harem master is demanding, and males may often only perform this role for a year or two.

Feature Investigation Questions

1. Tinbergen observed the activity of digger wasps as they prepared to leave the nest. Each time, the wasp hovered and flew around the nest for a period of time before leaving. Tinbergen suggested that during this time, the wasp was making a mental map of the nest site. He hypothesized that the wasp was using characteristics of the nest site, particularly landmarks, to help relocate it.
2. Tinbergen placed pinecones around the nest of the wasps. When the wasps left the nest, he removed the pinecones from the nest site and set them up in the same pattern a distance away, constructing a sham nest. For each trial, the wasps would go directly to the sham nest, which had the pinecones around it. This indicated to Tinbergen that the wasps identified the nest based on the pinecone landmarks.
3. No. Tinbergen also conducted an experiment to determine if the wasps were responding to the visual cue of the pinecones or the chemical cue of the pinecone scent. The results of this experiment indicated that the wasps responded to the visual cue of the pinecones and not their scent.

Test Yourself

1. d 2. d 3. d 4. c 5. c 6. d 7. b 8. c 9. a 10. c

Conceptual Questions

1. Ethology is the scientific study of animal behavior that focuses on the specific genetic and physiological mechanisms of behavior.
2. Certainty of paternity influences degree of parental care. With internal fertilization, certainty of paternity is relatively low. With external fertilization, eggs and sperm are deposited together, and paternity is more certain. This explains why males of some species, such as mouthbreeding cichlid fish, are more likely to engage in parental care.
3. In monogamy, each individual mates exclusively with one partner for at least one breeding cycle. In polygamy, individuals mate with more than one individual during a breeding cycle. There are two types of polygamy. In polygyny, one male mates with more than one female, and in polyandry, females mate with more than one male.

Chapter 56

Concept Checks

Figure 56.2 The total population size, *N*, would be estimated to be 110 × 100/20, or 550.

Figure 56.3 In a half-empty classroom, the distribution is often clumped because friends sit together.

Figure 56.7 (a) type III, (b) type II

Figure 56.11 $dN/dt = 0.1 \times 200\ (300)/500 = 12$.

Figure 56.13 Only density-dependent factors operate in this way.

Figure 56.19 There were very few juveniles in the population and many mature adults. The population would be in decline.

Figure 56.22 Many different ecological footprint calculators are available on the Web. Does altering inputs such as type of transportation, amount of meat eaten, or amount of waste generated make a difference?

Feature Investigation Questions

1. It became apparent that the sheep population was declining. Some individuals felt that the decline in the population was due to increased wolf predation having a negative effect on population growth. This led to the suggestion of culling the wolf population to reduce the level of predation on the sheep population.
2. The survivorship curve is very similar to a typical type I survivorship curve. This suggests that survival is high among young and reproductively active members of the population and that mortality rates are higher for older members of the population. One difference between the actual survivorship curve and a typical type I curve is that the mortality rate of very young sheep was higher in the actual curve, and then it leveled off after the second year. This suggests that very young and older sheep are more at risk for predation.
3. It was concluded that wolf predation was not the primary reason for the drop in the sheep population. It appeared that wolves prey on the vulnerable members of the population and not on the healthy, reproductively active members. The Park Service determined that several cold winters may have had a more important impact on the sheep population than wolf predation did. Based on these conclusions, the Park Service ended a wolf population control program.

Test Yourself

1. b 2. e 3. b 4. c 5. c 6. b 7. c 8. d 9. c 10. c

Conceptual Questions

1. A population can be defined as a group of interbreeding individuals occupying the same habitat at the same time. Population ecology is the study of how populations grow and what promotes and limits growth.
2. Population biologists first capture and tag the animals. The tagged animals are freed and assumed to mix freely with unmarked individuals in the population. When the population is resampled, the numbers of marked and unmarked individuals are recorded. The assumption is that the ratio of marked to unmarked individuals in the second sample is the same as the ratio of marked to unmarked individuals in the first sample, and in this way, an estimate of population size is obtained.
3. In promiscuity each female mates with a different male every year or breeding cycle. At medium values of *N*, $(K - N)/K$ is closer to a value of 1, and population growth is relatively large. If $K = 1{,}000$, $N = 500$, and $r = 0.1$, then

$$\frac{dN}{dt} = (0.1)(500) \times \frac{(1{,}000 - 500)}{1{,}000}$$

$$\frac{dN}{dt} = 25$$

However, if population sizes are low ($N = 100$), $(K - N)/K$ is so small that growth is low.

$$\frac{dN}{dt} = (0.1)(100) \times \frac{(1{,}000 - 100)}{1{,}000}$$

$$\frac{dN}{dt} = 9$$

By comparing these two examples with that shown in Section 56.3, we see that growth is small at high and low values of *N* and is greatest at immediate values of *N*. Growth is greatest when $N = K/2$. However, when expressed as a percentage, growth is greatest at low population sizes. Where $N = 100$, percentage growth = 9/100 = 9%. Where $N = 500$, percentage growth = 25/500 = 5%, and where $N = 900$, percentage growth = 9/100 = 1%.

Chapter 57

Concept Checks

Figure 57.2 Individual vultures often fight one another over small carcasses. These interactions would constitute intraspecific interference competition.

Figure 57.5 There would be 10 possible pairings (AB, AC, AD, AE, BC, BD, BC, CD, CE, DE), of which only neighboring species (AB, BC, CD, DE) competed. Therefore, competition would be expected in 4/10 pairings, or 40% of the cases.

Figure 57.8 A 1974 review by Tom Schoener examined segregation in a more wide-ranging literature review of over 80 species, including slime molds, mollusks, and insects, as well as birds. He found segregation by habitat occurred in the majority of the examples, 55%. The other most common form of segregation was by food type, 40%.

Figure 57.9 Omnivores, such as bears, can feed on both plant material, such as berries, and animals, such as salmon. As such, omnivores may act as both predators and herbivores depending on what they are feeding on.

Figure 57.10 Batesian mimicry has a positive effect for the mimic, and the model is unaffected, so it is a +/0 relationship, like commensalism. Müllerian mimicry has a positive effect on both species, so it is a +/+ relationship, like mutualism.

Figure 57.12 Because there is no evolutionary history between invasive predators and native prey, the native prey often have no defenses against these predators and are very easily caught and eaten.

Figure 57.14 Invertebrate herbivores can eat around mechanical defenses; therefore, chemical defenses are probably most effective against invertebrate herbivores.

Figure 57.20 It's an example of facultative mutualism, because in this case, both species can live without the other.

Figure 57.23 Fertilizer increases plant quality and hence herbivore density, which, in turn, increases the density of spiders. This is a bottom-up effect.

Feature Investigation Questions

1. The two species of barnacles can be found in the same intertidal zone, but there is a distinct difference in niche of each species. *Chthamalus stellatus* is found only in the upper intertidal zone. *Semibalanus balanoides* is found only in the lower tidal zone.
2. Connell moved rocks with young *Chthamalus* from the upper intertidal zone into the lower intertidal zone to allow *Semibalanus* to colonize the rocks. After the rocks were colonized by *Semibalanus*, he removed *Semibalanus* from one side of each rock and returned the rocks to the lower intertidal zone. This allowed Connell to observe the growth of *Chthamalus* in the presence and the absence of *Semibalanus*.
3. Connell observed that *Chthamalus* was more resistant to desiccation compared to *Semibalanus*. Though *Semibalanus* was the better competitor in the lower intertidal zone, the species was at a disadvantage in the upper intertidal zone when water levels were low. This allowed *Chthamalus* to flourish and outcompete *Semibalanus* in a different region of the intertidal zone.

Test Yourself

1. d 2. c 3. b 4. d 5. c 6. b 7. d 8. b 9. b 10. c

Conceptual Questions

1. The hypothesis states that two species with exactly the same requirements cannot live together in the same place and use the same resources, that is, occupy the same niche.
2. In Müllerian mimicry, many unpalatable species evolve to look the same, reinforcing the distasteful design; in Batesian mimicry, a palatable species mimics an unpalatable one.
3. There are at least three reasons why we don't see more herbivory in nature. First, plants possess an array of defensive chemicals, including alkaloids, phenolics, and terpenes. Second, many herbivore populations are reduced by the action of natural enemies. We see evidence for this in the world of biological control. Third, the low nutritive value of plants ensures herbivore populations remain low and unlikely to impact plant populations.

Chapter 58

Concept Checks

Figure 58.5 Species richness of trees doesn't increase because rainfall in the western United States is low compared to that in the east.

Figure 58.6 Hurricanes, tropical storms, heavy rainfall, and mudslides are disturbances that maintain a mosaic of disturbed and undisturbed habitats, favoring high species richness in the tropics.

Figure 58.10 As we walk forward from the edge of the glacier to the mouth of the inlet, we are walking backward in ecological time to communities that originated hundreds of years ago.

Figure 58.11 No, competition is also important. For example, the shade from later-arriving species, such as spruce trees, causes competitive exclusion of some of the original understory species.

Figure 58.13 Competition features more prominently. Although early colonists tend to make the habitat more favorable for later colonists, it is the later colonists who outcompete the earlier ones, and this fuels species change.

Figure 58.14 If a small island was extremely close to the mainland, it could continually receive migrating species from the source pool. Even though these species could not complete their life cycle on such a small island, extinctions would rarely be recorded because of this continual immigration.

Figure 58.15 At first glance, the change looks small, but the data are plotted on a log scale. On this scale, an increase in bird richness from 1.2 to 1.6 equals an increase from 16 to 40 species, a change of over 100%.

Feature Investigation Questions

1. Simberloff and Wilson were testing the three predictions of the theory of island biogeography. One prediction suggested that the number of species should increase with increasing island size. Another prediction suggested that the number of species should decrease with increasing distance of the island from the source pool. Finally, the researchers were testing the prediction that the turnover of species on islands should be considerable.
2. Simberloff and Wilson used the information gathered from the species survey to determine whether the same types of species recolonized the islands or if colonizing species were random.
3. The data suggested that species richness did increase with island size. Also, the researchers found that in all but one of the islands, the number of species was similar to the number of species before fumigation.

Test Yourself

1. c 2. c 3. d 4. b 5. c 6. d 7. a 8. d 9. b 10. c

Conceptual Questions

1. A community is an assemblage of many populations living in the same place at the same time. Community ecology studies how groups of species interact and form functional communities.
2.

Disturbance	Frequency	Severity of effects
Forest fire	Low to high, depending on lightning frequency	High to low, depending on frequency
Hurricane	Low	Severe
Tornado	Very low	Severe
Floods	Medium to high in riparian areas	Fairly low; many communities can recover quickly
Disease epidemics	Low	High; may cause catastrophic losses of species
Droughts	Low	Potentially severe
High winds	High	May kill large trees and create light gaps
Hard freezes	Low	May cause deaths to tropical species, such as mangroves

3. A community is in equilibrium when no change can be detected in the number of species and their population sizes over a given period of time.

Chapter 59

Concept Checks

Figure 59.3 It depends on the trophic level of their food, whether dead vegetation or dead animals. Many decomposers feed at multiple trophic levels.

Figure 59.6 The production efficiency is (16/823) × 100, or 1.9%.

Figure 59.13 On a population level, plant secondary metabolites can deter herbivores from feeding. However, on an ecosystem level, these effects are not as important because higher primary production tends to result in higher secondary production.

Figure 59.17 The greatest stores are in rocks and fossil fuels.

Figure 59.18 It fluctuates because less CO_2 is emitted from vegetation in the summer and more is emitted in the winter. This pattern is driven by the large land masses of the Northern Hemisphere relative to the smaller land masses of the Southern Hemisphere.

Figure 59.23 High levels occurred because prevailing westerly winds carried acid rain from the industrial areas of the Midwest, where it was produced, to areas of the U.S. northeast.

Feature Investigation Questions

1. The researchers were testing the effects of increased carbon dioxide levels on the forest ecosystem. The researchers were testing the effects of increased carbon dioxide levels on primary production as well as other trophic levels in the ecosystem.
2. By increasing the carbon dioxide levels in only half of the chambers, the researchers were maintaining the control treatments necessary for all scientific studies. By maintaining equal numbers of control and experimental treatments, the researchers could compare data to determine what effects the experimental treatment had on the ecosystem.
3. The increased carbon dioxide levels led to an increase in primary productivity, as expected. Since photosynthetic rate is limited by carbon dioxide levels, increases in the available carbon dioxide should increase photosynthetic rates. Interestingly, though, the increase in primary productivity did not lead to an increase in herbivory. The results indicated that herbivory actually decreased with increased carbon dioxide levels.

Test Yourself

1. d 2. d 3. d 4. a 5. d 6. a 7. a 8. b 9. c 10. d

Conceptual Questions

1. Autotrophs harvest light or chemical energy and store that energy in carbon compounds. Heterotrophs obtain their nutrition by eating other organisms.
2. Chain lengths are short in food webs because there is low production efficiency and only a 10% rate of energy transfer from one level to another, so only a few links can be supported.
3. The phosphorous cycle is a local cycle with no capacity for long-distance transport. Both the carbon and nitrogen cycles are global cycles with biological, geological, and atmospheric pools.

Chapter 60

Concept Checks

Figure 60.4 It is possible that the results are driven by what is known as a sampling effect. As the numbers of species in the community increase, so does the likelihood of including a "superspecies," a species with exceptionally large individuals that would use up resources. In communities with higher diversity, care has to be taken that increased diversity is driving the results, not the increased likelihood of including a superspecies.

Figure 60.6 The extinction rate could increase because an increasing human population requires more space to live, work, and grow food, resulting in less available habitat and resources for other species.

Figure 60.8 No, some species, such as self-fertilizing flowers, appear to be less affected by inbreeding.

Figure 60.9 The effective population size (N_e) would be = $(4 \times 125 \times 500) / (125 + 500)$, or 400.

Figure 60.12 Corridors might also promote the movement of invasive species or the spread of fire between areas.

Figure 60.13 They act as habitat corridors because they permit movement of species between forest fragments.

Feature Investigation Questions

1. The researchers hoped to replicate terrestrial communities that differed only in their level of biodiversity. This would allow the researchers to determine the relationship between biodiversity and ecological function.
2. The hypothesis was that ecological function was directly related to biodiversity. If biodiversity increased, the hypothesis suggested that ecological function should increase.
3. The researchers tested for ecosystem function by monitoring community respiration, decomposition, nutrient retention rates, and productivity. All of these indicate the efficiency of nutrient production and use in the ecosystem.

Test Yourself

1. d 2. e 3. a 4. c 5. c 6. e 7. e 8. a 9. c 10. b

Conceptual Questions

1. The first level is genetic diversity; the second is species diversity; and the third is ecosystem diversity.
2. The most vulnerable are those with small population sizes, low rates of population growth, *K*-selected (Chapter 56), with inbreeding and possible harem mating structure, tame and unafraid of humans, possibly limited to islands, flightless, possibly valuable to humans as timber, a source of meat or fur, or desirable by collectors (Chapter 60).
3. An umbrella species is a species whose habitat requirements are so large that protecting it would also protect many other species existing in the same habitat. A flagship species is a single large or instantly recognizable species typically chosen because it is attractive and thus more readily engenders support for its conservation. A keystone species is a species within the community that has a role out of proportion to its abundance.

Glossary

A

A band A wide, dark band in a myofibril produced by the orderly parallel arrangement of the thick filaments in the middle of each sarcomere.

abiotic The term used to describe interactions between organisms and their nonliving environment.

abortion A procedure or circumstance that causes the death of an embryo or fetus after implantation.

abscisic acid One of several plant hormones that help a plant cope with environmental stress.

absolute refractory period The period during an action potential when the inactivation gate of the voltage-gated sodium channel is closed; during this time, it is impossible to generate another action potential.

absorption The process in which digested nutrients are transported from the digestive cavity into an animal's circulatory system.

absorption spectrum A diagram that depicts the wavelengths of electromagnetic radiation that are absorbed by a pigment.

absorptive nutrition The process whereby an organism uses enzymes to digest organic materials and absorbs the resulting small food molecules into its cells.

absorptive state One of two alternating phases in the utilization of nutrients; occurs when ingested nutrients enter the blood from the gastrointestinal tract. The other phase is the postabsorptive state.

acclimatization A long-term and persistent physiological adaptation to an extreme environment.

accommodation In the vertebrate eye, the process in which contraction and relaxation of the ciliary muscles adjust the lens according to the angle at which light enters the eye.

acetylcholinesterase An enzyme located on membranes of muscle fibers in a neuromuscular junction; breaks down excess acetylcholine released into the synaptic cleft.

acid A molecule that releases hydrogen ions in solution.

acid hydrolase A hydrolytic enzyme found in lysosomes that functions at acidic pH and uses a molecule of water to break a covalent bond.

acid rain Precipitation with a pH of less than 5.6; results from the burning of fossil fuels.

acidic A solution that has a pH below 7.

acoelomate An animal that lacks a fluid-filled body cavity.

acquired antibiotic resistance The common phenomenon of a previously susceptible strain of bacteria becoming resistant to a specific antibiotic.

acquired immune deficiency syndrome (AIDS) A disease caused by the human immunodeficiency virus (HIV) that leads to a defect in the immune system of infected individuals.

acrocentric A chromosome in which the centromere is near one end.

acromegaly A condition in which a person's growth hormone level is abnormally elevated after puberty, causing many bones to thicken and enlarge.

acrosomal reaction An event in fertilization in which enzymes released from a sperm's acrosome break down the outer layers of an egg cell, allowing the entry of the sperm cell's nucleus into the egg cell.

acrosome A special structure at the tip of a sperm's head containing proteolytic enzymes that break down the protective outer layers of the egg cell at fertilization.

actin A cytoskeletal protein.

actin filament A thin type of protein filament composed of actin proteins that forms part of the cytoskeleton and supports the plasma membrane; plays a key role in cell strength, shape, and movement.

action potential An electrical signal along a cell's plasma membrane; occurs in animal neuron axons muscle cells and some plant cells.

action spectrum The rate of photosynthesis plotted as a function of different wavelengths of light.

activation energy An initial input of energy in a chemical reaction that allows the molecules to get close enough to cause a rearrangement of bonds.

activator A transcription factor that binds to DNA and increases the rate of transcription.

active immunity An animal's ability to fight off a pathogen to which it has been previously exposed. Active immunity can develop as a result of natural infection or artificial immunization.

active site The location in an enzyme where a chemical reaction takes place.

active transport The transport of a solute across a membrane against its gradient (from a region of low concentration to a region of higher concentration). Active transport requires an input of energy.

adaptations The processes and structures by which organisms adjust to changes in their environment.

adaptive radiation The process whereby a single ancestral species evolves into a wide array of descendant species that differ greatly in their habitat, form, or behavior.

adenine (A) A purine base found in DNA and RNA.

adenosine triphosphate (ATP) A molecule that is a common energy source for all cells.

adenylyl cyclase An enzyme in the plasma membrane that synthesizes cAMP from ATP.

adherens junction A mechanically strong cell junction between animal cells that typically occurs in bands. The cells are connected to each other via cadherins, and the cadherins are linked to actin filaments on the inside of the cells.

adhesion The ability of two different substances to cling to each other; the ability of water to be attracted to, and thereby adhere to, a surface that is not electrically neutral.

adiabatic cooling The process in which increasing elevation leads to a decrease in air temperature.

adventitious root A root that is produced on the surfaces of stems (and sometimes leaves) of vascular plants; also, roots that develop at the bases of stem cuttings.

aerenchyma Spongy plant tissue with large air spaces.

aerobic respiration A type of cellular respiration in which O_2 is consumed and CO_2 is released.

aerotolerant anaerobe A microorganism that does not use oxygen but is not poisoned by it either.

afferent arterioles Blood vessels that provide a pathway for blood into the glomeruli of the vertebrate kidney.

affinity The degree of attraction between an enzyme and its substrate.

aflatoxins Fungal toxins that cause liver cancer and are a major health concern worldwide.

age-specific fertility rate The rate of offspring production for females of a certain age; used to calculate how a population grows.

age structure The relative numbers of individuals of each defined age group in a population.

AIDS *See* acquired immune deficiency syndrome.

air sac A component of the avian respiratory system; air sacs—not lungs—expand when a bird inhales and shrink when it exhales. They do not participate in gas exchange, but help direct air through the lungs.

akinete A thick-walled, food-filled cell produced by certain bacteria or protists that enables them to survive unfavorable conditions in a dormant state.

aldosterone A steroid hormone made by the adrenal glands that regulates salt and water balance in vertebrates.

algae (singular, **alga**) A term that applies to about 10 phyla of protists that include both photosynthetic and nonphotosynthetic species; often also includes cyanobacteria.

alimentary canal In animals, the single elongated tube of a digestive system, with an opening at either end through which food and eventually wastes pass from one end to the other.

alkaline A solution that has a pH above 7.

alkaloids A group of secondary metabolites that contain nitrogen and usually have a cyclic, ringlike structure. Examples include caffeine and nicotine.

allantois One of the four extraembryonic membranes in the amniotic egg. It serves as a disposal sac for metabolic wastes.

Allee effect The phenomenon that some individuals will fail to mate successfully purely by chance, for example, because of the failure to find a mate.

allele A variant form of a gene.

allele frequency The number of copies of a particular allele in a population divided by the total number of alleles in that population.

allelochemical A powerful plant chemical, often a root exudate, that kills other plant species.

allelopathy The suppressed growth of one species due to the release of toxic chemicals by another species.

allopatric The term used to describe species occurring in different geographic areas.

allopatric speciation A form of speciation that occurs when a population becomes geographically isolated from other populations and evolves into one or more new species.

alloploid An organism having at least one set of chromosomes from two or more different species.

allosteric site A site on an enzyme where a molecule can bind noncovalently and affect the function of the active site.

alpha (α) helix A type of protein secondary structure in which a polypeptide forms a repeating helical structure stabilized by hydrogen bonds.

alternation of generations The phenomenon that occurs in plants and some protists in which the life cycle alternates between multicellular diploid

organisms, called sporophytes, and multicellular haploid organisms, called gametophytes.

alternative splicing The splicing of pre-mRNA in more than one way to create two or more different polypeptides.

altruism Behavior that appears to benefit others at a cost to oneself.

alveoli 1. Saclike structures in the lungs where gas exchange occurs. 2. Saclike cellular features of the protists known as alveolates.

Alzheimer disease (AD) The leading worldwide cause of dementia; characterized by a loss of memory and intellectual and emotional function (formerly called Alzheimer's disease).

AM fungi A phylum of fungi that forms mycorrhizal associations with plants.

amensalism One-sided competition between species, where the interaction is detrimental to one species but not to the other.

Ames test A test that helps ascertain whether or not an agent is a mutagen by using a strain of a bacterium, *Salmonella typhimurium*.

amino acid The building block of proteins. Amino acids have a common structure in which a carbon atom, called the α-carbon, is linked to an amino group (NH_2) and a carboxyl group (COOH). The α-carbon also is linked to a hydrogen atom and a particular side chain.

aminoacyl site (A site) One of three sites for tRNA binding in the ribosome during translation; the other two are the peptidyl site (P site) and the exit site (E site). The A site is where incoming tRNA molecules bind to the mRNA (except for the initiator tRNA).

aminoacyl tRNA *See* charged tRNA.

aminoacyl-tRNA synthetase An enzyme that catalyzes the attachment of amino acids to tRNA molecules.

amino terminus *See* N-terminus.

ammonia (NH_3) A highly toxic nitrogenous waste typically produced by many aquatic animal species.

ammonification The conversion of organic nitrogen to NH_3 and NH_4^+ during the nitrogen cycle.

amnion The innermost of the four extraembryonic membranes in the amniotic egg. It protects the developing embryo in a fluid-filled sac called the amniotic cavity.

amniotes A group of tetrapods with amniotic eggs that includes turtles, lizards, snakes, crocodiles, birds, and mammals.

amniotic egg A type of egg produced by amniotic animals that contains the developing embryo and the four separate extraembryonic membranes that it produces: the amnion, the yolk sac, the allantois, and the chorion.

amoeba (plural, **amoebae**) A protist that moves by pseudopodia, which involves extending cytoplasm into filaments or lobes.

amoebocyte A mobile cell within a sponge's mesophyl that absorbs food from choanocytes, digests it, and carries the nutrients to other cells.

amphibian An ectothermic, vertebrate animal that metamorphoses from a water-breathing to an air-breathing form but must return to the water to reproduce.

amphipathic Molecules containing a hydrophobic (water-fearing) region and a hydrophilic (water-loving) region.

ampulla (plural, **ampullae**) 1. A muscular sac at the base of each tube foot of a echinoderm; used to store water. 2. A bulge in the walls of the semicircular canals of the mammalian inner ear; important for sensing circular motions of the head.

amygdala An area of the vertebrate forebrain known to be critical for understanding and remembering emotional situations.

amylase A digestive enzyme in saliva and the pancreas involved in the digestion of starch.

anabolic reaction A metabolic pathway that involves the synthesis of larger molecules from smaller precursor molecules. Such reactions usually require an input of energy.

anabolism A metabolic pathway that results in the synthesis of cellular molecules and macromolecules; requires an input of energy.

anaerobic Refers to a process that occurs in the absence of oxygen; a form of metabolism that does not require oxygen.

anaerobic respiration The breakdown of organic molecules in the absence of oxygen.

anagenesis The pattern of speciation in which a single species is transformed into a different species over the course of many generations.

analogous structure A structure that is the result of convergent evolution. Such structures have arisen independently, two or more times, because species have occupied similar types of environments on Earth.

anaphase The phase of mitosis during which the sister chromatids separate from each other and move to opposite poles; the poles themselves also move farther apart.

anatomy The study of the morphology of organisms, such as plants and animals.

anchoring junction A type of junction between animal cells that attaches cells to each other and to the extracellular matrix (ECM).

androecium The aggregate of stamens that forms the third whorl of a flower.

androgens Steroid hormones produced by the male testes (and, to a lesser extent, the adrenal glands) that affect most aspects of male reproduction.

anemia A condition characterized by lower than normal levels of hemoglobin, which reduces the amount of oxygen that can be stored in the blood.

aneuploidy An alteration in the number of particular chromosomes so that the total number of chromosomes is not an exact multiple of a set.

angina pectoris Chest pain during exertion due to the heart being deprived of oxygen.

angiosperm A flowering plant. The term means enclosed seed, which reflects the presence of seeds within fruits.

animal cap assay A type of experiment used to identify proteins secreted by embryonic cells that induce cells in the animal pole to differentiate into mesoderm.

animal pole In triploblast organisms, the pole of the egg with less yolk and more cytoplasm.

Animalia A eukaryotic kingdom of the domain Eukarya.

animals Multicellular heterotrophs with cells that lack cell walls. Most animals have nerves, muscles, the capacity to move at some point in their life cycle, and the ability to reproduce sexually, with sperm fusing directly with eggs.

anion An ion that has a net negative charge.

annual A plant that dies after producing seed during its first year of life.

antagonist A muscle or group of muscles that produces oppositely directed movements at a joint.

antenna complex *See* light-harvesting complex.

anterior Refers to the end of an animal where the head is found.

anteroposterior axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the dorsoventral axis and the right-left axis.

anther The uppermost part of a flower stamen, consisting of a cluster of microsporangia that produce and release pollen.

antheridia Round or elongate gametangia that produce sperm in plants.

anthropoidea A member of a group of primates that includes the monkeys and the hominoidea; these species are larger-brained and diurnal.

antibiotic A chemical, usually made by microorganisms, that inhibits the growth of certain other microorganisms.

antibody A protein secreted by plasma cells that is part of the immune response; antibodies travel all over the body to reach antigens identical to those that stimulated their production, combine with these antigens, then guide an attack that eliminates the antigens or the cells bearing them.

anticodon A three-nucleotide sequence in tRNA that is complementary to a codon in mRNA.

antidiuretic hormone (ADH) A hormone secreted by the posterior pituitary gland that acts on kidney cells to decrease urine production.

antigen Any foreign molecule that the host does not recognize as self and that triggers a specific immune response.

antigen-presenting cells (APCs) Cells bearing fragments of antigen, called antigenic determinants or epitopes, complexed with the cell's major histocompatibility complex (MHC) proteins.

antiparallel The arrangement in DNA where one strand runs in the 5′ to 3′ direction while the other strand is oriented in the 3′ to 5′ direction.

antiporter A type of transporter that binds two or more ions or molecules and transports them in opposite directions across a membrane.

anus In mammals, the final portion of the rectum through which feces are expelled.

aorta In vertebrates, a large blood vessel that exits a ventricle of the heart and leads to the systemic circulation.

apical-basal-patterning genes A category of genes that are important in early stages of plant development during which the apical and basal axes are formed.

apical-basal polarity An architectural feature of plants in which they display an upper, apical pole and a lower, basal pole; shoot apical meristem occurs at the apical pole, and root apical meristem occurs at the basal pole.

apical constriction A cellular process during gastrulation that occurs in bottle cells, where a reduction in the diameter of the actin rings connected to the adherens junctions causes the cells to elongate toward their basal end.

apical meristem In plants, a group of actively dividing cells at a growing tip.

apical region The region of a plant seedling that produces the leaves and flowers.

apomixis A natural asexual reproductive process in which plant fruits and seeds are produced in the absence of fertilization.

apoplast The continuum of water-soaked cell walls and intercellular spaces in a plant.

apoplastic transport The movement of solutes through cell walls and the spaces between cells.

apoptosis Programmed cell death.

aposematic coloration Warning coloration that advertises an organism's unpalatable taste.
aquaporin A transport protein in the form of a channel that allows the rapid diffusion of water across the cell membrane.
aqueous humor A thin liquid in the anterior cavity behind the cornea of the vertebrate eye.
aqueous solution A solution made with water.
aquifer An underground water supply.
arbuscular mycorrhizae Symbiotic associations between AM fungi and the roots of vascular plants.
Archaea One of the three domains of life; the other two are Bacteria and Eukarya.
archaea When not capitalized, refers to a cell or species within the domain Archaea.
archegonia Flask-shaped plant gametangia that enclose an egg cell.
archenteron A cavity formed in an animal embryo during gastrulation that will become the organism's digestive tract.
area hypothesis The proposal that larger areas contain more species than smaller areas because they can support larger populations and a greater range of habitats.
arteriole A single-celled layer of endothelium surrounded by one or two layers of smooth muscle and connective tissue that delivers blood to the capillaries and distributes blood to regions of the body in proportion to metabolic demands.
artery A blood vessel that carries blood away from the heart.
artificial selection *See* selective breeding.
asci Fungal sporangia shaped like sacs that produce and release sexual ascospores.
ascocarp The type of fruiting body produced by ascomycete fungi.
ascomycetes A phylum of fungi that produce sexual spores in saclike asci located at the surfaces of fruiting bodies known as ascocarps.
ascospore The type of sexual spore produced by the ascomycete fungi.
aseptate The condition of not being partitioned into smaller cells; usually refers to fungal cells.
asexual reproduction A reproductive strategy that occurs when offspring are produced from a single parent, without the fusion of gametes from two parents. The offspring are therefore clones of the parent.
A site *See* aminoacyl site.
assimilation During the nitrogen cycle, the process by which plants and animals incorporate the ammonia and NO_3^- formed through nitrogen fixation and nitrification.
associative learning A change in behavior due to an association between a stimulus and a response.
asthma A disease in which the smooth muscles around the bronchioles contract more than usual, decreasing airflow in the lungs.
AT/GC rule Refers to the phenomenon that an A in one DNA strand always hydrogen-bonds with a T in the opposite strand, and a G in one strand always bonds with a C.
atherosclerosis The condition in which large plaques may occlude (block) the lumen of an artery.
atmospheric (barometric) pressure The pressure exerted by the gases in air on the body surfaces of animals.
atom The smallest functional unit of matter that forms all chemical substances and cannot be further broken down into other substances by ordinary chemical or physical means.
atomic mass An atom's mass relative to the mass of other atoms. By convention, the most common form of carbon, which has six protons and six neutrons, is assigned an atomic mass of exactly 12.
atomic nucleus The center of an atom; contains protons and neutrons.
atomic number The number of protons in an atom.
ATP *See* adenosine triphosphate.
ATP-dependent chromatin remodeling enzyme An enzyme that catalyzes a change in the positions of nucleosomes.
ATP synthase An enzyme that utilizes the energy stored in a H^+ electrochemical gradient for the synthesis of ATP via chemiosmosis.
atrial natriuretic peptide (ANP) A peptide secreted from the atria of the heart whenever blood levels of sodium increase; ANP causes a natriuresis by decreasing sodium reabsorption in the kidney tubules.
atrioventricular (AV) node Specialized cardiac cells in most vertebrates that sit near the junction of the atria and ventricles and conduct the electrical events from the atria to the ventricles.
atrioventricular (AV) valve A one-way valve into the ventricles of the vertebrate heart through which blood moves from the atria.
atrium In the heart, a chamber to collect blood from the tissues.
atrophy A reduction in the size of a structure, such as a muscle.
audition The ability to detect and interpret sound waves; present in vertebrates and arthropods.
autoimmune disease In humans and many other vertebrates, a disorder in which the body's normal state of immune tolerance breaks down, with the result that attacks are directed against the body's own cells and tissues.
autonomic nervous system The division of the peripheral nervous system that regulates homeostasis and organ function.
autonomous specification The unequal acquisition of cytoplasmic factors during cell division in a developing vertebrate embryo.
autophagosome A double-membrane structure enclosing cellular material destined to be degraded; produced by the process of autophagy.
autophagy A process whereby cellular material, such as a worn-out organelle, becomes enclosed in a double membrane and is degraded.
autosomes All of the chromosomes found in the cell nucleus of eukaryotes except for the sex chromosomes.
autotomy In echinoderms, the ability to detach a body part, such as a limb, that will later regenerate.
autotroph An organism that has metabolic pathways that use energy from either inorganic molecules or light to make organic molecules.
auxin One of several types of hormones considered to be "master" plant hormones because they influence plant structure, development, and behavior in many ways.
auxin efflux carrier One of several types of PIN proteins, which transport auxin out of plant cells.
auxin influx carrier A plasma membrane protein that transports auxin into plant cells.
auxin-response genes Plant genes that are regulated by the hormone auxin.
avirulence gene (*Avr* gene) A gene in a plant pathogen that encodes a virulence-enhancing elicitor, which causes plant disease.
Avogadro's number As first described by Italian physicist Amedeo Avogadro, 1 mole of any element contains the same number of atoms—6.022×10^{23}.
axillary bud A bud that occurs in the axil, the upper angle where a twig or leaf emerges from a stem.
axillary meristem A meristem produced in the axil, the upper angle where a twig or leaf emerges from a stem. Axillary meristems generate axillary buds, which can produce flowers or branches.
axon An extension of the plasma membrane of a neuron that is involved in sending signals to neighboring cells.
axon hillock The part of the axon closest to the cell body; typically where an action potential begins.
axon terminal The end of the axon that sends electrical or chemical messages to other cells.
axoneme The internal structure of eukaryotic flagella and cilia consisting of microtubules, the motor protein dynein, and linking proteins.

B

bacilli Rod-shaped prokaryotic cells.
backbone The linear arrangement of phosphates and sugar molecules in a DNA or RNA strand.
Bacteria One of the three domains of life; the other two are Archaea and Eukarya.
bacteria (singular, **bacterium**) When not capitalized, refers to a cell or species within the domain Bacteria.
bacterial artificial chromosome (BAC) A cloning vector derived from F factors that can contain large DNA inserts.
bacterial colony A clone of genetically identical cells formed from a single cell.
bacteriophage A virus that infects bacteria.
bacteroid A modified bacterial cell of the type known as rhizobia present in mature root nodules of some plants.
balanced polymorphism The phenomenon in which two or more alleles are kept in balance and maintained in a population over the course of many generations.
balancing selection A type of natural selection that maintains genetic diversity in a population.
balloon angioplasty A common treatment to restore blood flow through a blood vessel. A thin tube with a tiny, inflatable balloon at its tip is threaded through the artery to the diseased area; inflating the balloon compresses the plaque against the arterial wall, widening the lumen.
barometric pressure *See* atmospheric pressure.
baroreceptor A pressure-sensitive region within the walls of certain arteries that contains the endings of nerve cells; these regions sense and help to maintain blood pressure in the normal range for an animal.
Barr body A highly condensed X chromosome present in female mammals.
basal body A site at the base of flagella or cilia from which microtubules grow. Basal bodies are anchored on the cytosolic side of the plasma membrane.
basal metabolic rate (BMR) The metabolic rate of an animal under resting conditions, in a postabsorptive state, and at a standard temperature.
basal nuclei Clusters of neuronal cell bodies in the vertebrate forebrain that surround the thalamus and lie beneath the cerebral cortex; involved in planning and learning movements.
basal region The region of a plant seedling that produces the roots.

basal transcription A low level of transcription resulting from just the core promoter.
basal transcription apparatus In a eukaryotic structural gene, refers to the complex of RNA polymerase II, GTFs, and a DNA sequence containing a TATA box.
base 1. A molecule that when dissolved in water lowers the H^+ concentration. 2. A component of nucleotides that is a single or double ring of carbon and nitrogen atoms.
base pair The structure in which two bases in opposite strands of DNA hydrogen-bond with each other.
base substitution A mutation that involves the substitution of a single base in the DNA for another base.
basic local alignment search tool (BLAST) *See* BLAST.
basidia Club-shaped cells that produce sexual spores in basidiomycete fungi.
basidiocarp The type of fruiting body produced by basidiomycete fungi.
basidiomycetes A phylum of fungi whose sexual spores are produced on the surfaces of club-shaped structures (basidia).
basidiospore A sexual spore of the basidiomycete fungi.
basilar membrane A component of the mammalian ear that vibrates back and forth in response to sound and bends the stereocilia in one direction and then the other.
basophil A type of leukocyte that secretes the anticlotting factor heparin at the site of an infection, which helps flush out the infected site; basophils also secrete histamine, which attracts infection-fighting cells and proteins.
Batesian mimicry The mimicry of an unpalatable species (the model) by a palatable one (the mimic).
Bayesion method One method used to evaluate a phylogenetic tree based on an evolutionary model.
B cell A type of lymphocyte responsible for specific immunity.
behavior The observable response of organisms to external or internal stimuli.
behavioral ecology A subdiscipline of organismal ecology that focuses on how the behavior of an individual organism contributes to its survival and reproductive success, which, in turn, eventually affects the population density of the species.
benign tumor A precancerous mass of abnormal cells.
beta (β) pleated sheet A type of protein secondary structure in which regions of a polypeptide lie parallel to each other and are held together by hydrogen bonds to form a repeating zigzag shape.
bidirectional replication The process in which DNA replication proceeds outward from the origin in opposite directions.
biennial A plant that does not reproduce during the first year of life but may reproduce within the following year.
bilateral symmetry An architectural feature in which the body or organ of an organism can be divided along a vertical plane at the midline to create two halves.
Bilateria Bilaterally symmetric animals.
bile A substance produced by the liver that contains bicarbonate ions, cholesterol, phospholipids, a number of organic wastes, and a group of substances collectively termed bile salts.
bile salts A group of substances produced in the liver that solubilize dietary fat and increase its accessibility to digestive enzymes.
binary fission The process of cell division in bacteria and archaea in which one cell divides into two cells.
binocular vision A type of vision in animals having two eyes located at the front of the head; the overlapping images coming into both eyes are processed together in the brain to form one perception.
binomial nomenclature The standard method for naming species. Each species has a genus name and species epithet.
biochemistry The study of the chemistry of living organisms.
biodiversity The diversity of life forms in a given location.
biodiversity crisis The idea that there is currently an elevated loss of species on Earth, far beyond the normal extinction rate of species.
biofilm An aggregation of microorganisms that secrete adhesive mucilage, thereby gluing themselves to surfaces.
biogeochemical cycle The continuous movement of nutrients such as nitrogen, carbon, sulfur, and phosphorus from the physical environment to organisms and back.
biogeography The study of the geographic distribution of extinct and modern species.
bioinformatics A field of study that uses computers to study biological information.
biological control The use of an introduced species' natural enemies to control its proliferation.
biological nitrogen fixation Nitrogen fixation that is performed in nature by certain prokaryotes.
biological species concept An approach used to distinguish species, which states that a species is a group of individuals whose members have the potential to interbreed with one another in nature to produce viable, fertile offspring but cannot successfully interbreed with members of other species.
biology The study of life.
bioluminescence A phenomenon in living organisms in which chemical reactions give off light rather than heat.
biomagnification The increase in the concentration of a substance in living organisms from lower to higher trophic levels in a food web.
biomass A quantitative estimate of the total mass of living matter in a given area, usually measured in grams or kilograms per square meter.
biome A major type of habitat characterized by distinctive plant and animal life.
bioremediation The use of living organisms, usually microbes or plants, to detoxify polluted habitats such as dump sites or oil spills.
biosphere The regions on the surface of the Earth and in the atmosphere where living organisms exist.
biosynthetic reaction Also called an anabolic reaction; a chemical reaction in which small molecules are used to synthesize larger molecules.
biotechnology The use of living organisms or the products of living organisms for human benefit.
biotic The term used to describe interactions among organisms.
biparental inheritance An inheritance pattern in which both the male and female gametes contribute organellar genes to the offspring.
bipedal Having the ability to walk on two feet.
bipolar cells Cells in the vertebrate eye that make synapses with photoreceptors and relay responses to the ganglion cells.
bipolar disorder A neurological disorder characterized by alternating periods of euphoria and depression, resulting from an imbalance in neurotransmitter levels in the brain.
bivalent Homologous pairs of sister chromatids associated with each other, lying side by side.
blade The flattened portion of a leaf.
BLAST A computer program that can identify homologous genes that are found in a database.
blastocoel A cavity formed in a cleavage-stage vertebrate embryo (blastula); provides a space into which cells of the future digestive tract will migrate.
blastocyst The mammalian counterpart of a blastula.
blastoderm A flattened disc of dividing cells in the embryo of animals that undergo incomplete cleavage; occurs in birds and some fishes.
blastomeres The two half-size daughter cells produced by each cell division during cleavage.
blastopore A small opening created when a band of tissue invaginates during gastrulation. It forms the primary opening of the archenteron to the outside.
blastula An animal embryo at the stage when it forms an outer epithelial layer and an inner cavity.
blending inheritance An early hypothesis of inheritance that stated that the genetic material that dictates hereditary traits blends together from generation to generation, and the blended traits are then passed to the next generation.
blood A fluid connective tissue in animals consisting of cells and (in mammals) cell fragments suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules.
blood-doping An example of hormone misuse in which the number of red blood cells in the circulation is boosted to increase the oxygen-carrying capacity of the blood.
blood pressure The force exerted by blood on the walls of blood vessels; blood pressure is responsible for moving blood through the vessels.
body mass index (BMI) A method of assessing body fat and health risk that involves calculating the ratio of weight compared to height; weight in kilograms is divided by the square of the height in meters.
body plan The organization of cells, tissues, and organs within a multicellular organism; also known as a body pattern.
bone A relatively hard component of the vertebrate skeleton; a living, dynamic tissue composed of organic molecules and minerals.
bottleneck effect A situation in which a population size is dramatically reduced and then rebounds. While the population is small, genetic drift may rapidly reduce the genetic diversity of the population.
Bowman's capsule A saclike structure that houses the glomerulus at the beginning of the tubular component of a nephron in the mammalian kidney.
brain Organ of the central nervous system of animals that functions to process and integrate information.
brainstem The part of the vertebrate brain composed of the medulla oblongata, the pons, and the midbrain.
brassinosteroid One of several plant hormones that help a plant to cope with environmental stress.

bronchi (singular, **bronchus**) Tubes branching from the trachea and leading into the lungs.
bronchiole A thin-walled, small tube branching from the bronchi and leading to the alveoli in mammalian lungs.
bronchodilator A compound that binds to the muscles of the bronchioles of the lung and causes them to relax, thereby widening the bronchioles.
brown adipose tissue A specialized tissue in small mammals such as hibernating bats, small rodents living in cold environments, and many newborn mammals, including humans, that can help to generate heat and maintain body temperature.
brush border The collective name for the microvilli in the vertebrate small intestine.
bryophytes Liverworts, mosses, and hornworts, the modern nonvascular land plants.
buccal pumping A form of breathing in which animals take in water or air into their mouths, then raise the floor of the mouth, creating a positive pressure that pumps water or air across the gills or into the lungs; found in fishes and amphibians.
bud A miniature plant shoot having a dormant shoot apical meristem.
budding A form of asexual reproduction in which a portion of the parent organism pinches off to form a complete new individual.
buffer A compound that acts to minimize pH fluctuations in the fluids of living organisms. Buffer systems can raise or lower pH as needed.
bulbourethral glands Paired accessory glands in the human male reproductive system that secrete an alkaline mucus that protects sperm by neutralizing the acidity in the urethra.
bulk feeders Animals that eat food in large pieces.
bulk flow The mass movement of liquid in a plant caused by pressure, gravity, or both.

C

C_3 plant A plant that incorporates CO_2 into organic molecules via RuBP to make 3PG, a three-carbon molecule.
C_4 plant A plant that uses PEP carboxylase to initially fix CO_2 into a four-carbon molecule and later uses rubisco to fix CO_2 into simple sugars; an adaptation to hot, dry environments.
cadherin A cell adhesion molecule found in animal cells that promotes cell-to-cell adhesion.
calcitonin A hormone that plays a role in Ca^{2+} homeostasis in some vertebrates.
calcium wave A brief increase in cytosolic Ca^{2+} concentrations in an egg that has been penetrated by a sperm cell; the change in Ca^{2+} moves through the cell and contributes to the slow block to polyspermy.
callose A carbohydrate that plays crucial roles in plant development and plugging wounds in plant phloem.
calorie The amount of heat required to raise the temperature of 1 gram of water 1 degree Celsius.
Calvin cycle The second stage in the process of photosynthesis. During this cycle, ATP is used as a source of energy, and NADPH is used as a source of high-energy electrons so that CO_2 can be incorporated into carbohydrate.
calyx The sepals that form the outermost whorl of a flower.
Cambrian explosion An event during the Cambrian period (543 to 490 mya) in which there was an abrupt increase (on a geological scale) in the diversity of animal species.
cAMP *See* cyclic adenosine monophosphate.
CAM plants C_4 plants that open their stomata at night to take up carbon dioxide.
cancer A disease caused by gene mutations that lead to uncontrolled cell growth.
canopy The uppermost layer of tree foliage.
capillary A tiny thin-walled vessel that is the site of gas and nutrient exchange between the blood and interstitial fluid.
capping The process in which a 7-methylguanosine is covalently attached at the 5′ end of mature mRNAs of eukaryotes.
capsid A protein coat enclosing a virus's genome.
CAP site One of two regulatory sites near the *lac* promoter; this site is a DNA sequence recognized by the catabolite activator protein (CAP).
capsule A very thick, gelatinous glycocalyx produced by certain strains of bacteria that may help them avoid being destroyed by an animal's immune (defense) system.
carapace The hard protective cuticle covering the cephalothorax of a crustacean.
carbohydrate An organic molecule often with the general formula, $C(H_2O)$; a carbon-containing compound that includes starches, sugars, and cellulose.
carbon fixation A process in which carbon from inorganic CO_2 is incorporated into an organic molecule such as a carbohydrate.
carboxyl terminus *See* C-terminus.
carcinogen An agent that increases the likelihood of developing cancer, usually a mutagen.
carcinoma A cancer of epithelial cells.
cardiac cycle The events that produce a single heartbeat, which can be divided into two phases, diastole and systole.
cardiac muscle A type of muscle tissue found only in hearts in which physical and electrical connections between individual cells enable many of the cells to contract simultaneously.
cardiac output (CO) The amount of blood the heart pumps per unit time, usually expressed in units of L/min.
cardiovascular disease Diseases affecting the heart and blood vessels.
cardiovascular system A system containing three components: blood or hemolymph, blood vessels, and one or more hearts.
carnivore An animal that consumes animal flesh or fluids.
carotenoid A type of photosynthetic or protective pigment found in plastids that imparts a color that ranges from yellow to orange to red.
carpel A flower shoot organ that produces ovules that contain female gametophytes.
carrier *See* transporter.
carrying capacity (K) The upper boundary for a population size.
Casparian strips Suberin ribbons on the walls of endodermal cells of plant roots; prevent apoplastic transport of ions into vascular tissues.
caspase An enzyme that is activated during apoptosis.
catabolic reaction A metabolic pathway in which a molecule is broken down into smaller components, usually releasing energy.
catabolism A metabolic pathway that results in the breakdown of larger molecules into smaller molecules. Such reactions are often exergonic.
catabolite activator protein (CAP) An activator protein for the *lac* operon.
catabolite repression In bacteria, a process whereby transcriptional regulation is influenced by the presence of glucose.
catalase An enzyme within peroxisomes that breaks down hydrogen peroxide to water and oxygen gas.
catalyst An agent that speeds up the rate of a chemical reaction without being consumed during the reaction.
cataract An accumulation of protein in the lens of the eye; causes blurring and poor night vision.
cation An ion that has a net positive charge.
cation exchange With regard to soil, the process in which hydrogen ions are able to replace mineral cations on the surfaces of humus or clay particles.
cDNA *See* complementary DNA.
cDNA library A type of DNA library in which the inserts are derived from cDNA.
cecum The first portion of a vertebrate's large intestine.
cell The simplest unit of a living organism.
cell adhesion A vital function of the cell membrane that allows cells to bind to each other. Cell adhesion is critical in the formation of multicellular organisms and provides a way to convey positional information between neighboring cells.
cell adhesion molecule (CAM) A membrane protein found in animal cells that promotes cell adhesion.
cell biology The study of individual cells and their interactions with each other.
cell body A part of a neuron that contains the cell nucleus and other organelles.
cell coat Also called the glycocalyx, the carbohydrate-rich zone on the surface of animal cells that shields the cell from mechanical and physical damage.
cell communication The process through which cells can detect and respond to signals in their extracellular environment. In multicellular organisms, cell communication is also needed to coordinate cellular activities within the whole organism.
cell cycle The series of phases a eukaryotic cell progresses through from its origin until it divides by mitosis.
cell differentiation The phenomenon by which cells become specialized into particular cell types.
cell division The process in which one cell divides into two cells.
cell doctrine *See* cell theory.
cell junctions Specialized structures that adhere cells to each other and to the ECM.
cell-mediated immunity A type of specific immunity in which cytotoxic T cells directly attack and destroy infected body cells, cancer cells, or transplanted cells.
cell nucleus The membrane-bound area of a eukaryotic cell in which the genetic material is found.
cell plate In plant cells, a structure that forms a cell wall between the two daughter cells during cytokinesis.
cell signaling A vital function of the plasma membrane that involves cells sensing changes in their environment and communicating with each other.
cell surface receptor A receptor found in the plasma membrane that enables a cell to respond to different kinds of signaling molecules.
cell theory A theory that states that all organisms are made of cells, cells are the smallest units of living organisms, and new cells come from pre-existing cells by cell division.

cell-to-cell communication A form of cell communication that occurs between two different cells.
cellular differentiation The process by which different cells within a developing organism acquire specialized forms and functions due to the expression of cell-specific genes.
cellular respiration A process by which living cells obtain energy from organic molecules and release waste products.
cellular response Adaptation at the cellular level that involves a cell responding to signals in its environment.
cellulose The main macromolecule of the primary cell wall of plants and many algae; a polymer made of repeating molecules of glucose attached end to end.
cell wall A relatively rigid, porous structure located outside the plasma membrane of prokaryotic, plant, fungal, and certain protist cells; provides support and protection.
centiMorgan (cM) *See* map unit (mu).
central cell In the female gametophyte of a flowering plant, a large cell that contains two nuclei; after double fertilization, it forms the first cell of the nutritive endosperm tissue.
central dogma Refers to the steps of gene expression at the molecular level. DNA is transcribed into mRNA, and mRNA is translated into a polypeptide.
central nervous system (CNS) In vertebrates, the brain and spinal cord.
central region The region of a plant seedling that produces stem tissue.
central vacuole An organelle that often occupies 80% or more of the cell volume of plant cells and stores a large amount of water, enzymes, and inorganic ions.
central zone The area of a plant shoot meristem where undifferentiated stem cells are maintained.
centrioles A pair of structures within the centrosome of animal cells. Most plant cells and many protists lack centrioles.
centromere The region where the two sister chromatids are tightly associated; the centromere is an attachment site for kinetochore proteins.
centrosome A single structure often near the cell nucleus of eukaryotic cells that forms a nucleating site for the growth of microtubules; also called the microtubule-organizing center.
cephalization The localization of a brain and sensory structures at the anterior end of the body of animals.
cephalothorax The fused head and thorax structure in species of the class Arachnida and Crustacea.
cerebellum The part of the vertebrate hindbrain, along with the pons, responsible for monitoring and coordinating body movements.
cerebral cortex The surface layer of gray matter that forms the outer part of the cerebrum of the vertebrate brain.
cerebral ganglia A paired structure in the head of invertebrates that receives input from sensory cells and controls motor output.
cerebrospinal fluid Fluid that exists in ventricles within the central nervous system and surrounds the exterior of the brain and spinal cord; it absorbs physical shocks to the brain resulting from sudden movements or blows to the head.
cerebrum A region of the vertebrate forebrain that is responsible for the higher functions of conscious thought, planning, and emotion, as well as control of motor function.
cervix A fibrous structure at the end of the female vagina that forms the opening to the uterus.
channel A transmembrane protein that forms an open passageway for the direct diffusion of ions or molecules across a membrane.
chaperone A protein that keeps other proteins in an unfolded state during the process of post-translational sorting.
character A characteristic of an organism, such as the appearance of seeds, pods, flowers, or stems.
character displacement The tendency for two species to diverge in morphology and thus resource use because of competition.
character state A particular variant of a given trait.
charged tRNA A tRNA with its attached amino acid; also called aminoacyl tRNA.
charophyceans The lineages of freshwater green algae that are most closely related to the land plants.
checkpoint One of three critical regulatory points found in the cell cycle of eukaryotic cells. At these checkpoints, a variety of proteins act as sensors to determine if a cell is in the proper condition to divide.
checkpoint protein A protein that senses if a cell is in the proper condition to divide and prevents a cell from progressing through the cell cycle if it is not.
chemical energy The potential energy contained within covalent bonds in molecules.
chemical equilibrium A state in a chemical reaction in which the rate of formation of products equals the rate of formation of reactants.
chemical mutagen A chemical that causes mutations.
chemical reaction The formation and breaking of chemical bonds, resulting in a change in the composition of substances.
chemical selection Occurs when a chemical within a mixture has special properties or advantages that cause it to increase in amount. May have played a key role in the formation of an RNA world.
chemical synapse A synapse in which a chemical called a neurotransmitter is released from the axon terminal of a neuron and acts as a signal from the presynaptic to the postsynaptic cell.
chemiosmosis A process for making ATP in which energy stored in an ion electrochemical gradient is used to make ATP from ADP and P_i.
chemoautotroph An organism able to use energy obtained by chemical modifications of inorganic compounds to synthesize organic compounds.
chemoheterotroph An organism that must obtain organic molecules both for energy and as a carbon source.
chemoreceptor A sensory receptor in animals that responds to specific chemical compounds.
chiasma The connection at a crossover site of two chromosomes.
chimeric gene A gene formed from the fusion of two gene fragments to each other.
chitin A tough, nitrogen-containing polysaccharide that forms the external skeleton of many insects and the cell walls of fungi.
chlorophyll A photosynthetic green pigment found in the chloroplasts of plants, algae, and some bacteria.
chlorophyll *a* A type of chlorophyll pigment found in plants, algae, and cyanobacteria.
chlorophyll *b* A type of chlorophyll pigment found in plants, green algae, and some other photosynthetic organisms.
chloroplast A semiautonomous organelle found in plant and algal cells that carries out photosynthesis.
chloroplast genome The chromosome found in chloroplasts.
chlorosis The yellowing of plant leaves caused by various types of mineral deficiencies.
choanocyte A specialized cell of sponges that functions to trap and eat small particles.
chondrichthyans Members of the class Chondrichthyes, including sharks, skates, and rays.
chordate An organism that has or at some point in its life has had a notochord and a hollow dorsal nerve cord; includes all vertebrates and some invertebrates.
chorion One of the four extraembryonic membranes in the amniotic egg. It exchanges gases between the embryo and the surrounding air.
chorionic gonadotropin (CG) An LH-like hormone made by the blastocyst that maintains the corpus luteum.
chromatin Refers to the biochemical composition of chromosomes, which contain DNA and many types of proteins.
chromosome A discrete unit of genetic material composed of DNA and associated proteins. Eukaryotes have chromosomes in their cell nuclei and in plastids and mitochondria.
chromosome territory A distinct, nonoverlapping area where each chromosome is located within the cell nucleus of eukaryotic cells.
chromosome theory of inheritance An explanation of how the steps of meiosis account for the inheritance patterns observed by Mendel.
chylomicrons Large fat droplets coated with amphipathic proteins that perform an emulsifying function similar to that of bile salts; chylomicrons are formed in intestinal epithelial cells from absorbed fats in the diet.
chyme A solution of water and partially digested food particles in the stomach and small intestine.
chymotrypsin A protease involved in the breakdown of proteins in the small intestine.
chytrids Simple, early-diverging phyla of fungi; commonly found in aquatic habitats and moist soil, where they produce flagellate reproductive cells.
cilia (singular, **cilium**) Cell appendages that have the same internal structure as flagella and function like flagella to facilitate cell movement; cilia are shorter and more numerous on cells than are flagella.
ciliate A protist that moves by means of cilia, which are tiny hairlike extensions that occur on the outsides of cells and have the same internal structure as flagella.
circulatory system A system that transports necessary materials to all cells of an animal's body and transports waste products away from cells. Three basic types are gastrovascular cavities, open systems, and closed systems.
***cis*-acting element** *See cis*-effect.
***cis*-effect** A DNA segment that must be adjacent to the gene(s) that it regulates. The *lac* operator site is an example of a *cis*-acting element.
cisternae Flattened, fluid-filled tubules of the endoplasmic reticulum.
***cis/trans* isomers** Organic molecules with the same chemical composition but existing in two different configurations determined by the positions of hydrogen atoms on the two carbons of a C═C double bond. When the hydrogen

atoms are on the same side of the double bond, it is called a *cis* isomer; when on the opposite sides of the double bond, it is a *trans* isomer.

citric acid cycle A cycle that results in the breakdown of carbohydrates to carbon dioxide; also known as the Krebs cycle.

clade A group of species derived from a single common ancestor.

cladistic approach An approach used to construct a phylogenetic tree by comparing primitive and shared derived characters.

cladogenesis A pattern of speciation in which a species is divided into two or more species.

cladogram A phylogenetic tree constructed by using a cladistic approach.

clamp connection In basidiomycete fungi, a structure that helps distribute nuclei during cell division.

clasper An extension of the pelvic fin of a chondrichthyan, used by the male to transfer sperm to the female.

class In taxonomy, a subdivision of a phylum.

classical conditioning A type of associative learning in which an involuntary response comes to be associated positively or negatively with a stimulus that did not originally elicit the response.

cleavage A succession of rapid cell divisions with no significant growth that produces a hollow sphere of cells called a blastula.

cleavage furrow In animal cells, an area that constricts like a drawstring to separate the cells during cytokinesis.

climate The prevailing weather pattern of a given region.

climax community A distinct end point of succession.

clitoris Located at the anterior part of the labia minora, erectile tissue that becomes engorged with blood during sexual arousal and is very sensitive to sexual stimulation.

clonal deletion One of two mechanisms that explain why normal individuals lack active lymphocytes that respond to self components; T cells with receptors capable of binding self proteins are destroyed by apoptosis.

clonal inactivation One of two mechanisms that explain why normal individuals lack active lymphocytes that respond to self components; the process occurs outside the thymus and causes potentially self-reacting T cells to become nonresponsive.

clonal selection The process by which an antigen-stimulated lymphocyte divides and forms a clone of cells, each of which recognizes that particular antigen.

cloning Making many copies of something such as a DNA molecule.

closed circulatory system A circulatory system in which blood flows throughout an animal entirely within a series of vessels and is kept separate from the interstitial fluid.

closed conformation Tightly packed chromatin that cannot be transcribed into RNA.

clumped The most common pattern of dispersion within a population, in which individuals are gathered in small groups.

cnidocil On the surface of a cnidocyte, a hairlike trigger that detects stimuli.

cnidocyte A characteristic feature of cnidarians; a stinging cell that functions in defense or the capture of prey.

coacervates Droplets that form spontaneously from the association of charged polymers such as proteins, carbohydrates, or nucleic acids surrounded by water.

coactivator A protein that increases the rate of transcription but does not directly bind to the DNA itself.

coat protein A protein that surrounds a membrane vesicle and facilitates vesicle formation.

cocci Sphere-shaped prokaryotic cells.

cochlea A coiled structure in the inner ear of mammals that contains the auditory receptors (organ of Corti).

coding sequence The region of a gene or a DNA molecule that encodes the information for the amino acid sequence of a polypeptide.

coding strand The DNA strand opposite to the template (or noncoding strand).

codominance The phenomenon in which a single individual expresses two alleles.

codon A sequence of three nucleotide bases that specifies a particular amino acid or a stop codon; codons function during translation.

coefficient of relatedness (*r*) The probability that any two individuals will share a copy of a particular gene.

coelom A fluid-filled body cavity in an animal.

coelomate An animal with a true coelom.

coenzyme An organic molecule that participates in a chemical reaction with an enzyme but is left unchanged after the reaction is completed.

coevolution The process by which two or more species of organisms influence each other's evolutionary pathway.

cofactor Usually an inorganic ion that temporarily binds to the surface of an enzyme and promotes a chemical reaction.

cognitive learning The ability to solve problems with conscious thought and without direct environmental feedback.

cohesion The ability of like molecules to noncovalently bind to each other; the attraction of water molecules for each other.

cohesion-tension theory The explanation for long-distance water transport as the combined effect of the cohesive forces of water and evaporative tension.

cohort A group of organisms of the same age.

coleoptile A protective sheath that encloses the first bud of the epicotyl in a mature monocot embryo.

coleorhiza A protective envelope that encloses the young root of a monocot.

colinearity rule The phenomenon whereby the order of homeotic genes along the chromosome correlates with their expression along the anteroposterior axis of the body.

collagen A protein secreted from animal cells that forms large fibers in the extracellular matrix.

collecting duct A tubule in the mammalian kidney that collects urine from nephrons.

collenchyma cells Flexible cells that make up collenchyma tissue.

collenchyma tissue A plant ground tissue that provides support to plant organs.

colligative property A property of a solution that depends only on the concentration of solute molecules.

colloid A gel-like substance in the follicles of the thyroid gland.

colon A part of a vertebrate's large intestine consisting of three relatively straight segments—the ascending, transverse, and descending portions. The terminal portion of the descending colon is S-shaped, forming the sigmoid colon, which empties into the rectum.

colony hybridization A method that uses a labeled probe to identify bacterial colonies that contain a desired gene.

combinatorial control The phenomenon whereby a combination of many factors determines the expression of any given gene.

commensalism An interaction that benefits one species and leaves the other unaffected.

communication The use of specially designed visual, chemical, auditory, or tactile signals to modify the behavior of others.

community An assemblage of populations of different species that live in the same place at the same time.

community ecology The study of how populations of species interact and form functional communities.

compartmentalization A characteristic of eukaryotic cells in which many organelles separate the cell into different regions. Cellular compartmentalization allows a cell to carry out specialized chemical reactions in different places.

competent The term used to describe bacterial strains that have the ability to take up DNA from the environment.

competition An interaction that affects two or more species negatively, as they compete over food or other resources.

competitive exclusion hypothesis The proposal that two species with the same resource requirements cannot occupy the same niche.

competitive inhibitor A molecule that binds to the active site of an enzyme and inhibits the ability of the substrate to bind.

complement The family of plasma proteins that provides a means for extracellular killing of microbes without prior phagocytosis.

complementary Describes the specific base pairing that occurs between strands of nucleic acids; A pairs only with T (in DNA) or U (in RNA), and G pairs only with C.

complementary DNA (cDNA) DNA molecules that are made from mRNA as a starting material.

complete flower A flower that possesses all four types of flower organs.

complete metamorphosis During development in the majority of insects, a dramatic change in body form from larva to a very different looking adult.

compound A molecule composed of two or more different elements.

compound eyes Image-forming eyes in arthropods and some annelids consisting of several hundred to several thousand light detectors called ommatidia.

computational molecular biology An area of study that uses computers to characterize the molecular components of living things.

concentration The amount of a solute dissolved in a unit volume of solution.

condensation reaction A chemical reaction in which two or more molecules are combined into one larger molecule by covalent bonding, with the loss of a small molecule.

conditional specification The acquisition by cells of specific properties through a variety of cell-to-cell signaling mechanisms in a developing vertebrate embryo.

conditioned response The learned response that is elicited by a newly conditioned stimulus.

conditioned stimulus A new stimulus that is delivered at the same time as an old stimulus, and that over time, is sufficient to elicit the same response.

condom A sheathlike membrane worn over the penis; in addition to their contraceptive function, condoms significantly reduce the risk of sexually transmitted diseases.
conduction The process in which the body surface loses or gains heat through direct contact with cooler or warmer substances.
cone pigments The several types of visual pigments found in the cones of the vertebrate eye.
cones 1. Photoreceptors found in the vertebrate eye; they are less sensitive to low levels of light but can detect color. 2. The reproductive structures of coniferous plants.
congenital hypothyroidism A condition characterized by poor differentiation of the central nervous system due to a failure of neurons to become myelinated in fetal development; results in profound mental defects.
congestive heart failure The condition resulting from the failure of the heart to pump blood normally; results in fluid buildup in the lungs (congestion).
conidia A type of asexual reproductive cell produced by many fungi.
conifers A phylum of gymnosperm plants, Coniferophyta.
conjugation A type of genetic transfer between bacteria that involves a direct physical interaction between two bacterial cells.
connective tissue Clusters of cells that connect, anchor, and support the structures of an animal's body; includes blood, adipose (fat-storing) tissue, bone, cartilage, loose connective tissue, and dense connective tissue.
connexon A channel that forms gap junctions consisting of six connexin proteins in one cell aligned with six connexin proteins in an adjacent cell.
conservation biology The study that uses principles and knowledge from molecular biology, genetics, and ecology to protect the biological diversity of life.
conservative mechanism In this incorrect model for DNA replication, both parental strands of DNA remain together (are conserved) following DNA replication. The two newly made daughter strands also occur together.
consortia A community of many microbial species.
constant regions The portions of amino acid sequences in the heavy and light chains that are identical for all immunoglobulins of a given class.
constitutive gene An unregulated gene that has constant levels of expression in all conditions over time.
contig A series of clones that contain overlapping pieces of chromosomal DNA.
continental drift The process by which, over the course of billions of years, the major landmasses, known as the continents, have shifted their positions, changed their shapes, and, in some cases, have become separated from each other.
contraception The use of birth control procedures to prevent fertilization or implantation of a fertilized egg.
contractile vacuole A small, membrane enclosed, water-filled compartment that eliminates excess liquid from the cells of certain protists.
contrast In microscopy, relative differences in the lightness, darkness, or color between adjacent regions in a sample.
control group The sample in an experiment that is treated just like an experimental group except that it is not subjected to one particular variable.
convection The transfer of heat by the movement of air or water next to the body.
convergent evolution The process whereby two different species from different lineages show similar characteristics because they occupy similar environments.
convergent extension A cellular process during gastrulation that is crucial to development; two rows of cells merge to form a single elongated layer.
convergent trait *See* analogous structure.
coprophagy The practice of certain birds and mammals in which feces are consumed to maximize absorption of water and nutrients.
copulation The process of sperm being deposited within the reproductive tract of the female.
coral reef A type of aquatic biome found in warm, marine environments.
corepressor A small effector molecule that binds to a repressor protein to inhibit transcription.
core promoter Refers to the TATA box and the transcriptional start site of a eukaryotic structural gene.
Coriolis effect The effect of the Earth's rotation on the surface flow of wind.
cork cambium A secondary meristem in a plant that produces cork tissue.
cornea A thin, clear layer on the front of the vertebrate eye.
corolla The petals of a flower, which occur in the whorl to the inside of the calyx and the outside of the stamens.
corona The ciliated crown of members of the phylum Rotifera.
coronary artery An artery that carries oxygen and nutrients to the heart muscle.
coronary artery bypass A common treatment to restore blood flow through a coronary artery. A small piece of healthy blood vessel is removed from one part of the body and surgically grafted onto the coronary circulation in order to bypass the diseased artery.
coronary artery disease A condition that occurs when plaques form in the coronary arteries.
corpus callosum The major tract that connects the two hemispheres of the cerebrum.
corpus luteum A structure that develops from a ruptured follicle following ovulation; it is responsible for secreting hormones that stimulate the development of the uterus during pregnancy.
correlation A meaningful relationship between two variables.
cortex The area of a plant stem or root beneath the epidermis that is largely composed of parenchyma tissue.
cortical reaction An event in fertilization in which IP_3 and calcium signaling produces barriers to more than one sperm cell binding to and uniting with an egg; called the slow block to polyspermy.
cortisol A steroid hormone made by the adrenal cortex.
cotranslational sorting The sorting process in which the synthesis of certain eukaryotic proteins begins in the cytosol and then halts temporarily until the ribosome has become bound to the ER membrane.
cotransporter *See* symporter.
cotyledon An embryonic seed leaf.
countercurrent exchange mechanism An arrangement of water and blood flow in which water enters a fish's mouth and flows between the lamellae of the gills in the opposite direction to blood flowing through the lamellar capillaries.
countercurrent heat exchange A method of regulating heat loss to the environment; many animals conserve heat by returning it to the body's core and keeping the core much warmer than the extremities.
covalent bond A chemical bond in which two atoms share a pair of electrons.
CpG island A cluster of CpG sites. CG refers to the nucleotides of C and G in DNA, and p refers to a phosphodiester linkage.
cranial nerve A nerve in the peripheral nervous system that is directly connected to the brain.
craniate A chordate that has a brain encased in a skull and possesses a neural crest.
cranium A protective bony or cartilaginous housing that encases the brain of a craniate.
crenation The process of cell shrinkage that occurs if animal cells are placed in a hypertonic medium.
cristae Projections of the highly invaginated inner membrane of a mitochondrion.
critical innovations New features that foster the diversification of phyla.
critical period A limited period of time in which many animals develop species-specific patterns of behavior.
crop A storage organ that is a dilation of the lower esophagus; found in most birds and many invertebrates, including insects and some worms.
cross-bridge A region of myosin molecules that extend from the surface of the thick filaments toward the thin filaments in skeletal muscle.
cross-bridge cycle During muscle contraction, the sequence of events that occurs between the time when a cross-bridge binds to a thin filament and when it is set to repeat the process.
cross-fertilization Fertilization that involves the union of a female gamete and a male gamete from different individuals.
crossing over The exchange of genetic material between homologous chromosomes during meiosis; allows for increased variation in the genetic information that each parent may pass to the offspring.
cross-pollination The process in which a stigma receives pollen from a different plant of the same species.
cryptic coloration The blending of an organism with the background color of its habitat; also known as camouflage.
cryptochrome A type of blue-light receptor in plants and protists.
C-terminus The location of the last amino acid in a polypeptide; also known as the carboxyl terminus.
CT scan Computerized tomography, which is an X-ray technique used to examine the structure and activity level of the brain without anesthesia or surgery.
cupula A gelatinous structure within the lateral line organ of fishes that detects changes in water movement.
cuticle A coating of wax and cutin that helps to reduce water loss from plant surfaces. Also, a nonliving covering that serves to both support and protect an animal.
cycads A phylum of gymnosperm plants, Cycadophyta.
cyclic adenosine monophosphate (cAMP) A small effector molecule that acts as a second messenger and is produced from ATP.

cyclic AMP (cAMP) *See* cyclic adenosine monophosphate.
cyclic electron flow *See* cyclic photophosphorylation.
cyclic photophosphorylation During photosynthesis, a pattern of electron flow in the thylakoid membrane that is cyclic and generates ATP alone.
cyclin A protein responsible for advancing a cell through the phases of the cell cycle by binding to a cyclin-dependent kinase.
cyclin-dependent kinase (cdk) A protein responsible for advancing a cell through the phases of the cell cycle. Its function is dependent on the binding of a cyclin.
cyst A one-to-few celled structure that often has a thick, protective wall and can remain dormant through periods of unfavorable climate or low food availability.
cytogenetics The field of genetics that involves the microscopic examination of chromosomes.
cytokines A family of proteins that function in both nonspecific and specific immune defenses by providing a chemical communication network that synchronizes the components of the immune response.
cytokinesis The division of the cytoplasm to produce two distinct daughter cells.
cytokinin A type of plant hormone that promotes cell division.
cytoplasm The region of the cell that is contained within the plasma membrane.
cytoplasmic inheritance *See* extranuclear inheritance.
cytosine (C) A pyrimidine base found in DNA and RNA.
cytoskeleton In eukaryotes, a network of three different types of protein filaments in the cytosol called microtubules, intermediate filaments, and actin filaments.
cytosol The region of a eukaryotic cell that is inside the plasma membrane and outside the organelles.
cytotoxic T cell A type of lymphocyte that travels to the location of its target, binds to the target by combining with an antigen on it, and directly kills the target via secreted chemicals.

D

dalton (Da) A measure of atomic mass. One dalton equals one-twelfth the mass of a carbon atom.
data mining The extraction of useful information and often previously unknown relationships from sequence files and large databases.
database A large number of computer data files that are collected, stored in a single location, and organized for rapid search and retrieval.
daughter strand The newly made strand in DNA replication.
day-neutral plant A plant that flowers regardless of the night length, as long as day length meets the minimal requirements for plant growth.
deafness Hearing loss, usually caused by damage to the hair cells within the cochlea.
death-inducing signaling complex (DISC) A complex consisting of death receptors, FADD, and procaspase that initiates apoptosis via the extrinsic pathway.
death receptor A type of receptor found in the plasma membrane of eukaryotic cells that can promote apoptosis when it becomes activated.
decomposer A consumer that gets its energy from the remains and waste products of other organisms.
defecation The expulsion of feces that occurs through the anus of an animal's digestive canal.
defensive mutualism A mutually beneficial interaction often involving an animal defending a plant or herbivore in return for food or shelter.
deforestation The conversion of forested areas by humans to nonforested land.
degenerate In the genetic code, the observation that more than one codon can specify the same amino acid.
dehydration A reduction in the amount of water in the body.
dehydration reaction A type of condensation reaction in which a molecule of water is lost.
delayed implantation A reproductive cycle in which a fertilized egg reaches the uterus but does not implant until later, when environmental conditions are more favorable for the newly produced young.
delayed ovulation A reproductive cycle in which the ovarian cycle in females is halted before ovulation and sperm are stored and nourished in the female's uterus over the winter. Upon arousal from hibernation in the spring, the female ovulates one or more eggs, which are fertilized by the stored sperm.
deletion A type of mutation in which a segment of genetic material is missing.
demographic transition The shift in birth and death rates accompanying human societal development.
demography The study of birth rates, death rates, age distributions, and the sizes of populations.
dendrite A treelike extension of the plasma membrane of a neuron that receives electrical signals from other neurons.
dendritic cell A type of cell derived from bone marrow stem cells that plays an important role in nonspecific immunity; these cells are scattered throughout most tissues, where they perform various macrophage functions.
denitrification The reduction of nitrate to gaseous nitrogen.
density In the context of populations, the numbers of organisms in a given unit area.
density-dependent factor A mortality factor whose influence increases with the density of the population.
density-independent factor A mortality factor whose influence is not affected by changes in population density.
deoxynucleoside triphosphates Individual nucleotides with three phosphate groups.
deoxyribonucleic acid (DNA) One of two classes of nucleic acids; the other is ribonucleic acid (RNA). A DNA molecule consists of two strands of nucleotides coiled around each other to form a double helix, held together by hydrogen bonds according to the AT/GC rule.
deoxyribose A five-carbon sugar found in DNA.
depolarization The change in the membrane potential that occurs when a cell becomes less polarized, that is, less negative relative to the surrounding fluid.
dermal tissue The covering on various parts of a plant.
descent with modification Darwin's theory that existing life-forms on our planet are the product of the modification of pre-existing life-forms.
desertification The overstocking of land with domestic animals that can greatly reduce grass coverage through overgrazing, turning the area more desert-like.
desmosome A mechanically strong cell junction between animal cells that typically occurs in spotlike rivets.
determinate cleavage In animals, a characteristic of protostome development in which the fate of each embryonic cell is determined very early.
determinate growth A type of growth in plants that is of limited duration, such as the growth of flowers.
determined The term used to describe a cell that is destined to differentiate into a particular cell type.
detritivore *See* decomposer.
detritus Unconsumed plants that die and decompose, along with the dead remains of animals and animal waste products.
deuterostome An animal whose development exhibits radial, indeterminate cleavage and in which the blastopore becomes the anus; includes echinoderms and vertebrates.
development In biology, a series of changes in the state of a cell, tissue, organ, or organism; the underlying process that gives rise to the structure and function of living organisms.
developmental genetics A field of study aimed at understanding how gene expression controls the process of development.
diaphragm A large muscle that subdivides the thoracic cavity from the abdomen in mammals; contraction of the diaphragm enlarges the thoracic cavity during inhalation.
diastole The phase of the cardiac cycle in which the ventricles fill with blood coming from the atria through the open AV valves.
diazotroph A bacterium that fixes nitrogen.
dideoxy chain-termination method The most common method of DNA sequencing; utilizes dideoxynucleotides as a reagent.
differential gene regulation The phenomenon in which the expression of genes differs under various environmental conditions and in specialized cell types.
diffusion In a solution, the process that occurs when a solute moves from a region of high concentration to a region of lower concentration.
digestion The process of breaking down nutrients in food into smaller molecules that can be absorbed across the intestinal epithelia and directly used by cells.
digestive system In animals, the long tube through which food is processed. In a vertebrate, this system consists of the alimentary canal plus several associated structures.
dihybrid An offspring that is a hybrid with respect to two traits.
dihybrid cross A cross in which the inheritance of two different traits is followed.
dikaryotic The occurrence of two genetically distinct nuclei in the cells of fungal hyphae after mating has occurred.
dimorphic fungi Fungi that can exist in two different morphological forms.
dinosaur A term, meaning "terrible lizard," used to describe some of the extinct fossil reptiles.
dioecious The term to describe plants that produce staminate and carpellate flowers on separate plants.
diploblastic Having two distinct germ layers—ectoderm and endoderm but not mesoderm.
diploid Refers to cells containing two sets of chromosomes; designated as $2n$.
diploid-dominant species Species in which the diploid organism is the prevalent organism in the life cycle. Animals are an example.

direct calorimetry A method of determining basal metabolic rate that involves quantifying the amount of heat generated by the animal.
direct repair Refers to a DNA repair system in which an enzyme finds an incorrect structure in the DNA and directly converts it back to the correct structure.
directionality In a DNA or RNA strand, refers to the orientation of the sugar molecules within that strand. Can be 5′ to 3′ or 3′ to 5′.
directional selection A pattern of natural selection that favors individuals at one extreme of a phenotypic distribution.
disaccharide A carbohydrate composed of two monosaccharides.
discovery-based science The collection and analysis of data without the need for a preconceived hypothesis; also called discovery science.
discrete trait A trait with clearly defined phenotypic variants.
dispersion A pattern of spacing in which individuals in a population are clustered together or spread out to varying degrees.
dispersive mechanism In this incorrect model for DNA replication, segments of parental DNA and newly made DNA are interspersed in both strands following the replication process.
dispersive mutualism A mutually beneficial interaction often involving plants and pollinators that disperse their pollen, and plants and fruit eaters that disperse the plant's seeds.
dissociation constant An equilibrium constant between a ligand and a protein, such as a receptor or an enzyme.
distal convoluted tubule The segment of the tubule of the nephron through which fluid flows into one of the many collecting ducts in the kidney.
diversifying selection A pattern of natural selection that favors the survival of two or more different genotypes that produce different phenotypes.
diversity-stability hypothesis The proposal that species-rich communities are more stable than those with fewer species.
DNA (deoxyribonucleic acid) The genetic material that provides a blueprint for the organization, development, and function of living things.
DNA fingerprinting A technology that identifies particular individuals using properties of their DNA.
DNA helicase An enzyme that uses ATP to separate DNA strands during DNA replication.
DNA library A collection of recombinant vectors, each containing a particular fragment of chromosomal DNA (cDNA).
DNA ligase An enzyme that catalyzes the formation of a covalent bond between nucleotides in adjacent DNA fragments to complete the replication process.
DNA methylase An enzyme that attaches methyl groups to bases in DNA.
DNA methylation A process in which methyl groups are attached to bases in DNA.
DNA microarray A technology used to monitor the expression of thousands of genes simultaneously.
DNA polymerase An enzyme responsible for covalently linking nucleotides together during DNA replication.
DNA primase An enzyme that synthesizes a primer for DNA replication.
DNA repair systems One of several systems to reverse DNA damage before a permanent mutation can occur.
DNA replication The process by which DNA is copied.
DNase An enzyme that digests DNA.
DNA sequencing A method to determine the base sequence of DNA.
DNA supercoiling A method of compacting chromosomes through the formation of additional coils around the long, thin DNA molecule.
DNA topoisomerase An enzyme that alleviates DNA supercoiling during DNA replication.
DNA transposon A type of transposable element that moves as a DNA molecule.
domain 1. A defined region of a protein with a distinct structure and function. 2. One of the three major categories of life: Bacteria, Archaea, and Eukarya.
domestication A process that involves artificial selection of plants or animals for traits desirable to humans.
dominant A term that describes the displayed trait in a heterozygote.
dominant species A species that has a large effect in a community because of its high abundance or high biomass.
dormancy A phase of metabolic slowdown in a plant.
dorsal Refers to the upper side of an animal.
dorsoventral axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the anteroposterior axis and the right-left axis.
dosage compensation The phenomenon that gene dosage is compensated between males and females. In mammals, the inactivation of one X chromosome in the female reduces the number of expressed copies (doses) of X-linked genes from two to one.
double bond A bond that occurs when the atoms of a molecule share two pairs of electrons.
double fertilization In angiosperms, the process in which two different fertilization events occur, producing both a zygote and the first cell of a nutritive endosperm tissue.
double helix Two strands of DNA hydrogen-bonded with each other. In a DNA double helix, two DNA strands are twisted together to form a structure that resembles a spiral staircase.
Down syndrome A human disorder caused by the inheritance of three copies of chromosome 21.
duplication A type of mutation in which a section of a chromosome occurs two or more times.
dynamic instability The oscillation of a single microtubule between growing and shortening phases; important in many cellular activities, including the sorting of chromosomes during cell division.

E

Ecdysozoa A clade of molting animals that encompasses primarily the arthropods and nematodes.
echolocation The phenomenon in which certain species listen for echoes of high-frequency sound waves in order to determine the distance and location of an object.
ECM *See* extracellular matrix.
ecological footprint The amount of productive land needed to support each person on Earth.
ecological species concept An approach used to distinguish species; considers a species within its native environment and states that each species occupies its own ecological niche.
ecology The study of interactions among organisms and between organisms and their environments.
ecosystem The biotic community of organisms in an area as well as the abiotic environment affecting that community.
ecosystem engineer A keystone species that creates, modifies, and maintains habitats.
ecosystems ecology The study of the flow of energy and cycling of nutrients among organisms within a community and between organisms and the environment.
ecotypes Genetically distinct populations adapted to their local environments.
ectoderm In animals, the outermost layer of cells formed during gastrulation that covers the surface of the embryo and differentiates into the epidermis and nervous system.
ectomycorrhizae Beneficial interactions between temperate forest trees and soil fungi.
ectoparasite A parasite that lives on the outside of the host's body.
ectotherm An animal whose body temperature changes with the environmental temperature.
edge effect A special physical condition that exists at the boundary or edge of an area.
effective population size The number of individuals that contribute genes to future populations, often smaller than the actual population size.
effector A molecule that directly influences cellular responses.
effector cell A cloned lymphocyte that carries out the attack response during specific immunity.
efferent arteriole A blood vessel that carries blood away from a glomerulus of the vertebrate kidney.
egg cell The female gamete; also called an ovum.
ejaculation The movement of semen through the urethra by contraction of muscles at the base of the penis.
ejaculatory duct The structure in the male reproductive system through which sperm leave the vas deferens and enter the urethra.
elastin A protein that makes up elastic fibers in the extracellular matrix of animals.
electrical synapse A synapse that directly passes electric current from the presynaptic to the postsynaptic cell via gap junctions.
electrocardiogram (ECG or EKG) A record of the electrical impulses generated by the cells of the heart during the cardiac cycle.
electrochemical gradient The combined effect of both an electrical and chemical gradient across a membrane; determines the direction that an ion will move.
electrogenic pump A pump that generates an electrical gradient across a membrane.
electromagnetic receptor A sensory receptor in animals that detects radiation within a wide range of the electromagnetic spectrum, including visible, ultraviolet, and infrared light, as well as electrical and magnetic fields in some animals.
electromagnetic spectrum All possible wavelengths of electromagnetic radiation, from relatively short wavelengths (gamma rays) to much longer wavelengths (radio waves).
electron A negatively charged particle found in orbitals around an atomic nucleus.
electron microscope A microscope that uses an electron beam for illumination.
electron transport chain (ETC) A group of protein complexes and small organic molecules within the inner membranes of mitochondria and chloroplasts and the plasma membrane of prokaryotes. The components accept and donate

electrons to each other in a linear manner and produce a H^+ electrochemical gradient.

electronegativity A measure of an atom's ability to attract electrons to its outer shell from another atom.

element A substance composed of specific types of atoms that cannot be further broken down by ordinary chemical or physical means.

elicitor A compound produced by bacterial and fungal pathogens that promotes virulence.

elimination In animals, the process of undigested material passing out of the body.

elongation factor A protein that is needed for the growth of a polypeptide during translation.

elongation stage The second step in transcription or translation where RNA strands or polypeptides are made, respectively.

embryo The early stages of development in a multicellular organism during which the organization of the organism is largely formed.

embryogenesis The process by which embryos develop from single-celled zygotes by mitotic divisions.

embryonic development The process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts.

embryonic germ cell (EG cell) A cell in the early mammalian embryo that later gives rise to sperm or egg cells. These cells are pluripotent.

embryonic stem cell (ES cell) A cell in the early mammalian embryo that can differentiate into almost every cell type of the body. These cells are pluripotent.

embryophyte A synonym for the land plants.

emerging virus A newly arising virus.

emphysema A progressive disease characterized by a loss of elastic recoil ability of the lungs, usually resulting from chronic tobacco smoking.

empirical thought Thought that relies on observation to form an idea or hypothesis, rather than trying to understand life from a nonphysical or spiritual point of view.

emulsification A process during digestion that disrupts large lipid droplets into many tiny droplets, thereby increasing their total surface area and exposure to lipase action.

enantiomer One of a pair of stereoisomers that exist as mirror images.

endangered species Those species that are in danger of extinction throughout all or a significant portion of their range.

endemic The term to describe organisms that are naturally found only in a particular location.

endergonic Refers to chemical reactions that require an addition of free energy and do not proceed spontaneously.

endocrine disruptor A chemical found in polluted water and soil that resembles a natural hormone; a common example are chemicals that resemble estrogen and can bind to estrogen receptors in animals.

endocrine gland A structure that contains epithelial cells that secrete hormone molecules into the bloodstream, where they circulate throughout the body.

endocrine system All the endocrine glands and other organs containing hormone-secreting cells.

endocytosis A process in which the plasma membrane invaginates, or folds inward, to form a vesicle that brings substances into the cell.

endoderm In animals, the innermost layer of cells formed during gastrulation; lines the gut and gives rise to many internal organs.

endodermis In vascular plants, a thin cylinder of root tissue that forms a barrier between the root cortex and the central core of vascular tissue.

endomembrane system A network of membranes that includes the nuclear envelope, the endoplasmic reticulum, Golgi apparatus, lysosomes, vacuoles, and plasma membrane.

endomycorrhizae Partnerships between plants and fungi in which the fungal hyphae grow into the spaces between root cell walls and plasma membranes.

endoparasite A parasite that lives inside the host's body.

endophyte A mutualistic fungus that lives compatibly within the tissues of various types of plants.

endoplasmic reticulum (ER) A convoluted network of membranes in a cell's cytoplasm that forms flattened, fluid-filled tubules or cisternae.

endoskeleton An internal hard skeleton covered by soft tissue; present in echinoderms and vertebrates.

endosperm A nutritive tissue that increases the efficiency with which food is stored and used in the seeds of flowering plants.

endospore A cell with a tough coat that is produced in certain bacteria and then released when the enclosing bacterial cell dies and breaks down.

endosporic gametophyte A plant gametophyte that grows within the confines of microspore or megaspore walls.

endosymbiont A smaller species that lives within a larger species in a symbiotic relationship.

endosymbiosis A symbiotic relationship in which the smaller species—the symbiont—lives inside the larger species.

endosymbiosis theory A theory that mitochondria and chloroplasts originated from bacteria that took up residence within a primordial eukaryotic cell.

endosymbiotic Describes a relationship in which one organism lives inside the other.

endothelium The single-celled inner layer of a blood vessel; forms a smooth lining in contact with the blood.

endotherm An animal that generates its own internal heat and maintains a relatively stable body temperature independent of the environment.

endothermic A term to describe the ability of an organism to generate and retain body heat through its metabolism.

energy The ability to promote change or to do work.

energy expenditure The amount of energy an animal uses in a given period of time to power all of its metabolic requirements.

energy flow The movement of energy through an ecosystem.

energy intermediate A molecule such as ATP or NADH that stores energy and is used to drive endergonic reactions in cells.

energy shell In an atom, an energy level of electrons occupied by one or more orbitals; each energy level is a characteristic distance from the nucleus, with outer shells having more energy than inner shells.

enhancement effect The phenomenon in which maximal activation of the pigments in photosystems I and II is achieved when organisms are exposed to two wavelengths of light.

enhancer A response element in eukaryotes that increases the rate of transcription.

enthalpy (*H*) The total energy of a system.

entomology The study of insects.

entropy The degree of disorder of a system.

environmental science The application of ecology to real-world problems.

enzyme A protein that acts as a catalyst to speed up a chemical reaction in a cell.

enzyme-linked receptor A receptor found in all living species that typically has two important domains: an extracellular domain, which binds a signaling molecule, and an intracellular domain, which has a catalytic function.

enzyme-substrate complex The binding between an enzyme and its substrate.

eosinophil A type of phagocyte found in large numbers in mucosal surfaces lining the gastrointestinal, respiratory, and urinary tracts, where they fight off parasitic infections.

epicotyl The portion of an embryonic plant stem with two tiny leaves in a first bud; located above the point of attachment of the cotyledons.

epidermis A layer of dermal tissue that helps protect a plant from damage.

epididymis A coiled, tubular structure located on the surface of the testis in which sperm complete their differentiation.

epigenetic inheritance An inheritance pattern in which modification of a gene or chromosome during egg formation, sperm formation, or early stages of embryonic growth alters gene expression in a way that is fixed during an individual's lifetime.

epinephrine A hormone secreted by the adrenal glands; also known as adrenaline.

episome A plasmid that can integrate into a bacterial chromosome.

epistasis A gene interaction in which the alleles of one gene mask the expression of the alleles of another gene.

epithalamus A region of the vertebrate forebrain that includes the pineal gland.

epithelial tissue In animals, a sheet of densely packed cells that covers the body, covers individual organs, and lines the walls of various cavities inside the body.

epitopes Antigenic determinants; the peptide fragments of an antigen that are complexed to MHC proteins and presented to a helper T cell.

equilibrium 1. In a chemical reaction, occurs when the rate of the forward reaction is balanced by the rate of the reverse reaction. 2. In a population, the situation in which the population size stays the same.

equilibrium model of island biogeography A model to explain the process of succession on new islands; states that the number of species on an island tends toward an equilibrium number that is determined by the balance between immigration rates and extinction rates.

equilibrium potential In membrane physiology, the membrane potential at which the flow of an ion is at equilibrium, with no net movement in either direction.

ER lumen A single compartment enclosed by the ER membrane.

ER signal sequence A sorting signal in a polypeptide usually located near the amino terminus that is recognized by SRP (signal recognition particle) and directs the polypeptide to the ER membrane.

erythrocyte A cell that serves the critical function of transporting oxygen throughout an animal's body; also known as a red blood cell.

erythropoietin (EPO) A hormone made by the liver and kidneys in response to any situation where additional red blood cells are required.
E site *See* exit site.
esophagus In animals, the tubular structure that forms a pathway from the throat to the stomach.
essential amino acids Those amino acids that are required in the diet of particular organisms.
essential fatty acid A polyunsaturated fatty acid, such as linoleic acid, that cannot be synthesized by animal cells and must therefore be consumed in the diet.
essential nutrient In animals, a compound that cannot be synthesized from any ingested or stored precursor molecule and so must be obtained in the diet in its complete form. In plants, those substances needed to complete reproduction while avoiding the symptoms of nutrient deficiency.
estradiol The major estrogen in many vertebrates, including humans.
estrogens Steroid hormones produced by the ovaries that affect most aspects of female reproduction.
ethology Scientific studies of animal behavior.
ethylene A plant hormone that is particularly important in coordinating plant developmental and stress responses.
euchromatin The less condensed regions of a chromosome; areas that are capable of gene transcription.
eudicots One of the two largest lineages of flowering plants in which the embryo possesses two seed leaves.
Eukarya One of the three domains of life; the other two are Bacteria and Archaea.
eukaryote One of the two categories into which all forms of life can be placed. The distinguishing feature of eukaryotes is cell compartmentalization, including a cell nucleus; includes protists, fungi, plants, and animals.
eukaryotic Refers to organisms having cells with internal compartments that serve various functions; includes all members of the domain Eukarya.
Eumetazoa A subgroup of animals having more than one type of tissue and, for the most part, different types of organs.
euphyll A leaf with branched veins.
euphyllophytes The clade that includes pteridophytes and seed plants.
euploid An organism that has a chromosome number that is a multiple of a chromosome set ($1n$, $2n$, $3n$, etc.).
eusociality An extreme form of altruism in social insects in which the vast majority of females, known as workers, do not reproduce. Instead, they help one reproductive female (the queen) raise offspring.
Eustachian tube In mammals, a connection from the middle ear to the pharynx; maintains the pressure in the middle ear at atmospheric pressure.
eustele In plants, a ring of vascular tissue arranged around a central pith of nonvascular tissue; typical of progymnosperms, gymnosperms, and angiosperms.
eutherian A placental mammal and member of the subclass Eutheria.
eutrophic Waters that contain relatively high levels of nutrients such as phosphate or nitrogen and typically exhibit high levels of primary productivity and low levels of biodiversity.
eutrophication The process by which elevated nutrient levels in a body of water lead to an overgrowth of algae or aquatic plants and a subsequent depletion of water oxygen levels when these photosynthesizers decay.
evaporation The transformation of water from the liquid to the gaseous state at normal temperatures. Animals use evaporation as a means of losing excess body heat.
evapotranspiration rate The rate at which water moves into the atmosphere through the processes of evaporation from the soil and transpiration of plants.
evolution The phenomenon that populations of organisms change over the course of many generations. As a result, some organisms become more successful at survival and reproduction.
evolutionarily conserved The term used to describe homologous DNA sequences that are very similar or identical between different species.
evolutionary developmental biology (evo-devo) A field of biology that compares the development of different organisms in an attempt to understand ancestral relationships between organisms and the developmental mechanisms that bring about evolutionary change.
evolutionary lineage concept An approach used to distinguish species; states that a species is derived from a single distinct lineage and has its own evolutionary tendencies and historical fate.
excitable cell The term used to describe neurons and muscle cells because they have the capacity to generate electrical signals.
excitation-contraction coupling The sequence of events by which an action potential in the plasma membrane of a muscle fiber leads to cross-bridge activity.
excitatory postsynaptic potential (EPSP) The response from an excitatory neurotransmitter that depolarizes the postsynaptic membrane; the depolarization brings the membrane potential closer to the threshold potential that would trigger an action potential.
excretion In animals, the process of expelling waste or harmful materials from the body.
exercise Any physical activity that increases an animal's metabolic rate.
exergonic Refers to chemical reactions that release free energy and occur spontaneously.
exit site (E site) One of three sites for tRNA binding in the ribosome during translation; the other two are the peptidyl site (P site) and the aminoacyl site (A site). The uncharged tRNA exits from the E site.
exocrine gland A gland in which epithelial cells secrete chemicals into a duct, which carries those molecules directly to another structure or to the outside surface of the body.
exocytosis A process in which material inside a cell is packaged into vesicles and excreted into the extracellular medium.
exon A portion of RNA that is found in the mature mRNA molecule after splicing is finished.
exon shuffling A form of mutation in which exons and their flanking introns are inserted into genes and thereby create proteins with additional functional domains.
exonuclease An enzyme that cleaves off nucleotides, one at a time, from the end of a DNA or RNA molecule.
exoskeleton An external skeleton made of chitin and protein that surrounds and protects most of the body surface of animals such as insects.
exosome A multiprotein complex that degrades mRNA.
expansin A protein that occurs in the plant cell wall and fosters cell enlargement.
experimental group The sample in an experiment that is subjected to some type of variation that does not occur for the control group.
exploitation competition Competition in which organisms compete indirectly through the consumption of a limited resource.
exponential growth Rapid population growth that occurs when the per capita growth rate remains above zero.
extensor A muscle that straightens a limb at a joint.
external fertilization Fertilization that occurs in aquatic environments, when eggs and sperm are released into the water in close enough proximity for fertilization to occur.
external intercostal muscles Muscles of the rib cage that contract during inhalation, thereby expanding the chest.
extinction The end of the existence of a species or a group of species.
extinction vortex A downward spiral toward extinction from which a species cannot naturally recover.
extracellular fluid The fluid in an organism's body that is outside of the cells.
extracellular matrix (ECM) A network of material that is secreted from animal cells and forms a complex meshwork outside of cells. The ECM provides strength, support, and organization.
extranuclear inheritance In eukaryotes, the transmission of genes that are located outside the cell nucleus.
extremophile An organism that occurs primarily in extreme habitats.
eye The visual organ in animals that detects light and sends signals to the brain.
eyecup An eye in planaria that detects light and its direction but which does not form an image.

F

facilitated diffusion A method of passive transport that involves the aid of a transport protein.
facilitation A mechanism for succession in which a species facilitates or makes the environment more suitable for subsequent species.
facultative anaerobe A microorganism that can use oxygen in aerobic respiration, obtain energy via anaerobic fermentation, or use inorganic chemical reactions to obtain energy.
facultative mutualism An interaction between mutualistic species that is beneficial but not essential to the survival and reproduction of either species.
family In taxonomy, a subdivision of an order.
fast block to polyspermy A depolarization of the egg that blocks other sperm from binding to the egg membrane proteins.
fast fiber A skeletal muscle fiber containing myosin with a high rate of ATP hydrolysis.
fast-glycolytic fiber A skeletal muscle fiber that has high myosin ATPase activity but cannot make as much ATP as oxidative fibers because its source of ATP is glycolysis; best suited for rapid, intense actions.
fast-oxidative fiber A skeletal muscle fiber that has high myosin ATPase activity and can make large amounts of ATP; used for long-term activities.
fate The ultimate morphological features that a cell or a group of cells will adopt.
fate mapping A technique in which a small population of cells within an embryo is

specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development.

feedback inhibition A form of regulation in which the product of a metabolic pathway inhibits an enzyme that acts early in the pathway, thus preventing the overaccumulation of the product.

feedforward regulation The process by which an animal's body begins preparing for a change in some variable before it even occurs.

female-enforced monogamy hypothesis The hypothesis that a male is monogamous due to various actions employed by his female mate.

female gametophyte A haploid multicellular plant generation that produces one or more eggs but does not produce sperm cells.

fermentation The breakdown of organic molecules to produce energy without any net oxidation of an organic molecule.

Ferrell cell The middle cell in the three-cell model of atmospheric circulation.

fertilization The union of two gametes, such as an egg cell with a sperm cell, to form a zygote.

fertilizer A soil addition that enhances plant growth by providing essential elements.

fetus The maturing embryo after the eighth week of gestation in humans.

fever An increase in an animal's temperature due to infection.

F factor A type of bacterial plasmid called a fertility factor that plays a role in bacterial conjugation.

F_1 generation The first filial generation in a genetic cross.

F_2 generation The second filial generation in a genetic cross.

fiber A type of tough-walled plant cell that provides support.

fibrin A protein that forms a meshwork of threadlike fibers that wrap around and between platelets and blood cells, enlarging and thickening a blood clot.

fibrous root system The root system of monocots, which consists of multiple adventitious roots that grow from the stem base.

fight-or-flight The response of vertebrates to real or perceived danger; associated with increased activity of the sympathetic branch of the autonomic nervous system.

filament 1. The elongate portion of a flower's stamen; contains vascular tissue that delivers nutrients from parental sporophytes to anthers. 2. In fishes, a part of the gills.

filtrate In the process of filtration in an excretory system, the material that passes through the filter and enters the excretory organ for either further processing or excretion.

filtration The passive removal of water and small solutes from the blood during the production of urine.

finite rate of increase In ecology, the ratio of a population size from one year to the next.

first law of thermodynamics States that energy cannot be created or destroyed; also called the law of conservation of energy.

fitness The relative likelihood that a genotype will contribute to the gene pool of the next generation as compared with other genotypes.

5′ cap The 7-methylguanosine cap structure at the 5′ end of most mature mRNAs in eukaryotes.

fixed action pattern (FAP) An animal behavior that, once initiated, will continue until completed.

fixed nitrogen Atmospheric nitrogen that has been combined with other elements into a form of nitrogen that can be used by plants. An example is ammonia, NH_3.

flagella (singular, **flagellum**) Relatively long cell appendages that facilitate cellular movement or the movement of extracellular fluids.

flagellate A protist that uses one or more flagella to move in water or cause water motions useful in feeding.

flagship species A single large or instantly recognizable species.

flame cell A cell that exists primarily to maintain osmotic balance between an organism's body and surrounding fluids; present in flatworms.

flavonoid A type of phenolic secondary metabolite that provides plants with protection from UV damage or imparts color to flowers.

flexor A muscle that bends a limb at a joint.

florigen The hypothesized flowering hormone, now identified as the FT (flowering time) protein that moves from leaves, where it is produced, into the shoot apex.

flower A reproductive shoot; a short stem that produces reproductive organs instead of leaves.

flowering plants The angiosperms, which produce ovules within the protective ovaries of flowers. The ovules develop into seeds, and the ovaries develop into fruits, which function in seed dispersal.

flow-through system The method of ventilation in fishes in which water moves unidirectionally such that the gills are constantly in contact with fresh, oxygenated water. Buccal pumping and ram ventilation are examples.

fluid-feeder An animal that licks or sucks fluid from plants or animals and does not need teeth except to puncture an animal's skin.

fluidity A property of biomembranes in which individual molecules remain in close association yet have the ability to move rotationally or laterally within the plane of the membrane. Membranes are semifluid.

fluid-mosaic model The accepted model of the plasma membrane; its basic framework is the semifluid phospholipid bilayer with a mosaic of proteins. Carbohydrates may be attached to the lipids or proteins.

fMRI *See* functional magnetic resonance imaging.

focal adhesion A mechanically strong cell junction that connects an animal cell to the extracellular matrix (ECM).

follicle A structure within an animal ovary where each ovum undergoes growth and development before it is released.

follicle-stimulating hormone (FSH) A gonadotropin that stimulates follicle development.

food chain A linear depiction of energy flow between organisms, with each organism feeding on and deriving energy from the preceding organism.

food-induced thermogenesis A rise in metabolic rate for a few hours after eating that produces heat.

food vacuole *See* phagocytic vacuole.

food web A complex model of interconnected food chains in which there are multiple links between species.

foot In mollusks, a muscular structure usually used for movement.

forebrain One of three major divisions of the vertebrate brain; the other two divisions are the midbrain and hindbrain.

fossil Recognizable preserved remains of past life on Earth.

fossil fuel A fuel formed in the Earth from protist, plant, or animal remains, such as coal, petroleum, and natural gas.

founder effect Genetic drift that occurs when a small group of individuals separates from a larger population and establishes a colony in a new location.

fovea A small area on the retina directly behind the lens, where an image is most sharply focused.

frameshift mutation A mutation that involves the addition or deletion of a number of nucleotides that are not in multiples of three.

free energy (*G*) In living organisms, the amount of available energy that can be used to do work.

free radical A molecule containing an atom with a single, unpaired electron in its outer shell. A free radical is unstable and interacts with other molecules by removing electrons from their atoms.

frequency In regard to sound, the number of complete wavelengths that occur in 1 second, measured in hertz (Hz).

frontal lobe One of four lobes of the cerebral cortex of the human brain; important in a variety of functions, including judgment and conscious thought.

fruit A structure that develops from flower organs, encloses seeds, and fosters seed dispersal in the environment.

fruiting bodies The visible fungal reproductive structures that are composed of densely packed hyphae that typically grow out of the substrate.

functional genomics Genomic methods aimed at studying the expression of a genome.

functional group A group of atoms with chemical features that are functionally important. Each functional group exhibits the same properties in all molecules in which it occurs.

functional magnetic resonance imaging (fMRI) A technique used to determine changes in brain activity while a person is performing specific tasks.

Fungi A eukaryotic kingdom of the domain Eukarya.

fungus-like protists Heterotrophic protists that often resemble true fungi in having threadlike, filamentous bodies and absorbing nutrients from their environment.

G

G_0 A phase in which cells exit the cell cycle and postpone making the decision to divide.

G_1 The first gap phase of the cell cycle.

G_2 The second gap phase of the cell cycle.

gallbladder In many vertebrates, a small sac underneath the liver that is a storage site for bile; allows the release of large amounts of bile to be precisely timed to the consumption of fats.

gametangia Specialized structures produced by many land plants in which developing gametes are protected by a jacket of tissue.

gamete A haploid cell that is involved with sexual reproduction, such as a sperm or egg cell.

gametic life cycle A type of life cycle where all cells except the gametes are diploid, and gametes are produced by meiosis.

gametogenesis The formation of gametes.

gametophyte In plants and many multicellular protists, the haploid stage that produces gametes by mitosis.

ganglion A group of neuronal cell bodies in the peripheral nervous system that are involved in a similar function.

ganglion cells Cells in the vertebrate eye that send their axons into the optic nerve.
gap gene A type of segmentation gene; a mutation in this type of gene may cause several adjacent segments to be missing in the larva.
gap junction A type of junction between animal cells that provides a passageway for intercellular transport.
gas exchange The process of moving oxygen and carbon dioxide in opposite directions between the environment and blood and between blood and cells.
gas vesicle A cytoplasmic structure used to adjust buoyancy in cyanobacteria and certain other bacteria that live in aquatic habitats.
gastrovascular cavity In certain invertebrates such as cnidarians, a body cavity with a single opening to the outside; it functions as both a digestive system and circulatory system.
gastrula A stage of an animal embryo that is the result of gastrulation and has three cellular layers: the ectoderm, endoderm, and mesoderm.
gastrulation In animals, a process in which an area in the blastula invaginates and folds inward, creating different embryonic cell layers called germ layers.
gated A property of many channels that allows them to open and close to control the diffusion of solutes through a membrane.
gel electrophoresis A technique used to separate macromolecules by using an electric field that causes them to pass through a gel matrix.
gene A unit of heredity that contributes to the characteristics or traits of an organism. At the molecular level, a gene is composed of organized sequences of DNA.
gene addition The insertion of a cloned gene into the genome of an organism.
gene amplification An increase in the copy number of a gene.
gene cloning The process of making multiple copies of a gene of interest.
gene expression Gene function both at the level of traits and at the molecular level.
gene family A group of homologous genes within a single species.
gene flow Occurs when individuals migrate between different populations and results in changes in the genetic composition of the resulting populations.
gene interaction A situation in which a single trait is controlled by two or more genes.
gene knockout An organism in which both copies of a functional gene have been replaced with nonfunctional copies. Experimentally, this can occur via gene replacement.
gene mutation A relatively small change in DNA structure that alters a particular gene.
gene pool All of the genes in a population.
genera (singular, **genus**) In taxonomy, a subdivision of a family.
general lineage concept A widely accepted approach used to distinguish species; states that each species is a population of an independently evolving lineage.
general transcription factors (GTFs) Five different proteins that play a role in initiating transcription at the core promoter of structural genes in eukaryotes.
generative cell In a seed plant, one of the cells resulting from the division of a microspore; a generative cell divides to produce two sperm cells.
gene regulation The ability of cells to control their level of gene expression.
gene replacement The phenomenon in which a cloned gene recombines with the normal gene on a chromosome and replaces it.
gene therapy The introduction of cloned genes into living cells in an attempt to cure disease.
genetic code A code that specifies the relationship between the sequence of nucleotides in the codons found in mRNA and the sequence of amino acids in a polypeptide.
genetic drift The random change in a population's allele frequencies from one generation to the next that is attributable to chance. It occurs more quickly in small populations.
genetic engineering The direct manipulation of genes for practical purposes.
genetic map A chart that shows the linear arrangement of genes along a chromosome.
genetic mapping The use of genetic crosses to determine the linear order of genes that are linked to each other along the same chromosome.
genetically modified organisms (GMOs) *See* transgenic.
gene transfer The process by which genetic material is transferred from one bacterial cell to another.
genome The complete genetic composition of a cell or a species.
genomic imprinting A phenomenon in which a segment of DNA is imprinted, or marked, in a way that affects gene expression throughout the life of the individual who inherits that DNA.
genomic library A type of DNA library in which the inserts are derived from chromosomal DNA.
genomics Techniques that are used in the molecular analysis of the entire genome of a species.
genotype The genetic composition of an individual.
genotype frequency In a population, the number of individuals with a given genotype divided by the total number of individuals.
geological timescale A time line of the Earth's history from its origin about 4.55 billion years ago to the present.
germination In plants, the process in which an embryo absorbs water, becomes metabolically active, and grows out of the seed coat, producing a seedling.
germ layer An embryonic cell layer such as ectoderm, mesoderm, or endoderm.
germ line Cells that give rise to gametes such as egg and sperm cells.
germ plasm Cytoplasmic determinants that help define and specify the primordial germ cells in the gastrula stage of animal development.
gestation *See* pregnancy.
giant axon A very large axon in certain species such as squids that facilitates high-speed neuronal conduction and rapid responses to stimuli.
gibberellic acid A type of gibberellin.
gibberellin A plant hormone that stimulates both cell division and cell elongation.
gills Specialized filamentous organs in aquatic animals that are used to obtain oxygen and eliminate carbon dioxide.
ginkgos A phylum of gymnosperms; Ginkgophyta.
gizzard The muscular portion of the stomach of birds and some reptiles that is capable of grinding food into smaller fragments.
glaucoma A condition in which drainage of aqueous humor in the eye becomes blocked and the pressure inside the eye increases. If untreated, this pressure damages cells in the retina and leads to irreversible loss of vision.
glia Cells that surround the neurons; a major class of cells in nervous systems that perform various functions.
global warming A gradual elevation of the Earth's surface temperature caused by an increasing greenhouse effect.
glomerular filtration rate (GFR) The rate at which a filtrate of plasma is formed in all the glomeruli of the vertebrate kidneys.
glomerulus A cluster of interconnected, fenestrated capillaries in the renal corpuscle of the kidney; the site of filtration in the kidney.
glucagon A hormone found in animals that stimulates the processes of glycogenolysis, gluconeogenesis, and the synthesis of ketones in the liver.
glucocorticoid A steroid hormone that regulates glucose balance and helps prepare the body for stress situations.
gluconeogenesis A mechanism for maintaining blood glucose level; enzymes in the liver convert noncarbohydrate precursors into glucose, which is then secreted into the blood.
glucose sparing A metabolic adjustment that reserves the glucose produced by the liver for use by the nervous system.
glycocalyx 1. An outer viscous covering surrounding a bacterium that traps water and helps protect bacteria from drying out. 2. A carbohydrate-rich zone on the surface of animal cells; also called a cell coat.
glycogen A polysaccharide found in animal cells (especially liver and skeletal muscle) and sometimes called animal starch; also, the major carbohydrate storage of fungi.
glycogenolysis A mechanism for maintaining blood glucose level; stored glycogen can be broken down into molecules of glucose which are then secreted into the blood.
glycolipid A lipid that has carbohydrate attached to it.
glycolysis A metabolic pathway that breaks down glucose to pyruvate.
glycolytic fiber A skeletal muscle fiber that has few mitochondria but possesses both a high concentration of glycolytic enzymes and large stores of glycogen.
glycoprotein A protein that has carbohydrate attached to it.
glycosaminoglycan (GAG) The most abundant type of polysaccharide in the extracellular matrix (ECM) of animals, consisting of repeating disaccharide units that give a gel-like character to the ECM of animals.
glycosidic bond A bond formed between two sugar molecules.
glycosylation The attachment of carbohydrate to a protein or lipid, producing a glycoprotein or glycolipid.
glyoxysome A specialized organelle within plant seeds that contains enzymes needed to convert fats to sugars.
gnathostomes All vertebrate species that possess jaws.
gnetophytes A phylum of gymnosperms; Gnetophyta.
Golgi apparatus A stack of flattened, membrane-bound compartments that performs three overlapping functions: secretion, processing, and protein sorting.
gonadotropins Hormones secreted by the anterior pituitary gland that are the same in both sexes; gonadotropins influence the ability of the testes and ovaries to produce the sex steroids.

gonads The testes in males and the ovaries in females, where the gametes are formed.
G protein An intracellular protein that binds guanosine triphosphate (GTP) and guanosine diphosphate (GDP) and participates in intracellular signaling pathways.
G-protein-coupled receptors (GPCRs) A common type of receptor found in the cells of eukaryotic species that interacts with G proteins to initiate a cellular response.
graded potential A depolarization or hyperpolarization in a neuron that varies with the strength of a stimulus.
gradualism A concept suggesting that species evolve continuously over long spans of time.
grain The characteristic single-seeded fruit of cereal grasses such as rice, corn, barley, and wheat.
Gram stain A staining process that can help to identify bacteria and predict their responses to antibiotics.
granum A structure composed of stacked membrane-bound thylakoids within a chloroplast.
gravitropism Plant growth in response to the force of gravity.
gray matter Brain tissue that consists of neuronal cell bodies, dendrites, and some unmyelinated axons.
greenhouse effect The process in which short-wave solar radiation passes through the atmosphere to warm the Earth but is radiated back to space as long-wave infrared radiation. Much of this radiation is reflected by atmospheric gases back to Earth's surface, causing its temperature to rise.
groove In the DNA double helix, an indentation where the atoms of the bases make contact with the surrounding water.
gross primary production (GPP) The measure of biomass production by photosynthetic organisms; equivalent to the carbon fixed during photosynthesis.
ground meristem In plants, a type of primary plant tissue meristem that gives rise to ground tissue.
ground tissue Most of the body of a plant, which has a variety of functions, including photosynthesis, storage of carbohydrates, and support. Ground tissue can be subdivided into three types: parenchyma, collenchyma, and sclerenchyma.
group selection A premise that attempts to explain altruism. States that natural selection produces outcomes beneficial for the whole group or species rather than for individuals.
growth An increase in weight or size.
growth factors Proteins in animals that stimulate certain cells to grow and divide.
growth hormone (GH) A hormone produced in vertebrates by the anterior pituitary gland; GH acts on the liver to produce insulin-like growth factor-1 (IGF-1).
guanine (G) A purine base found in DNA and RNA.
guard cell A specialized plant cell that allows epidermal pores (stomata) to close when conditions are too dry and to open under moist conditions, allowing the entry of CO_2 needed for photosynthesis.
gustation The sense of taste.
gut The gastrointestinal (GI) tract of an animal.
guttation Droplets of water at the edges of leaves that are the result of root pressure.
gymnosperm A plant that produces seeds that are exposed rather than seeds enclosed in fruits.
gynoecium The aggregate of carpels that forms the innermost whorl of a flower.

H

habituation The form of nonassociative learning in which an organism learns to ignore a repeated stimulus.
Hadley cell The most prominent of the three cells in the three-cell model of atmospheric circulation; the cell nearest to the equator.
hair cell A mechanoreceptor in animals that is a specialized epithelial cell with deformable stereocilia.
half-life 1. In the case of organic molecules in a cell, refers to the time it takes for 50% of the molecules to be broken down and recycled. 2. In the case of radioisotopes, the time it takes for 50% of the molecules to decay and emit radiation.
halophile A bacterium or archaeon that can live in an extremely salty environment.
halophyte A plant that can tolerate higher than normal salt concentrations and can occupy coastal salt marshes or saline deserts.
Hamilton's rule The proposal that an altruistic gene will be favored by natural selection when $rB > C$, where r is the coefficient of relatedness of the donor (the altruist) to the recipient, B is the benefit received by the recipient, and C is the cost incurred by the donor.
haplodiploid system A genetic system in which females develop from fertilized eggs and are diploid but males develop from unfertilized eggs and are haploid.
haploid Containing one set of chromosomes; designated as $1n$.
haploid-dominant species Species in which the haploid organism is the prevalent organism in the life cycle. Examples include fungi and some protists.
haplorrhini Larger-brained diurnal species of primates; includes monkeys, gibbons, orangutans, gorillas, chimpanzees, and humans.
Hardy-Weinberg equation An equation ($p^2 + 2pq + q^2 = 1$) that relates allele and genotype frequencies; the equation predicts an equilibrium if no new mutations are formed, no natural selection occurs, the population size is very large, the population does not migrate, and mating is random.
heart A muscular structure that pumps blood through blood vessels.
heart attack *See* myocardial infarction (MI).
heat of fusion The amount of heat energy that must be withdrawn or released from a substance to cause it to change from the liquid to the solid state.
heat of vaporization The heat required to vaporize 1 mole of any substance at its boiling point under standard pressure.
heavy chain A part of an immunoglobulin molecule.
H^+ electrochemical gradient A transmembrane gradient for H^+ composed of both a membrane potential and a concentration difference for H^+ across a membrane.
helper T cell A type of lymphocyte that assists in the activation and function of B cells and cytotoxic T cells.
hematocrit The volume of blood that is composed of red blood cells, usually between 40 and 65% in vertebrates.
hemidesmosome A mechanically strong cell junction that connects an animal cell to the extracellular matrix (ECM).
hemiparasite A parasitic organism that photosynthesizes, but lacks a root system to draw water and thus depends on its host for that function.
hemispheres The two halves of the cerebrum.
hemizygous The term used to describe the single copy of an X-linked gene in a male.
hemocyanin A copper-containing pigment that binds oxygen and gives blood or hemolymph a bluish tint.
hemodialysis A medical procedure used to artificially perform the kidneys' function.
hemoglobin An iron-containing protein that binds oxygen and is found within the cytosol of red blood cells.
hemolymph Blood and interstitial fluid combined in one fluid compartment; present in many invertebrates.
hemophilia An inherited disorder characterized by the deficiency of a specific blood clotting factor.
hemorrhage A loss of blood from a ruptured blood vessel.
herbaceous plant A plant that produces little or no wood and is composed mostly of primary vascular tissues.
herbivore An animal that eats only plants.
herbivory Refers to herbivores feeding on plants.
hermaphrodite In animals, an individual that can produce both sperm and eggs.
hermaphroditism A form of sexual reproduction in which individuals have both male and female reproductive systems.
heterochromatin The highly compacted regions of chromosomes that are usually transcriptionally inactive because of their tight conformation.
heterochrony Evolutionary changes in the rate or timing of developmental events.
heterocyst A specialized cell of some cyanobacteria in which nitrogen fixation occurs.
heterospory In plants, the formation of two different types of spores: microspores and megaspores; microspores produce male gametophytes, and megaspores produce female gametophytes.
heterotherm An animal that has a body temperature that is not constant; both exotherms and endotherms may be heterotherms.
heterotroph Organisms that cannot produce their own organic molecules and thus must obtain organic food from other organisms.
heterotrophic Requiring organic food from the environment.
heterozygote advantage A phenomenon in which a heterozygote has a higher Darwinian fitness than either corresponding homozygote.
heterozygous An individual with two different alleles of the same gene.
hibernation The state of torpor in an animal that can last for months.
highly repetitive sequence A DNA sequence found tens of thousands or even millions of times throughout a genome.
hindbrain One of three major divisions of the vertebrate brain; the other two divisions are the midbrain and forebrain.
hippocampus The area of the vertebrate forebrain that functions in establishing memories for spatial locations, facts, and the sequence of events.
histone acetyltransferase An enzyme that loosens the compaction of chromatin by attaching acetyl groups to histone proteins.
histone code hypothesis Refers to the pattern of histone modification recognized by particular proteins. The pattern of covalent modifications of amino terminus tails provides binding sites for proteins that subsequently affect the degree of chromatin compaction.

histones A group of proteins involved in the formation of nucleosomes that aid in the compaction of eukaryotic DNA.
HIV *See* human immunodeficiency virus.
holoblastic cleavage A complete type of cell cleavage in certain animals in which the entire zygote is bisected into two equal-sized blastomeres.
holoparasite A parasitic organism that lacks chlorophyll and is totally dependent on a host plant for its water and nutrients.
homeobox A 180-bp sequence within the coding sequence of homeotic genes.
homeodomain A region of a homeotic protein that functions in binding to the DNA.
homeostasis The process whereby living organisms regulate their cells and bodies to maintain relatively stable internal conditions.
homeostatic control system A system designed to regulate particular variables in an animal's body, such as body temperature; consists of a set point, sensor, integrator, and effectors.
homeotherm An animal that maintains its body temperature within a narrow range.
homeotic gene A gene that controls the developmental fate of particular segments or regions of an animal's body.
hominin Either an extinct or modern species of humans.
hominoidea (hominoid) A member of a group of primates that includes gibbons, orangutans, gorillas, chimpanzees, and humans.
homologous genes Genes derived from the same ancestral gene that have accumulated random mutations that make their sequences slightly different.
homologous structures Structures that are similar to each other because they are derived from the same ancestral structure.
homologue A member of a pair of chromosomes in a diploid organism.
homology A fundamental similarity that occurs due to descent from a common ancestor.
homozygous An individual with two identical copies of an allele.
horizontal gene transfer A process in which an organism incorporates genetic material from another organism without being the offspring of that organism.
hormone A chemical messenger that is produced in a gland or other structure and acts on distant target cells in one or more parts of an animal or plant.
hornworts A phylum of bryophytes; Anthocerophyta.
host The prey organism in a parasitic association.
host cell 1. A cell that is infected by a virus, fungus, or a bacterium. 2. A eukaryotic cell that contains photosynthetic or nonphotosynthetic endosymbionts.
host plant resistance The ability of plants to prevent herbivory.
host range The number of species and cell types that a virus or bacterium can infect.
hot spot A human-impacted geographic area with a large number of endemic species. To qualify as a hot spot, a region must contain at least 1,500 species of endemic vascular plants and have lost at least 70% of its original habitat.
***Hox* genes** In animals, a class of genes involved in pattern formation in early embryos.
Human Genome Project A 13-year international effort coordinated by the U.S. Department of Energy and the National Institutes of Health that characterized and sequenced the entire human genome.
human immunodeficiency virus (HIV) A retrovirus that is the causative agent of acquired immune deficiency syndrome (AIDS).
humoral immunity A type of specific immunity in which plasma cells secrete antibodies that bind to antigens.
humus A collective term for the organic constituents of soils.
hybridization A situation in which two individuals with different characteristics are mated or crossed to each other; the offspring are referred to as hybrids.
hybrid zone An area where two populations can interbreed.
hydrocarbon Molecules with predominantly hydrogen–carbon bonds.
hydrogen bond A weak chemical attraction between a partially positive hydrogen atom of a polar molecule and a partially negative atom of another polar molecule.
hydrolysis reaction A chemical reaction that utilizes water to break apart molecules.
hydrophilic Refers to ions and molecules that contain polar covalent bonds and will dissolve in water.
hydrophobic Refers to molecules that do not have partial charges and therefore are not attracted to water molecules. Such molecules are composed predominantly of carbon and hydrogen and are relatively insoluble in water.
hydrostatic skeleton A fluid-filled body cavity in certain soft-bodied invertebrates that is surrounded by muscles and provides support and shape.
hydroxide ion An anion with the formula, OH^-.
hypermutation A process that primarily involves numerous C to T point mutations that are crucial to enabling lymphocytes to produce a diverse array of immunoglobulins capable of recognizing many different antigens.
hyperpolarization The change in the membrane potential that occurs when the cell becomes more polarized.
hypersensitive response (HR) A plant's local defensive response to pathogen attack.
hyperthermophile An organism that thrives in extremely hot temperatures.
hyperthyroidism A medical condition resulting from a hyperactive thyroid gland.
hypertonic Any solution that causes a cell to shrink due to osmosis of water out of the cell.
hypha A microscopic, branched filament of the body of a fungus.
hypocotyl The portion of an embryonic plant stem located below the point of attachment of the cotyledons.
hypothalamus A part of the vertebrate brain located below the thalamus; it controls functions of the gastrointestinal and reproductive systems, among others, and regulates many basic behaviors such as eating and drinking.
hypothesis In biology, a proposed explanation for a natural phenomenon based on previous observations or experimental studies.
hypothesis testing Also known as the scientific method, a strategy for testing the validity of a hypothesis.
hypothyroidism A medical condition resulting from an underactive thyroid gland.
hypotonic Any solution that causes a cell to swell when placed in that solution.
H zone In a myofibril, a narrow, light region in the center of the A band that corresponds to the space between the two sets of thin filaments in each sarcomere.

I

I band In a myofibril, a light band that lies between the A bands of two adjacent sarcomeres.
immune system The cells and organs within an animal's body that contribute to immune defenses.
immune tolerance The process by which the body distinguishes between self and nonself components.
immunity The ability of an animal to ward off internal threats, including harmful microorganisms, foreign molecules, and abnormal cells such as cancer cells.
immunoglobulin A Y-shaped protein with two heavy chains and two light chains that provides immunity to foreign substances; antibodies are a type of immunoglobulin.
immunological memory The immune system's ability to produce a secondary immune response.
imperfect flower A flower that lacks either stamens or carpels.
implantation The first event of pregnancy, when the blastocyst embeds within the uterine endometrium.
imprinting 1. The development of a species-specific pattern of behavior that occurs during a critical period; a form of learning, with a large innate component. 2. In genetics, the marking of DNA that occurs differently between males and females.
inactivation gate A string of amino acids that juts out from a channel protein into the cytosol and blocks the movement of ions through the channel.
inborn error of metabolism A genetic defect in the ability to metabolize certain compounds.
inbreeding Mating among genetically related relatives.
inbreeding depression The phenomenon whereby inbreeding produces homozygotes that are less fit, thereby decreasing the reproductive success of a population.
inclusive fitness The term used to designate the total number of copies of genes passed on through one's relatives, as well as one's own reproductive output.
incomplete dominance The phenomenon in which a heterozygote that carries two different alleles exhibits a phenotype that is intermediate between the corresponding homozygous individuals.
incomplete flower A flower that lacks one or more of the four flower organ types.
incomplete metamorphosis During development in some insects, a gradual change in body form from a nymph into an adult.
incurrent siphon A structure in a tunicate used to draw water through the mouth.
indeterminate cleavage In animals, a characteristic of deuterostome development in which each cell produced by early cleavage retains the ability to develop into a complete embryo.
indeterminate growth Growth in which plant shoot apical meristems continuously produce new stem tissues and leaves, as long as conditions remain favorable.
indicator species A species whose status provides information on the overall health of an ecosystem.
indirect calorimetry A method of determining basal metabolic rate in which the rate at which an animal uses oxygen is measured.
individualistic model A view of the nature of a community that considers it to be an assemblage

of species coexisting primarily because of similarities in their physiological requirements and tolerances.

individual selection The proposal that adaptive traits generally are selected for because they benefit the survival and reproduction of the individual rather than the group.

induced fit Occurs when a substrate(s) binds to an enzyme and the enzyme undergoes a conformational change that causes the substrate(s) to bind more tightly to the enzyme.

induced mutation A mutation brought about by environmental agents that enter the cell and then alter the structure of DNA.

inducer In transcription, a small effector molecule that increases the rate of transcription.

inducible operon In this type of operon, the presence of a small effector molecule causes transcription to occur.

induction 1. In development, the process by which a cell or group of cells governs the developmental fate of neighboring cells. 2. In molecular genetics, refers to the process by which transcription has been turned on by the presence of a small effector molecule.

industrial nitrogen fixation The human activity of producing nitrogen fertilizers.

infertility The inability to produce viable offspring.

inflammation An innate local response to infection or injury characterized by local redness, swelling, heat, and pain.

inflorescence A cluster of flowers on a plant.

infundibular stalk The structure that physically connects the hypothalamus to the pituitary gland.

ingestion In animals, the act of taking food into the body.

ingroup In a cladogram, a group of interest.

inheritance The acquisition of traits by their transmission from parent to offspring.

inheritance of acquired characteristics Jean-Baptiste Lamarck's incorrect hypothesis that species change over the course of many generations by adapting to new environments.

inhibition A mechanism for succession in which early colonists exclude subsequent colonists.

inhibitory postsynaptic potential (IPSP) The response from an inhibitory neurotransmitter that hyperpolarizes the postsynaptic membrane; this hyperpolarization reduces the likelihood of an action potential.

initiation factor A protein that facilitates the interactions between mRNA, the first tRNA, and the ribosomal subunits during the initiation stage of translation.

initiation stage The first step in the process of transcription or translation.

initiator tRNA A specific tRNA that recognizes the start codon AUG in mRNA and binds to it, initiating translation.

innate The term used to describe behaviors that seem to be genetically programmed.

inner bark The thin layer of secondary phloem that carries out most of the sugar transport in a woody stem.

inner ear One of the three main compartments of the mammalian ear. The inner ear is composed of the bony cochlea and the vestibular system, which plays a role in balance.

inner segment The part of the vertebrate photoreceptors (rods and cones) that contains the cell nucleus and cytoplasmic organelles.

inorganic chemistry The study of the nature of atoms and molecules, with the exception of those that contain rings or chains of carbon.

insulin A hormone found in animals that regulates metabolism in several ways, primarily by regulating the blood glucose concentration.

insulin-like growth factor-1 (IGF-1) A hormone in mammals that stimulates the elongation of bones, especially during puberty.

integral membrane protein A protein that cannot be released from the membrane unless it is dissolved with an organic solvent or detergent. Includes transmembrane proteins and lipid-anchored proteins.

integrase An enzyme, sometimes encoded by viruses, that catalyzes the integration of the viral genome into a host-cell chromosome.

integrin A cell adhesion molecule found in animal cells that connects cells to the extracellular matrix.

integument In plants, a structure that encloses the megasporangium to form an ovule.

interference competition Competition in which organisms interact directly with one another by physical force or intimidation.

interferon A protein that generally inhibits viral replication inside host cells.

intermediate-disturbance hypothesis The proposal that moderately disturbed communities are more diverse than undisturbed or highly disturbed communities.

intermediate filament A type of protein filament of the cytoskeleton that helps maintain cell shape and rigidity.

internal fertilization Fertilization that occurs in terrestrial animals in which sperm are deposited within the reproductive tract of the female during copulation.

interneuron A type of neuron that forms interconnections between other neurons.

internode The region of a plant stem between adjacent nodes.

interphase The G_1, S, and G_2 phases of the cell cycle. It is the portion of the cell cycle during which the chromosomes are decondensed and found in the nucleus.

intersexual selection Sexual selection between members of the opposite sex.

interspecies hybrid The offspring resulting from the mating of two different species.

interspecific competition Competition between individuals of different species.

interstitial fluid The fluid that surrounds cells.

intertidal zone The area where the land meets the sea, which is alternately submerged and exposed by the daily cycle of tides.

intracellular fluid The fluid inside cells.

intranuclear spindle A spindle that forms within an intact nuclear envelope during nuclear division in fungi and some protists.

intrasexual selection Sexual selection between members of the same sex.

intraspecific competition Competition between individuals of the same species.

intrauterine device (IUD) A small object that is placed in the uterus and interferes with the endometrial preparation required for acceptance of the blastocyst; used as a form of contraception.

intrinsic rate of increase The situation in which conditions are optimal for a population and the per capita growth rate is at its maximum rate.

introduced species A species moved by humans from a native location to another location.

intron Intervening DNA sequences that are found in between the coding sequences of genes.

invagination The act of pinching inward, as during early embryonic development in animals.

invasive cell A cancer cell that can invade healthy tissues.

invasive species Introduced species that spread on their own, often outcompeting native species for space and resources.

inverse density-dependent factor A mortality factor whose influence decreases as population size or density increases.

inversion A type of mutation that involves a change in the direction of the genetic material along a single chromosome.

invertebrate An animal that lacks vertebrae.

in vitro Meaning, "in glass." An alternative to studying a process in living cells that involves isolating and purifying cellular components and studying their functions outside the cell.

in vivo Meaning, "in life." Studying a process in living cells or organisms.

involution During embryogenesis, the folding back of sheets of surface cells into the interior of an embryo.

iodine-deficient goiter An overgrown thyroid gland that is incapable of making thyroid hormone due to a lack of dietary iodine.

ion An atom or molecule that gains or loses one or more electrons and acquires a net electric charge.

ion electrochemical gradient A dual gradient for an ion that is composed of both an electrical gradient and a chemical gradient for that ion.

ionic bond The bond that occurs when a cation binds to an anion.

ionotropic receptor One of two types of postsynaptic receptors, the other being a metabotropic receptor. Consists of a ligand-gated ion channel that opens in response to binding of a neurotransmitter.

iris The circle of pigmented smooth muscle and connective tissue that is responsible for eye color.

iron regulatory element (IRE) A response element within the ferritin mRNA to which the iron regulatory protein binds.

iron regulatory protein (IRP) An RNA-binding protein that regulates the translation of the mRNA that encodes ferritin.

islets of Langerhans Spherical clusters of endocrine cells that are scattered throughout the pancreas; the cells secrete insulin or glucagon, among other hormones.

isomers Two structures with an identical molecular formula but different structures and characteristics.

isotonic Condition in which the solute concentrations on both sides of a plasma membrane are equal, which does not cause a cell to shrink or swell.

isotope An element that exists in multiple forms that differ in the number of neutrons they contain.

iteroparity The pattern of repeated reproduction at intervals throughout an organism's life cycle.

J

joint The juncture where two or more bones of a vertebrate endoskeleton come together.

juvenile hormone A hormone made in arthropods that inhibits maturation from a larva into a pupa.

K

karyogamy The process of nuclear fusion.

karyotype A photographic representation of the chromosomes in an actively dividing cell.

K_d The dissociation constant between a ligand and its receptor.

ketones Small compounds generated from fatty acids. Ketones are made in the liver and released into the blood to provide an important energy source during prolonged fasting for many tissues, including the brain.
keystone species A species within a community that has a role out of proportion to its abundance.
kidney The major excretory organ found in all vertebrates.
kilocalorie (kcal) One thousand calories; the amount of heat energy required to raise the temperature of 1 kg of water by 1 degree Celsius.
kinesis A movement in response to a stimulus, but one that is not directed toward or away from the source of the stimulus.
kinetic energy Energy associated with movement.
kinetic skull A characteristic of lizards and snakes in which the joints between various parts of the skull are extremely mobile.
kinetochore A group of proteins that bind to a centromere and are necessary for sorting each chromosome.
kingdom A taxonomic group; the second largest division after domain.
kin selection Selection for behavior that lowers an individual's own fitness but enhances the reproductive success of a relative.
K_M The substrate concentration at which an enzyme-catalyzed reaction is half of its maximal value.
knowledge The awareness and understanding of information.
Koch's postulates A series of steps used to determine whether a particular organism causes a specific disease.
K-selected species A type of life history strategy where species have a low rate of per capita population growth but good competitive ability.
K/T event An ancient cataclysm that involved at least one large meteorite or comet that crashed into the Earth near the present-day Yucatán Peninsula in Mexico about 65 million years ago.

L

labia majora In the female genitalia, large outer folds that surround the external opening of the reproductive tract.
labia minora In the female genitalia, smaller, inner folds near the external opening of the reproductive tract.
labor The strong rhythmic contractions of the uterus that serve to deliver a fetus during childbirth.
***lac* operon** An operon in the genome of *E. coli* that contains the genes for the enzymes that allow it to metabolize lactose.
lac repressor A repressor protein that regulates the *lac* operon.
lactation In mammals, a period after birth in which the young are nurtured by milk produced by the mother.
lacteal A lymphatic vessel in the center of each intestinal villus; lipids are absorbed by the lacteals, which eventually empty into the circulatory system.
lagging strand During DNA replication, a DNA strand made as a series of small Okazaki fragments that are eventually connected to each other to form a continuous strand.
lamellae Platelike structures in the internal gills of fishes that branch from structures called filaments; gas exchange occurs here.
larva A free-living organism that is morphologically very different from the embryo and adult.
larynx The segment of the respiratory tract that contains the vocal cords.
latent The term used to describe a prophage or provirus that remains inactive for a long time.
lateral line system Microscopic sensory organs in fishes and some toads that allows them to detect movement in surrounding water.
lateral meristem *See* secondary meristem.
law of independent assortment States that the alleles of different genes assort independently of each other during gamete formation.
law of segregation States that two copies of a gene segregate from each other during gamete formation and during transmission from parent to offspring.
leaching The dissolution and removal of inorganic ions as water percolates through materials such as soil.
leading strand During DNA replication, a DNA strand made in the same direction that the replication fork is moving. The strand is synthesized as one long continuous molecule.
leaf abscission The process by which a leaf drops after the formation of an abscission zone.
leaflet 1. Half of a phospholipid bilayer. 2. A portion of a compound leaf.
leaf primordia Small outgrowths that occur at the sides of a shoot apical meristem and develop into young leaves.
leaf vein In plants, a bundle of vascular tissue in a leaf.
learning The ability of an animal to make modifications to a behavior based on previous experience; the process by which new information is acquired.
leaves Flattened plant organs that emerge from stems and function in photosynthesis.
leghemoglobin A protein found in legume plants that helps to regulate local oxygen concentrations around rhizobial bacteroids in root nodules.
legume A member of the pea (bean) family; also their distinctive fruits.
lek A designated communal courting area.
lens 1. A structure of the eye that focuses light. 2. The glass components of a light microscope or the electromagnetic parts of an electron microscope that allow the production of magnified images of microscopic structures.
lentic Refers to a freshwater habitat characterized by standing water.
leptin A hormone produced by adipose cells in proportion to fat mass; controls appetite and metabolic rate.
leukocyte A cell that develops from the marrow of certain bones of vertebrates; all leukocytes (also known as white blood cells) perform vital functions that defend the body against infection and disease.
lichens The mutualistic association between particular fungi and certain photosynthetic green algae or cyanobacteria. This association results in a body form distinctive from that of either partner alone.
Liebig's law of the minimum States that species' biomass or abundance is limited by the scarcest factor.
life cycle The sequence of events that characterize the steps of development of the individuals of a given species.
life table A table that provides data on the number of living individuals in a population in particular age classes.
ligand An ion or molecule that binds to a protein, such as an enzyme or a receptor.
ligand-gated ion channel A type of cell surface receptor that binds a ligand and functions as an ion channel. Ligand binding either opens or closes a channel.
ligand•receptor complex The structure formed when a ligand and its receptor noncovalently bind.
light chain 1. A part of an immunoglobulin molecule. 2. Two of the polypeptides that comprise each myosin molecule.
light-harvesting complex A component of photosystem II and photosystem I composed of several dozen pigment molecules that are anchored to proteins in the thylakoid membranes of a chloroplast. The role of these complexes is to absorb photons of light.
light microscope A microscope that utilizes light for illumination.
light reactions The first of two stages in the process of photosynthesis. During the light reactions, photosystem II and photosystem I absorb light energy and produce ATP, NADPH, and O_2.
lignin A tough polymer that adds strength and decay resistance to cell walls of tracheids, vessel elements, and other cells of plants.
lignophytes Modern and fossil seed plants and seedless ancestors that produced wood.
limbic system In the vertebrate forebrain, the areas involved in the formation and expression of emotions; also plays a role in learning, memory, and the perception of smells.
limiting factor A factor whose amount or concentration limits the rate of a biological process or a chemical reaction.
lineage A progression of changes in a series of ancestors.
line transect A sampling technique used by plant ecologists in which the number of plants located along a length of string are counted.
linkage The phenomenon that two genes close together on the same chromosome are transmitted as a unit.
linkage group A group of genes that usually stay together during meiosis.
lipase The major fat-digesting enzyme from the pancreas.
lipid A molecule composed predominantly of hydrogen and carbon atoms. Lipids are nonpolar and therefore very insoluble in water. They include fats (triglycerides), phospholipids, and steroids.
lipid-anchored protein A type of integral membrane protein that is attached to the membrane via a lipid molecule.
lipid-exchange protein A protein that extracts a lipid from one membrane, diffuses through the cell, and inserts the lipid into another membrane.
lipid raft In a membrane, a group of lipids and proteins that float together as a unit in a larger sea of lipids.
lipopolysaccharides Lipids with covalently bound carbohydrates; prevalent in the thin, outer envelope that encloses the cell walls of Gram-negative bacteria.
liposome A vesicle surrounded by a lipid bilayer.
liver An organ in vertebrates that performs diverse metabolic functions and is the site of bile production.
liverworts A phylum of bryophytes; formally called Hepatophyta.
lobe fins The Actinistia (coelacanths), Dipnoi (lungfishes), and tetrapods; also called Sarcopterygii.
lobe-finned fishes Fishes in which the fins are part of the body; the fins are supported by skeletal extensions of the pectoral and pelvic areas.

locomotion The movement of an animal from place to place.
locus The physical location of a gene on a chromosome.
logistic growth The pattern in which the growth of a population typically slows down as it approaches the carrying capacity.
long-day plant A plant that flowers in spring or early summer, when the night period is shorter (and thus the day length is longer) than a defined period.
long-term potentiation (LTP) The long-lasting strengthening of the connection between neurons that is believed to be part of the mechanism of learning and memory.
loop domain In bacteria, a chromosomal segment that is folded into loops by the attachment to proteins; a method of compacting bacterial chromosomes.
loop of Henle A segment of the tubule of the nephron of the kidney containing a sharp hairpin-like loop that contributes to reabsorption of ions and water. It consists of a descending limb coming from the proximal tubule and an ascending limb leading to the distal tubule.
lophophore A horseshoe-shaped crown of tentacles used for feeding in several invertebrate species.
Lophotrochozoa A clade of animals that encompasses the mollusks, annelids, and several other phyla; they are distinguished by two morphological features—the lophophore, a crown of tentacles used for feeding, and the trochophore larva, a distinct larval stage.
lotic Refers to a freshwater habitat characterized by running water.
lumen The internal space of an organelle.
lungfishes The Dipnoi; fish with primitive lungs that live in oxygen-poor freshwater swamps and ponds.
lungs In terrestrial vertebrates, internal paired structures used to bring oxygen into the circulatory system and remove carbon dioxide.
luteinizing hormone (LH) A gonadotropin that controls the production of sex steroids in both males and females.
lycophyll A relatively small leaf having a single unbranched vein; produced by lycophytes.
lycophytes Members of a phylum of vascular land plants whose leaves are lycophylls; Lycopodiophyta.
lymphatic system A system of vessels along with a group of organs and tissues where most leukocytes reside. The lymphatic vessels collect excess interstitial fluid and return it to the blood.
lymphocytes A type of leukocyte that is responsible for specific immunity; the two types are B cells and T cells.
lysogenic cycle The growth cycle of a bacteriophage consisting of integration, prophage replication, and excision.
lysosome A small organelle found in animal cells that contains acid hydrolases that degrade macromolecules.
lytic cycle The growth cycle of a bacteriophage in which the production and release of new viruses lyses the host cell.

M

macroalgae Photosynthetic protists that can be seen with the unaided eye; also known as seaweeds.
macroevolution Evolutionary changes that create new species and groups of species.
macromolecule Many molecules bonded together to form a polymer. Carbohydrates, proteins, and nucleic acids (for example, DNA and RNA) are important macromolecules found in living organisms.
macronutrient An element required by plants in amounts of at least 1 g/kg of plant dry matter.
macroparasite A parasite that lives in a host but releases infective juvenile stages outside the host's body.
macrophage A type of phagocyte capable of engulfing viruses and bacteria.
macular degeneration An eye condition in which photoreceptor cells in and around the fovea of the retina are lost; one of the leading causes of blindness in the U.S.
madreporite A sievelike plate on the surface of an echinoderm where water enters the water vascular system.
magnetic resonance imaging (MRI) An imaging method that relies on the use of magnetic fields and radio waves to visualize the internal structure of an organism's body.
magnification The ratio between the size of an image produced by a microscope and a sample's actual size.
major depressive disorder A neurological disorder characterized by feelings of despair and sadness, resulting from an imbalance in neurotransmitter levels in the brain.
major groove A groove that spirals around the DNA double helix; provides a location where a protein can bind to a particular sequence of bases and affect the expression of a gene.
major histocompatibility complex (MHC) A gene family that encodes the plasma membrane self proteins that must be complexed with an antigen for T-cell recognition to occur.
male-assistance hypothesis A hypothesis to explain the existence of monogamy that maintains that males remain with females to help them rear their offspring.
male gametophyte A haploid multicellular plant life cycle stage that produces sperm.
malignant tumor A growth of cells that has progressed to the cancerous stage.
Malpighian tubules Delicate projections from the digestive tract of insects and some other taxa that function as an excretory organ.
mammal A vertebrate that is a member of the class Mammalia that nourishes its young with milk secreted by mammary glands. Another distinguishing feature is hair.
mammary gland A gland in female mammals that secretes milk.
manganese cluster A site where the oxidation of water occurs in photosystem II during photosynthesis.
mantle In mollusks, a fold of skin draped over the visceral mass that secretes a shell in those species that form shells.
mantle cavity The chamber in a mollusk mantle that houses delicate gills.
many-eyes hypothesis The idea that increased group size decreases predators' success because of increased detection of predators.
map distance The distance between genes along chromosomes, which is calculated as the number of recombinant offspring divided by the total number of offspring times 100.
mapping The process of determining the relative locations of genes or other DNA segments along a chromosome.
map unit (mu) A unit of distance on a chromosome equivalent to a 1% recombination frequency.
mark-recapture technique The capture and tagging of animals so they can be released and recaptured, allowing an estimate of population size.
marsupial A member of a group of seven mammalian orders and about 280 species found in the subclass Metatheria.
mass extinction When many species become extinct at the same time.
mass-specific BMR The amount of energy expended per gram of body mass.
mastax The circular muscular pharynx in the mouth of rotifers.
mast cell A type of cell derived from bone marrow stem cells that plays an important role in nonspecific immunity.
masting The synchronous production of many progeny by all individuals in a population; serves to satiate predators and thereby allow some progeny to survive.
mate-guarding hypothesis The hypothesis that a male is monogamous to prevent his mate from being fertilized by other males.
maternal effect An inheritance pattern in which the genotype of the mother determines the phenotype of her offspring.
maternal effect gene A gene that follows a maternal effect inheritance pattern.
maternal inheritance A phenomenon in which offspring inherit particular genes only from the female parent (through the egg).
matrotrophy In plants, the phenomenon in which zygotes remain enclosed within gametophyte tissues, where they are sheltered and fed.
matter Anything that has mass and takes up space.
maturation promoting factor (MPF) A factor, now known to be a complex of cyclin and cyclin-dependent kinase, important in the division of all types of eukaryotic cells.
mature mRNA In eukaryotes, transcription produces a long RNA, pre-mRNA, which undergoes certain processing events before it exits the nucleus; mature mRNA is the final functional product.
maximum likelihood One method used to evaluate a phylogenetic tree based on an evolutionary model.
mean fitness of the population The average reproductive success of members of a population.
mechanoreceptor A sensory receptor in animals that transduces mechanical energy such as pressure, touch, stretch, movement, and sound.
mediator A large protein complex that plays a role in initiating transcription at the core promoter of structural genes in eukaryotes.
medulla oblongata The part of the vertebrate hindbrain that coordinates many basic reflexes and bodily functions, such as breathing.
medusa A type of cnidarian body form that is motile and usually floats mouth down.
megadiversity country Those countries with the greatest numbers of species; used in targeting areas for conservation.
megaspore In seed plants and some seedless plants, a large spore that produces a female gametophyte within the spore wall.
meiosis The process by which haploid cells are produced from a cell that was originally diploid.
meiosis I The first division of meiosis in which the homologues are separated into different cells.
meiosis II The second division of meiosis in which sister chromatids are separated into different cells.
Meissner's corpuscles Structures that sense touch and light pressure and lie just beneath the skin surface of an animal.
melatonin A hormone produced by the pineal gland of vertebrates; plays a role in light-

dependent behaviors such as seasonal reproduction and daily rhythms.

membrane attack complex (MAC) A multiunit protein formed by the activation of complement proteins; the complex creates water channels in the microbial plasma membrane and causes the microbe to swell and burst.

membrane potential The difference between the electric charges outside and inside a cell; also called a potential difference (or voltage).

membrane transport The movement of ions or molecules across a cell membrane.

memory The retention of information over time.

memory cells A cloned lymphocyte that remains poised to recognize a returning antigen; a component of specific immunity.

Mendelian inheritance The inheritance patterns of genes that segregate and assort independently.

meninges Three layers of sheathlike membranes that cover and protect the brain and spinal cord.

meningitis A potentially life-threatening infectious disease in which the meninges become inflamed.

menopause The event during which a woman permanently stops having ovarian cycles.

menstrual cycle The cyclical changes that occur in the uterus in parallel with the ovarian cycle in a female mammal. Also called the uterine cycle.

menstruation A period of bleeding at the beginning of the menstrual cycle in a female mammal.

meristem In plants, an organized tissue that includes actively dividing cells and a reservoir of stem cells.

meroblastic cleavage An incomplete type of cell cleavage in which only the region of the egg containing cytoplasm at the animal pole undergoes cell division. Occurs in birds and some fishes.

merozygote A strain of bacteria containing an F′ factor.

mesoderm In animals, a layer of cells formed during gastrulation that develops between the ectoderm and endoderm; gives rise to the skeleton, muscles, and much of the circulatory system.

mesoglea A gelatinous substance between the epidermis and the gastrodermis in the Radiata.

mesohyl A gelatinous, protein-rich matrix in between the choanocytes and the epithelial cells of a sponge.

mesophyll The internal tissue of a plant leaf; the site of photosynthesis.

messenger RNA (mRNA) RNA that contains the information to specify a polypeptide with a particular amino acid sequence.

metabolic cycle A biochemical cycle in which particular molecules enter while others leave; the process is cyclical because it involves a series of organic molecules that are regenerated with each turn of the cycle.

metabolic pathway In living cells, a series of chemical reactions in which each step is catalyzed by a specific enzyme.

metabolic rate The total energy expenditure of an organism per unit of time.

metabolism The sum total of all chemical reactions that occur within an organism. Also, a specific set of chemical reactions occurring at the cellular level.

metabotropic receptor A G-protein-coupled receptor that initiates a signaling pathway in response to a neurotransmitter. One of two types of postsynaptic receptors, the other being an ionotropic receptor.

metacentric A chromosome in which the centromere is near the middle.

metagenomics A field of study that seeks to identify and analyze the collective microbial genomes contained in a community of organisms, including those not easily cultured in the laboratory.

metamorphosis The process in which a pupal or juvenile organism changes into a mature adult with very different characteristics.

metanephridia Excretory organs found in a variety of invertebrates.

metanephridial system The filtration system used by annelids to filter out wastes and excess water.

metaphase The phase of mitosis during which the chromosomes are aligned along the metaphase plate.

metaphase plate A plane halfway between the poles of the spindle apparatus on which the sister chromatids align during the metaphase stage of mitosis.

metastasis The process by which cancer cells spread from their original location to distant parts of the body.

Metazoa The collective term for animals.

methanogens Several groups of anaerobic archaea that convert CO_2, methyl groups, or acetate to methane, and release it from their cells.

methanotroph An aerobic bacterium that consumes methane.

methyl-CpG-binding protein A protein that binds methylated sequences and inhibits transcription.

micelle The sphere formed by long amphipathic molecules when they are mixed with water. In animals, micelles aid in the absorption of poorly soluble products during digestion.

microbiome All of the microorganisms in a particular environment.

microclimate Local variations of the climate within a given area.

microevolution Changes in a population's gene pool from generation to generation.

microfilament *See* actin filament.

micrograph An image taken with the aid of a microscope.

micronutrient An element required by plants in amounts at, or less than, 0.1 g/kg of plant dry matter; also known as a trace element.

microparasite A parasite that multiplies within its host, usually within the cells.

micropyle A small opening in the integument of a seed plant ovule through which a pollen tube grows.

microRNAs (miRNAs) Small RNA molecules, typically 22 nucleotides in length, that silence the expression of specific mRNAs by inhibiting translation.

microscope A magnification tool that enables researchers to study very small structures such as cells.

microspore In seed plants and some seedless plants, a relatively small spore that produces a male gametophyte within the spore wall.

microtubule A type of hollow protein filament composed of tubulin proteins that is part of the cytoskeleton and is important for cell shape, organization, and movement.

microtubule-organizing center *See* centrosome.

microvilli Small projections in the surface membranes of epithelial cells in the small intestine and many other absorptive cells.

midbrain One of three major divisions of the vertebrate brain; the other two divisions are the hindbrain and the forebrain.

middle ear One of the three main compartments of the mammalian ear; contains three small bones called ossicles that connect the eardrum with the oval window.

middle lamella An extracellular layer in plants composed primarily of carbohydrate; cements adjacent plant cell walls together.

migration Long-range seasonal movement among animals in order to feed or breed.

mimicry The resemblance of an organism (the mimic) to another organism (the model).

mineral An inorganic ion or inorganic molecule required by a living organism.

mineralization The general process by which phosphorus, nitrogen, CO_2, and other minerals are released from organic compounds.

mineralocorticoid A steroid hormone such as aldosterone that regulates the balance of sodium and potassium ions in the body.

minor groove A smaller groove that spirals around the DNA double helix.

miRNA *See* microRNAs.

missense mutation A base substitution that changes a single amino acid in a polypeptide sequence.

mitochondrial genome The chromosome found in mitochondria.

mitochondrial matrix A compartment inside the inner membrane of a mitochondrion.

mitochondrion A semiautonomous organelle found in eukaryotic cells that supplies most of a cell's ATP.

mitogen-activated protein kinase (MAP kinase) A type of protein kinase that is involved with promoting cell division.

mitosis In eukaryotes, the process in which nuclear division results in two nuclei, each of which receives the same complement of chromosomes.

mitotic cell division A process whereby a eukaryotic cell divides to produce two new cells that are genetically identical to the original cell.

mitotic spindle The structure responsible for organizing and sorting the chromosomes during mitosis; also called the mitotic spindle apparatus.

mixotroph An organism that is able to use autotrophy as well as phagotrophy or osmotrophy to obtain organic nutrients.

M line In a myofibril, a narrow, dark band in the center of the H zone where proteins link the central regions of adjacent thick filaments.

model organism An organism studied by many different researchers so they can compare their results and determine scientific principles that apply more broadly to other species.

moderately repetitive sequence A DNA sequence found a few hundred to several thousand times in a genome.

molar A term used to describe a solution's molarity; a 1 molar solution contains 1 mole of a solute in 1 L of water.

molarity The number of moles of a solute dissolved in 1 L of water.

mole The amount of any substance that contains the same number of particles as there are atoms in exactly 12 g of carbon.

molecular biology A field of study spawned largely by genetic technology that looks at the structure and function of the molecules of life.

molecular clock A method for estimating evolutionary time; based on the observation that neutral mutations occur at a relatively constant rate.

molecular evolution The molecular changes in genetic material that underlie the phenotypic changes associated with evolution.

molecular formula A representation of a molecule that consists of the chemical symbols for all of

the atoms present and subscripts that indicate how many of those atoms are present.

molecular homologies Similarities at the molecular level that indicate that living species evolved from a common ancestor or interrelated group of common ancestors.

molecular mass The sum of the atomic masses of all the atoms in a molecule.

molecular pharming An avenue of research that involves the production of medically important proteins in agricultural crops or animals.

molecular systematics A field of study that involves the analysis of genetic data, such as DNA sequences, to identify and study genetic homology and construct phylogenetic trees.

molecule Two or more atoms that are connected by chemical bonds.

monoclonal antibodies Antibodies of a specific type that are derived from a single clone of cells.

monocots One of the two largest lineages of flowering plants in which the embryo produces a single seed leaf.

monocular vision A type of vision in animals that have eyes on the sides of the head; the animal sees a wide area at one time, though depth perception is reduced.

monocyte A type of phagocyte that circulates in the blood for only a few days, after which it takes up permanent residence in various organs as a macrophage.

monoecious The term to describe plants that produce carpellate and staminate flowers on the same plant.

monogamy A mating system in which one male mates with one female, and most individuals have mates.

monohybrid The F_1 offspring, also called single-trait hybrids, of true-breeding parents that differ with regard to a single trait.

monohybrid cross A cross in which the inheritance of only one trait is followed.

monomer An organic molecule that can be used to form larger molecules (polymers) consisting of many repeating units of the monomer.

monomorphic gene A gene that exists predominantly as a single allele in a population.

monophagous The term used to describe parasites that feed on one or a few closely related species.

monophyletic group A group of species, a taxon, consisting of the most recent common ancestor and all of its descendants.

monosaccharide A simple sugar.

monosomic An aneuploid organism that has one too few chromosomes.

monotreme A member of the mammalian order Monotremata, which consists of three species found in Australia and New Guinea: the duck-billed platypus and two species of echidna.

morphogen A molecule that imparts positional information and promotes developmental changes at the cellular level.

morphogenesis The process that creates morphology.

morphology The structure or form of a body part or an entire organism.

morula An early stage in a mammalian embryo in which physical contact between cells is maximized by compaction.

mosaic An individual with somatic cells that are genetically different from each other.

mosses A phylum of bryophytes; Bryophyta.

motor end plate The region of a skeletal muscle cell that lies beneath an axon terminal at the neuromuscular junction.

motor neuron A neuron that sends signals away from the central nervous system and elicits some type of response.

motor protein A category of cellular proteins that uses ATP as a source of energy to promote movement; consists of three domains called the head, hinge, and tail.

movement corridor Thin strips of habitat that may permit the movement of individuals between larger habitat patches.

M phase The sequential events of mitosis and cytokinesis.

mRNA *See* messenger RNA.

Müllerian mimicry A type of mimicry in which many noxious species converge to look the same, thus reinforcing the basic distasteful design.

multicellular Describes an organism consisting of more than one cell, particularly when cell-to-cell adherence and signaling processes and cellular specialization can be demonstrated.

multimeric protein A protein with more than one polypeptide chain; also said to have a quarternary structure.

multiple alleles Refers to the occurrence of a gene that exists as three or more alleles in a population.

multiple sclerosis (MS) A disease in which the patient's own body attacks and destroys myelin as if it were a foreign substance; impairs the function of myelinated neurons that control movement, speech, memory, and emotion.

multipotent A term used to describe a stem cell that can differentiate into several cell types, but far fewer than pluripotent cells.

muscle A grouping of muscle cells (fibers) bound together by a succession of connective tissue layers.

muscle fibers Individual cells within a muscle.

muscle tissue Bundles of muscle fibers that are specialized to contract when stimulated.

muscular dystrophy A group of diseases associated with progressive degeneration of skeletal and cardiac muscle fibers.

mutagen An agent known to cause mutation.

mutant allele An allele that has been altered by mutation.

mutation A heritable change in the genetic material of an organism.

mutualism A symbiotic interaction in which both species benefit.

myasthenia gravis A disease characterized by loss of ACh receptors on skeletal muscle, due to the body's own immune system destroying the receptors.

mycelium A fungal body composed of microscopic branched filaments known as hyphae.

mycorrhizae Associations between the hyphae of certain fungi and the roots of plants.

myelin sheath In the nervous system, an insulating layer made up of specialized glial cells wrapped around the axons.

myocardial infarction (MI) The death of cardiac muscle cells, which can occur if a region of the heart is deprived of blood for an extended time.

myofibrils Individual muscle cells within a muscle, each of which contains thick and thin filaments.

myogenic heart A heart in which the signaling mechanism that initiates contraction resides within the cardiac muscle itself.

myoglobin An oxygen-binding protein that provides an intracellular reservoir of oxygen for muscle fibers.

myosin A motor protein found abundantly in muscle cells and also in other cell types.

N

NAD^+ Nicotinamide adenine dinucleotide; a dinucleotide that functions as an energy intermediate molecule. It combines with two electrons and H^+ to form NADH.

NADPH Nicotinamide adenine dinucleotide phosphate; an energy intermediate that provides the energy and electrons to drive the Calvin cycle during photosynthesis.

natural killer (NK) cells A type of leukocyte that participates in both nonspecific and specific immunity; recognizes general features on the surface of cancer cells or any virus-infected cells.

natural selection The process that eliminates those individuals that are less likely to survive and reproduce in a particular environment, while allowing other individuals with traits that confer greater reproductive success to increase in numbers.

nauplius The first larval stage in a crustacean.

navigation A mechanism of migration that involves the ability not only to follow a compass bearing but also to set or adjust it.

negative control Transcriptional regulation by repressor proteins.

negative feedback loop A homeostatic system in animals in which a change in the variable being regulated brings about responses that move the variable in the opposite direction.

negative frequency-dependent selection A pattern of natural selection in which the fitness of a genotype decreases when its frequency becomes higher; the result is a balanced polymorphism.

negative pressure filling The mechanism by which reptiles, birds, and mammals ventilate their lungs.

nekton Free-swimming animals in the open ocean that can swim against currents to locate food.

nematocyst In a cnidarian, a powerful capsule with an inverted coiled and barbed thread that functions to immobilize small prey.

neocortex The layer of the brain that evolved most recently in mammals.

nephron One of several million single-cell-thick tubules that are the functional units of the mammalian kidney.

Nernst equation The formula that gives the equilibrium potential for an ion at any given concentration gradient.

nerve A structure found in the peripheral nervous system that is composed of multiple myelinated neurons bound by connective tissue; carries information to or from the central nervous system.

nerve cord In many invertebrates, a ventral structure that extends from the anterior end of the animal to the tail; a dorsal nerve cord is found in chordates.

nerve net Interconnected neurons with no central control organ.

nervous system Groups of cells that sense internal and environmental changes and transmit signals that enable an animal to respond in an appropriate way.

nervous tissue Clusters of cells that initiate and conduct electrical signals from one part of an animal's body to another part.

net primary production (NPP) Gross primary production minus the energy lost in plant cellular respiration.

net reproductive rate The population growth rate per generation.

neural crest In vertebrates, a group of embryonic cells derived from ectoderm that disperse

throughout the embryo and contribute to the development of the skeleton and other structures, including peripheral nerves.

neural tube In chordates, a structure formed from ectoderm located dorsal to the notochord; all neurons and their supporting cells in the central nervous system originate from neural precursor cells derived from the neural tube.

neurogenesis The production of new neurons by cell division.

neurogenic heart A heart that will not beat unless it receives regular electrical impulses from the nervous system.

neurohormone A hormone made in and secreted by neurons whose cell bodies are in the hypothalamus.

neuromodulator Another term for a neuropeptide, which is a neurotransmitter that can alter or modulate the response of a postsynaptic neuron to other neurotransmitters.

neuromuscular junction The junction between a motor neuron's axon and a skeletal or cardiac muscle fiber.

neuron A highly specialized cell found in nervous systems of animals that communicates with other cells by electrical or chemical signals.

neuroscience The scientific study of nervous systems.

neurotransmitter A small signaling molecule that is released from an axon terminal and diffuses to a postsynaptic cell where it elicits a response.

neurulation The embryological process responsible for initiating central nervous system formation.

neutral theory of evolution States that most genetic variation is due to the accumulation of neutral mutations that have attained high frequencies in a population via genetic drift.

neutral variation Genetic variation in which natural selection does not favor any particular genotype.

neutralism The phenomenon in which two species occur together but do not interact in any measurable way.

neutron A neutral particle found in the center of an atom.

neutrophil A type of phagocyte and the most abundant type of leukocyte. Neutrophils engulf bacteria by endocytosis.

nitrification The conversion by soil bacteria of NH_3 or NH_4^+ to nitrate (NO_3^-), a form of nitrogen commonly used by plants.

nitrogen fixation A specialized metabolic process in which certain prokaryotes use the enzyme nitrogenase to convert inert atmospheric nitrogen gas into ammonia; also, the industrial process by which humans produce ammonia fertilizer from nitrogen gas.

nitrogenase An enzyme used in the biological process of fixing nitrogen.

nitrogen-limitation hypothesis The proposal that organisms select food based on its nitrogen content.

nitrogenous wastes Degradation products of proteins and nucleic acids that are toxic at high concentrations and must be eliminated from the body.

nociceptor A sensory receptor in animals that responds to extreme heat, cold, and pressure, as well as to certain molecules such as acids; also known as a pain receptor.

nocturnal enuresis Bed-wetting.

node The region of a plant stem from which one or more leaves, branches, or buds emerge.

nodes of Ranvier Exposed areas in the axons of myelinated neurons that contain many voltage-gated Na^+ channels and are the sites of regeneration of action potentials.

Nod factor Nodulation factor; a substance produced by nitrogen-fixing bacteria in response to flavonoids secreted from the roots of potential host plants. Nod factors bind to receptors in plant root membranes, starting a process that allows the bacteria to invade roots.

nodule A small swelling on a plant root that contains nitrogen-fixing bacteria.

nodulin One of several plant proteins that foster root nodule development.

noncoding strand *See* template strand.

noncompetitive inhibitor A molecule that binds to an enzyme at a location that is outside the active site and inhibits the enzyme's function.

noncyclic electron flow The combined action of photosystem II and photosystem I in which electrons flow in a linear manner to produce NADPH.

non-Darwinian evolution The idea that much of the modern variation in gene sequences is explained by neutral variation rather than adaptive variation.

nondisjunction An event in which the chromosomes do not sort properly during cell division.

nonpolar covalent bond A strong bond formed between two atoms of similar electronegativities in which electrons are shared between the atoms.

nonpolar molecule A molecule composed predominantly of nonpolar bonds.

nonrandom mating The phenomenon that individuals choose their mates based on their genotypes or phenotypes.

nonrecombinant An offspring whose combination of traits has not changed from the parental generation.

nonsense codon *See* stop codon.

nonsense mutation A mutation that changes a normal codon into a stop codon; this causes translation to be terminated earlier than expected, producing a truncated polypeptide.

nonshivering thermogenesis An increase in an animal's metabolic rate that is not due to increased muscle activity; occurs primarily in brown adipose tissue.

nonspecific (innate) immunity The body's defenses that are present at birth and act against foreign materials in much the same way regardless of their specific identity; includes the skin and mucous membranes, plus various cellular and chemical defenses.

nonvascular plant A plant that does not produce lignified vascular tissue; includes the bryophytes.

norepinephrine A type of neurotransmitter; also known as noradrenaline.

norm of reaction A description of how a trait may change depending on environmental conditions.

notochord A defining characteristic of all chordate embryos; consists of a flexible rod that lies between the digestive tract and the nerve cord.

N-terminus The location of the first amino acid in a polypeptide; also known as the amino terminus.

nuclear envelope A double-membrane structure that encloses the cell's nucleus.

nuclear genome The chromosomes found in the nucleus of a eukaryotic cell.

nuclear lamina A collection of filamentous proteins that line the inner nuclear membrane; part of the nuclear matrix.

nuclear matrix A filamentous network of proteins that is found inside the nucleus and lines the inner nuclear membrane. The nuclear matrix serves to organize the chromosomes.

nuclear pore A passageway for the movement of molecules and macromolecules into and out of the nucleus; formed where the inner and outer nuclear membranes make contact with each other.

nucleic acid An organic molecule composed of nucleotides. The two types of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).

nucleoid region A site in a bacterial cell where the genetic material (DNA) is located.

nucleolus A prominent region in the nucleus of nondividing cells where ribosome assembly occurs.

nucleosome A structural unit of eukaryotic chromosomes composed of an octamer of histones (eight histone proteins) wrapped with DNA.

nucleotide An organic molecule having three components: one or more phosphate groups, a five-carbon sugar (either deoxyribose or ribose), and a single or double ring of carbon and nitrogen atoms known as a base.

nucleotide excision repair (NER) A common type of DNA repair system that removes (excises) and repairs a region of the DNA where damage has occurred.

nucleus (plural, **nuclei**) 1. In cell biology, an organelle found in eukaryotic cells that contains most of the cell's genetic material. 2. In chemistry, the region of an atom that contains protons and neutrons. 3. In neurobiology, a group of neuronal cell bodies in the brain that are devoted to a particular function.

nutrient Any substance taken up by a living organism that is needed for survival, growth, development, repair, or reproduction.

O

obese According to current National Institutes of Health guidelines, a person having a body mass index (BMI) of 30 kg/m^2 or more.

obligate aerobes Microorganisms that require oxygen.

obligate anaerobes Microorganisms that are poisoned by oxygen.

obligatory mutualism An interaction in which two mutualistic species cannot live without each other.

occipital lobe One of four lobes of the cerebral cortex of the human brain; controls aspects of vision and color recognition.

ocelli Photosensitive organs in some animal species.

octet rule The phenomenon that some atoms are most stable when their outer shell is full with eight electrons.

Okazaki fragments Short segments of DNA synthesized in the lagging strand during DNA replication.

olfaction The sense of smell.

olfactory bulbs Part of the limbic system of the forebrain of vertebrates; the olfactory bulbs carry information about odors to the brain.

oligodendrocytes Glial cells that produce the myelin sheath around neurons in the central nervous system.

oligotrophic The term used to describe aquatic systems that are low in nutrients such as phosphate and combined nitrogen and are consequently low in primary productivity and biomass, but typically high in species diversity.

ommatidium An independent visual unit in the eye of insects that functions as a separate photoreceptor capable of forming an independent image.

omnivore An animal that has the ability to eat and survive on both plant and animal products.
oncogene A type of mutant gene derived from a proto-oncogene. An oncogene is overactive, thus contributing to uncontrolled cell growth and promoting cancer.
one gene–one enzyme hypothesis An early hypothesis by Beadle and Tatum that suggested that one gene encodes one enzyme. It was later modified to the one gene–one polypeptide theory.
one gene–one polypeptide theory The concept that one structural gene codes for one polypeptide.
oogenesis Gametogenesis in a female animal resulting in the production of an egg cell.
oogonia (singular, **oogonium**) In animals, diploid germ cells that give rise to the female gametes, the eggs.
open circulatory system In animals, a circulatory system in which hemolymph, which is not different than the interstitial fluid, flows throughout the body and is not confined to special vessels.
open complex Also called the transcription bubble; a small bubble-like structure between two DNA strands that occurs during transcription.
open conformation Loosely packed chromatin that can be transcribed into RNA.
operant conditioning A form of behavior modification; a type of associative learning in which an animal's behavior is reinforced by a consequence, either a reward or a punishment.
operator A DNA sequence in bacteria that is recognized by activator or repressor proteins that regulate the level of gene transcription.
operculum A protective flap that covers the gills of a bony fish.
operon An arrangement of two or more genes in bacteria that are under the transcriptional control of a single promoter.
opposable thumb A thumb that can be placed opposite the fingers of the same hand; gives animals a precision grip that enables the manipulation of small objects.
opsin A protein that is a component of visual pigments in the vertebrate eye.
opsonization The process by which an antibody binds to a pathogen and provides a means to link the pathogen with a phagocyte.
optic disc In vertebrates, the point on the retina where the optic nerve leaves the eye.
optic nerve A structure of the vertebrate eye that carries electrical signals to the brain.
optimal foraging The concept that in a given circumstance, an animal seeks to obtain the most energy possible with the least expenditure of energy.
optimality theory The theory that predicts an animal should behave in a way that maximizes the benefits of a behavior minus its costs.
orbital The region surrounding the nucleus of an atom where the probability is high of finding a particular electron.
order In taxonomy, a subdivision of a class.
organ Two or more types of tissue combined to perform a common function.
organelle A subcellular structure or membrane-bound compartment with its own unique structure and function.
organic chemistry The study of carbon-containing molecules.
organic farming The production of crops without the use of commercial inorganic fertilizers, growth substances, and pesticides.
organic molecule A carbon-containing molecule, so named because they are found in living organisms.
organism A living thing that maintains an internal order that is separated from the environment.
organismal ecology The investigation of how adaptations and choices by individuals affect their reproduction and survival.
organismic model A view of the nature of a community that considers it to be equivalent to a superorganism; individuals, populations, and communities have a relationship to each other that resembles the associations found between cells, tissues, and organs.
organizing center A group of cells in a plant shoot meristem that ensures the proper organization of the meristem and preserves the correct number of actively dividing stem cells.
organogenesis The developmental stage during which cells and tissues form organs in animal embryos.
organ system Different organs that work together to perform an overall function in an organism.
orientation A mechanism of migration in which animals have the ability to follow a compass bearing and travel in a straight line.
origin of replication A site within a chromosome that serves as a starting point for DNA replication.
ortholog A homologous gene in different species.
osmoconformer An animal whose osmolarity conforms to that of its environment.
osmolarity The solute concentration of a solution of water, expressed as milliosmoles/liter (mOsm/L).
osmoregulator An animal that maintains stable internal salt concentrations and osmolarities, even when living in water with very different osmolarities than its body fluids.
osmosis The movement of water across membranes to balance solute concentrations. Water diffuses from a solution that is hypotonic (lower solute concentration) into a solution that is hypertonic (higher solute concentration).
osmotic adjustment The process by which a plant modifies the solute concentration of its cytosol.
osmotic lysis Occurs when a cell in a hypotonic environment takes up so much water that it ruptures.
osmotic pressure The hydrostatic pressure required to stop the net flow of water across a membrane due to osmosis.
osmotroph An organism that relies on osmotrophy (uptake of small organic molecules) as a form of nutrition.
osteomalacia Bone deformation in adults due to inadequate mineral intake or absorption from the intestines.
osteoporosis A disease in which the mineral and organic components of bone are reduced.
otoliths Granules of calcium carbonate found in the gelatinous substance that embeds hair cells in the vertebrate ear.
outer bark Protective layers of mostly dead cork cells that cover the outside of woody stems and roots.
outer ear One of the three main compartments of the mammalian ear; consists of the external ear, or pinna, and the auditory canal.
outer segment The highly convoluted plasma membranes found in the rods and cones of the eye.
outgroup In a cladogram, a species or group of species that does not exhibit one or more shared derived characters found in the ingroup.
ovarian cycle The events beginning with the development of an ovarian follicle, followed by release of a secondary oocyte, and concluding with formation and subsequent degeneration of a corpus luteum.
ovaries (singular, **ovary**) 1. In animals, the female gonads where eggs are formed. 2. In plants, the lowermost portion of the pistil that encloses and protects the ovules.
overweight According to current National Institutes of Health guidelines, a person having a body mass index (BMI) of 25 kg/m^2 or more.
oviduct A thin tube with undulating fimbriae (fingerlike structures) that is connected to the uterus and extends out to the ovary; also called the fallopian tube.
oviparity Development of an embryo outside the mother, usually in a protective shell or other structure from which the young hatch.
oviparous An animal whose young hatch from eggs laid outside the mother's body.
ovoviparous An animal that retains fertilized eggs covered by a protective sheath or other structure within the body, where the young hatch.
ovoviviparity Development of an embryo involving aspects of both viviparity and oviparity; fertilized eggs covered with a protective sheath are produced and hatch inside the mother's body, but the offspring receive no nourishment from the mother.
ovulation The process by which a mature oocyte is released from an ovary.
ovule In a seed plant, a megaspore-producing megasporangium and enclosing tissues known as integuments.
ovum (plural, **ova**) *See* egg.
oxidation A process that involves the removal of electrons; occurs during the breakdown of small organic molecules.
oxidative fiber A skeletal muscle fiber that contains numerous mitochondria and has a high capacity for oxidative phosphorylation.
oxidative phosphorylation A process during which NADH and $FADH_2$ are oxidized to make more ATP via the phosphorylation of ADP.
oxygen-hemoglobin dissociation curve A curve that represents the relationship between the partial pressure of oxygen and the binding of oxygen to hemoglobin proteins.
oxytocin A hormone secreted by the posterior pituitary gland that stimulates contractions of the smooth muscles in the uterus of a pregnant mammal, facilitating the birth process; after birth, it is important in milk secretion.

P

pacemaker *See* sinoatrial (SA) node.
Pacinian corpuscles Structures located deep beneath the surface of an animal's skin that respond to deep pressure or vibration.
paedomorphosis The retention of juvenile traits in an adult organism.
pair-rule gene A type of segmentation gene; a mutation in this gene may cause alternating segments or parts of segments to be deleted.
paleontologist A scientist who studies fossils.
palisade parenchyma Photosynthetic ground tissue of the plant leaf mesophyll that consists of closely packed, elongate cells adapted to efficiently absorb sunlight.
palmate A type of leaf vein pattern in which veins radiate outward, resembling an open hand.

pancreas In vertebrates, an elongated gland located behind the stomach that secretes digestive enzymes and a fluid rich in bicarbonate ions.
parabronchi In birds, a series of parallel air tubes that make up the lungs and are the regions of gas exchange.
paracrine Refers to a type of cellular communication in which molecules are released into the interstitial fluid and act on nearby cells.
paralogs Homologous genes within a single species.
paraphyletic group A group of organisms that contains a common ancestor and some, but not all, of its descendants.
parapodia Fleshy, footlike structures in the polychaetes that are pushed into the substrate to provide traction during movement.
parasite A predatory organism that feeds off another organism but does not normally kill it.
parasitism A symbiotic association in which one organism feeds off another but does not normally kill it.
parasympathetic division The division of the autonomic nervous system that is involved in maintaining and restoring body functions.
parathyroid hormone (PTH) A hormone that acts on bone to stimulate the activity of cells that dissolve the mineral part of bone.
Parazoa A subgroup of animals lacking specialized tissue types or organs, although they may have several distinct types of cells; the one phylum in this group is the Porifera (sponges).
parenchyma cell A type of plant cell that is thin-walled and alive at maturity.
parenchyma tissue A plant ground tissue that is composed of parenchyma cells.
parental strand The original strand in DNA replication.
parietal lobe One of four lobes of the cerebral cortex of the human brain; receives and interprets sensory input from visual and somatic pathways.
parthenogenesis An asexual process in which an offspring develops from an unfertilized egg.
partial pressure The individual pressure of each gas in the air; the sum of these pressures is known as atmospheric pressure.
particulate inheritance The idea that the determinants of hereditary traits are transmitted intact from one generation to the next.
parturition The birth of an organism.
passive diffusion Diffusion through a membrane without the aid of a transport protein.
passive immunity A type of acquired immunity that confers protection against disease through the direct transfer of antibodies from one individual to another.
passive transport The diffusion of a solute across a membrane in a process that is energetically favorable and does not require an input of energy.
paternal inheritance A pattern in which only the male gamete contributes particular genes to the offspring.
pathogen A microorganism that causes disease symptoms in its host.
pattern formation The process that gives rise to a plant or animal with a particular body structure.
pedal glands Glands in the foot of a rotifer that secrete a sticky substance that aids in attachment to the substrate.
pedicel 1. A flower stalk. 2. A narrow, waistlike point of attachment between the body parts of spiders and some insects.
pedigree analysis An examination of the inheritance of human traits in families.
pedipalps In spiders, a pair of appendages that have various sensory, predatory, or reproductive functions.
peer-review process A procedure in which experts in a particular area evaluate papers submitted to scientific journals.
pelagic zone The open ocean, where the water depth averages 4,000 m and nutrient concentrations are typically low.
penis A male external accessory sex organ found in many animals that is involved in copulation.
pentadactyl limb A limb ending in five digits.
PEP carboxylase An enzyme in C_4 plants that adds CO_2 to phosphoenolpyruvate (PEP) to produce the four-carbon compound oxaloacetate.
pepsin An active enzyme in the stomach that begins the digestion of protein.
peptide bond The covalent bond that links amino acids in a polypeptide.
peptidoglycan A polymer composed of carbohydrates cross-linked with peptides that is an important component of the cell walls of most bacteria.
peptidyl site (P site) One of three sites for tRNA binding in the ribosome during translation; the other two are the aminoacyl site (A site) and the exit site (E site). The P site holds the tRNA carrying the growing polypeptide chain.
peptidyl transfer reaction During translation, the transfer of the polypeptide from the tRNA in the P site to the amino acid at the A site.
per capita growth rate The per capita birth rate minus the per capita death rate; the rate that determines how populations grow over any time period.
perception An awareness of the sensations that are experienced.
perennial A plant that lives for more than 2 years, often producing seeds each year after it reaches reproductive maturity.
perfect flower A flower that has both stamens and carpels.
perianth The term that refers to flower petals and sepals collectively.
pericarp The wall of a plant's fruit.
pericycle A cylinder of plant tissue having cell division (meristematic) capacity that encloses the root vascular tissue.
peripheral membrane protein A protein that is noncovalently bound to regions of integral membrane proteins that project out from the membrane, or they are noncovalently bound to the polar head groups of phospholipids.
peripheral nervous system (PNS) In vertebrates, all nerves and ganglia outside the brain and spinal cord.
peripheral zone The area of a plant shoot meristem that contains dividing cells that will eventually differentiate into plant structures.
periphyton Communities of microorganisms that are attached by mucilage to underwater surfaces such as rocks, sand, and plants.
peristalsis In animals, the rhythmic, spontaneous waves of muscle contractions that propel food through the digestive system.
peritubular capillaries Capillaries near the junction of the cortex and medulla that surround the nephron of the mammalian kidney.
permafrost A layer of permanently frozen soil found in tundra.
peroxisome A relatively small organelle found in all eukaryotic cells that catalyzes detoxifying reactions.
personalized medicine A medical practice in which information about a patient's genotype is used to individualize their medical care.
petal A flower organ that usually serves to attract insects or other animals for pollen transport.
petiole A stalk that connects a leaf to the stem of a plant.
P generation The parental generation in a genetic cross.
pH The mathematical expression of a solution's hydrogen ion concentration, defined as the negative logarithm to the base 10 of the H^+ concentration.
phage *See* bacteriophage.
phagocyte A cell capable of phagocytosis; phagocytes provide nonspecific defense against pathogens that enter the body.
phagocytic vacuole A vacuole that functions in the degradation of food particles or bacteria; also called a food vacuole.
phagocytosis A form of endocytosis that involves the formation of a membrane vesicle, called a phagocytic vacuole, which engulfs a particle such as a bacterium.
phagotroph An organism that specializes in phagotrophy (particle feeding) by means of phagocytosis as a form of nutrition.
pharyngeal slit A defining characteristic of all chordate embryos. In early-diverging chordates, pharyngeal slits develop into a filter-feeding device, and in some advanced chordates, they form gills.
pharynx A portion of the vertebrate alimentary canal; also known as the throat.
phenolics A group of secondary metabolites that contain a benzene ring covalently linked to a single hydroxyl group. Includes tannins, lignins, and flavonoids.
phenotype The characteristics of an organism that are the result of the expression of its genes.
pheromone A powerful chemical attractant used to manipulate the behavior of others.
phloem A specialized conducting tissue in a plant's stem.
phloem loading The process of conveying sugars to sieve-tube elements for long-distance transport.
phoresy A form of commensalism in which individuals of one species use individuals of a second species for transportation.
phosphodiesterase An enzyme that breaks down cAMP into AMP.
phosphodiester linkage Refers to a double linkage (two phosphoester bonds) that holds together adjacent nucleotides in DNA and RNA strands.
phospholipid A class of lipids that are similar in structure to triglycerides, but the third hydroxyl group of glycerol is linked to a phosphate group instead of a fatty acid; a key component of biological membranes.
phospholipid bilayer The basic framework of the cellular membrane, consisting of two layers of lipids.
phosphorylation The attachment of a phosphate to a molecule.
photic zone A fairly narrow zone close to the surface of an aquatic environment, where light is sufficient to allow photosynthesis to exceed respiration.
photoautotroph An organism that uses the energy from light to make organic molecules from inorganic sources.
photoheterotroph An organism that is able to use light energy to generate ATP but must take in organic compounds from the environment.

photon A discrete particle that makes up light. A photon is massless and travels in a wavelike pattern.
photoperiodism A plant's ability to measure and respond to amounts of light; used as a way of detecting seasonal change.
photoreceptor A specialized cell in an animal that responds to visible light energy.
photorespiration The metabolic process occurring in C_3 plants that occurs when the enzyme rubisco combines with oxygen instead of carbon dioxide and produces only one molecule of 3PG instead of two, thereby reducing photosynthetic efficiency.
photosynthesis The process whereby light energy is captured by plant, algal, or bacterial cells and is used to synthesize organic molecules from CO_2 and H_2O (or H_2S).
photosystem I (PSI) A distinct complex of proteins and pigment molecules in chloroplasts that absorbs light during the light reactions of photosynthesis.
photosystem II (PSII) A distinct complex of proteins and pigment molecules in chloroplasts that generates oxygen from water during the light reactions of photosynthesis.
phototropin The main blue-light sensor involved in phototropism in plants.
phototropism The tendency of a plant to grow toward a light source.
phylogenetic tree A diagram that describes a phylogeny; such a tree is a hypothesis of the evolutionary relationships among various species, based on the information available to and gathered by systematists.
phylogeny The evolutionary history of a species or group of species.
phylum (plural, **phyla**) In taxonomy, a subdivision of a kingdom.
physical mutagen A physical agent, such as UV light, that causes mutations.
physiological ecology A subdiscipline of organismal ecology that investigates how organisms are physiologically adapted to their environment and how the environment impacts the distribution of species.
physiology The study of the functions of cells and body parts of living organisms.
phytochrome A red and far-red-light receptor in plants.
phytoplankton Microscopic photosynthetic protists that float in the water column or actively move through water.
phytoremediation The process of removing harmful metals from soils by growing hyperaccumulator plants on metal-contaminated soils, then harvesting and burning the plants to ashes for disposal and/or metal recovery.
pigment A molecule that can absorb light energy.
pili (singular, **pilus**) Threadlike surface appendages that allow prokaryotes to attach to each other during mating or to move across surfaces.
piloting A mechanism of migration in which an animal moves from one familiar landmark to the next.
pinnate A type of leaf vein pattern in which veins appear feather-like.
pinocytosis A form of endocytosis that involves the formation of membrane vesicles from the plasma membrane as a way for cells to internalize the extracellular fluid.
pistil A flower structure that may consist of a single carpel or multiple, fused carpels and is differentiated into stigma, style, and ovary.
pit A thin-walled circular area in a plant cell wall where secondary wall materials such as lignin are absent and through which water moves.
pitch The tone of a sound wave that depends on its length and frequency.
pituitary dwarfism A condition in which a person's anterior pituitary gland fails to make adequate amounts of GH during childhood; results in stunted growth. The currently accepted name is short stature.
pituitary giant A person who has a tumor of the GH-secreting cells of the anterior pituitary gland and thus produces excess GH during childhood and, if untreated, during adulthood; the person can grow very tall before growth ceases after puberty.
pituitary gland A multilobed endocrine gland sitting directly below the hypothalamus of the brain.
placenta A structure through which humans and other eutherian mammals retain and nourish their young within the uterus via the transfer of nutrients and gases.
placental transfer tissue In plants, a nutritive tissue that aids in the transfer of nutrients from maternal parent to embryo.
plant A multicellular eukaryotic organism that is photosynthetic, generally lives on land, and is adapted in many ways to cope with the environmental stresses of life on land.
Plantae A eukaryotic kingdom of the domain Eukarya.
plant tissue culture A laboratory process to produce thousands of identical plants having the same desirable characteristics.
plaque 1. A deposit of lipids, fibrous tissue, and smooth muscle cells that may develop inside arterial walls. 2. A bacterial biofilm that may form on the surfaces of teeth.
plasma The fluid part of blood that contains water and dissolved solutes.
plasma cell A cell that synthesizes and secretes antibodies.
plasma membrane The biomembrane that separates the internal contents of a cell from its external environment.
plasmid A small circular piece of DNA found naturally in many strains of bacteria and occasionally in eukaryotic cells; can be used as a vector in cloning experiments.
plasmodesma (plural, **plasmodesmata**) A membrane-lined, ER-containing channel that connects the cytoplasm of adjacent plant cells.
plasmogamy The fusion of the cytoplasm between two gametes.
plasmolysis The shrinkage of algal or plant cytoplasm that occurs when water leaves the cell by osmosis, with the result that the plasma membrane no longer presses on the cell wall.
plastid A general name given to organelles found in plant and algal cells that are bound by two membranes and contain DNA and large amounts of either chlorophyll (in chloroplasts), carotenoids (in chromoplasts), or starch (in amyloplasts).
platelets Cell fragments in the blood of mammals that play a crucial role in the formation of blood clots.
pleiotropy The phenomenon in which a mutation in a single gene can have multiple effects on an individual's phenotype.
pleural sac A double layer of moist sheathlike membranes that encases each lung.
pluripotent Refers to the ability of embryonic stem cells to differentiate into almost every cell type of the body.
point mutation A mutation that affects only a single base pair within DNA or that involves the addition or deletion of a single base pair to a DNA sequence.
polar cell The highest latitude cell in the three-cell model of atmospheric circulation.
polar covalent bond A covalent bond between two atoms that have different electronegativities; the shared electrons are closer to the atom of higher electronegativity than the atom of lower electronegativity. This distribution of electrons around the atoms creates a polarity, or difference in electric charge, across the molecule.
polarized 1. In cell biology, refers to cells that have different sides, such as the apical and basal sides of epithelial cells. 2. In neuroscience, refers to the electrical gradient across a neuron's plasma membrane.
polar molecule A molecule containing significant numbers of polar bonds.
polar transport The process whereby auxin flows primarily downward in shoots.
pole A structure of the spindle apparatus defined by each centrosome.
pollen In seed plants, tiny male gametophytes enclosed by sporopollenin-containing microspore walls.
pollen coat A layer of material that covers the sporopollenin-rich pollen wall.
pollen grain The immature male gametophyte of a seed plant.
pollen tube In seed plants, a long, thin tube produced by a pollen grain that delivers sperm to the ovule.
pollen wall A tough, sporopollenin wall at the surface of a pollen grain.
pollination The process in which pollen grains are transported to an angiosperm flower or a gymnosperm cone primarily by means of wind or animal pollinators.
pollination syndromes The pattern of coevolved traits between particular types of flowers and their specific pollinators.
pollinator An animal that carries pollen between angiosperm flowers or cones of gymnosperms.
polyandry A mating system in which one female mates with several males, but males mate with only one female.
poly A tail A string of adenine nucleotides at the 3′ end of most mature mRNAs in eukaryotes.
polycistronic mRNA An mRNA that contains the coding sequences for two or more structural genes.
polycythemia A condition of increased hemoglobin due to increased hematocrit.
polygenic A trait in which several or many genes contribute to the outcome of the trait.
polygyny A mating system in which one male mates with several females in a single breeding season, but females mate with only one male.
polyketides A group of secondary metabolites produced by diverse organisms. Examples include streptomycin, erythromycin, and tetracycline.
polymer A large molecule formed by linking many smaller molecules called monomers.
polymerase chain reaction (PCR) A technique to make many copies of a gene in vitro; primers are used that flank the region of DNA to be amplified.
polymorphic gene A gene that commonly exists as two or more alleles in a population.
polymorphism The phenomenon that many traits or genes may display variation within a population.

polyp A type of cnidarian body form that is sessile and occurs mouth up.
polypeptide A linear sequence of amino acids; the term denotes structure.
polyphagous Parasites that feed on many host species.
polyphyletic group A group of organisms that consists of members of several evolutionary lines and does not include the most recent common ancestor of the included lineages.
polyploid An organism that has three or more sets of chromosomes.
polyploidy In an organism, the state of having three or more sets of chromosomes.
polysaccharide Many monosaccharides linked to form long polymers.
pons The part of the vertebrate hindbrain, along with the cerebellum, responsible for monitoring and coordinating body movements.
population A group of individuals of the same species that occupy the same environment and can interbreed with one another.
population ecology The study of how populations grow and what factors promote or limit growth.
population genetics The study of genes and genotypes in a population.
portal vein A vein that not only collects blood from capillaries—like all veins—but also forms another set of capillaries, as opposed to returning the blood directly to the heart.
positional information Molecules that are provided to a cell that allow it to determine its position relative to other cells.
positive control Transcriptional regulation by activator proteins.
positive feedback loop In animals, the acceleration of a process, leading to what is sometimes called an explosive system.
positive pressure filling The method by which amphibians ventilate their lungs. The animals gulp air and force it under pressure into the lungs, as if inflating a balloon.
postabsorptive state One of two alternating phases in the utilization of nutrients; occurs when the gastrointestinal tract is empty of nutrients and the body's own stores must supply energy. The other phase is the absorptive state.
postanal tail A defining characteristic of all chordate embryos; consists of a tail of variable length that extends posterior to the anal opening.
posterior Refers to the rear (tail-end) of an animal.
postsynaptic cell The cell that receives the electrical or chemical signal sent from a neuron.
post-translational covalent modification A process of changing the structure of a protein, usually by covalently attaching functional groups; this process greatly increases the diversity of the proteome.
post-translational sorting The uptake of proteins into the nucleus, mitochondria, chloroplasts, or peroxisomes that occurs after the protein is completely made in the cytosol (that is, completely translated).
postzygotic isolating mechanism A mechanism that prevents interbreeding by blocking the development of a viable and fertile individual after fertilization has taken place.
potential energy The stored energy that a substance possesses due to its structure or location.
power stroke In muscle, a conformation change in the myosin cross-bridge that results in binding between myosin and actin and the movement of the actin filament.
P protein Phloem protein; the proteinaceous material used by plant phloem as a response to wounding.
prebiotic soup The medium formed by the slow accumulation of organic molecules in the early oceans over a long period of time prior to the existence of life.
predation An interaction in which the action of a predator results in the death of its prey.
predator An animal that kills its prey.
prediction An expected outcome based on a hypothesis that can be shown to be correct or incorrect through observation or experimentation.
pregnancy The time during which a developing embryo and fetus grows within the uterus of the mother. The period of pregnancy is also known as gestation.
preinitiation complex The structure of the completed assembly of RNA polymerase II and GTFs at the TATA box prior to transcription of eukaryotic structural genes.
pre-mRNA In eukaryotes, the mRNA transcript prior to any processing.
pressure-flow hypothesis Explains sugar translocation in plants as a process driven by differences in turgor pressure between cells of a sugar source, where sugar is produced, and cells of a sugar sink, where sugar is consumed.
pressure potential (P) The component of water potential due to hydrostatic pressure.
presynaptic cell The neuron that sends an electrical or chemical signal to another cell.
prezygotic isolating mechanism A mechanism that stops interbreeding by preventing the formation of a zygote.
primary active transport A type of transport that involves pumps that directly use energy to transport a solute against a gradient.
primary cell wall In plants, a relatively thin and flexible cell wall that is synthesized first between two newly made daughter cells.
primary consumer An organism that obtains its food by eating primary producers; also called a herbivore.
primary electron acceptor The molecule to which a high-energy electron from an excited pigment molecule such as $P680^*$ is transferred during photosynthesis.
primary endosymbiosis The process by which a eukaryotic host cell acquires prokaryotic endosymbionts. Mitochondria and the plastids of green and red algae are examples of organelles that originated with primary endosymbiosis.
primary growth Plant growth that occurs from primary meristems and produces primary tissues and organs of diverse types.
primary immune response The response to an initial exposure to an antigen.
primary meristem A meristematic tissue that increases plant length and produces new organs.
primary metabolism The synthesis and breakdown of molecules and macromolecules that are found in all forms of life and are essential for cell structure and function.
primary oocytes In animals, cells that undergo meiosis to begin the process of egg production.
primary plastid A plastid that originated from a prokaryote as the result of primary endosymbiosis.
primary producer An autotroph, which typically harvests light energy from the sun; located at the base of the food chain.
primary spermatocytes In animals, cells that undergo meiosis to begin the process of sperm production.
primary structure The linear sequence of amino acids of a polypeptide; one of four levels of protein structure.
primary succession Succession on newly exposed sites that were not previously occupied by soil and vegetation.
primary vascular tissue Plant tissue composed of primary xylem and phloem, which is the conducting tissue of nonwoody plants.
primer A short segment of RNA, typically 10 to 12 nucleotides in length, that is needed to begin DNA replication.
primordial germ cells (PGCs) In animals, the embryonic cells that eventually give rise to gametes.
principle of parsimony The concept that the preferred hypothesis is the one that is the simplest.
principle of species individuality A view of the nature of a community in which each species is distributed according to its physiological needs and population dynamics; most communities intergrade continuously, and competition does not create distinct vegetational zones.
prion An infectious protein that causes disease by inducing the abnormal folding of other protein molecules.
probability The chance that an event will have a particular outcome.
proboscis The coiled tongue of a butterfly or moth, which can be uncoiled, enabling it to drink nectar from flowers.
procambium In plants, a type of primary tissue meristem that produces vascular tissue.
producer An organism that synthesizes the organic compounds used by other organisms for food.
product The end result of a chemical reaction.
production efficiency The percentage of energy assimilated by an organism that becomes incorporated into new biomass.
productivity hypothesis The proposal that greater production by plants results in greater overall species richness.
product rule The probability that two or more independent events will occur is equal to the product of their individual probabilities.
progesterone A hormone secreted by the female ovaries that plays a key role in pregnancy.
progymnosperms An extinct group of plants having wood but not seeds, which evolved before the gymnosperms.
prokaryote One of the two categories into which all forms of life can be placed. Prokaryotes lack a nucleus and include bacteria and archaea.
prokaryotic Refers to organisms having cells lacking a membrane-enclosed nucleus and cell compartmentalization; includes all members of the domains Bacteria and Archaea.
prometaphase The phase of mitosis during which the mitotic spindle is completely formed.
promiscuous In ecology, a term for animals that have different sexual mates every year or breeding season.
promoter The site in the DNA where transcription begins.
proofreading The ability of DNA polymerase to identify a mismatched nucleotide and remove it from the daughter strand.
prophage Refers to the DNA of a phage that has become integrated into a bacterial chromosome.
prophase The phase of mitosis during which the chromosomes condense and the nuclear membrane begins to vesiculate.
proplastid Unspecialized structures that form plastids.

prostate gland A structure in the male reproductive system that secretes a thin fluid that protects sperm once they are deposited within the female reproductive tract.
prosthetic group Small molecules that are permanently attached to the surface of an enzyme and aid in catalysis.
protease An enzyme that cuts proteins into smaller polypeptides.
proteasome A molecular machine that is the primary pathway for protein degradation in archaea and eukaryotic cells.
protein A functional unit composed of one or more polypeptides. Each polypeptide is composed of a linear sequence of amino acids.
protein kinase An enzyme that transfers phosphate groups from ATP to a protein.
protein kinase cascade The sequential activation of multiple protein kinases.
protein phosphatase An enzyme responsible for removing phosphate groups from proteins.
protein-protein interactions The specific interactions between proteins that occur during many critical cellular processes.
protein subunit An individual polypeptide within a functional protein; most functional proteins are composed of two or more polypeptides.
proteoglycan A glycosaminoglycan in the extracellular matrix linked to a core protein.
proteolysis A processing event within a cell in which enzymes called proteases cut proteins into smaller polypeptides.
proteome The complete complement of proteins that a cell or organism can make.
proteomics Techniques used to identify and study groups of proteins.
prothoracicotropic hormone (PTTH) A hormone produced in certain invertebrates that stimulates a pair of endocrine glands called the prothoracic glands.
protist A eukaryotic organism that is not a member of the animal, plant, or fungal kingdoms; lives in moist habitats and is typically microscopic in size.
Protista Formerly a eukaryotic kingdom. Most protists can be placed into seven eukaryotic supergroups.
protobiont The term used to describe the first nonliving structures that evolved into living cells.
protoderm In plants, a type of primary tissue meristem that generates the outermost dermal tissue.
proton A positively charged particle found in the nucleus of an atom. The number of protons in an atom is called the atomic number and defines each type of element.
protonephridia Simple excretory organs found in flatworms that are used to filter out wastes and excess water.
proton-motive force *See* H^+ electrochemical gradient.
proto-oncogene A normal gene that, if mutated, can become an oncogene.
protostome An animal whose development exhibits spiral determinate cleavage and in which the blastopore becomes the mouth; includes mollusks, annelid worms, and arthropods.
protozoa A term commonly used to describe diverse heterotrophic protists.
proventriculus The glandular portion of the stomach of a bird.
provirus Refers to viral DNA that has become incorporated into a eukaryotic chromosome.
proximal convoluted tubule The segment of the tubule of the nephron in the kidney that drains Bowman's capsule.
proximate cause A specific genetic and physiological mechanism of behavior.
pseudocoelomate An animal with a pseudocoelom.
P site *See* peptidyl site.
pteridophytes A phylum of vascular plants having euphylls, but not seeds; Pteridophyta.
pulmocutaneous circulation The routing of blood from the heart to the gas exchange organs (lungs and skin) of frogs and some other amphibians.
pulmonary circulation The pumping of blood from the right side of the heart to the lungs to pick up oxygen from the atmosphere and release carbon dioxide.
pulmonary hypertension A condition that usually results from a diseased or damaged left ventricle that fails to pump out the usual amount of blood with each beat of the heart. This causes blood to back up in the pulmonary vessels, raising their pressure.
pulse-chase experiment A procedure in which researchers administer a pulse of radioactively labeled materials to cells so that they make radioactive products. This is followed by the addition of nonlabeled materials called a chase.
pump A transporter that directly couples its conformational changes to an energy source, such as ATP hydrolysis.
punctuated equilibrium A concept that suggests that the tempo of evolution is more sporadic than gradual. Species rapidly evolve into new species followed by long periods of equilibrium with little evolutionary change.
Punnett square A common method for predicting the outcome of simple genetic crosses.
pupa A developmental stage in some insects that undergo metamorphosis; occurs between the larval and adult stages.
pupil A small opening in the eye of a vertebrate that transmits different patterns of light emitted from images in the animal's field of view.
purine The bases adenine (A) and guanine (G), with double rings of carbon and nitrogen atoms.
pyramid of biomass A measure of trophic-level transfer efficiency in which the organisms at each trophic level are weighed.
pyramid of energy A measure of trophic-level transfer efficiency in which rates of energy production are used rather than biomass.
pyramid of numbers An expression of trophic-level transfer efficiency in which the number of individuals decreases at each trophic level, with a huge number of individuals at the base and fewer individuals at the top.
pyrimidine The bases thymine (T), cytosine (C), and uracil (U) with a single ring of carbon and nitrogen atoms.

Q

quadrat A sampling device used by plant ecologists consisting of a square frame that often encloses 0.25 m^2.
quantitative trait A trait that shows continuous variation over a range of phenotypes.
quaternary structure The association of two or more polypeptides to form a protein; one of four levels of protein structure.
quorum sensing A mechanism by which prokaryotic cells are able to communicate by chemical means when they reach a critical population size.

R

radial cleavage A mechanism of animal development in which the cleavage planes are either parallel or perpendicular to the vertical axis of the embryo.
radial loop domain A loop of chromatin, often 25,000 to 200,000 base pairs in size, that is anchored to the nuclear matrix.
radial pattern A characteristic of the body pattern of plants.
radial symmetry 1. In plants, an architectural feature in which embryos display a cylindrical shape, which is retained in the stems and roots of seedlings and mature plants. In addition, new leaves or flower parts are produced in circular whorls, or spirals, around shoot tips. 2. In animals, an architectural feature in which the body can be divided into symmetrical halves by many different longitudinal planes along a central axis.
Radiata Radially symmetric animals; includes cnidarians and ctenophores.
radiation The emission of electromagnetic waves by the surfaces of objects; a method of heat exchange in animals.
radicle An embryonic root, which extends from the plant hypocotyl.
radioisotope An isotope found in nature that is inherently unstable and usually does not exist for long periods of time. Such isotopes decay and emit energy in the form of radiation.
radioisotope dating A common way to estimate the age of a fossil by analyzing the elemental isotopes within the accompanying rock.
radula A unique, protrusible, tonguelike organ in a mollusk that has many teeth and is used to eat plants, scrape food particles off of rocks, or bore into shells of other species.
rain shadow An area on the side of a mountain that is sheltered from the wind and experiences less precipitation.
ram ventilation A mechanism used by fishes to ventilate their gills; fishes swim or face upstream with their mouths open, allowing water to enter into their buccal cavity and across their gills.
random The rarest pattern of dispersion within a population, in which the location of individuals lacks a pattern.
random sampling error The deviation between the observed and the expected outcomes.
rate-limiting step The slowest step in a pathway.
ray-finned fishes The Actinopterygii, which includes all bony fishes except the coelacanths and lungfishes.
reabsorption In the production of urine, the process in which useful solutes in the filtrate are recaptured and transported back into the body fluids of an animal.
reactant A substance that participates in a chemical reaction and becomes changed by that reaction.
reading frame Refers to the way in which codons are read during translation, in groups of three bases beginning with the start codon.
receptacle The enlarged region at the tip of a flower peduncle to which flower parts are attached.
receptor 1. A cellular protein that recognizes a signaling molecule. 2. A structure capable of detecting changes in the environment of an animal, such as a touch receptor.
receptor-mediated endocytosis A common form of endocytosis in which a receptor is specific for a given cargo.

receptor potential The membrane potential in a sensory receptor cell of an animal.
receptor tyrosine kinase A type of enzyme-linked receptor found in animal cells that can attach phosphate groups onto tyrosines that are found in the receptor itself or in other cellular proteins.
recessive A term that describes a trait that is masked by the presence of a dominant trait in a heterozygote.
reciprocal translocation A type of mutation in which two different types of chromosomes exchange pieces, thereby producing two abnormal chromosomes carrying translocations.
recombinant An offspring that has a different combination of traits from the parental generation.
recombinant DNA technology The use of laboratory techniques to isolate and manipulate fragments of DNA.
recombinant vector A vector containing a piece of chromosomal DNA.
recombination frequency The frequency of crossing over between two genes.
red blood cell *See* erythrocyte.
redox reaction A type of reaction in which an electron that is removed during the oxidation of an atom or molecule is transferred to another atom or molecule, which becomes reduced; short for a reduction-oxidation reaction.
reduction A process that involves the addition of electrons to an atom or molecule.
reductionism An approach that involves reducing complex systems to simpler components as a way to understand how the system works. In biology, reductionists study the parts of a cell or organism as individual units.
redundancy hypothesis A biodiversity proposal that is an alternative to the rivet hypothesis. In this model, most species are said to be redundant because they could simply be eliminated or replaced by others with no effect.
reflex arc A simple circuit that allows an organism to respond rapidly to inputs from sensory neurons and consists of only a few neurons.
regeneration A form of asexual reproduction in which a complete organism forms from small fragments of its body.
regulatory element In eukaryotes, a DNA sequence that is recognized by regulatory transcription factors and regulates the expression of genes.
regulatory gene A gene whose function is to regulate the expression of other genes.
regulatory sequence In the regulation of transcription, a DNA sequence that functions as a binding site for genetic regulatory proteins. Regulatory sequences control whether a gene is turned on or off.
regulatory transcription factor A protein that binds to DNA in the vicinity of a promoter and affects the rate of transcription of one or more nearby genes.
relative abundance The frequency of occurrence of species in a community.
relative refractory period The period near the end of an action potential when voltage-gated potassium channels are still open; during this time a new action potential can be generated if a stimulus is sufficiently strong to raise the membrane potential to threshold.
relative water content (RWC) The property often used to gauge the water content of a plant organ or entire plant; RWC integrates the water potential of all cells within an organ or plant and is thus a measure of relative turgidity.
release factor A protein that recognizes a stop codon in the termination stage of translation and promotes the termination of translation.
renal corpuscle A filtering component in the nephron of the kidney.
repetitive sequence Short DNA sequences that are present in many copies in a genome.
replica plating A technique in which a replica of bacterial colonies is transferred from one petri plate to a new petri plate.
replication 1. The copying of DNA strands. 2. The performing of experiments several or many times.
replication fork The area where two DNA strands have separated and new strands are being synthesized.
repressible operon In this type of operon, a small effector molecule inhibits transcription.
repressor A transcription factor that binds to DNA and inhibits transcription.
reproduce To generate offspring by sexual or asexual means.
reproductive cloning The cloning of a multicellular organism, such as a plant or animal.
reproductive isolating mechanisms Mechanisms that prevent interbreeding between different species.
reproductive isolation Refers to the concept that a species cannot successfully interbreed with other species.
reproductive success The likelihood of contributing fertile offspring to the next generation.
resistance (R) The tendency of blood vessels to slow down the flow of blood through their lumens.
resistance gene (R gene) A plant gene that has evolved as part of a defense system in response to pathogen attack.
resolution In microscopy, the ability to observe two adjacent objects as distinct from one another; a measure of the clarity of an image.
resonance energy transfer The process by which energy (not an electron itself) can be transferred to adjacent pigment molecules during photosynthesis.
resource partitioning The differentiation of niches, both in space and time, that enables similar species to coexist in a community.
respiration Metabolic reactions that a cell uses to get energy from food molecules and release waste products.
respiratory centers Several regions of the brainstem in vertebrates that initiate expansion of the lungs.
respiratory chain *See* electron transport chain.
respiratory distress syndrome of the newborn The situation in which a human baby is born prematurely, before sufficient surfactant is produced in the lungs, causing the collapse of many alveoli.
respiratory pigment A large protein that contains one or more metal atoms that bind to oxygen.
respiratory system All components of the body that contribute to the exchange of gas between the external environment and the blood; in mammals, includes the nose, mouth, airways, and lungs and the muscles and connective tissues that encase these structures within the thoracic (chest) cavity.
resting potential The difference in charges across the plasma membrane in an unstimulated neuron.
restoration ecology The full or partial repair or replacement of biological habitats and/or their populations that have been damaged.
rest-or-digest The response of vertebrates to situations associated with nonstressful states, such as feeding; mediated by the parasympathetic branch of the autonomic nervous system.
restriction enzyme An enzyme that recognizes particular DNA sequences and cleaves the DNA backbone at two sites.
restriction point A point in the cell cycle in which a cell has become committed to divide.
restriction sites The base sequences recognized by restriction enzymes.
reticular formation An array of nuclei in the brainstem of vertebrates that plays a major role in controlling states such as sleep and arousal.
retina A sheetlike layer of photoreceptors at the back of the vertebrate eye.
retinal A derivative of vitamin A that is capable of absorbing light energy; a component of visual pigments in the vertebrate eye.
retroelement A type of transposable element that moves via an RNA intermediate.
retrovirus An RNA virus that utilizes reverse transcription to produce viral DNA that can be integrated into the host cell genome.
reverse transcriptase A viral enzyme that catalyzes the synthesis of viral DNA starting with viral RNA as a template.
rhizobia The collective term for proteobacteria involved in nitrogen-fixation symbioses with plants.
rhodopsin The visual pigment in the rods of the vertebrate eye.
ribonucleic acid (RNA) One of two classes of nucleic acids; the other is deoxyribonucleic acid (DNA). RNA consists of a single strand of nucleotides.
ribonucleoprotein A complex between an RNA molecule and a protein.
ribose A five-carbon sugar found in RNA.
ribosomal RNA (rRNA) An RNA that forms part of ribosomes, which provide the site where translation occurs.
ribosome A structure composed of proteins and rRNA that provides the site where polypeptide synthesis occurs.
ribozyme A biological catalyst that is an RNA molecule.
rickets A condition in children characterized by bone deformations due to inadequate mineral intake or malabsorption in the intestines.
right-left axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the dorsoventral axis and the anteroposterior axis.
ring canal A central disc in the water vascular system of echinoderms.
rivet hypothesis An alternative to the diversity-stability hypothesis of biodiversity. In this model, species are like the rivets on an airplane, with each species playing a small but critical role in keeping the plane (the ecosystem) airborne.
RNA *See* ribonucleic acid.
RNA-induced silencing complex (RISC) A complex consisting of miRNA or siRNA and proteins; mediates RNA interference.
RNA interference (RNAi) Refers to a type of mRNA silencing; miRNA or siRNA interferes with the proper expression of an mRNA.
RNA polymerase The enzyme that synthesizes strands of RNA during gene transcription.
RNA processing A step in gene expression between transcription and translation in eukaryotes; the RNA transcript, termed pre-mRNA, is modified in ways that make it a functionally active mRNA.

RNase An enzyme that digests RNA.
RNA world A hypothetical period on primitive Earth when both the information needed for life and the enzymatic activity of living cells were contained solely in RNA molecules.
rods Photoreceptors found in the vertebrate eye; they are very sensitive to low-intensity light but do not readily discriminate different colors. Rods are utilized mostly at night, and they send signals to the brain that generate a black-and-white visual image.
"roid" rage Extremely aggressive behavior brought about by androgen administration.
root A plant organ that provides anchorage in the soil and also fosters efficient uptake of water and minerals.
root apical meristem (RAM) The region of rapidly dividing cells at plant root tips.
root hair A specialized, long, thin root epidermal cell that functions to absorb water and minerals, usually from soil.
root meristem The collection of cells at the root tip that generate all of the tissues of a plant root.
root pressure Osmotic pressure within roots that causes water to rise for some distance through a plant stem, under conditions of high soil moisture or low transpiration.
root-shoot axis The general body pattern of plants in which the root grows downward and the shoot grows upward.
root system The collection of roots and root branches produced by root apical meristems.
rough endoplasmic reticulum (rough ER) The part of the ER that is studded with ribosomes; this region plays a key role in the initial synthesis and sorting of proteins that are destined for the ER, Golgi apparatus, lysosomes, vacuoles, plasma membrane, or outside of the cell.
rRNA *See* ribosomal RNA.
***r*-selected species** A type of life history strategy, where species have a high rate of per capita population growth but poor competitive ability.
rubisco The enzyme that catalyzes the first step in the Calvin cycle in which CO_2 is incorporated into an organic molecule.
Ruffini corpuscle Tactile (touch) receptors in the skin of mammals that respond to deep pressure and vibration.
ruminants Animals such as sheep, goats, llamas, and cows that have complex stomachs consisting of several chambers.

S

saltatory conduction The conduction of an action potential along an axon in which the action potential is regenerated at each node of Ranvier instead of along the entire length of the axon.
sarcoma A tumor of connective tissue such as bone or cartilage.
sarcomere One complete unit of the repeating pattern of thick and thin filaments within a myofibril.
sarcoplasmic reticulum A cellular organelle that provides a muscle fiber's source of the calcium involved in muscle contraction; a specialized form of the endoplasmic reticulum.
satiety A feeling of fullness.
satiety signal A response to eating that removes the sensation of hunger and sets the time period before hunger returns again.
saturated fatty acid A fatty acid in which all the carbons are linked by single covalent bonds.
scanning electron microscopy (SEM) A type of microscopy that utilizes an electron beam to produce an image of the three-dimensional surface of biological samples.
scavenger An animal that eats the remains of dead animals.
Schwann cells The glial cells that form myelin on axons that travel outside the brain and spinal cord.
science In biology, the observation, identification, experimental investigation, and theoretical explanation of natural phenomena.
scientific method A series of steps to test the validity of a hypothesis. This approach often involves a comparison between control and experimental groups.
sclera The white of the vertebrate eye; a strong outer sheath that in the front is continuous with a thin, clear layer known as the cornea.
sclereid Star- or stone-shaped plant cells having tough, lignified cell walls.
sclerenchyma tissue A rigid plant ground tissue composed of tough-walled fibers and sclereids.
secondary active transport A type of membrane transport that involves the utilization of a pre-existing gradient to drive the active transport of another solute.
secondary cell wall A thick rigid plant cell wall that is synthesized and deposited between the plasma membrane and the primary cell wall after a plant cell matures and has stopped increasing in size.
secondary consumer An organism that eats primary consumers; also called a carnivore.
secondary endosymbiosis A process that occurs when a eukaryotic host cell acquires a eukaryotic endosymbiont having a primary plastid.
secondary growth Plant growth that occurs from secondary meristems and increases the girth of woody plant stems and roots.
secondary immune response An immediate and heightened production of additional specific antibodies against the particular antigen that previously elicited a primary immune response.
secondary meristem A meristem in woody plants forming a ring of actively dividing cells that encircle the stem.
secondary metabolism The synthesis of chemicals that are not essential for cell structure and growth and are usually not required for cell survival but are advantageous to the organism.
secondary metabolite Molecules that are produced by secondary metabolism.
secondary oocyte In animals, the large haploid cell that is produced when a primary oocyte undergoes meiosis I during oogenesis.
secondary phloem The inner bark of a woody plant.
secondary plastid A plastid that has originated by the endosymbiotic incorporation of a eukaryotic cell containing a primary plastid into a eukaryotic host cell.
secondary production The measure of production of heterotrophs and decomposers.
secondary spermatocytes In animals, the haploid cells produced when a primary spermatocyte undergoes meiosis I during spermatogenesis.
secondary structure The bending or twisting of proteins into α helices or β sheets; one of four levels of protein structure.
secondary succession Succession on a site that has previously supported life but has undergone a disturbance.
secondary xylem In plants, a type of secondary vascular tissue that is also known as wood.
second law of thermodynamics States that the transfer of energy or the transformation of energy from one form to another increases the entropy, or degree of disorder, of a system.
second messengers Small molecules or ions that relay signals inside the cell.
secretion 1. The export of a substance from a cell. 2. In the production of urine, the process in which some solutes are actively transported into the tubules of the excretory organ; this supplements the amount of a solute that would normally be removed by filtration alone.
secretory pathway A pathway for the movement of larger substances, such as carbohydrates and proteins, out of a cell.
secretory vesicle A membrane vesicle carrying different types of materials that fuses with the cell's plasma membrane to release the contents extracellularly.
seed A reproductive structure having specialized tissues that enclose plant embryos; produced by gymnosperms and flowering plants, usually as the result of sexual reproduction.
seed coat A hard and tough covering that develops from the ovule's integuments and protects a plant embryo.
seed plant The informal name for gymnosperms and angiosperms.
segmentation The division of an animal's body into clearly defined regions.
segmentation gene A gene that controls the segmentation pattern of an animal embryo.
segment-polarity gene A type of segmentation gene; a mutation in this gene causes portions of segments to be missing either an anterior or a posterior region and for adjacent regions to become mirror images of each other.
segregate To separate, as in chromosomes during mitosis.
selectable marker A gene whose presence can allow organisms (such as bacteria) to grow under a certain set of conditions. For example, an antibiotic-resistance gene is a selectable marker that allows bacteria to grow in the presence of the antibiotic.
selective breeding Programs and procedures designed to modify traits in domesticated species.
selectively permeable The property of membranes that allows the passage of certain ions or molecules but not others.
selective serotonin reuptake inhibitors Drugs used to treat major depressive disorder that act by increasing concentrations of serotonin in the brain.
self-fertilization Fertilization that involves the union of a female gamete and male gamete from the same individual.
self-incompatibility (SI) Rejection of pollen that is genetically too similar to the pistil of a plant.
selfish DNA hypothesis The hypothesis that transposable elements exist because they have the characteristics that allow them to insert themselves into the host cell DNA but do not provide any advantage.
self-pollination The process in which pollen from the anthers of a flower is transferred to the stigma of the same flower or between flowers of the same plant.
self-splicing The phenomenon that RNA itself can catalyze the removal of its own intron(s); occurs in rRNA and tRNA.
SEM *See* scanning electron microscopy.
semelparity A reproductive pattern in which organisms produce all of their offspring in a single reproductive event.
semen A mixture containing fluid and sperm that is released during ejaculation.

semicircular canals Structures of the vertebrate ear that can detect circular motions of the head.
semiconservative mechanism The correct model for DNA replication; double-stranded DNA is half conserved following replication, resulting in new double-stranded DNA containing one parental strand and one daughter strand.
semifluid A quality of motion within biomembranes; considered two-dimensional because movement occurs only within the plane of the membrane.
semilunar valves One-way valves into the systemic and pulmonary arteries through which blood is pumped from the ventricles.
seminal vesicles Paired accessory glands in the male reproductive system that secrete fructose, the main nutrient for sperm, into the urethra.
seminiferous tubule A tightly packed tubule in the testis, where spermatogenesis takes place.
senescent Cells that have doubled many times and have reached a point where they have lost the capacity to divide any further.
sense A system in an animal that consists of sensory cells that respond to a specific type of chemical or physical stimulus and send signals to the central nervous system, where the signals are received and interpreted.
sensory neuron A neuron that detects or senses information from the outside world, such as light, sound, touch, and heat; sensory neurons also detect internal body conditions such as blood pressure and body temperature.
sensory receptor In animals, a specialized cell whose function is to receive sensory inputs.
sensory transduction The process by which incoming stimuli are converted into neural signals.
sepal A flower organ that occurs in a whorl located outside whorls of petals of eudicot plants.
septum (plural, **septa**) A cross wall; examples include the cross walls that divide the hyphae of most fungi into many small cells and the structure that separates the old and new chambers of a nautilus.
sere Each phase of succession in a community; also called a seral stage.
setae Chitinous bristles in the integument of many invertebrates.
set point The normal value for a controlled variable, such as blood pressure, in an animal.
sex chromosomes A distinctive pair of chromosomes that are different in males and females.
sex-influenced inheritance The phenomenon in which an allele is dominant in one sex but recessive in the other.
sex linked Refers to genes that are found on one sex chromosome but not on the other.
sex pili Hairlike structures made by bacterial F^+ cells that bind specifically to other F^- cells.
sexual dimorphism A pronounced difference in the morphologies of the two sexes within a species.
sexual reproduction A process that requires a fertilization event in which two gametes unite to produce a cell called a zygote.
sexual selection A type of natural selection that is directed at certain traits of sexually reproducing species that make it more likely for individuals to find or choose a mate and/or engage in successful mating.
Shannon diversity index (H_S) A means of measuring the diversity of a community; $H_S = -\Sigma p_i \ln p_i$.
shared derived character A trait that is shared by a group of organisms but not by a distant common ancestor.
shared primitive character A trait shared with a distant ancestor.
shattering The process by which ears of wild grain crops break apart and disperse seeds.
shell A tough, protective covering on an amniotic egg that is impermeable to water and prevents the embryo from drying out.
shivering thermogenesis Rapid muscle contractions in an animal, without any locomotion, in order to raise body temperature.
shoot The portion of a plant comprised of stems and leaves.
shoot apical meristem (SAM) The region of rapidly dividing plant cells at plant shoot apices.
shoot meristem The tissue that produces all aerial parts of the plant, which include the stems as well as lateral structures such as leaves and flowers.
shoot system The collection of plant organs produced by shoot apical meristems.
short-day plant A plant that flowers only when the night length is longer than a defined period.
short stature A condition characterized by stunted growth; formerly called pituitary dwarfism.
short tandem repeat sequences (STRs) Short sequences repeated many times in a row and found in multiple sites in the genome of humans and other species; often vary in length among different individuals.
shotgun DNA sequencing A strategy for sequencing an entire genome by randomly sequencing many different DNA fragments.
sickle-cell disease A disease due to a genetic mutation in a hemoglobin gene in which sickle-shaped red blood cells are less able to move smoothly through capillaries and can block blood flow, resulting in severe pain and cell death of the surrounding tissue.
sieve plate The perforated end wall of a mature sieve-tube element.
sieve plate pore One of many perforations in a plant's sieve plate.
sieve-tube elements A component of the phloem tissues of flowering plants; thin-walled cells arranged end to end to form transport pipes.
sigma factor A protein that plays a key role in bacterial promoter recognition and recruits RNA polymerase to the promoter.
signal Regarding cell communication, an incoming or outgoing agent that influences the properties of cells.
signal recognition particle (SRP) A protein/RNA complex that recognizes the ER signal sequence of a polypeptide, pauses translation, and directs the ribosome to the ER to complete translation.
signal transduction pathway A group of proteins that convert an initial signal to a different signal inside a cell.
sign stimulus In animals, a trigger that initiates a fixed-action pattern of behavior.
silencer A regulatory element in eukaryotes that prevents transcription of a given gene.
silencing RNAs (siRNAs) Small RNA molecules, typically 22 nucleotides in length, that silence the expression of specific mRNAs by promoting their degradation.
silent mutation A gene mutation that does not alter the amino acid sequence of the polypeptide, even though the nucleotide sequence has changed.
simple Mendelian inheritance The inheritance pattern of traits affected by a single gene that is found in two variants, one of which is completely dominant over the other.
simple translocation A type of mutation in which a single piece of chromosome is attached to another chromosome.
single-factor cross *See* monohybrid cross.
single nucleotide polymorphism (SNP) A type of genetic variation in a population in which a particular gene sequence varies at a single nucleotide.
single-strand binding protein A protein that binds to both of the single strands of parental DNA and prevents them from re-forming a double helix during DNA replication.
sinoatrial (SA) node A collection of modified cardiac cells in the right atrium of most vertebrates that spontaneously and rhythmically generates action potentials that spread across the entire atria; also known as the pacemaker of the heart.
siRNAS *See* silencing RNAs.
sister chromatids The two duplicated chromatids that are still joined to each other after DNA replication.
skeletal muscle A type of muscle tissue that is attached by tendons to bones in vertebrates and to the exoskeleton of invertebrates.
skeleton A structure or structures that serve one or more functions related to support, protection, and locomotion.
sliding filament mechanism The way in which a muscle fiber shortens during muscle contraction.
SLOSS debate In conservation biology, the debate over whether it is preferable to protect one single, large reserve or several smaller ones.
slow block to polyspermy Events initiated by the release of Ca^{2+} that produce barriers to more sperm penetrating an already fertilized egg.
slow fiber A skeletal muscle fiber containing myosin with a low rate of ATP hydrolysis.
slow-oxidative fiber A skeletal muscle fiber that has a low rate of myosin ATP hydrolysis but has the ability to make large amounts of ATP; used for prolonged, regular activity.
small effector molecule With regard to transcription, refers to a molecule that exerts its effects by binding to a regulatory transcription factor, causing a conformational change in the protein.
small intestine In vertebrates, a tube that leads from the stomach to the large intestine where nearly all digestion of food and absorption of food nutrients and water occur.
smooth endoplasmic reticulum (smooth ER) The part of the ER that is not studded with ribosomes. This region is continuous with the rough ER and functions in diverse metabolic processes such as detoxification, carbohydrate metabolism, accumulation of calcium ions, and synthesis and modification of lipids.
smooth muscle A type of muscle tissue that surrounds hollow tubes and cavities inside the body's organs; it is not under conscious control.
soil horizon Layers of soil, ranging from topsoil to bedrock.
solute A substance dissolved in a liquid.
solute potential (S) The component of water potential due to the presence of solute molecules.
solution A liquid that contains one or more dissolved solutes.
solvent The liquid in which a solute is dissolved.
soma *See* cell body.
somatic cell The type of cell that constitutes all cells of an animal or plant body except those that give rise to gametes.
somatic embryogenesis The production of plant embryos from body (somatic) cells.
somatic nervous system The division of the peripheral nervous system that senses the external environmental conditions and controls skeletal muscles.

somites Blocklike structures resulting from the segmentation of mesoderm during neurulation.
soredia An asexual reproductive structure produced by lichens consisting of small clumps of hyphae surrounding a few algal cells that can disperse in wind currents.
sorting signal A short amino acid sequence in a protein that directs the protein to its correct location; also known as a traffic signal.
source pool The pool of species on the mainland that is available to colonize an island.
spatial summation Occurs when two or more postsynaptic potentials are generated at one time along different regions of the dendrites and their depolarizations and hyperpolarizations sum together.
speciation The formation of new species.
species A group of related organisms that share a distinctive form in nature and (for sexually reproducing species) are capable of interbreeding.
species-area effect The relationship between the amount of available area and the number of species present.
species concepts Different approaches for distinguishing species.
species diversity A measure of biological diversity that incorporates both the number of species in an area and the relative distribution of individuals among species.
species interactions A part of the study of population ecology that focuses on interactions such as predation, competition, parasitism, mutualism, and commensalism.
species richness The numbers of species in a community.
specific heat The amount of energy required to raise the temperature of 1 gram of a substance by 1°C.
specific (acquired) immunity An immunity defense that develops only after the body is exposed to foreign substances; believed to be unique to vertebrates.
specificity Refers to the concept that enzymes recognize specific substrates.
Spemann's organizer An extremely important morphogenetic field in the early gastrula; the organizer secretes morphogens responsible for inducing the formation of a new embryonic axis.
spermatids In animals, the haploid cells produced when the secondary spermatocytes undergo meiosis II; these cells eventually differentiate into sperm cells.
spermatogenesis Gametogenesis in a male animal resulting in the production of sperm.
spermatogonia (singular, **spermatogonium**) In animals, diploid germ cells that give rise to the male gametes, the spermatozoa.
spermatophytes All of the living and fossil seed plant phyla.
sperm cell Refers to a male gamete that is generally smaller than the female gamete (egg); also called a sperm.
sperm storage A method of synchronizing the production of offspring with favorable environmental conditions in which female animals store and nourish sperm in their reproductive tract for long periods of time.
S phase The DNA synthesis phase of the cell cycle.
spicules Needle-like structures that are usually made of silica and form lattice-like skeletons in sponges, possibly helping to reduce predation.
spinal cord In chordates, the structure that connects the brain to all areas of the body and together with the brain constitutes the central nervous system.
spinal nerve A nerve that connects the peripheral nervous system and the spinal cord.
spiracle A pore on the body surface of insects that leads to the trachea.
spiral cleavage A mechanism of animal development in which the planes of cell cleavage are oblique to the axis of the embryo.
spirilli Rigid, spiral-shaped prokaryotic cells.
spirochaetes Flexible, spiral-shaped prokaryotic cells.
spliceosome A complex of several subunits known as snRNPs that removes introns from eukaryotic pre-mRNA.
splicing The process whereby introns are removed from RNA and the remaining exons are connected to each other.
spongin A tough protein that lends skeletal support to a sponge.
spongocoel A central cavity in the body of a sponge.
spongy parenchyma Photosynthetic ground tissue of the plant leaf mesophyll that contains round cells separated by abundant air spaces.
spontaneous mutation A mutation resulting from abnormalities in biological processes.
sporangia Structures that produce and disperse the spores of plants, fungi, or protists.
spore A haploid, typically single-celled reproductive structure of fungi and plants that is dispersed into the environment and is able to grow into a new fungal mycelium or plant gametophyte in a suitable habitat.
sporic life cycle *See* alternation of generations.
sporophyte The diploid generation of plants or multicellular protists that have a sporic life cycle; this generation produces haploid spores by the process of meiosis.
sporopollenin The tough material that composes much of the walls of plant spores and helps to prevent cellular damage during transport in air.
stabilizing selection A pattern of natural selection that favors the survival of individuals with intermediate phenotypes.
stamen A flower organ that produces the male gametophyte, pollen.
standard metabolic rate (SMR) The metabolic rate of ectotherms measured at a standard temperature for each species—one that approximates the average temperature that a species normally encounters.
standing crop The total biomass in an ecosystem at any one point in time.
starch A polysaccharide composed of repeating glucose units that is produced by the cells of plants and some algal protists.
start codon A three-base sequence—usually AUG—that specifies the first amino acid in a polypeptide.
statocyst An organ of equilibrium found in many invertebrate species.
statoliths 1. Tiny granules of sand or other dense objects located in a statocyst that aid equilibrium in many invertebrates. 2. In plants, a starch-heavy plastid that allows both roots and shoots to detect gravity.
stem A plant organ that produces buds, leaves, branches, and reproductive structures.
stem cell A cell that divides so that one daughter cell remains a stem cell and the other can differentiate into a specialized cell type. Stem cells construct the bodies of all animals and plants.
stereocilia Deformable projections from epithelial cells called hair cells that are bent by movements of fluid or other stimuli.
stereoisomers Isomers with identical bonding relationships, but different spatial positioning of their atoms.
sternum The breastbone of a vertebrate.
steroid A lipid containing four interconnected rings of carbon atoms; functions as a hormone in animals and plants.
steroid receptor A transcription factor that recognizes a steroid hormone and usually functions as a transcriptional activator.
sticky ends Single-stranded ends of DNA fragments that will hydrogen-bond to each other due to their complementary sequences.
stigma In a flower, the topmost portion of the pistil, which receives and recognizes pollen of the appropriate species or genotype.
stomach A saclike organ in some animals that most likely evolved as a means of storing food; it partially digests some of the macromolecules in food and regulates the rate at which the contents empty into the small intestine.
stomata Surface pores on plant surfaces that can be closed to retain water or open to allow the entry of CO_2 needed for photosynthesis and the exit of oxygen and water vapor.
stop codon One of three three-base sequences—UAA, UAG, and UGA—that signals the end of translation; also called termination codon or nonsense codon.
strain Within a given species, a lineage that has genetic differences compared to another lineage.
strand A structure of DNA (or RNA) formed by the covalent linkage of nucleotides in a linear manner.
strepsirrhini Smaller species of primates; includes bush babies, lemurs, and pottos.
stretch receptor A type of mechanoreceptor found widely in an animal's organs and muscle tissues that can be distended.
striated muscle Skeletal and cardiac muscle with a series of light and dark bands perpendicular to the muscle's long axis.
stroke The condition that occurs when blood flow to part of the brain is disrupted.
stroke volume (SV) The amount of blood ejected with each beat, or stroke, of the heart.
stroma The fluid-filled region of the chloroplast between the thylakoid membrane and the inner membrane.
stromatolite A layered calcium carbonate structure in an aquatic environment generally produced by cyanobacteria.
strong acid An acid that completely ionizes in solution.
structural gene Refers to most genes, which produce an mRNA molecule that contains the information to specify a polypeptide with a particular amino acid sequence.
structural isomers Isomers that contain the same atoms but in different bonding relationships.
style In a flower, the elongate portion of the pistil through which the pollen tube grows.
stylet A sharp, piercing organ in the mouth of nematodes and some insects.
submetacentric A chromosome in which the centromere is off center.
subsidence zones Areas of high pressure that are the sites of the world's tropical deserts because the subsiding air is relatively dry, having released all of its moisture over the equator.
subspecies A subdivision of a species; this designation is used when two or more geographically restricted groups of the same species differ, but not enough to warrant their placement into separate species.
substrate 1. The reactant molecules and/or ions that bind to an enzyme at the active site and participate in a chemical reaction. 2. The organic

compounds such as soil or rotting wood that fungi use as food.

substrate-level phosphorylation A method of synthesizing ATP that occurs when an enzyme directly transfers a phosphate from an organic molecule to ADP.

succession The gradual and continuous change in species composition and community structure over time.

sugar sink The plant tissues or organs in which more sugar is consumed than is produced by photosynthesis.

sugar source The plant tissues or organs that produce more sugar than they consume in respiration.

sum rule The probability that one of two or more mutually exclusive outcomes will occur is the sum of the probabilities of the possible outcomes.

supergroup One of the seven subdivisions of the domain Eukarya.

surface area/volume (SA/V) ratio The ratio between a structure's surface area and the volume in which the structure is contained.

surface tension A measure of how difficult it is to break the interface between a liquid and air.

surfactant A mixture of proteins and amphipathic lipids produced in certain alveolar cells that prevents the collapse of alveoli by reducing surface tension in the lungs.

survivorship curve A graphical plot of the numbers of surviving individuals at each age in a population.

suspension feeder An aquatic animal that sifts water, filtering out the organic matter and expelling the rest.

suspensor A short chain of cells at the base of an early angiosperm embryo that provides anchorage and nutrients.

swim bladder A gas-filled, balloon-like structure that helps a fish to remain buoyant in the water even when the fish is completely stationary.

symbiosis An intimate association between two or more organisms of different species.

symbiotic Describes a relationship in which two or more different species live in direct contact with each other.

sympathetic division The division of the autonomic nervous system that is responsible for rapidly activating body systems to provide immediate energy in response to danger or stress.

sympatric The term used to describe species occurring in the same geographic area.

sympatric speciation A form of speciation that occurs when members of a species that initially occupy the same habitat within the same range diverge into two or more different species.

symplast All of a plant's protoplasts (the cell contents without the cell walls) and plasmodesmata.

symplastic transport The movement of a substance from the cytosol of one cell to the cytosol of an adjacent cell via membrane-lined channels called plasmodesmata.

symplesiomorphy *See* shared primitive character.

symporter A type of transporter that binds two or more ions or molecules and transports them in the same direction across a membrane; also called a cotransporter.

synapomorphy *See* shared derived character.

synapse A junction where a nerve terminal meets a target neuron, muscle cell, or gland and through which an electrical or chemical signal passes.

synapsis The process of forming a bivalent.

synaptic cleft The extracellular space between a neuron and its target cell.

synaptic plasticity The formation of additional synaptic connections that occurs as a result of learning.

synaptic signaling A specialized form of paracrine signaling that occurs in the nervous system of animals.

synergids In the female gametophyte of a flowering plant, the two cells adjacent to the egg cell that help to import nutrients from maternal sporophyte tissues.

syntrophy The phenomenon in which one species lives off the products of another species.

systematics The study of biological diversity and evolutionary relationships among organisms, both extinct and modern.

systemic acquired resistance (SAR) A whole-plant defensive response to pathogenic microorganisms.

systemic circulation The pumping of blood from the left side of an animal's heart to the body to drop off oxygen and nutrients and pick up carbon dioxide and wastes. The blood then returns to the right side of the heart.

systemic hypertension An arterial blood pressure above normal; in humans, normal blood pressure ranges from systolic/diastolic pressures of about 90/60 to 120/80 mmHg; often called hypertension or high blood pressure.

systems biology A field of study in which researchers investigate living organisms in terms of their underlying networks—groups of structural and functional connections—rather than their individual molecular components.

systole The second phase of the cardiac cycle, in which the ventricles contract and eject the blood through the open semilunar valves.

T

tagmata The fusion of body segments into functional units.

taproot system The root system of eudicots, consisting of one main root with many branch roots.

taste buds Structures located in the mouth and tongue of vertebrates that contain the sensory cells, supporting cells, and associated neuronal endings that contribute to taste sensation.

TATA box One of three features found in most eukaryotic promoters; the others are the transcriptional start site and regulatory elements.

taxis A directed type of response to a stimulus that is either toward or away from the stimulus.

taxon A group of species that are evolutionarily related to each other. In taxonomy, each species is placed into several taxons that form a hierarchy from large (domain) to small (genus).

taxonomy The field of biology that is concerned with the theory, practice, and rules of classifying living and extinct organisms and viruses.

T cell A type of lymphocyte that directly kills infected, mutated, or transplanted cells.

telocentric A chromosome in which the centromere is at the end.

telomerase An enzyme that catalyzes the replication of the telomere.

telomere A region at the ends of eukaryotic chromosomes where a specialized form of DNA replication occurs.

telophase The phase of mitosis during which the chromosomes decondense and the nuclear membrane re-forms.

TEM *See* transmission electron microscopy.

temperate phage A bacteriophage that may spend some of its time in the lysogenic cycle.

template strand The DNA strand that is used as a template for RNA synthesis or DNA replication.

temporal lobe One of four lobes of the cerebral cortex of human brain; necessary for language, hearing, and some types of memory.

temporal summation Occurs when two or more postsynaptic potentials arrive at the same location in a dendrite in quick succession and their depolarizations and hyperpolarizations sum together.

tepal A flower perianth part that cannot be distinguished by appearance as a petal or a sepal.

termination codon *See* stop codon.

termination stage The final stage of transcription or translation in which the process ends.

terminator A sequence that specifies the end of transcription.

terpenoids A group of secondary metabolites synthesized from five-carbon isoprene units. An example is β-carotene, which gives carrots their orange color.

territory A fixed area in which an individual or group excludes other members of its own species, and sometimes other species, by aggressive behavior or territory marking.

tertiary consumer An organism that feeds on secondary consumers.

tertiary endosymbiosis The acquisition by eukaryotic protist host cells of plastids from cells that possess secondary plastids.

tertiary plastid A plastid acquired by the incorporation into a host cell of an endosymbiont having a secondary plastid.

tertiary structure The three-dimensional shape of a single polypeptide; one of four levels of protein structure.

testcross A cross to determine if an individual with a dominant phenotype is a homozygote or a heterozygote. Also, a cross to determine if two different genes are linked.

testes (singular, **testis**) In animals, the male gonads, where sperm are produced.

testosterone The primary androgen in many vertebrates, including humans.

tetrad *See* bivalent.

tetraploid An organism or cell that has four sets of chromosomes.

tetrapod A vertebrate animal having four legs or leglike appendages.

thalamus A region of the vertebrate forebrain that plays a major role in relaying sensory information to appropriate parts of the cerebrum and, in turn, sending outputs from the cerebrum to other parts of the brain.

theory In biology, a broad explanation of some aspect of the natural world that is substantiated by a large body of evidence. Biological theories incorporate observations, hypothesis testing, and the laws of other disciplines such as chemistry and physics. A theory makes valid predictions.

thermodynamics The study of energy interconversions.

thermoreceptor A sensory receptor in animals that responds to cold and heat.

theropods A group of bipedal saurischian dinosaurs.

thick filament A section of the repeating pattern in a myofibril composed almost entirely of the motor protein myosin.

thigmotropism Touch responses in plants.

thin filament A section of the repeating pattern in a myofibril that contains the cytoskeletal protein actin, as well as two other proteins—troponin and tropomyosin—that play important roles in regulating contraction.

30-nm fiber Nucleosome units organized into a more compact structure that is 30 nm in diameter.
thoracic breathing Breathing in which coordinated contractions of muscles expand the rib cage, creating a negative pressure to suck air in and then forcing it out later; found in amniotes.
threatened species Those species that are likely to become endangered in the future.
threshold concentration The concentration above which a morphogen will exert its effects but below which it is ineffective.
threshold potential The membrane potential, typically around −50mV, which is sufficient to trigger an action potential in an electrically excitable cell such as a neuron.
thrifty genes Genes that boosted our ancestors' ability to store fat from each feast in order to sustain them through the next famine.
thrombocytes Intact cells in the blood of vertebrates other than mammals that play a crucial role in the formation of blood clots; in mammals, cell fragments called platelets serve this function.
thylakoid A flattened, platelike membranous region found in cyanobacterial cells and the chloroplasts of photosynthetic protists and plants; the location of the light reactions of photosynthesis.
thylakoid lumen The fluid-filled compartment within the thylakoid.
thylakoid membrane A membrane within the chloroplast that forms many flattened, fluid-filled tubules that enclose a single, convoluted compartment. It contains chlorophyll and is the site where the light-dependent reactions of photosynthesis occurs.
thymine (T) A pyrimidine base found in DNA.
thymine dimer In DNA, a type of pyrimidine dimer that can cause a mutation; a site where two adjacent thymine bases become covalently cross-linked to each other.
thyroglobulin A protein found in the colloid of the thyroid gland that is involved in the formation of thyroid hormones.
thyroxine (T_4) A weakly active thyroid hormone that contains iodine and helps regulate metabolic rate; it is converted by cells into the more active triiodothyronine (T_3).
tidal ventilation A type of breathing in mammals in which the lungs are inflated with air and then the chest muscles and diaphragm relax and recoil back to their original positions as an animal exhales. During exhalation, air leaves via the same route that it entered during inhalation, and no new oxygen is delivered to the airways at that time.
tidal volume The volume of air that is normally breathed in and out at rest.
tight junction A type of junction between animal cells that forms a tight seal between adjacent epithelial cells and thereby prevents molecules from leaking between cells; also called an occluding junction.
Ti plasmid Tumor-inducing plasmid found in *Agrobacterium tumefaciens*; it is used as a cloning vector to transfer genes into plant cells.
tissue The association of many cells of the same type, for example, muscle tissue.
tolerance A mechanism for succession in which any species can start the succession, but the eventual climax community is reached in a somewhat orderly fashion; early species neither facilitate nor inhibit subsequent colonists.
tonoplast The membrane of the central vacuole in a plant or algal cell.
torpor The strategy in endotherms of lowering internal body temperature to just a few degrees above that of the environment in order to conserve energy.
torus The nonporous, flexible central region of a conifer pit that functions like a valve.
total fertility rate The average number of live births a female has during her lifetime.
total peripheral resistance (TPR) The sum of all the resistance in all arterioles.
totipotent The ability of a fertilized egg to produce all of the cell types in the adult organism; also the ability of unspecialized plant cells to regenerate an adult plant.
toxins Compounds that have adverse effects in living organisms; often produced by various protist and plant species.
trace element An element that is essential for normal function in living organisms but is required in extremely small quantities.
trachea 1. A sturdy tube arising from the spiracles of an insect's body; involved in respiration. 2. The name of the tube leading to the lungs of air-breathing vertebrates.
tracheal system The respiratory system of insects consisting of a series of finely branched air tubes called tracheae; air enters and exits the tracheae through spiracles, which are pores on the body surface.
tracheary elements Water-conducting cells in plants that, when mature, are always dead and empty of cytosol; include tracheids and vessel elements.
tracheid A type of dead, lignified plant cell in xylem that conducts water, along with dissolved minerals; also provides structural support.
tracheophytes A term used to describe vascular plants.
tract A parallel bundle of myelinated axons in the central nervous system.
traffic signal *See* sorting signal.
trait An identifiable characteristic; usually refers to a variant.
transcription The use of a gene sequence to make a copy of RNA.
transcriptional start site The site in a eukaryotic promoter where transcription begins.
transcription factor A protein that influences the ability of RNA polymerase to transcribe genes.
transduction A type of genetic transfer between bacteria in which a virus infects a bacterial cell and then subsequently transfers some of that cell's DNA to another bacterium.
***trans*-effect** In both prokaryotes and eukaryotes, a form of genetic regulation that can occur even though two DNA segments are not physically adjacent. The action of the lac repressor on the *lac* operon is a *trans*-effect.
transepithelial transport The process of moving solutes across an epithelium, such as in the gut of animals.
transfer RNA (tRNA) An RNA that carries amino acids and is used to translate mRNA into polypeptides.
transformation A type of genetic transfer between bacteria in which a segment of DNA from the environment is taken up by a competent cell and incorporated into the bacterial chromosome.
transgenic The term used to describe an organism that carries genes that were introduced using molecular techniques such as gene cloning.
transitional form An organism that provides a link between earlier and later forms in evolution.
transition state In a chemical reaction, a state in which the original bonds have stretched to their limit; once this state is reached, the reaction can proceed to the formation of products.
translation The process of synthesizing a specific polypeptide on a ribosome.
translocation 1. A type of mutation in which one segment of a chromosome becomes attached to a different chromosome. 2. A process in plants in which phloem transports substances from a source to a sink.
transmembrane gradient A situation in which the concentration of a solute is higher on one side of a membrane than on the other.
transmembrane protein A protein that has one or more regions that are physically embedded in the hydrophobic region of a cell membrane's phospholipid bilayer.
transmembrane segment A region of a membrane protein that is a stretch of nonpolar amino acids that spans or traverses the membrane from one leaflet to the other.
transmembrane transport The export of material from one cell into the intercellular space and then into an adjacent cell.
transmission electron microscopy (TEM) A type of microscopy in which a beam of electrons is transmitted through a biological sample to form an image on a photographic plate or screen.
transpiration The evaporative loss of water from plant surfaces into sun-heated air.
transporter A membrane protein that binds a solute and undergoes a conformational change to allow the movement of the solute across a membrane; also called a carrier.
transport protein Proteins embedded within the phospholipid bilayer that allow plasma membranes to be selectively permeable by providing a passageway for the movement of some but not all substances across the membrane.
transposable element (TE) A segment of DNA that can move from one site to another.
transposase An enzyme that facilitates transposition.
transposition The process in which a short segment of DNA moves within a cell from its original site to a new site in the genome.
transverse tubules (T-tubules) Invaginations of the plasma membrane of skeletal muscle cells that open to the extracellular fluid and conduct action potentials from the outer surface to the myofibrils.
triacylglycerol *See* triglyceride.
trichome A projection, often hairlike, from the epidermal tissue of a plant that offers protection from excessive light, ultraviolet radiation, extreme air temperature, or attack by herbivores.
triglyceride A molecule composed of three fatty acids linked by ester bonds to a molecule of glycerol; also known as a triacylglycerol.
triiodothyronine (T_3) A thyroid hormone that contains iodine and helps regulate metabolic rate.
triplet A group of three bases that function as a codon.
triploblastic Having three distinct germ layers—endoderm, ectoderm, and mesoderm.
triploid An organism or cell that has three sets of chromosomes.
trisomic An aneuploid organism that has one too many chromosomes.
tRNA *See* transfer RNA.
trochophore larva A distinct larval stage of many invertebrate phyla.
trophic level Each feeding level in a food chain.
trophic-level transfer efficiency The amount of energy at a trophic level that is acquired by

the trophic level above and incorporated into biomass.

trophic mutualism A mutually beneficial interaction between two species in which both species receive the benefit of resources.

tropism In plants, a growth response that is dependent on a stimulus that occurs in a particular direction.

tropomyosin A rod-shaped protein that plays an important role in regulating muscle contraction.

troponin A small globular-shaped protein that plays an important role in regulating muscle contraction through its ability to bind Ca^{2+}.

***trp* operon** An operon of *E. coli* that encodes enzymes required to make the amino acid tryptophan, a building block of cellular proteins.

true-breeding line A strain that continues to exhibit the same trait after several generations of self-fertilization or inbreeding.

trypsin A protease involved in the breakdown of proteins in the small intestine.

t-snare A protein in a target membrane that recognizes a v-snare in a membrane vesicle.

tubal ligation A means of contraception that involves the cutting and sealing of the fallopian tubes in a woman, thereby preventing movement of a fertilized egg into the uterus.

tube cell In a seed plant, one of the cells resulting from the division of a microspore; stores proteins and forms the pollen tube.

tube feet Echinoderm structures that function in movement, gas exchange, feeding, and excretion.

tumor An abnormal overgrowth of cells.

tumor-suppressor gene A gene that when normal (that is, not mutant) encodes a protein that prevents cancer; however, when a mutation eliminates its function, cancer may occur.

tunic A nonliving structure that encloses a tunicate, made of protein and a cellulose-like material called tunicin.

turgid The term used to describe a plant cell whose cytosol is so full of water that the plasma membrane presses right up against the cell wall; as a result, turgid cells are firm or swollen.

turgor pressure *See* osmotic pressure.

20-hydroxyecdysone A hormone produced by the prothoracic glands of arthropods that stimulates molting.

two-factor cross *See* dihybrid cross.

type 1 diabetes mellitus (T1DM) A disease in which the pancreas does not produce sufficient insulin; as a result, extracellular glucose cannot cross plasma membranes, and glucose accumulates to very high concentrations in the blood.

type 2 diabetes mellitus (T2DM) A disease in which the pancreas produces sufficient insulin, but the cells of the body lose much of their ability to respond to insulin.

U

ubiquitin A small protein in eukaryotic cells that directs unwanted proteins to a proteasome by its covalent attachment.

ultimate cause The reason a particular behavior evolved, in terms of its effect on reproductive success.

umbrella species A species whose habitat requirements are so large that protecting them would protect many other species existing in the same habitat.

unconditioned response An action that is elicited by an unconditioned stimulus.

unconditioned stimulus A trigger that elicits an original response.

uniform A pattern of dispersion within a population in which individuals maintain a certain minimum distance between themselves to produce an evenly spaced distribution.

uniporter A type of transporter that binds a single ion or molecule and transports it across a membrane.

unipotent A term used to describe a stem cell found in the adult that can produce daughter cells that differentiate into only one cell type.

unsaturated The quality of a lipid containing one or more C═C double bonds.

unsaturated fatty acid A fatty acid that contains one or more C═C double bonds.

upwelling In the ocean, a process that carries mineral nutrients from the bottom waters to the surface.

uracil (U) A pyrimidine base found in RNA.

urea A nitrogenous waste commonly produced in many terrestrial species, including mammals.

uremia A condition characterized by the presence of nitrogenous wastes, such as urea, in the blood; typically results from kidney disease.

ureter A structure in the mammalian urinary system through which urine flows from the kidney into the urinary bladder.

urethra The structure in the mammalian urinary system through which urine is eliminated from the body.

uric acid A nitrogenous waste produced by birds, insects, and reptiles.

urinary bladder The structure in the mammalian urinary system that collects urine before it is eliminated.

urinary system The structures that collectively act to filter blood or hemolymph and excrete wastes, while recapturing useful compounds.

urine The part of the filtrate formed in the kidney that remains after all reabsorption of solutes and water is complete.

uterine cycle *See* menstrual cycle.

uterus A small, pear-shaped organ capable of enlarging and specialized for carrying a developing fetus in female mammals.

V

vaccination The injection into the body of small quantities of weakened or dead pathogens, resulting in the development of immunity to those pathogens without causing disease.

vacuole Specialized compartments found in eukaryotic cells that function in storage, the regulation of cell volume, and degradation.

vagina The birth canal of female mammals; also functions to receive sperm during copulation.

vaginal diaphragm A barrier method of preventing fertilization in which a diaphragm is placed in the upper part of the vagina just prior to intercourse; blocks movement of sperm to the cervix.

valence electron An electron in the outer shell of an atom that is available to combine with other atoms. Such electrons allow atoms to form chemical bonds with each other.

van der Waals forces Attractive forces between molecules in close proximity to each other, caused by the variations in the distribution of electron density around individual atoms.

variable region A unique domain within an immunoglobulin that serves as the antigen-binding site.

vasa recta capillaries Capillaries in the medulla in the nephron of the kidney.

vascular bundle Primary plant vascular tissues that occur in a cluster.

vascular cambium A secondary meristematic tissue of plants that produces both wood and inner bark.

vascular plant A plant that contains vascular tissue. Includes all modern plant species except liverworts, hornworts, and mosses.

vascular tissue Plant tissue that provides both structural support and conduction of water, minerals, and organic compounds.

vas deferens A muscular tube through which sperm leave the epididymis.

vasectomy A surgical procedure in men that severs the vas deferens, thereby preventing the release of sperm at ejaculation.

vasoconstriction A decrease in blood vessel radius; an important mechanism for directing blood flow away from specific regions of the body.

vasodilation An increase in blood vessel radius; an important mechanism for directing blood flow to specific regions of the body.

vasotocin A peptide hormone that is responsible for regulating salt and water balance in the blood of nonmammalian vertebrates.

vector A type of DNA that acts as a carrier of a DNA segment that is to be cloned.

vegetal pole In triploblast organisms, the pole of the egg where the yolk is most concentrated.

vegetative growth The production of new nonreproductive tissues by the shoot apical meristem and root apical meristem during seedling development and growth of mature plants.

vein 1. In animals, a blood vessel that returns blood to the heart. 2. In plants, a bundle of vascular tissue in a leaf.

veliger In mollusks, a free-swimming larva that has a rudimentary foot, shell, and mantle.

ventilation The process of bringing oxygenated water or air into contact with a respiratory surface such as gills or lungs.

ventral Refers to the lower side of an animal.

ventricle In the heart, a chamber that pumps blood out of the heart.

venule A small, thin-walled extension of a capillary that empties into larger vessels called veins that return blood to the heart for another trip around the circulation.

vertebrae A bony or cartilaginous column of interlocking structures that provides support and also protects the nerve cord, which lies within its tubelike structure.

vertebrate An organism with a backbone.

vertical evolution A process in which species evolve from pre-existing species by the accumulation of mutations.

vesicle A small membrane-enclosed sac within a cell.

vessel In a plant, a pipeline-like file of dead, water-conducting vessel elements.

vessel element A type of plant cell in xylem that conducts water, along with dissolved minerals and certain organic compounds.

vestibular system The organ of balance in vertebrates, located in the inner ear next to the cochlea.

vestigial structure An anatomical feature that has no apparent function but resembles a structure of a presumed ancestor.

vibrios Comma-shaped prokaryotic cells.

villi Finger-like projections extending from the luminal surface into the lumen of the small intestine; these are specializations that aid in digestion and absorption.

viral envelope A structure enclosing a viral capsid that consists of a membrane derived from the plasma membrane of the host cell; is embedded with virally encoded spike glycoproteins.
viral genome The genetic material of a virus.
viral reproductive cycle The series of steps that result in the production of new viruses during a viral infection.
viral vector A type of vector used in cloning experiments that is derived from a virus.
viroid An RNA particle that infects plant cells.
virulence The ability of a microorganism to cause disease.
virulent phage A phage that follows only the lytic cycle.
virus A small infectious particle that consists of nucleic acid enclosed in a protein coat.
visceral mass In mollusks, a structure that rests atop the foot and contains the internal organs.
vitamin An organic nutrient that serves as a coenzyme for metabolic and biosynthetic reactions.
vitamin D A vitamin that is converted into a hormone in the body; regulates the calcium level in the blood through an effect on intestinal transport of calcium ions.
vitreous humor A thick liquid in the large posterior cavity of the vertebrate eye, which helps maintain the shape of the eye.
viviparity Development of an embryo within the mother, resulting in a live birth.
viviparous The term used to describe an animal whose embryos develop within the uterus, receiving nourishment from the mother via a placenta.
V_{max} The maximal velocity of an enzyme-catalyzed reaction.
volt A unit of measurement of potential difference in charge (electrical force) such as the difference between the interior and exterior of a cell.
voltage-gated ion channels Ion channels that open and close in response to changes in the amount of electric charge across a membrane.
v-snare A protein incorporated into a vesicle membrane during vesicle formation that is recognized by a t-snare in a target membrane.

W

water potential The potential energy of water.
water vascular system A network of canals powered by water pressure generated by the contraction of muscles; enables extension and contraction of the tube feet, allowing echinoderms to move slowly.
wavelength The distance from the peak of one sound wave or light wave to the next.
waxy cuticle A protective, waterproof layer of polyester and wax present on most surfaces of vascular plant sporophytes.
weak acid An acid that only partially ionizes in solution.
weathering The physical and chemical breakdown of rock.
white blood cell *See* leukocyte.
white matter Brain tissue that consists of myelinated axons that are bundled together in large numbers to form tracts.
whorls In a flower, concentric rings of sepals and petals (or tepals), stamens, and carpels.
wild-type allele One or more prevalent alleles in a population.
wood A secondary plant tissue composed of numerous pipelike arrays of dead, empty, water-conducting cells whose walls are strengthened by an exceptionally tough secondary metabolite known as lignin.
woody plant A type of plant that produces both primary and secondary vascular tissues.

X

xenoestrogen A synthetic compound that exerts estrogen-like actions or, in some cases, inhibits the actions of the body's own estrogen.
X inactivation The phenomenon in which one X chromosome in the somatic cells of female mammals is inactivated, meaning that its genes are not expressed.
X inactivation center (Xic) A short region on the X chromosome known to play a critical role in X inactivation.
X-linked gene A gene found on the X chromosome but not on the Y.
X-linked inheritance The pattern displayed by pairs of dominant and recessive alleles located on X chromosomes.
X-ray crystallography A technique in which researchers purify molecules and cause them to form a crystal. When a crystal is exposed to X-rays, the resulting pattern can be analyzed mathematically to determine the three-dimensional structure of the crystal's components.
xylem A specialized conducting tissue in plants that transports water, minerals, and some organic compounds.
xylem loading The process by which root xylem parenchyma cells transport ions and water across their membranes into the long-distance conducting cells of the xylem, which include the vessel elements and tracheids.

Y

yeast A fungus that can occur as a single cell and that reproduces by budding.
yolk sac One of the four extraembryonic membranes in the amniotic egg. The yolk sac encloses a stockpile of nutrients, in the form of yolk, for the developing embryo.

Z

zero population growth The situation in which no changes in population size occur.
Z line A network of proteins in a myofibril that anchors thin filaments at the ends of each sarcomere.
zona pellucida The glycoprotein covering that surrounds a mature oocyte.
zone of elongation The area above the root apical meristem of a plant where cells extend by water uptake, thereby dramatically increasing root length.
zone of maturation The area above the zone of elongation in a plant root where root cell differentiation and tissue specialization occur.
zooplankton Aquatic organisms drifting in the open ocean or fresh water; includes minute animals consisting of some worms, copepods, tiny jellyfish, and the small larvae of invertebrates and fishes.
Z scheme A model depicting the series of energy changes of an electron during the light reactions of photosynthesis. The electron absorbs light energy twice, resulting in an energy curve with a zigzag shape.
zygomycete A phylum of fungi that produces distinctive, large zygospores as the result of sexual reproduction.
zygospore A dark-pigmented, thick-walled spore that matures within the zygosporangium of zygomycete fungi during sexual reproduction.
zygote A diploid cell formed by the fusion of two haploid gametes.
zygotic life cycle The type of life cycle of most unicellular protists in which haploid cells develop into gametes. Two gametes then fuse to produce a diploid zygote.

Suggested Answers to Collaborative Questions

Chapter 1

1. Most biologists would say that theories are true, but maybe students who are new to the discipline don't feel the same way. There are a variety of ways to decide if things are true: experimentation, logic, hearing it from experts, faith, etc. This discussion may be interesting because it may help you decide how you determine whether or not things are true. Maybe you've never thought about this before.
2. The male and female alligators don't have different genomes. Somehow, temperature affects the proteome. There are a lot of possible things that could happen. For example, higher temperature could cause a protein that is needed for female development to unfold and not work properly. The main idea is that temperature affects protein structure and function and thereby influences the proteome. Some proteins regulate genes and control the genome. If these proteins were affected by temperature, they could control which proteins are made at high and low temperatures.

Chapter 2

1. Protons—These are positively charged particles that are found in the center of the atom which is referred to as the nucleus. The number of protons an atom has is called the atomic number, and this defines each type of element. This particle makes up approximately half of the mass of an atom, which is referred to as the atomic mass.

   Neutrons—These are neutral (uncharged) particles that are found in the nucleus of the atom. For most atoms of biological importance, the number of neutrons is equal to the number of protons in an atom, but this is not always the case. Atoms with the same number of protons but different numbers of neutrons are called isotopes of each other.

   Electrons—These are negatively charged particles that are found in orbitals around the nucleus. For atoms, the number of protons is equal to the number of electrons. Therefore, an atom has no overall net charge. If electrons are added to an atom or taken away, this will change the charge of the atom, which is now called an ion, thereby changing its properties and reactivity.
2. The partial electric charges around the hydrogen and oxygen atoms in a water molecule make water a good solvent for many of the chemicals important for life in organisms, such as ions and polar compounds.

   Water can directly participate in types of chemical reactions called hydrolysis reactions, which among other things are important in the conversion of certain large molecules into smaller units that are biologically important.

   Water has a high heat of vaporization, which means that it takes a great deal of heat to change its state from a liquid to a gas. As a result of this, most of the water in our planet is in liquid form, which is required to support life.

   Water also has a high heat of fusion and requires a great deal of energy to be removed from it to turn it from a liquid to a solid. As a result of this, liquid water is very stable and resistant to temperature change, making it ideal for living organisms.

   Also see Figure 2.20.

Chapter 3

1. Monosaccharides—These are monomers and the most simple of the sugars, carbohydrates that often, but not always, taste sweet. A prime example of this type of sugar is glucose, which is used by many organisms in the production of ATP.

   Disaccharides—These consist of two monosaccharides covalently bonded together. Sucrose is an example of this type of sugar. This is accomplished through a dehydration reaction by removing hydrogen from one monosaccharide and a hydroxyl from the other, resulting in the loss of a molecule of water.

   Polysaccharides—These are polymers that consist of many monosaccharides bonded together. Some examples of polysaccharides are

   Glycogen—this is the storage form of glucose in animals.

   Starch—this is the storage form of glucose in plants.

   Cellulose—this molecule serves as a support molecule in plants.
2. Protection—protect organisms from attack against disease. Organisms develop specific proteins to fight against specific diseases.

   Enzymes—increase the rates of chemical reactions. Without these proteins, metabolism would slow down and stop.

   Gene expression and regulation—involved in transcribing genes (converting DNA into RNA), regulating the activity of genes, and synthesizing polypeptides.

   Cell signaling—needed for a cell to communicate with other cells and with the environment.

   Motor proteins—allow cellular movements.

   Transporters—allow the movement of ions and molecules across cellular membranes.

Chapter 4

1. The term genome refers to the entire genetic complement of a cell, which codes for all of the proteins that a cell can produce. If a cell needs to manufacture a protein, it must get the instructions on how to build it from the DNA, which is found inside of the nucleus. The proteome is the entire collection of proteins that a cell can make. The production of proteins inside the cell is very dynamic and constantly changing inside the cell based on current conditions in and out of the cell. During different times of a cell's life, it will be required to make different proteins based on the current function of the cell. This is accomplished by accessing different genes from the DNA of the cell. Within each cell is the entire genetic complement of the organism, yet each individual cell will use only part of it to produce the proteins it needs.
2. See Figures 4.5 and 4.7 for how the nucleus, ER, and Golgi are arranged relative to each other. The nucleus and ER are continuous with each other. The two membranes of the nuclear envelop meet at the nuclear pores. The ER and Golgi share material via membrane vesicles.

Chapter 5

1. Perhaps the main reason why plasma membrane proteins are good targets for drugs is because the drug doesn't have to get into the cell

to affect the protein's function. Also, plasma membrane proteins play a variety of important roles in the structure and function of cells, making them good targets for drugs. To determine if any particular plasma membrane protein is the target of a drug, you need to have a method to determine if the protein is working properly. For example, if a protein transports glucose into the cell, you need to have a method to measure glucose uptake. In this case, you could add radiolabeled glucose outside the cell and monitor its uptake over time. If you thought a drug was affecting such a glucose transporter, the rate of glucose uptake would be determined in the presence and absence of the drug. If the glucose transporter was the target of the drug, you would expect the drug to have an effect on the rate of glucose transport.

2. Diffusion: The main advantage is that a cell doesn't have to expend any energy to transport the solute. The disadvantages are that it's not very specific, and it cannot achieve active transport.

   Facilitated diffusion: The advantage is that it can specifically move solutes across the membrane down their gradients. The disadvantage is that it cannot achieve active transport.

   Active transport: The advantages are that it can specifically move solutes across a membrane and it can move them against a gradient. A disadvantage is that it uses up energy in the process.

   Endocytosis: The main advantage is that it can move large things across the membrane. A disadvantage would be that it is a pretty complicated process, which uses a lot of cellular components.

Chapter 6

1. Living cells acquire energy to maintain their internal order. This energy comes in different forms. Light energy powers photosynthesis, which then supplies organic molecules that store and release energy. Living cells are not defying the second law of thermodynamics because the law applies to the whole universe. Although cells are highly ordered, the maintenance of cell order increases the net entropy of the universe. For example, cells give off heat, which affects the disorder of their surroundings.
2. Having a common energy source allows a cell to make fewer proteins and thereby keep its biochemical composition simpler. It would take a lot of energy to make a Na^+/K^+-ATPase, a Na^+/K^+-glucosase, a Na^+/K^+-sucrase, and a Na^+/K^+-fatty acidase. Also, having fewer proteins allows a species to have a smaller genome, which improves efficiency.

Chapter 7

1. Compared to most forms of anaerobic respiration and fermentation, an advantage of aerobic respiration is that it generates more ATP. However, a disadvantage is that it requires oxygen which may not be available or, in the case of muscle exertion, may be used up very quickly. The main advantage of anaerobic respiration and fermentation is that cells can keep making ATP even if oxygen is not available.
2. Secondary metabolites play a variety of roles, many of which are involved with defense (bad odor or taste) or attraction (nice odor or a pretty color). With regard to starting a biotech company, the secondary metabolites that are used as drugs or spices might be good choices, because there is a large market for them. You might find new drugs or spices by screening many different species of plants, bacteria, etc., in search of new secondary metabolites that no one has yet discovered.

Chapter 8

1. A heterotroph does not have to live in a sunny location. Many heterotrophs have a wide variety of foods they can eat to sustain their life. However, photoautotrophs can rely on light for their energy needs, which is oftentimes plentiful. On the other hand, when light is not plentiful, phototrophs have trouble staying alive.
2. Under hot and dry conditions, C4 or CAM plants have the advantage of not requiring as much water, and also they are more efficient because they avoid photorespiration. With regard to genes, introducing the gene that encodes PEP carboxylase would be helpful. Also, adding genes that change leaf structure so that both mesophyll and bundle sheath cells would be formed might be possible, though that would be more complicated.

Chapter 9

1. Direct intercellular signaling—In multicellular organisms, there is usually some form of direct contact between adjacent cells so they can communicate with each other and exchange chemicals between cells. Without this communication, organs and tissues would not work correctly. For example, in the lungs, cilia are needed to work in rhythmic movements to sweep unwanted particles out of the lungs. This could not be achieved without direct cell-to-cell communication.

   Contact-dependent signaling—In this type of signaling, membrane-bound signals on one cell bind to the receptors on an adjacent cell. This occurs when portions of nerve cells grow and make contact with other nerve cells or muscle cells, thus allowing the cells to work together.

   Autocrine signaling—Some cells secrete signals that act on themselves as well as cells of the same type that are close by. Autocrine signaling is often important for groups of cells to sense cell density.

   Paracrine signaling—In paracrine signaling, a specific cell secretes a signaling molecule that influences the behavior of target cells in close proximity to the signaling cell. This signal is usually short lived, thereby keeping the effects very local. An example of this is found in the nervous system, where signaling chemicals called neurotransmitters communicate specific messages to target cells.

   Hormone signaling—This form of signaling acts over long distances. Certain cells secrete hormones that are carried through vessels in plants and animals and cause a cellular response in distant cells. Epinephrine in humans is an example.
2. All cells in a multicellular organism contain the same genes and have the ability to make every single protein in that organism's proteome. However, in multicellular organisms, genes are turned on and off in different patterns and in different parts of an organism's body. These patterns are very important in order for cells to work correctly. This concept is known as differential gene regulation. Because of differential gene regulation, specific parts of the body respond to the same hormone in different ways. For example, in the cardiovascular system, the hormone epinephrine constricts blood vessels and increases heart rate, whereas in the respiratory system, it relaxes the airways, and in the skin, it simulates sweating. Even though the hormone is the same in all cases, what that hormone does in each cell type varies greatly. This allows the different cell types in a multicellular organism to coordinate their responses to hormones and environmental changes.

Chapter 10

1. With regard to similarities, the ECM of animals and plants both provide strength, support, and organization to the cells of their respective organisms. The ECM of animals is much more protein rich, containing protein fibers, such as collagen, that provide tensile strength. By comparison, cellulose, which is composed of carbohydrate, forms fibers within plant cell walls that can impart a high amount of strength to the ECM. Plant cell walls contain relatively little protein. Another difference between animals and plants is that all plant cells are surrounded by a cell wall, whereas the amount of ECM around animal cells varies greatly from tissue to tissue.
2. A drug that binds to a CAM and inhibits the spread of cancer might be causing the CAMs in adjacent cells to bind more tightly to each other. This would make it difficult for the cancer cells to spread through a tissue. However, a harmful side effect is that having cell-to-cell junctions that are too strong might inhibit normal cell function. For example, certain tissues, like those lining the blood vessels, need to expand and contract. Having cell-to-cell junctions that are very tight might inhibit these changes.

Chapter 11

1. Step 1. Isolate and purify DNA from resistant bacteria.

   Step 2. In three separate tubes, add DNase, RNase, or protease.

   Step 3. Add sensitive bacteria to each tube. A small percentage may be transformed.

   Step 4. Plate on Petri plates containing tetracycline.

   Expected results: Tetracycline-resistant colonies should grow only when the DNA has been exposed to RNase and protease, but not to DNase.

2. There are many possibilities. You could use a DNA-specific chemical and show that it causes heritable mutations. Perhaps you could inject an oocyte with a piece of DNA and produce a mouse with a new trait.

Chapter 12

1. The RNA components of spliceosomes and ribosomes perform both structural and catalytic roles. In the case of spliceosomes, the RNA is thought to catalyze the splicing reactions. In ribosomes, an rRNA catalyzes the peptidyl transfer reaction. Proteins are needed in spliceosomes and ribosomes to perform a structural role. They hold the RNA in the correct configuration so that its catalytic function is achieved.
2. This could be a very long list. There are similarities along several lines:
   1. There is a lot of molecular recognition going on, either between two nucleic acid molecules or between proteins and nucleic acid molecules. Students may see these as similarities or differences, depending on their point of view.
   2. There is biosynthesis going on in both processes. Small building blocks are being connected together. This requires an input of energy.
   3. There are genetic signals that determine the beginning and ending of these processes.

   There are also many differences:
   1. Transcription produces an RNA molecule with a similar structure to the DNA, whereas translation produces a polypeptide with a structure that is very different from RNA.
   2. Depending on your point of view, it seems that translation is more biochemically complex, requiring more proteins and RNA molecules to accomplish the task.

Chapter 13

1. Transcriptional regulation is the most efficient form of regulation from the point of view of energy. If a protein is not needed by a cell, turning off the gene (via a repressor protein) prevents the synthesis of the mRNA as well as the protein itself. Therefore, the cell does not waste energy making a protein it doesn't need. On the other hand, transcriptional control is fairly slow because it takes time to transcribe a gene and synthesize a polypeptide. By comparison, the regulation of protein function via feedback inhibition or covalent modification is very fast. Translational control, which involves the regulation of mRNA translation, is in the middle. It is not as efficient as transcriptional control because mRNA is made, but it is faster than transcriptional control. However, it is not as fast as the regulation of protein function.
2. It could be in the DNA-binding domain, so the receptor would not recognize GREs.

   It could be in the chaperone-binding domain, so the chaperone would not be released when the hormone binds.

   It could be in the dimerization domain, so the receptor would not dimerize.

   It could be in the nuclear localization domain, so the receptor would not travel into the nucleus.

   It could be in the domain that activates RNA polymerase, so the receptor would not activate transcription, even though it could bind to GREs.

Chapter 14

1. A mutation is a heritable change in the genetic material. A mutation can be passed from mother cell to daughter cell or the mutation can occur during gamete formation and be passed from parent to offspring. The word mutation is often associated with negative effects but this is not always the case. Mutation increases the genetic variability of a species. If a mutation is favorable, it will be beneficial to that individual and may increase its reproductive success. Likewise, such favorable mutations may be passed to offspring. Over time, this process may increase the frequency of the mutation in a population. On the other hand, however, most mutations are unfavorable and decrease the survival or reproductive success of individuals. These mutations tend to be eliminated from populations.
2. It's a matter of opinion. Some ideas might be the following:
   a. Testing of mutagens would enable us to know what the mutagens are and thereby avoid them. On the other hand, one might argue that there are so many now, that it's difficult to avoid them anyway.
   b. Investigating molecular effects may help us find a cure for diseases such as cancer or help us to prevent mutations. On the other hand, it may not.
   c. Similarly, investigating DNA repair mechanisms may lead to ways of preventing mutations. On the other hand, it may not.
   d. Other places: educating the public about mutagens; tighter regulations of substances that contain mutagens; alternative methods of agriculture that may diminish the level of mutagens in food; and many others.

Chapter 15

1. During interphase, the chromosomes are greatly extended. In this conformation, they might get tangled up with each other and not sort properly during meiosis and mitosis. The condensation process probably occurs so that the chromosomes easily align along the equatorial plate during metaphase without getting tangled up.
2. It's not possible to give a direct answer, but the point is for students to be able to draw chromosomes in different configurations and understand the various phases. The chromosomes may or may not be
   1. in homologous pairs;
   2. connected as sister chromatids;
   3. associated in bivalents;
   4. lined up in metaphase;
   5. moving toward the poles;

   and so on.

Chapter 16

1. a. Chromosomes contain the genetic information that is passed from parent to offspring and from one cell to another. Genes, the basic units of genetics, are found on these chromosomes.
   b. Chromosomes are replicated, and each chromosome retains its individuality (the same number and type of genes) during cell division and gamete formation.
   c. The nucleus of a diploid cell contains two sets of chromosomes that are found in homologous pairs. Half of these chromosomes come from the mother, and the other half come from the father, and each set of chromosomes carry a full complement of genes.
   d. During meiosis, one member of each chromosome pair segregates into one daughter nucleus, and its homologue segregates into the other daughter nucleus. Each of the resulting haploid cells contains only one set of chromosomes. During the formation of haploid cells, the members of different chromosome pairs segregate independently of each other.
   e. Gametes are haploid cells that combine to form diploid cells during fertilization, with each gamete transmitting one set of chromosomes to the offspring.

Tenets 2, 3, and 4 were largely determined via microscopy. Tenets 1 and 5 were deduced both via crosses and via microscopy. Modern techniques to verify this theory could involve a variety of cloning techniques that are described in Chapters 20 and 21.

2. In X-linked recessive inheritance, it is much more common for males to be affected. In autosomal recessive inheritance, there is an equal chance of males and females being affected (unless there is a sex influence, in which an allele is dominant in one sex but recessive in the opposite sex). For X-linked dominant inheritance, affected males would produce 100% affected daughters and not transmit the trait to their sons. This would not be true for autosomal dominant traits, where there is an equal chance of males and females being affected.

Chapter 17

1. The discussion is a matter of opinion. Some may say that Mendel withheld data, but others may not feel that way.
2. Both X inactivation and genomic imprinting are examples of epigenetic inheritance in which a chromosome or a gene is silenced during the lifetime of an individual but not over the course of two or more generations. They are different in that X inactivation occurs during embryonic development and creates a mosaic pattern, whereas genomic imprinting occurs during gametogenesis, so an offspring inherits a silenced copy of a gene from one parent and an active copy from the other.

Chapter 18

1. A common hypothesis for the origin of viruses is they evolved from macromolecules inside living cells. The precursors of the first viruses may have been plasmids—small, circular DNA molecules that exist independently of chromosomal DNA. Alternatively, viruses may be an example of regressive evolution—the reduction of a trait or traits over time. This hypothesis proposes that viruses are degenerate cells that have retained the minimal genetic information essential for reproduction. A third possibility is that viruses did not evolve from living cells but instead evolved in parallel with cellular organisms.
2. It is not a form of sexual reproduction, in which two distinct parents produce gametes that unite to form a new individual. However, conjugation is similar to sexual reproduction in the sense that the genetic material from two cells is somewhat mixed. In conjugation, there is not the mixing of two genomes, one from each gamete. Instead, there is a transfer of genetic material from one cell to another. This transfer can alter the combination of genetic traits in the recipient cell.

Chapter 19

1. The network should involve a hierarchy in which maternal effect genes control the three types of gap genes, which then control the homeotic genes, which then control the master transcription factors that lead to cell differentiation. Hundreds of genes play a role in the developmental network to produce an entire fly. Several dozen different genes form a network to specify one segment.
2. A phenotypically normal female fly can be homozygous for a loss-of-function allele in the *bicoid* gene. Her mother would have to be heterozygous and carry a copy of the normal dominant allele. The offspring of a phenotypically normal female fly that was homozygous for a loss-of-function allele in the *bicoid* gene would all be abnormal because of the maternal effect.

Chapter 20

1. There are many possible answers. Examples include research advances, such as studying and sequencing genes, and practical applications, such as making human insulin in bacteria or making Bt corn.
2. Many issues could be discussed. These include philosophical issues, religious issues, etc.

Chapter 21

1. The prokaryotic genome typically consists of a single chromosome ranging from several hundred thousand to a few million base pairs in length. Most prokaryotes contain only a single chromosome although there may be multiple copies present within a single cell. Bacterial chromosomes are predominantly circular in structure although linear chromosomes are found in several species. When compared to the eukaryotic genome, the prokaryotic genome is less complex, lacking centromeres and telomeres, and having a single origin of replication. In addition, the prokaryote genome has relatively little repetitive DNA.

   The genome found in eukaryotes is usually found in sets of linear chromosomes. The genome of simple eukaryotes carries only a few thousand genes, whereas the genome of more complex eukaryotes may contain tens of thousands of genes. Unlike the genome of prokaryotes, the chromosomes found in eukaryotes are much more complex, having centromeres, telomeres, and multiple origins of replication. Unlike prokaryotes, eukaryotes have more repetitive DNA, ranging from moderate to high.
2. This sequence is from the β-globin gene found in humans.

Chapter 22

1. The reducing atmosphere hypothesis—This hypothesis is based largely on geological evidence. By examining what chemicals were in the primitive atmosphere at the time when life arose, scientists have determined that the basic chemicals needed to form organic molecules were present. By combining these primitive inorganic molecules, more complex molecules such as amino acids and nucleotides could be formed.

   The extraterrestrial hypothesis—This hypothesis postulates that the first organic molecules may have come from fallen bodies from space such as meteorites. Because certain meteorites called carbonaceous chondrites contain organic carbon, these bodies may have added the first organic molecules to our planet.

   Deep sea vents—This hypothesis proposes that the key organic molecules that started life may have originated in deep sea vents. Because these vents have the necessary chemicals and high temperatures, life on our planet may have began here.

   The favored hypothesis is a matter of opinion.
2. Protobionts had (1) a boundary, such as a membrane, that separated the internal contents of the protobiont from the external environment; (2) polymers inside the protobiont contained information; (3) polymers inside had enzymatic functions; and (4) protobionts were capable of self-replication. However, they were not as biochemically complex as living cells and were not capable of precise self-reproduction. However, it's difficult to describe a clear distinction between a protobiont and a living cell.

Chapter 23

1. Evolution is a heritable change in one or more characteristics in a species over time. Evolution means change. Evolution can occur on a small scale in the case of a single gene or on a larger scale in the case of the formation of a new species. By comparison, natural selection is one process that causes evolution to happen. Natural selection occurs because some individuals (with a higher fitness) are more likely to survive and reproduce, and others are not. Over many generations, natural selection leads to adaptation.
2. a. Fossil record—When fossils are compared according to their age from oldest to youngest, successive evolutionary change becomes apparent.

   b. Biogeography—Unique species found on islands and other remote areas have arisen because the species in these areas have evolved in isolation from the rest of the world.

   c. Convergent evolution—Two different species from different lineages sometimes become anatomically similar because they occupy similar environments. This indicates that natural selection promotes adaptation to a given environment.

   d. Selective breeding—The traits in domesticated species have been profoundly modified by artificial selection practices.

   e. Anatomical homologies—Evolutionarily related species may possess homologous structures that have been modified in ways that allow them to be used differently by each species.

f. Developmental homologies—Embryonic development often reveals similar anatomical features that suggest past evolutionary relationships.

g. Molecular homologies—Certain molecular characteristics are found in all cells, suggesting that all living species are derived from a common ancestor.

The observations that someone may find the most or least convincing are a matter of opinion.

Chapter 24

1. a. Random mutation is the source of genetic variation that may lead to antibiotic resistance. A random mutation may create an antibiotic-resistance allele. This could occur in different ways. Many antibiotics exert their effects by binding to an essential cellular protein within the microorganism and inhibiting its function. A random mutation could occur in the gene that encodes such an essential cellular protein; this could alter the structure of the protein in a way that would prevent the antibiotic from binding to the protein or inhibiting its function. As another possibility, microorganisms, which are killed by antibiotics, possess many enzymes, which degrade related compounds. A random mutation could occur in a gene that encodes a degradative enzyme so that the enzyme now recognizes the antibiotic and degrades it.

   b. When random mutations occur, they may be lost due to genetic drift. This is particularly likely when the frequency of the mutation is very low in a large population. Alternatively (and much less likely), a random mutation that confers antibiotic resistance could become fixed in a population.

   c. If a random mutation occurs that confers antibiotic resistance and if the mutation is not lost by genetic drift, natural selection will favor the growth of microorganisms that carry the antibiotic-resistance allele if the organisms are exposed to the antibiotic. Therefore, if antibiotics are widely used, this will kill microorganisms that are sensitive and favor the proliferation of ones that happen to carry antibiotic-resistance alleles.

2. Note: These four types of selection are also discussed in the answer to Conceptual Question 2. With regard to similarities, all of them are related to fitness. The relative differences in the patterns depend on which individuals have the highest fitness and whether or not the environment is heterogeneous. In directional selection, one allele is favored usually because the homozygote carrying that allele has the highest fitness. In this case, the phenotype is at an extreme end of a distribution. By comparison, in stabilizing selection, an intermediate phenotype provides the highest fitness, whereas in some forms of balancing selection (heterozygote advantage), the heterozygote has the highest fitness. In other forms of balancing selection (negative frequency-dependent selection), the fitness depends on the frequency of a genotype. Disruptive selection is a bit different because the fitness depends on the environment, and the environment, in this case, is heterogeneous.

Chapter 25

1. A species is a population of organisms that maintains a distinctive set of attributes in nature. According to de Quieroz's general lineage concept, each species is a population of an independently evolving lineage. One of the major driving forces behind speciation is geographic isolation. If a population is geographically isolated from another population of the same species, then genes will not mix between these two populations. As a result of this isolation, any mutations or shifts in allele frequency which occur in one population will be independent of those that occur in the other. As different genetic changes accumulate in the two populations, they may eventually become reproductively isolated. In other cases, such as polyploidy, abrupt genetic events can cause reproductive isolation.

2. a. Allopatric speciation may occur because the offspring would be geographically isolated from the original population.

   b. Sympatric speciation may occur if polyploidy plants are formed that cannot successfully interbreed with members of the original population.

   c. Allopatric speciation may occur due to geographic isolation, though some limited inbreeding may occur in hybrid zones where the narrow streams are found.

Chapter 26

1. Taxonomy is the field of biology that is concerned with the theory, practice, and rules of classifying living and extinct organisms and viruses. In taxonomy, scientists place organisms into distinct groups based on similarities and differences. This allows scientists to more easily appreciate the similarities and differences between groups of species. With regard to applications, many are possible. In the field of conservation, knowing that a group is a unique species may intensify its conservation efforts if its population becomes small. In agriculture, knowing that two species are or are not closely related may influence whether or not a breeder will attempt to make interspecies hybrids.

2. Systematics is the study of biological diversity based on evolutionary relationships that places organisms into taxonomic groups. By studying similarities and differences among species, biologists gain information about the evolutionary history of an organism (its phylogeny), and this helps scientists understand the relationship between ancestors and their descendants. A goal of systematics is to create a phylogenetic tree, which is a diagram that describes an organism's phylogeny. By studying the branching points of a phylogenetic tree, biologists can group species according to common ancestors. Systematics attempts to organize species into monophyletic groups, which means that each group includes an ancestral species and all of its descendants leading to the species in question. As new information becomes available to scientists, trees are revised to accommodate that information.

   With regard to three ways to choose a tree, the principle of parsimony is good because it is unbiased. However, it may not always identify the correct tree, and it may be confounded by convergent evolution. Maximum likelihood and Bayesian methods are also good, but assumptions in their evolutionary models may not always be correct, which can lead to errors.

Chapter 27

1. Take samples. Try to grow bacteria from the samples on many types of nutrient media. When colonies grow, isolate different types and perform Gram-staining. Use a microscope to observe cells from samples and cultures, looking for variations in cell shape, aggregation, cell wall features, and flagella. Use references to classify different bacteria into phyla. Extract DNA from samples, and sequence ribosomal RNA gene regions. Use references to classify the ribosomal gene sequences into phyla.

2. Collect samples from the contaminated sites. Try to grow bacteria from the sites on media that contain relatively small amounts of the nutrients generally needed by bacteria, but also small amounts of the materials to be degraded. If bacteria grow, transfer the colonies to media containing larger amounts of the material in question. Cells that grow on such media could be further studied to determine if they are degrading the substance while using it as a carbon source.

Chapter 28

1. You could compare the structure of the cysts with those described in the literature. You could try to germinate the cysts in the laboratory, on growth media containing extracts from insects, then compare any protists that result to literature descriptions of known species. You could carefully clean the cysts, then extract DNA from them, and amplify and sequence the DNA for comparison to databases.

2. You could isolate the two seaweeds into pure culture and grow each in the laboratory, using temperature conditions correlating with those present in the natural environment. You could then switch the temperature conditions experienced by the two cultures. If the two organisms are actually different generations of the same species, each may eventually appear in cultures originating from the other generation. You would probably also want to extract, amplify, and sequence genes from the two organisms to see if the sequences are the same. Whether or not they are the same, you would have obtained information

essential to describing the one or two new seaweed species, thereby aiding our knowledge of the world's biodiversity.

Chapter 29

1. Modern complex charophycean algae are almost all aquatic, suggesting that ancient plant ancestors probably were also. If so, ancestral algae would not have experienced a scarcity of water for fertilization as might the land plants. Early land plants probably also encountered greater risk of drying.
2. Placental transfer tissues supply developing embryos with food from their parents. This food allows embryos to grow into sporophytes that can produce many more spores than could zygotes. Sporangia protect developing spores. Plant spores are protected by tough sporopollenin walls during their dispersal in air. Gametophytes produce gametangia that protect delicate gametes. Vascular tissues allow food and water conduction to occur within the bodies of sporophytes. Waxy cuticles protect sporophytes from drying and attack by disease organisms. Stomata allow for gas exchange when conditions are moist but aid water conservation under arid conditions. Seeds allow plants to grow in a wide array of habitats. Flowers foster the development of seeds, and fruits aid seed dispersal.

Chapter 30

1. You would have to travel to the tropics or subtropics to find wild cycads and *Gnetum,* to China to find *Ginkgo* closest to the wild condition, to desert regions of North America to find wild *Ephedra,* to deserts of Namibia in southwestern Africa to find *Welwitschia mirabilis.* You should be able to locate diverse wild conifers in temperate and northern forests around the world.
2. In order to try to identify the nonflowering seed plant group that is closest to the ancestry of flowering plants, you could sequence as many genes as possible, perhaps even whole genomes, from diverse living gymnosperms and compare them to the genes or genomes of early-diverging flowering plants. But even this mighty effort might not help very much if angiosperms' closest seed plant relatives are extinct. You could organize a major fossil hunting effort with collaborators from around the world who sample rocks about 150 million years old or older. The group could look for previously unknown phyla of seed plants and/or carefully compare known fossils of appropriate age for clues to the origin of flowering plants.

Chapter 31

1. Many fungi live within the soil, where they break down organic compounds in dead organisms. These decomposers get rid of wastes and help recycle minerals, making them available for uptake by plants. Other soil fungi trap and kill nematodes, small soil animals from which the fungi obtain organic food. By so doing, fungi help to control populations of nematodes that attack plants, thereby protecting plants. Some fungi are parasites that live within the bodies of plants and animals, absorbing nutrients from them, and often killing the host in the process. Such fungi help to control populations of weeds and insects. Certain fungi live compatibly within plants, especially grasses, helping the plants to withstand biological and physical stresses. Most plants have mycorrhizal fungal partners that help them obtain water and minerals from soil. Lichens are very common on tree trunks, rocks, and soil. These partnerships of fungi and algae or cyanobacteria help to generate soils and add to its fertility. The fruiting bodies of fungi serve as food for animals (but experts recommend that people generally should not collect fungi from the wild for use as food, because many fungal fruiting bodies are toxic to humans).
2. You could search for information about the ectomycorrhizal fungi that are normally present in natural populations of *Pinus resinosa.* You could search for information about how to inoculate the roots of your pine seedlings with the appropriate strains of mycorrhizal fungi. This might include locating a source of soil harboring such fungi, perhaps from an undisturbed natural pine forest. Bearing in mind that such natural soil might also harbor fungal pathogens that might attack the delicate seedlings, you might also try to locate a source of laboratory-grown fungal inoculum.

Chapter 32

1. **Positive impacts:** food sources, pets, transportation, drug testing, guide dogs, jewelry, clothes, pollination of flowers and agricultural crops, ecotourism, decomposition, nutrient cycling, and biological control of pests.

   Negative impacts: parasites, pests, vectors of disease, competitors for food, some potentially harmful to humans.
2. **Similarities:** monophyletic clade; early split between Parazoa and Eumetazoa; early split between Radiata and Bilateria; Deuterostomes contain only Echinodermata and Chordata.

   Differences: Lophophorata are protostomes, not deuterostomes; nematodes and arthropods are members of the Ecdysozoa; the presence or absence of a coelom is not a useful taxonomic character; protostomes are split into two clades, the Lophotrochozoa and the Ecdysozoa.

Chapter 33

1. Over 90% of insects exhibit complete metamorphisis, including beetles, butterflies, moths, flies, wasps, ants, dragonflies, and many other orders. Complete metamorphisis is also common in marine animals. Most cnidarians exist as a polyp and medusa stage. Trematodes exist in a variety of juvenile body forms. Many species of mollusks possess a trochophore larva, and crustaceans develop via different larval stages, the first of which is known as a nauplius. Echinoderms develop first into free-swimming larvae, which later become more sedentary adults. In short, complete metamorphisis is very common among animals.
2. All chordates have four basic features common to all species within the phylum Chordata. These characteristics are not persistent throughout the life of all chordates, but appear during some time in the organism's life.
   1. Notochord—At some point in the life of a chordate, it has a support rod that lies between the digestive tract and the nerve cord. In higher vertebrates, the notochord is replaced by a jointed structure called the vertebral column and only remains as the soft material within the discs of the vertebrae.
   2. Dorsal, hollow nerve cord—In nonchordate invertebrates, the nerve cord is a solid tube that lies ventral to the digestive system. In the chordates, it is hollow and lies dorsal to the digestive system and the notochord. In vertebrates, this structure is commonly called the spinal cord. It attaches to the brain and sends and receives information to and from the body.
   3. Pharyngeal slits—In lower chordates such as the tunicate and the cephalochordates, the pharyngeal gill slits are used primarily for removing particulate matter from the water, which is known as filter feeding. In fishes and some amphibians, the gill slits are used for respiration. In higher vertebrates, the pharyngeal pouches are present only during embryonic development and give rise to structures in the neck and head region.
   4. Postanal tail—All chordates possess a tail during some time in the organism's life. In most chordates, this tail is kept throughout the life of the organism and serves a wide variety of functions. In some vertebrates such as humans, this tail is present only during embryonic development.

Chapter 34

1. Vertebrates can swim, crawl, walk or hop or run, burrow, slither, or fly. Fishes most commonly swim, though some may be able to crawl on land. Many amphibians, such as frogs, can swim and hop, while salamanders walk. Caecilians, however, burrow in the ground. Many reptiles can swim, walk, and even run, but the snakes slither along the ground. Most birds fly and all can walk or run, while penguins and some others can swim. Among the mammals, all these forms of locomotion are utilized, from flying bats and swimming whales to running dogs and burrowing moles.

2. Mammals evolved from small mammal-like lizards called therapsids about 220 million years ago. Since mammals evolved from reptiles, early mammals laid eggs like their reptilian ancestors. Even though this evolution took place millions of years ago, today there are still egg-laying mammals, called monotremes. Monotremes differ from all other mammals because they lay eggs. There are only three species of monotremes alive in the world today, and they are found only in Australia and New Guinea.

   The rest of the mammals all give birth to live young, although one group, the marsupials, give birth to young during a very immature stage of development, and the young make their way to a ventral pouch, where they continue their embryonic development. Like their monotreme cousins, the 260 known marsupial species are mostly found in Australia.

   All other mammals are considered eutherians, or placental mammals. Even though marsupials have a placenta, it is short-lived and not as complex as that in eutherians. In eutherians, the placenta is a much more complex and long-lasting structure that gives nutrients to the developing embryo. This prolongs the gestation period, and as a result of this, eutherian offspring are born at a much more developed state and have greater chance for survival. Today, eutherians are the most common mammal and are found all over the Earth.

Chapter 35

1. On a cut tree stump you would be able to locate the outer bark, secondary xylem, and annual rings, but the inner bark and vascular cambium would likely be too thin for you to see without the use of a microscope.
2. You would expect shoot growth to be particularly responsive to light, humidity, temperature, wind, and carbon dioxide concentration, because these physical factors influence photosynthesis. You would expect soil water, soil minerals, obstructing soil particles (such as rocks), and gravity to most strongly affect the growth of underground root systems.

Chapter 36

1. Natural plants produce bad-tasting secondary metabolites that keep herbivores from completely destroying them. Humans have taste receptors similar to those of other animals. Thus, the defensive chemicals taste bad to us also.
2. You could try to identify secondary metabolites that are distasteful to the particular herbivores but not distasteful or toxic to humans. If such compounds can be identified, you could determine which pathway enzymes for synthesizing these metabolites are missing from the crop plant or expressed at too low a level. You could try to use genetic engineering or conventional breeding techniques to add the missing enzymes to the crop genome, or increase the levels of metabolite expression. Alternatively, you could try to modify the crop so that it exudes volatile compounds that attract the enemies of the herbivores.

Chapter 37

1. You could start by deciding what kind of crop you want to grow and then research the mineral nutritional needs of that crop. Then you would have the soil analyzed to determine if the soil is deficient in one or more minerals, and apply the appropriate amount and type of organic or inorganic fertilizer. If the soil is deficient in nitrogen, you might choose to first grow a crop of clover or alfalfa, legumes whose symbiotic rhizobia enrich the soil with fixed nitrogen.
2. You could plant native vegetation along the edges of the stream. The vegetation would not only foster native wildlife, but also absorb nutrients in rainwater draining from your crop fields. This action would reduce the amount of minerals that enters the stream and thereby prevent the formation of harmful growths of cyanobacteria, algae, and aquatic plants. In addition, you could monitor the fertility status of your crop fields by having the soil tested for the mineral nutrient levels your crops require. Then you could apply the minimal amounts of fertilizer needed to supply the needs of your crops. This action would help to prevent excess minerals from washing into the stream and save you money.

Chapter 38

1. You could experimentally determine how effectively your crop plants obtain water and soil nutrient ions and how resistant your plant is to water loss under different simulated climate regimes. You could measure the relative water content of plants grown under different conditions of soil moisture. You might want to examine the extent of the root system, how thick the cuticle is, how responsive the stomata are to drought conditions, and whether or not your crop can use root pressure to refill xylem that has become embolized as the result of cold or drought. You might want to examine your crop for its ability to balance cytoplasmic osmotic conditions with solutes and protect membranes from plasmolysis damage.
2. If you see or imagine tall trees growing closely together, you can assume that soil moisture is high on average, because trees transpire huge quantities of water obtained from the soil. If you see or imagine abundant or low-growing plants, such as might occur in a grassland, you can deduce that soil water is relatively low, but constant enough to prevent plant death. If you see or imagine a desert, with relatively few plants visible, you can deduce that soil water is very low or sporadically available and that the plants present likely have specific adaptations allowing them to cope with water stress.

Chapter 39

1. Orchid flowers are bilaterally symmetrical because they can be cut by only one plane that would produce two identical halves. Bilateral symmetry is associated with bee pollination, and, in fact, bees do pollinate many orchids, though other pollination processes are involved in some cases. For example, Chinese botanists recently reported the case of an orchid that inhabits a windless site that is too dry for animal pollinators. This orchid has adapted to its unusual pollination circumstances by producing anthers that grow in a pattern that allows self-pollination. Because the gene *CYCLOIDEA* is involved in the development of bilaterally symmetrical flowers in at least two distantly related eudicot plants (snapdragon and *Gerbera*), it is reasonable to hypothesize that orchids, which are monocots, might possess a similar gene.
2. If egg cells and sperm cells are genetically similar, they could contribute the same deleterious recessive genes to the offspring, with the result that offspring would be homozygous for such genes, which would then be expressed. Humans avoid this process by cultural prohibitions against mating between close relatives. Plants avoid this problem by using self-incompatibility systems (among other processes). Self-incompatibility prevents pollen that is too closely related to stigma cells from delivering sperm cells to eggs in ovules.

Chapter 40

1. ***Negative feedback loop***—In a negative feedback loop, the system is working to return to homeostasis. Sometimes there is a physiological disturbance that pushes a system away from homeostasis. When this occurs, the organism must bring this system back to homeostasis. An example of this is when the human body temperature exceeds 37°C. When this occurs, compensatory mechanisms such as perspiring will occur until homeostasis (37°C) is achieved.

   Positive feedback loop—In a positive feedback loop, instead of moving toward homeostasis, the system is moving away from homeostasis. Positive feedback is much less common in nature than negative feedback. The process of birth in mammals is an example of a positive feedback loop. As the fetus pushes against the cervix of the mother, nerve signals from the cervix relay a signal to the brain and endocrine system, which, in turn, produce chemicals that cause stronger uterine contractions. The strong contractions stimulate the brain to make more chemicals that intensify the contractions even more, eventually resulting in the birth of the newborn.

2. All animals are multicellular, which means they are composed of many cells, unlike unicellular organisms such as bacteria. The cells in an animal's body are organized into groups of similar cells called tissues, such as epithelial, connective, muscle, and nervous tissue. When two or more types of tissues are arranged in a specific pattern, the resulting structure is called an organ. The lungs, heart, kidney, and liver are all examples of organs that are found in many animals. When several different organs work together to perform an overall function, it is called an organ system. The digestive, reproductive, and nervous systems are all major organ systems found in most animals.

Chapter 41

1. The nervous system of many animals is divided into the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS is composed of a brain and a nerve cord, which in vertebrates is the spinal cord. A major function of the brain is to interpret stimuli from all parts of the body. Once the stimulus is interpreted, the brain determines what response is necessary. The PNS consists of neurons and processes that are outside of the CNS but which connect to it. The PNS receives stimuli from the body and the environment and conveys it to the CNS for interpretation. In addition to receiving stimuli, the PNS is what allows the animal to respond to stimuli if a response is necessary. The distinction between a CNS and PNS is less clear in many invertebrates with simpler nervous systems.
2. The cell body—This is the part of the neuron that contains the nucleus and other organelles that are required to keep the cell alive.

   The dendrites—These are branched structures arising from the cell body. They receive chemical messages from other neurons and direct those signals to the cell body.

   The axon—This is the part of the neuron that transmits the electrical information away from the cell body and sends it to the next cell. The action potentials in an axon begin at the axon hillock, nearest the cell body, and end at the axon terminal. Most neurons have a single axon, but it may have branches.

   Myelin sheath—This is an insulating layer produced by glia cells that surrounds some axons in the nervous systems of vertebrates. The myelin sheath increases the speed of transmission of electrical impulses (action potentials) as they pass down the axon.

Chapter 42

1. Almost all animals have a nervous system, ranging from very simple to very complex. The simplest type of nervous system is the nerve net, which is found in cnidarians. In this type of nervous system, there is no structure analogous to a brain; all neurons are connected to each other in a network and can be activated at once. As a result, cnidarians can contract and move large areas of their bodies and tentacles at the same time in response to a predator. Other types of nervous systems concentrate neurons into ganglia. The function of the ganglia is to integrate inputs from the sense organs and control motor outputs such as locomotion. In addition to having ganglia, nerve cords in some invertebrates run along the ventral portion of the body starting with the ganglia in the head and ending in the tail region. These cords receive stimuli and allow the animal to respond to those stimuli if necessary.
2. The hindbrain—This is an extension of the spinal cord, and it includes the cerebellum and pons, which are responsible for monitoring and coordinating body movements. The pons also plays a role in regulating breathing. The medulla oblongata is also part of the hindbrain and is responsible for coordinating and controlling many of the body's functions, such as heart rate, breathing rate, digestion, swallowing, and vomiting. Together, the pons and medulla give rise to the cranial nerves and are part of the reticular formation.

   The midbrain—This part of the brain acts as a processing center for many of the sensory inputs, such as vision, smell, and hearing. In addition, it also has tracts that pass information on to other parts of the brain for interpretation. It also forms part of the reticular formation along with the medulla oblongata and the pons.

   The forebrain—This is the part of the brain responsible for the higher functions of consciousness, thought, and emotion. Most of the forebrain consists of a part called the cerebrum, which is the largest part of the vertebrate brain and includes the basal nuclei, the limbic system, and the cerebral cortex. The basal nuclei are involved in planning and learning movements. They also function via a complex circuitry to initiate or inhibit movements. The limbic system is primarily involved in the formation and expression of emotions and also plays a role in learning, memory, and the perception of smells. The cerebral cortex is involved with processing many complex sensory inputs and relaying motor outputs. These functions are also associated with learning and memory. The thalamus plays a major role in filtering and relaying sensory information to appropriate parts of the cerebrum and, in turn, sending outputs from the cerebrum to other parts of the brain. The hypothalamus controls functions of the gastrointestinal and reproductive systems and regulates many basic behaviors such as eating and drinking. This area has great importance for homeostasis of the body and the control of behavior. The epithalamus plays roles in the formation of cerebrospinal fluid, the control of food and water intake, and rhythmic and seasonal behaviors in some vertebrates.

Chapter 43

1. Mechanoreceptors detect physical stimuli such as sound, pressure, touch, and movement. These stimuli deform the mechanoreceptors, thus sending information to the central nervous system for interpretation.

   The lateral line system—These are sensory receptors that detect changes in water movement and are predominantly found in fishes (and some toads). In this sensory system, a series of pores and canals run along the sides and head of the fish and open up into the water. As the water around the fish is moved, it bends stereocilia which are attached to hair cells in the lateral line pores. As a result of this bending, sensory information is sent to the brain for interpretation and response.

   Skin receptors—Different types of sensory receptors are located at different depths below the surface of the skin. Some receptors are designed to detect light pressure, while others are deeper and detect much deeper pressure. Pressure on the skin deforms the receptors, triggering membrane depolarization.
2. Eye cup—This is the simplest of all the eyes found in animals. It consists of a cup containing photoreceptor cells that send information to the nervous system to be interpreted. This type of eye is able to differentiate between the presence and absence of light, and its direction, but doesn't form a visual image. An example of this type of eye is found in flatworms.

   Compound eye—This eye consists of several hundred to several thousand light detectors called ommatidia. Each ommatidium makes up one facet of the compound eye. By comparing images from many ommatidia, the eye forms an image that is sent to the brain for interpretation. This type of eye is found in arthropods, such as insects and crustaceans, and some annelids.

   Single lens eye—Unlike the compound eye, which has hundreds or thousands of lenses, this type of eye has only one lens; it is found in vertebrates and in some mollusks, snails, and annelids. Images are transmitted through a hole in the eye, called the pupil, and pass through a single lens. The image is then projected to the back of the eye onto the retina, which contains the photoreceptors. Changes in light induce electrical changes in retinal cells, which are transmitted via the optic nerves to the brain for interpretation.

Chapter 44

1. Three basic types of skeletons are found in animals: hydrostatic skeletons, exoskeletons, and endoskeletons. For all three types of skeletons, the main functions are support, protection, and locomotion.

   Hydrostatic skeleton—This is the type of skeleton found in most soft-bodied invertebrates such as cnidarians and earthworms. Since water is nearly incompressible, the animal can achieve locomotion by exerting muscular force against a fluid-filled cavity.

Exoskeleton—This is an external skeleton that surrounds the animal and provides support, protection, and an anchoring place for muscles involved in movement. The complexity, shape, thickness, and durability vary greatly from species to species, depending on where the organism lives and how it moves. In most instances, the exoskeleton does not grow along with the organism and must periodically be shed to accommodate an increase in body size. Exoskeletons can be found in arthropods.

Endoskeleton—Unlike exoskeletons, endoskeletons are internal and grow along with the organism. In all cases, endoskeletons are made up of minerals such as calcium, magnesium, and phosphate, but their complexity and exact composition depend on the type of organism and how it moves and lives. Endoskeletons can be found in all echinoderms, some sponges, and all vertebrates.

2. Skeletal muscle attaches via connective tissue to bone and is involved in locomotion and the movement of limbs and other body structures. It is under voluntary control. Due to its striped appearance when viewed under a microscope, skeletal muscle is also referred to as striated muscle. The striations are the myofibrils arranged in sarcomeres.

   Smooth muscle gets its name because it has no striations when viewed under a microscrope. It surrounds and forms the outer lining of hollow organs and tubes, including organs of the digestive, cardiovascular, and respiratory systems. Unlike skeletal muscle, smooth muscle is not under voluntary control; it contracts and relaxes spontaneously or in response to changes in neural input.

   Cardiac muscle is found in the heart. This striated type of muscle is responsible for generating the force that propels blood out of the heart and throughout the circulatory system.

Chapter 45

1. Suspension feeders—Some animals are suspension feeders, which sift water and filter out the organic matter it contains. This type of feeding is predominantly done by sessile invertebrates, which use mucus-covered cilia to trap suspended particles of organic matter, but is also found in baleen whales.

   Bulk feeders—These are animals that eat food in large pieces and may be omnivores, herbivores, or carnivores. Food may be sliced, torn, scraped, chopped, chewed, or swallowed whole.

   Fluid-feeders—These are animals that drink the nectar of plants or suck the blood of animals. Examples include nectar-drinking birds and blood-sucking worms and bats.

2. A nutrient is any substance that is consumed by an organism and is needed for survival, growth, development, tissue repair, or reproduction. By that definition, water is a nutrient.

   Essential amino acids—These are amino acids that in many animals cannot be made by cellular metabolism and must be obtained through the diet. Without these essential amino acids, animals would not be able to manufacture the proteins required for the animal to live. Many herbivores, however, cannot obtain these amino acids through their diet; such animals have the ability to manufacture these amino acids themselves.

   Essential fatty acids—Many of the fatty acids that animals need to function cannot be made by the animal's cells. These fatty acids must be obtained through the animal's diet and are known as essential fatty acids. These fatty acids can be obtained by either eating plants or animals.

   Vitamins—These are organic nutrients that serve as coenzymes for many metabolic pathways in animal bodies. For metabolism to function, these vitamins must be obtained through the diet. Without the proper balance of vitamins, severe health issues can occur.

   Minerals—These are important inorganic molecules that animals require to build skeletons, balance salt concentrations in their body fluids, and produce electric currents for normal function of the nervous system and muscles. Many of these important minerals are required only in trace amounts and can be stored in certain body structures, such as the skeleton, to reduce the risk of mineral deficiency.

Chapter 46

1. Organisms that are ectothermic depend on external heat sources to warm the body. Consequently, these animals tend to require less energy consumption. One disadvantage of being ectothermic is that ectotherms can be maximally active only during warm times of the day or during warm times of the year. All invertebrates, fishes, amphibians, and reptiles are ectothermic and rely on environmental heat sources and behavioral mechanisms to regulate their body temperatures.

   Endothermic animals regulate their body temperatures from within despite changes in the environment, although their body temperature may be influenced by their external environment. An advantage of endothermy is the ability to be maximally active at any time; this allows endotherms to inhabit all climates. One of the costs of endothermy is that it requires considerable energy expenditure and a high metabolic rate to generate internal heat. The high metabolic demands require high energy consumption, and such animals must feed often enough to supply that energy. Overheating is also a concern in animals with a high metabolic rate, particularly when they are active on hot days. Birds and mammals are examples of endotherms.

   Homeotherms maintain body temperature within a relatively narrow range at all times. Heterotherms, by contrast, do not. All animals fall into two categories, either ectotherm or endotherm, and either homeotherm or heterotherm.

2. The four types of heat exchange between animals and the environment include radiation, conduction, convection, and evaporation.

   Radiation—This is the emission of electromagnetic waves from objects such as the sun or a warm body. If an animal is warmer than its surrounding environment, then heat is given off (radiated) by that animal. Conversely, if the outside environment is warmer than an animal's body, the animal will gain heat by radiation from the environment.

   Conduction—This is the exchange of heat through direct contact with a warmer or cooler substance such as water or a solid substrate. The greater the difference in temperature between an animal's body and the substance it is in contact with, the more heat will be exchanged. The density of the substrate touching the animal and the surface area of the animal's body in contact with the substrate will also influence the amount of heat exchanged.

   Convection—This is the transfer of heat by the movement of air or water currents next to the body. A person standing before a fan on a hot day loses heat more quickly because the warm air near his or her body is carried away by convection more quickly. This helps maintain a gradient for further loss of heat from the body.

   Evaporation—This exchange is achieved through the loss or evaporation of water from the skin or mucous membranes of an animal. Heat energy causes water to move from the liquid phase to the gas phase. As it does so, the gaseous water carries heat with it, thereby cooling an animal's body and lowering its body temperature.

Chapter 47

1. Blood consists of water, dissolved solutes, and several types of cells or cell fragments.

   Plasma is a yellowish solution of water and solutes, making up 35–60% of the total volume of blood in vertebrates. It transports water and organic and inorganic nutrients absorbed from the digestive tract, dissolved oxygen, waste products of metabolism like carbon dioxide, and other molecules produced by cells and secreted into the blood.

   Leukocytes, or white blood cells, of several types defend the body against infection and disease.

   Erythrocytes, or red blood cells, contain hemoglobin and transport oxygen throughout the body.

   Platelets play a crucial role in the formation of blood clots.

2. ***Single circulation***—This is the type of closed circulatory system found in fishes and is the simplest type of circulation found in vertebrates. In this system, deoxygenated blood from the tissues is

returned to the two-chambered heart, which then pumps the blood to the gills. In the gills, blood picks up oxygen and unloads carbon dioxide, then circulates to the tissues to drop off oxygen and nutrients and pick up carbon dioxide and wastes. Arteries are the blood vessels that carry blood away from the heart, and veins carry blood to the heart. There is no boost in blood pressure after blood leaves the gills.

Double circulation—This is the type of circulatory system found in crocodiles, birds, and mammals and is divided into two parts: the systemic and pulmonary circulations. In the systemic circulation, blood is pumped from the left side of the heart to the body to drop off oxygen and nutrients and pick up carbon dioxide and wastes. The blood then returns to the right side of the heart. In the pulmonary circulation, the right side of the heart provides a second pumping mechanism that sends blood to the lungs to release carbon dioxide and pick up oxygen from the atmosphere. Due to the fact that the heart is divided into a right and left side, it acts as two hearts in one, which increases the efficiency of the circulation. Amphibians and most reptiles have a circulation with features of both types.

Chapter 48

1. Animals exchange gases with an aqueous environment in two major ways: (1) across the skin or body surface and (2) via gills. In small invertebrates with bodies that are only a few cell layers thick, oxygen and carbon dioxide can rapidly diffuse across the body surface and to the interior parts of the animal. As a result, they require no special respiratory organs such as lungs or gills. Diffusion of gases across the body surface occurs in most amphibians; they have skin that is highly permeable to oxygen and carbon dioxide. Although these amphibians require gills or lungs for most of their oxygen and carbon dioxide exchange, diffusion of gases across the skin represents an important adaptation for amphibious life.

   Most exclusively aquatic animals other than marine mammals have specialized respiratory structures called gills. These can be either uncovered extensions from the body surface called external gills, or they can be enclosed in a protective cavity, in which case they are called internal gills. External gills may be concentrated in one part of the body, or they may be scattered over a large area. Having external gills has two major drawbacks. One is that the gills can be damaged by the environment, and the other is that the constant waving of the elaborate-looking gills that occurs for adequate ventilation to take place can draw the attention of predators.

   In internal gills—which are found in fishes—the gills are covered by a bony plate called an operculum. This structure acts to aid in ventilation by helping to draw oxygenated water over the gills. In addition, the operculum provides protection to the gills and decreases the chances of damage by the environment.

2. Air enters either through the nose or the mouth and passes on to the pharynx. The nose and pharynx help to filter, warm, and moisturize the air that enters from the outside world. This part of the respiratory system also produces mucus, which helps to trap particles from the air. After the pharynx, the air moves to the larynx and then to the trachea. The trachea is also lined with mucus-producing cells, which trap particles that were missed by the nose and pharynx. In addition, the trachea is lined with ciliated epithelium that moves the mucus to the pharynx where it is swallowed. After the trachea, the respiratory system divides into two tubes—the right bronchus and the left bronchus—before dividing into smaller tubes called bronchioles. At the ends of the bronchioles there are saclike structures called alveoli that are surrounded by capillaries. It is at the alveoli that the exchange of oxygen and carbon dioxide takes place. The breathing process is facilitated by the intercostal muscles, which lie between the ribs and a large dome-shaped muscle called the diaphragm. The action of these two groups of muscles creates a negative pressure that enables the animal to inhale air.

Chapter 49

1. Protonephridia are composed of a series of branching tubules that filter fluid from the body cavity. Cilia are used to draw the filtrate into the excretory system. Solutes that are important to the organism can be reabsorbed into the interstitial fluid. The remaining filtrate ultimately empties into nephridiopores leading to the outside of the animal. An example of this type of excretory system is found in flatworms.

   Metanephridia are pairs of tubules in each body segment of annelid worms. Interstitial fluid is filtered through structures called nephrostomes. As the filtrate passes down the tubule of the metanephridia, salts and other beneficial solutes are reabsorbed into capillaries before the dilute urine is excreted via nephridiopores.

2. The first part of the nephron is called the renal corpuscle, where the filtrate from the glomerular capillaries enters Bowman's capsule. From there, the filtrate passes on to the proximal convoluted tubule, where most of the reabsorption of useful solutes occurs. After the proximal tubule, fluid moves into the loop of Henle, where additional water and salt are reabsorbed. Next, the fluid enters the distal convoluted tubule, where fine-tuning of solute reabsorption and secretion takes place. Finally, the fluid in the distal convoluted tubule empties into a collecting duct, where the final composition of urine is established before it leaves the body.

Chapter 50

1. Two hormones, 20-hydroxyecdysone and juvenile hormone, play major roles in insect development. Ecdysone is secreted by a pair of glands called the prothoracic glands. Twenty-hydroxyecdysone stimulates rapid differentiation and causes the larva to molt. Juvenile hormone is secreted by the corpus allatum, and its main responsibility is to control the nature of the molt induced by 20-hydroxyecdysone. Not until the levels of juvenile hormone decline to nearly zero does the molt result in the transition from a larva to a pupa.
2. Androgens such as testosterone control reproduction in males and are produced in the testes. Progesterone and estrogens such as estradiol and progesterone control reproduction in females and are produced in the ovaries. Mineralocorticoids such as aldosterone are produced by the glomerulosa cells of the adrenal cortex and act to regulate salt and water balance. Glucocorticoids such as cortisol are produced by the fasciculata cells of the adrenal cortex; these hormones are catabolic, suppress the immune system, and are an important part of the response to stress. The hormone 1,25-dihydroxyvitamin D is derived from precursors in the skin or formed from dietary vitamin D. It acts to increase Ca^{2+} absorption from the intestines.

Chapter 51

1. Asexual reproduction is the production of offspring from a single parent without the fusion of male and female gametes. Examples include budding, regeneration, and parthenogenesis.
2. External fertilization—Eggs are fertilized by sperm outside of the female's body in aquatic environments; eggs and sperm must be released in close proximity for fertilization to occur. Often, certain behaviors bring male and female gametes into close contact. For example, a male frog clasping onto a female stimulates her to release her eggs, and the male to release sperm. One disadvantage of external fertilization is that eggs and sperm are vulnerable to predation and damage.

   Internal fertilization—Sperm are deposited within the female through a process called copulation. This process protects the gametes from environmental hazards and guarantees that sperm are placed in close proximity to eggs. Once eggs are fertilized, they begin their development within the female, which protects developing embryos from environmental hazards and predation.

Chapter 52

1. During gastrulation, the hollow ball of cells called the blastula is converted into a highly organized structure with three germ layers—endoderm, mesoderm, and ectoderm. These partially differentiated cells ultimately give rise to all of the tissues in the embryo. The three germ layers occupy discrete regions within the embryo—outer ectoderm, middle mesoderm, and inner endoderm. Each of these germ layers will give rise to distinct tissue types. Ectoderm will give rise

to the epidermis and nervous system tissue. Mesoderm will give rise to muscle, bone, and blood. Endoderm will give rise to organs in the respiratory and digestive systems. Finally, another major event that occurs during gastrulation is the formation of the archenteron, which will become the digestive tract.

2. Neurulation is the formation of the neural tube within the embryo. In the first part of neurulation, the ectoderm overlaying the notochord thickens, forming the neural plate. In the dorsal region of the embryo, cells of the neural plate begin to elongate along the anteroposterior axis. Next, the center of the neural plate begins to develop the neural groove, a depression down the center. The lateral edges of the neural plate begin to fold up, creating a valley-like structure along the neural plate. Third, the edges of the neural plate begin to fold and converge toward each other, generating a tubelike structure that is not yet sealed on the dorsal side. Finally, the dorsal-most cells on either side of the developing neural tube fuse with each other, resulting in closure of the neural tube. At the same time, the ectoderm on either side of the neural tube comes together and fuses, forming the epidermis of the embryo.

Chapter 53

1. Three types of pathogens that affect the health of animals are bacteria, viruses, and eukaryotic parasites.

   Bacteria—These organisms can either damage tissues directly or release into the bloodstream toxins that can disrupt functions in other parts of the body. Bacteria are responsible for many of the diseases in humans, including strep throat, food poisoning, Lyme disease, and pneumonia. These organisms can gain entry through direct contact with open wounds, through the respiratory system, or through ingestion of food or water.

   Viruses—These pathogens are nucleic acids enclosed within a protein coat and are much smaller than bacteria. They must infect a host cell and commandeer its cellular machinery and energy sources to make more viruses. Like bacteria, viruses cause many common human diseases, including influenza, HIV infection/AIDS, herpes, and the common cold.

   Eukaryotic parasites—These are unicellular eukaryotic organisms such as fungi, protozoa, and some worms. These organisms can damage tissue and extract nutrients from the host organism. Among the many parasitic diseases that affect humans are malaria, and roundworm and tapeworm infestations.

2. Helper T cells are involved in numerous aspects of immune defense. These include binding to antigen fragments complexed to Class II MHC proteins on the surface of antigen-presenting cells, such as macrophages. This process activates the helper T cell, stimulating it to divide and enabling it to secrete IL-2 and other cytokines. The cytokines, in turn, stimulate B cells and cytotoxic T cells. Helper T cells, once activated, also bind to B cells and stimulate B cell clonal selection.

Chapter 54

1. Ensure the park is burned frequently. More frequent fires use up fuel supplies and ensure future fires do not burn out of control. Yosemite allows fires to burn in 80% of the park. Prior to 2008, the area outside the park hadn't had a big fire for 20 years, leaving bushes and shrubs to grow unchecked. The recent proliferation of homes in the area decreased the opportunities for controlled burns.
2. The answer depends on where the course is being taught. Answering this question is an excellent way to get students to think about the world that surrounds them every day.

Chapter 55

1. Just as with geese, young cranes exhibit imprinting behavior. Human researchers took advantage of this behavior and encouraged young cranes to imprint on humans dressed in crane suits. They even flew behind ultralight planes piloted by crane-suited researchers, following them to their overwintering sites.
2. Chemical—Chemical communication is often used among animals to mark territory or food sources or to attract mates.

   Sound—This method of communication has a long range. It is a good method of communication between members of the same species, especially members of the opposite sex.

   Visual—In courtship, animals use a vast number of visual signals to identify and select potential mates. One drawback is that by the time visual communication has been established, the two organisms will be in close proximity to each other and conflict could occur.

   Tactile—Many individuals of the same species communicate through direct contact with each other. Tactile information is often used by insects, for example, to convey information about food.

Chapter 56

1. The first type are called *r*-selected species. This type of species typically produces a large number of offspring, shows little parental care, has a short life span, is small in size, and has rapid growth. Insects and weeds are excellent examples of this type of life history strategy.

   The second type are called *K*-selected species. This type of species typically produces a small number of offspring, shows a lot of parental care, has a long life span, is large in size, and has slow growth. Elephants and maple trees are excellent examples of this type of life history strategy.
2. In a social setting, such as a cafeteria, students often show a clumped dispersion pattern. This is because friends often sit together to eat, perhaps near windows, creating a clumped pattern. In half-full classrooms, clumped dispersions also occur. In a full classroom, the dispersion pattern is uniform, with a similar distance separating each student from the next. Uniform dispersion patterns can also arise at test times in half-full classrooms where the professor or instructor requires students to spread out and maintain an empty seat between them. Random patterns are rarer. However, an aerial view of a campus between class times may reveal a random pattern as students travel in different directions to different classes at different times, often independently of other students.

Chapter 57

1. Without their natural enemies, herbivore numbers can increase rapidly and may decimate local vegetation, which is what happened in Yellowstone National Park prior to wolf reintroduction. Wolf reintroduction in the 1990s reduced the abundance of elk, which, in turn, promoted the growth of two major food plants, aspen and willow trees. The beneficial effects didn't stop there. Increased tree numbers increased the abundance of song birds, which perch and feed in the trees. Beaver numbers also increased because of more trees that they could chop down and feed on.
2. Many animals have developed chemical defenses to prevent them from being eaten by a predator. Poisons and toxins are examples of this type of antipredator defense. If a predator eats an animal that is poisonous, the toxin may cause the predator to become sick, thus deterring that predator from eating other members of that species. Aposematic coloration, or warning coloration, advertises an organism's unpalatable taste. Cryptic coloration or camouflage allows the animal to blend into its surroundings through the color or the shape of its body. In mimicry, noxious species converge to look the same (Müllerian mimicry) or a palatable species evolves to resemble an unpalatable species (Batesian mimicry). In intimidation, an animal puts on a display to intimidate the would-be predator. One of the most common methods of this type of defense is when the prey item makes itself look bigger. Fighting, escape, armor, and masting are other types of antipredator defenses.

Chapter 58

1. The time hypothesis predicts that the number of species increases over time and that temperate regions have less-rich communities than tropical regions. This is due to the fact that temperate regions have just recently recovered from a glacial period and species that could possibly live in temperate regions have not yet migrated back into the

recently exposed area. One drawback to this hypothesis is that it has limited applications to marine ecosystems.

The area hypothesis proposes that larger areas contain more species than smaller areas because they support a greater diversity of habitats and larger populations are less prone to extinctions. However, the area hypothesis seems unable to explain why, if increased richness is linked to increased area, there are not more species in the vast contiguous landmass of Asia, a large area with low species richness.

The productivity hypothesis proposes that greater production by plants results in greater overall species richness. An increase in plant biomass leads to an increase in the number of herbivores and hence an increase in the number of predator, parasite, and scavenger species. There are exceptions to this hypothesis. For example, there are parts of the tropical seas that have low productivity but high richness, and parts of the sub-Antarctic Ocean that have high productivity but low species richness.

Because there are exceptions to each of these hypotheses, it is likely that for any given point on Earth, species richness may be affected by the interaction of several different factors.

2.

Relative abundance of species				H_S	Maximum possible diversity
Community	Species 1	Species 2	Species 3		
1	90	10	—	0.325	0.693
2	50	50	—	0.693	0.693
3	80	10	10	0.638	1.10
4	33.3	33.3	33.3	1.10	1.10

Chapter 59

1. At the base of the food chain is a group of organisms called the primary producers. These are generally plants, algae, and photosynthetic prokaryotes collectively known as autotrophs. Next are the primary consumers, which feed on the primary producers. These organisms are sometimes referred to as herbivores. Third are the secondary consumers, which feed on primary consumers. These are also called carnivores. Next are the tertiary consumers, which feed on the secondary consumers. Finally, we have the detritivores and decomposers. These organisms feed on decaying organisms from all trophic levels.
2. As we learned in Chapter 54, most scientists believe atmospheric CO_2 levels will have reached about 700 ppm by the end of the century, though extrapolation from Figure 59.18 puts the level closer to 550 ppm. The effects of such an increase are many and varied. Global warming will increase and cause a shift in the distribution of many organisms. Other organisms that cannot easily move, such as those on islands or mountain tops, will go extinct. Precipitation rates will change with most areas getting wetter, but some deserts and continental interiors becoming drier. As we learned from Chapter 54, such changes may affect the frequency of disease. Changing temperatures will also alter the phenology, or timing, of many events, such as bud burst and the reproductive cycles of many organisms. For example, frogs and birds may start to breed earlier in the year. In addition, increased levels of CO_2 will further reduce foliar nitrogen and lower herbivory levels. In theory, reduced foliar nitrogen in leaf litter could change decomposition rates and affect rates of nutrient cycling in both terrestrial and aquatic ecosystems. Greater plant productivity could also elevate litterfall, increasing the frequency and severity of wildfires. Elevated CO_2 could increase the acidity of the oceans, increasing mortality of corals and other sensitive organisms.

Chapter 60

1. Introduced species, also referred to as exotic species, are species that are moved by humans from their native habitat to a different location. As a result, the introduced species may interfere with and possibly outcompete native species for resources or feed on native species. If the introduced species outcompetes or preys heavily on the native species, then the native species may become threatened, endangered, or extinct.

   Habitat destruction is predominantly a result of deforestation through the removal of trees and plants from a habitat. As a result of this removal of habitat, species are forced into smaller and smaller habitats, thereby increasing the stress placed on the species who reside there. This habitat reduction, if left unchecked, may result in the extinction of one or many species.

   Direct exploitation occurs when an organism is overharvested by humans. As a result, the number of individuals is greatly reduced, thus putting pressure on the population. If too many individuals are removed, reproduction becomes difficult, and due to the decrease in population size and genetic diversity, the species may become extinct.
2. Because your goal is to maximize biodiversity, you would choose an area rich in species, not necessarily endemic species. According to the principles we discussed in Chapter 57, you would try to select an area where the individuals are spread fairly evenly among species, maximizing the Shannon diversity index. According to the theoretical tenets laid out in Figure 60.12, you might establish a series of small parks, containing a diverse array of habitats, rather than one large park. You might minimize the amount of edge in each of these parks by maximizing the area : perimeter ratio. You might also decide to link the parks by a series of habitat corridors to minimize extinctions. Finally, you would try to ensure that the park is adequately patrolled, to minimize poaching.
