**Reinforced Binding**

What does it mean?

This textbook is widely adopted by colleges and universities yet it is frequently used in high school for teaching Advanced Placement\*, honors and electives courses. Since high schools frequently adopt for several years, it is important that a textbook can withstand the wear and tear of usage by multiple students. To ensure durability, McGraw-Hill has elected to manufacture this textbook in compliance with the "Manufacturing Standards and Specifications for Textbook Administrators" (MSST) published by the National Association of State Textbook Administrators (NASTA). The MSST manufacturing guidelines provide minimum standards for the binding, paper type, and other physical characteristics of a text with the goal of making it more durable.

# Brief Contents

**Preface** v

**Guided Tour** x

**Contents** xxi

## **Part I** *The Molecular Basis of Life* 1

- 1 The Science of Biology 1
- 2 The Nature of Molecules and the Properties of Water 17
- 3 The Chemical Building Blocks of Life 33

## **Part II** *The Biology of the Cell* 59

- 4 Cell Structure 59
- 5 Membranes 88
- 6 Energy and Metabolism 107
- 7 How Cells Harvest Energy 122
- 8 Photosynthesis 147
- 9 Cell Communication 168
- 10 How Cells Divide 186

## **Part III** *Genetic and Molecular Biology* 207

- 11 Sexual Reproduction and Meiosis 207
- 12 Patterns of Inheritance 221
- 13 Chromosomes, Mapping, and the Meiosis–Inheritance Connection 239
- 14 DNA: The Genetic Material 256
- 15 Genes and How They Work 278
- 16 Control of Gene Expression 304
- 17 Biotechnology 327
- 18 Genomics 352
- 19 Cellular Mechanisms & Development 372

## **Part IV** *Evolution* 396

- 20 Genes Within Populations 396
- 21 The Evidence for Evolution 417
- 22 The Origin of Species 436
- 23 Systematics and the Phylogenetic Revolution 456
- 24 Genome Evolution 474
- 25 Evolution of Development 492

## **Part V** *The Diversity of Life* 507

- 26 The Tree of Life 507
- 27 Viruses 528
- 28 Prokaryotes 545

- 29 Protists 567
- 30 Green Plants 588
- 31 Fungi 614
- 32 Overview of Animal Diversity 633
- 33 Noncoelomate Invertebrates 649
- 34 Coelomate Invertebrates 666
- 35 Vertebrates 693

## **Part VI** *Plant Form and Function* 729

- 36 Plant Form 729
- 37 Vegetative Plant Development 753
- 38 Transport in Plants 769
- 39 Plant Nutrition and Soils 786
- 40 Plant Defense Responses 802
- 41 Sensory Systems in Plants 814
- 42 Plant Reproduction 839

## **Part VII** *Animal Form and Function* 863

- 43 The Animal Body and Principles of Regulation 863
- 44 The Nervous System 887
- 45 Sensory Systems 915
- 46 The Endocrine System 937

# About the Authors

Pictured left to right: Susan Rundell Singer, Jonathan Losos, Kenneth Mason

**Kenneth Mason** is a lecturer at the University of Iowa where he teaches introductory biology. He was formerly at Purdue University where for 6 years he was responsible for the largest introductory biology course on campus and collaborated with chemistry and physics faculty on an innovative new course supported by the National Science Foundation that combined biology, chemistry, and physics. Prior to Purdue, he was on the faculty at the University of Kansas for 11 years, where he did research on the genetics of pigmentation in amphibians, publishing both original work and reviews on the topic. While there he taught a variety of courses, was involved in curricular issues, and wrote the lab manual for an upper division genetics laboratory course. His latest move to the University of Iowa was precipitated by his wife's being named president of the University of Iowa.

**Jonathan Losos** is the Monique and Philip Lehner Professor for the Study of Latin America in the Department of Organismic and Evolutionary Biology and curator of herpetology at the Museum of Comparative Zoology at Harvard University. Losos's research has focused on studying patterns of adaptive radiation and evolutionary diversification in lizards. The recipient of several awards, including the prestigious Theodosius Dobzhansky and David Starr Jordan Prizes, and the Edward Osborne-Wilson Naturalist Award. Losos has published more than 100 scientific articles.

**Susan Rundell Singer** is the Laurence McKinley Gould Professor of the Natural Sciences in the department of biology at Carleton College in Northfield, Minnesota, where she has taught introductory biology, plant biology, genetics, plant development, and developmental genetics for 23 years. Her research interests focus on the development and evolution of flowering plants. Singer has authored numerous scientific publications on plant development, contributed chapters to developmental biology texts, and is actively involved with the education efforts of several professional societies. She received the American Society of Plant Biology's Excellence in Teaching Award, serves on the National Academies Board on Science Education, and chaired the National Research Council study committee that produced *America's Lab Report*.

# Committed To Excellence

This edition continues the evolution of the new Raven & Johnson's *Biology*. The author team is committed to continually improving the text, keeping the student and learning foremost. We have an improved design and updated pedagogical features to complement the new art program and completely revised content of the transformative eighth edition of *Biology*. This latest edition of the text maintains the clear, accessible, and engaging writing style of past editions while maintaining the clear emphasis on evolution and scientific inquiry that made this a leading textbook for students majoring in biology. This emphasis on the organizing power of evolution is combined with a modern integration of the importance of cellular and molecular biology and genomics to offer our readers a text that is student-friendly while containing current content discussed from the most modern perspective.

We are committed to producing the best possible text for both student and faculty. Lead author, Kenneth Mason (University of Iowa) has taught majors biology at three different major public universities for more than 15 years. Jonathan Losos (Harvard University) is at the cutting edge of evolutionary biology research and has taught evolutionary biology to both biology majors and nonmajors students. Susan Rundell Singer (Carleton College) has been deeply involved in science education policy issues on a national level.

The extensive nature of the revision for the eighth edition allowed the incorporation of the most current possible content throughout. This has been continued in the ninth edition. Here we provide a more consistent approach to concepts so that the reader is not buried in detail in one chapter and left wondering how something works in another. In all chapters, we provide a modern perspective emphasizing the structure and function of macromolecules and the evolutionary process that has led to this structure and function.

This modern approach is illustrated with two examples. First, genomics are not given one chapter and otherwise ignored. Instead, results from the analysis of genomes are presented in context across the text. It is important that these results are provided in the context of our traditional approaches and not just lumped into a single chapter. We do not ignore the unique features of this approach and therefore provide two chapters devoted to genomics and to genome evolution.

A second example is expanded coverage of noncoding RNA. It is hard to believe how rapidly miRNA have moved from a mere curiosity to a major topic in gene expression. We have included both new text and graphics on this important topic. The results from complete genome sequencing have highlighted this important category of RNA that was largely ignored in past texts.

The revised physiology unit has been further updated to strengthen the evolutionary basis for understanding this section. The single chapter on circulation and respiration has been broken into two to provide a more reasonable amount of material for the student in each chapter. The coverage of temperature regulation has also been moved to the introductory chapter 43: The Animal Body and Principles of Regulation to provide a concrete example of regulation. All of this should enhance readability for the student as well as integrate this material even closer with the rest of the text.

The entire approach throughout the text is to emphasize important biological concepts. This conceptual approach is supported by an evolutionary perspective and an emphasis on scientific inquiry. Rather than present only dry facts, our conceptual view combines an emphasis on scientific inquiry.

## Our Consistent Themes

It is important to have consistent themes that organize and unify a text. A number of themes are used throughout the book to unify the broad-ranging material that makes up modern biology. This begins with the primary goal of this textbook to provide a comprehensive understanding of evolutionary theory and the scientific basis for this view. We use an experimental framework combining both historical and contemporary research examples to help students appreciate the progressive and integrated nature of science.

### *Biology Is Based on an Understanding of Evolution*

When Peter Raven and George Johnson began work on *Biology* in 1982 they set out to write a text that presented biology the way they taught in their classrooms—as the product of evolution. We bear in mind always that all biology “only makes sense in the light of evolution;” so this text is enhanced by a consistent evolutionary theme that is woven throughout the text, and we have enhanced this theme in the ninth edition.

The enhanced evolutionary thread can be found in obvious examples such as the two chapters on molecular evolution, but can also be seen throughout the text. As each section considers the current state of knowledge, the “what” of biological phenomenon, they also consider how each system may have arisen by evolution, the “where it came from” of biological phenomenon.

We added an explicit phylogenetic perspective to the understanding of animal form and function. This is most obvious in the numerous figures containing phylogenies in the form and function chapters. The diversity material is supported by the most up-to-date approach to phylogenies of both

animals and plants. Together these current approaches add even more evolutionary support to a text that set the standard for the integration of evolution in biology.

Our approach allows evolution to be dealt with in the context in which it is relevant. The material throughout this book is considered not only in terms of present structure and function, but how that structure and function may have arisen via evolution by natural selection.

### ***Biology Uses the Methods of Scientific Inquiry***

Another unifying theme within the text is that knowledge arises from experimental work that moves us progressively forward. The use of historical and experimental approaches throughout allow the student not only to see where the field is now, but more importantly, how we arrived here. The incredible expansion of knowledge in biology has created challenges for authors in deciding what content to keep, and to what level an introductory text should strive. We have tried to keep as much historical context as possible and to provide this within an experimental framework consistently throughout the text.

We use a variety of approaches to expose the student to scientific inquiry. We use our new Scientific Thinking figures to walk through an experiment and its implications. These figures always use material that is relevant to the story being told. Data are also provided throughout the text, and other figures illustrate how we arrived at our current view of the topics that make up the different sections. Students are provided with Inquiry Questions to stimulate thinking about the material throughout the book. The questions often involve data that are presented in figures, but are not limited to this approach, also leading the student to question the material in the text as well.

### ***Biology Is an Integrative Science***

The explosion of molecular information has reverberated throughout all areas of biological study. Scientists are increasingly able to describe complicated processes in terms of the

This chapter covers one of the fastest-progressing fields in biology. It must cover fundamental topics as well as a wide variety of real and potential applications of the technology. The chapter does all of this well. There is good continuity from one section to the next, which I find important to make the text “readable.”

*Michael Lentz*  
*University of North Florida*

interaction of specific molecules, and this knowledge of life at the molecular level has illuminated relationships that were previously unknown. Using this cutting-edge information, we more strongly connect the different areas of biology in this edition.

One example of this integration concerns the structure and function of biological molecules—an emphasis of modern biology. This edition brings that focus to the entire book, using this as a theme to weave together the different aspects of content material with a modern perspective. Given the enormous amount of information that has accumulated in recent years, this emphasis on structure and function provides a necessary thread integrating these new perspectives into the fabric of the traditional biology text.

Although all current biology texts have added a genomics chapter, our text was one of the first to do so. This chapter has been updated, and we have added a chapter on the evolution of genomes. More importantly, the results from the analysis of genomes and the proteomes they encode have been added throughout the book wherever this information is relevant. This allows a more modern perspective throughout the book rather than limiting it to a few chapters. Examples, for instance, can be found in the diversity chapters, where classification of some organisms were updated based on new findings revealed by molecular techniques.

This systems approach to biology also shows up at the level of chapter organization. We introduce genomes in the genetics section in the context of learning about DNA and genomics. We then come back to this topic with an entire chapter at the end of the evolution unit where we look at the evolution of genomes, followed by a chapter on the evolution of development, which leads into our unit on the diversity of organisms.

Similarly, we introduce the topic of development with a chapter in the genetics section, return to it in the evolution unit, and dedicate chapters to it in both the plant and animal units. This layering of concepts is important because we believe that students best understand evolution, development, physiology, and ecology when they can reflect on the connections between the microscopic and macroscopic levels of organization.

We’re excited about how we moved the previous high-quality textbook forward in a significant way for a new generation of students. All of us have extensive experience teaching undergraduate biology, and we’ve used this knowledge as a guide in producing a text that is up to date, beautifully illustrated, and pedagogically sound for the student. We’ve also worked to provide clear explicit learning objectives, and more closely integrate the text with its media support materials to provide instructors with an excellent complement to their teaching.

***Ken Mason, Jonathan Losos, Susan Rundell Singer***

# Cutting Edge Science

## Changes to the Ninth Edition

### Part I: The Molecular Basis of Life

The material in this section does not change much with time. However, we have updated it to make it more friendly to the student. The student is introduced to the pedagogical features that characterize the book here: learning objectives with various levels of cognitive difficulty, scientific thinking figures, and an integrated approach to guide the student through complex material.

In chapter 1, the idea of emergent properties has been clarified and material added to emphasize the nonequilibrium nature of biology. This will help introduce students to the fundamental nature of biological systems and prepare them for the rest of the book.

### Part II: Biology of the Cell

The overall organization of this section was retained, but material on cell junctions and cell-to-cell interactions was moved from chapter 9 to chapter 4, where it forms a natural conclusion to cell structure. Within chapter 4 microsome/peroxisome biogenesis was clarified to complete the picture of cell structure. The nature of trans fats is clarified, a subject students are likely to have been exposed to but not understand. A brief discussion of the distribution of lipids in different membranes was also added.

**Chapter 7**—The organization of chapter 7 was improved for greater clarity. ATP structure and function is introduced earlier, and the opening summary section covering all of respiration was removed. This allows the information to unfold in a way that is easier to digest. A new analogy was added for the mechanism of ATP synthase to make this difficult enzyme more approachable.

**Chapter 8**—The section on bacterial photosynthesis was completely rewritten for clarity and accuracy. In addition to the emphasis we always had on the experimental history of photosynthesis, the scientific thinking figures for chapters 7 and 8 are complementary and cross referenced to reinforce how we accumulate evidence for complex phenomenon such as chemiosmosis.

**Chapter 9**—The removal of the cell junction material keeps the focus of chapter 9 on signaling through receptors, making this difficult topic more accessible. The distribution of G protein-coupled receptor genes in humans and mouse was updated.

**Chapter 10**—The discussion of bacterial cell division was updated again to reflect the enormous change in our view of this field. The organization of the chapter was tightened, by combining mitosis and cytokinesis as M phase. Not only is this a consensus view in the field, it simplifies the overall organization for greater clarity.

### Part III: Genetic and Molecular Biology

The overall organization of this section remains the same. The splitting of transmission genetics into two chapters allows students to first be introduced to general principles, then tie these back to the behavior of chromosomes and the more complex topics related to genetic mapping.

Content changes in the molecular genetics portion of this section are intended to do two things: (1) update material that is the most rapidly changing in the entire book, and (2) introduce the idea that RNA plays a much greater role now than appreciated in the past. The view of RNA has undergone a revolution that is underappreciated in introductory textbooks. This has led to a complete updating of the section in chapter 16 on small RNAs complete with new graphics to go with the greatly expanded and reorganized text. This new section should both introduce students to exciting new material and organize it so as to make it coherent with the rest of the chapter. The new material is put into historical context and updated to distinguish between siRNA and miRNA, and the mechanisms of RNA silencing. Material on the classical bacterial operons *trp* and *lac* was also refined for greater clarity.

**Chapter 11**—The information on meiotic cohesins and protection of cohesins during meiosis I was clarified and updated. This is critical for students to understand how meiosis actually works as opposed to memorizing a series of events.

**Chapter 12**—The second example of epistasis, which did not have graphical support in the eighth edition, was removed. This allows the remaining example to be explored in greater detail. The organization of the explication of Mendel's principles was tightened to improve clarity.

**Chapter 14**—Material on the eukaryotic replisome was updated and the graphics for this refined from the last edition. Archaeal replication proteins are also introduced to give the student a more complete view of replication.

**Chapter 15**—Has been tightened considerably. The example of sickle cell anemia was moved from chapter 13 to 15, where it fits more naturally in a discussion of how mutations affect gene function.

**Chapter 17**—Our goal is to help students apply what they've learned about molecular biology to answering important biological questions. This chapter has been revised to balance newer technologies with approaches that continue to be used in both the research and education communities. RNAi applications to diseases like macular degeneration and next-generation sequencing technology are introduced by building on what the student already knows about DNA replication, transcription, and PCR.

**Chapter 18**—Our book is unique in having two chapters on genomes. The first extends the molecular unit to the scale of whole genomes, and chapter 24 focuses

on comparative genomics after students have learned about evolution. This organization is core to our full integration of evolution throughout the book. Chapter 18 has been revised to demonstrate the broad relevance of genomics, from understanding the evolution of speech to identifying the source of the 2001 anthrax attacks.

**Chapter 19**—The material on stem cells was completely rewritten and updated. The content was reorganized to put it into an even more solid historical context using the idea of nuclear reprogramming, and how this led to both the cloning of mammals and embryonic stem cells. New information on induced pluripotent stem cells is included to keep this as current as possible. This topic is one that is of general interest and is another subject about which students have significant misinformation. We strove to provide clear, well-organized information.

#### **Part IV: Evolution**

The evolution chapters were updated with new examples. A strong emphasis on the role of experimental approaches to studying evolutionary phenomena has been maintained and enhanced.

**Chapter 20**—The various processes that can lead to evolutionary change within populations are discussed in detail. Notably, these processes are not considered in isolation, but explored through how they interact.

**Chapter 21**—This chapter presents a state-of-the-art discussion of the power of natural selection to produce evolutionary change and the ever-increasing documentation in the fossil record of evolutionary transitions through time. It also discusses a variety of phenomena that only make sense if evolution has occurred and concludes with a critique of arguments posed against the existence of evolution.

**Chapter 22**—The process of speciation and evolutionary diversification is considered in this chapter. It includes current disagreements on how species are identified and how speciation operates.

**Chapter 23**—An up-to-date discussion of not only how phylogenies are inferred, but their broad and central role in comparative biology is the focus of chapter 23.

**Chapter 24**—This chapter has been revised to incorporate the rapidly growing number of fully sequenced genomes in a conceptual manner. We included the paradigm-changing findings that noncoding DNA plays a critical role in regulating DNA expression. This chapter and chapter 25 illustrate how we integrate both evolution and molecular biology throughout our text.

**Chapter 25**—With updated examples we explore the changing perspectives on the evolution of development. Specifically, the field is shifting away from the simplified view that changes in regulatory regions of genes are responsible for the evolution of form.

#### **Part V: Diversity of Life on Earth**

In revising the diversity chapters (protist, plants, and fungi) our emphasis was on integrating an evolutionary theme. The fungi chapter was restructured to reflect the current phylogenies while keeping species that are familiar to instructors at the fore. While competitors have two plant diversity chapters, we have one. We integrated the diversity of flowers and pollination strategies, as well as fruit diversity into the plant unit to enable students to fully appreciate morphological diversity because they have already learned about plant structure and development.

**Chapter 26**—This chapter has been updated so instructors have the option of using it as a stand-alone diversity chapter if their syllabus is too crowded to include the extensive coverage of diversity in the unit. Endosymbiosis has been consolidated in this chapter (moving some of the content from chapter 4).

**Chapter 27**—Material on archaeal viruses was added to incorporate this area of active research that is often ignored. The approach to HIV drug treatments was completely redone with revised strategies and updated graphics. The discussions of prions and viroids were also revised.

**Chapter 28**—All health statistics in chapter 28 were updated, including information on TB, HIV and STDs. A discussion on archaeal photosynthesis was added to the section on microbial metabolism.

**Chapter 30**—Findings of several plant genome projects informed the revision of the plant chapter. The remarkable desiccation tolerance of moss is emphasized in a Scientific Thinking figure exploring the genes involved in desiccation tolerance. New findings on correlations between the rate of pollen tube growth and the origins of the angiosperms have also been integrated into the chapter.

**Chapter 31**—Since the previous edition, much has been learned about the evolution of fungi, fundamentally changing relationships among groups. We revised the fungal phylogenies in this chapter to conform with the current understanding of fungal evolution, while contextualizing the older taxonomic groupings that may be more familiar to some readers.

**Chapters 32–34**—These chapters have been completely overhauled to emphasize the latest understanding, synthesizing molecular and morphological information, on the phylogeny of animals. We refocused these chapters to emphasize the differences in major morphological, behavioral, and ecological features that differentiate the major animal groups, placing a strong emphasis on understanding the organism in the context of its environment. Chapter 32 is an overview, which could be used as a standalone chapter, setting the stage for Chapters 33 on non-coelomate animals and Chapter 34 on coelomates.

**Chapter 35**—This chapter on vertebrates was revised to incorporate current ideas on vertebrate phylogeny and to emphasize the phylogenetic approach to understanding evolutionary diversification.

## Part VI: Plant Form and Function

As with the animal unit we incorporated an evolutionary theme. In the Scientific Thinking figures, as well as the text, we challenge the students to combine morphological, developmental, and molecular approaches to asking questions about plants. The goal is to help students integrate their conceptual understanding over multiple levels of organization. In addition, most of the questions at the end of the chapter are new.

**Chapter 36**—The section on leaf development has been updated to include a molecular analysis of the role of a key gene, *UNIFOLIATA*, in compound leaf development.

**Chapter 39**—Throughout the unit we included relevant examples to illustrate core concepts in plant biology. Here we added information about the effect of pH on germination and included a Scientific Thinking figure to more fully engage the student in considering pH effects in an agricultural context. The discussion of elevated CO<sub>2</sub> levels and increased temperatures on plant growth was updated. The very complex interactions affecting carbon and nitrogen content in plants is addressed at the level of plant and cell physiology. In addition, they are discussed at the ecosystem level later in the text in a more coherent presentation of the effects of climate change.

**Chapter 41**—The section of phytochrome was reorganized and updated. The emphasis is on guiding the student away from the historic examples of morphological responses to different day lengths to a clear, coherent understanding of how red and far red light affect the conformation of phytochrome and the signaling pathway it affects.

## Part VII: Animal Form and Function

Several organizational changes were made to this section to enhance overall coherence. The entire section was reinterpreted with the intent of better integrating evolution into all topics. The material on temperature regulation was moved from chapter 50 (8E) to the introductory chapter 43. This both provides an illustrative example to the introduction to homeostasis and removes a formerly artificial combination of temperature control and osmotic control. Respiration and circulation were made into separate chapters (49 and 50), allowing for greater clarity and removing an overly long chapter that was a barrier to understanding.

**Chapter 44**—The material on synaptic plasticity was rewritten with new graphics added. And in chapter 46 the addition of learning objectives and our integrated pedagogical tools make a complex topic more approachable. A new Scientific Thinking figure was added as well.

**Chapter 51**—The osmotic regulation material in this chapter is more coherent as a separate section without the temperature regulation material.

**Chapter 52**—This chapter was reorganized and restructured to emphasize the existence of innate versus adaptive immunity. This replaces the old paradigm of nonspecific versus specific immunity. This reorganization and new material also emphasize the evolutionary basis of innate immunity, which exists in invertebrates and vertebrates.

**Chapter 54**—The material on organizer function was updated. The Scientific Thinking figure uses molecular approaches introduced in part III and a figure that was already in the chapter. This figure is much more pedagogically useful in this repurposing than as a static figure and illustrates the use of these figures.

## Part VIII: Ecology and Behavior

The ecology chapters have been revised with a particular focus on providing up-to-date information on current environmental issues, both in terms of the problems that exist and the potential action that can be taken to ameliorate them.

**Chapter 55**—Completely revised with a strong emphasis on neuroethological approaches to understanding behavioral patterns, this chapter emphasizes modern molecular approaches to the study of behavior.

**Chapter 56**—Considers the ecology of individuals and populations and includes up-to-date discussion of human population growth.

**Chapter 57**—The ecology of communities is discussed in the context of the various ecological processes that mediate interactions between co-occurring species. With updated examples, chapter 57 illustrates how different processes can interact, as well as emphasizing the experimental approach to the study of ecology.

**Chapter 58**—This chapter focuses on the dynamics of ecosystems. It has been updated to emphasize current understanding of the how ecosystems function.

**Chapter 59**—The chapter has been extensively updated to provide the latest information on factors affecting the environment and human health with a clear focus on the biosphere and current environmental threats.

**Chapter 60**—And finally, chapter 60 considers conservation biology, emphasizing the causes of species endangerment and what can be done. Data and examples provide the latest information and thinking on conservation issues.

# Committed to Preparing Students for the Future

## Understand Biology With the Help of . . .

### Integrated Learning Outcomes

Each section begins with specific Learning Outcomes that represent each major concept. At the end of each section, Learning Outcomes Reviews serve as a check to help students confirm their understanding of the concepts in that section. Questions at the end of the Learning Outcomes Review ask students to think critically about what they have read.

Any opportunity to identify “learning outcomes” is a welcome addition; we are forced more and more to identify these in learning assessments. I would use these as a guide for students to understand the minimum material they are expected to learn from each section.

Michael Lentz  
University of North Florida

### 22.1 The Nature of Species and the Biological Species Concept

#### Learning Outcomes

1. Distinguish between the biological species concept and the ecological species concept.
2. Define the two kinds of reproductive isolating mechanisms.
3. Describe the relationship of reproductive isolating mechanisms to the biological species concept.

### 22.1 The Nature of Species and the Biological Species Concept

#### Learning Outcomes

1. Distinguish between the biological species concept and the ecological species concept.
2. Define the two kinds of reproductive isolating mechanisms.

#### The biological species concept focuses on the ability to exchange genes

What can account for both the distinctiveness of sympatric species and the connectedness of geographically separate populations of the same species? One obvious possibility is that each species exchanges genetic material only with other members of its species. If sympatric species commonly exchanged genes, which they generally do not, we might expect such species to rapidly lose their distinctions, as the gene pools (that is, all of the alleles present in a species) of the different species became homogenized. Conversely, the ability of geographically distant populations of a single species to share genes through the process of gene flow may keep these populations integrated as members of the same species.

Based on these ideas, in 1942 the evolutionary biologist Ernst Mayr set forth the **biological species concept**, which defines *species* as “. . . groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.”

In other words, the biological species concept says that a species is composed of populations whose members mate with each other and produce fertile offspring—or would do so if they came into contact. Conversely, populations whose members do not mate with each other or who cannot produce fertile offspring are said to be **reproductively isolated** and, therefore, are members of different species.

What causes reproductive isolation? If organisms interbreed or cannot produce fertile offspring, they clearly are different species. However, some populations that are reared separate species can interbreed and produce fertile offspring.

**Figure 22.1** Geographic variation in the milk snake, *Lampropeltis triangulum*. Although subspecies are phenotypically quite distinctive from one another, they are connected by populations that are phenotypically intermediate.

ended by each species, they usually reveal great differences. In other words, even though we might have trouble distinguishing them, the organisms themselves have no such difficulties.

#### Populations of a species exhibit geographic variation

Within a single species, individuals in populations that occur in different areas may be distinct from one another. Such groups of distinctive individuals may be classified as **subspecies** (the vague term *race* has a similar connotation, but is no longer commonly used). In areas where these populations occur close to one another, individuals often exhibit combinations of features characteristic of both populations (Figure 22.1). In other words, even though geographically distant populations may appear distinct, they are usually connected by intervening populations that are intermediate in their characteristics.

Chapter 22 The Origin of Species 437

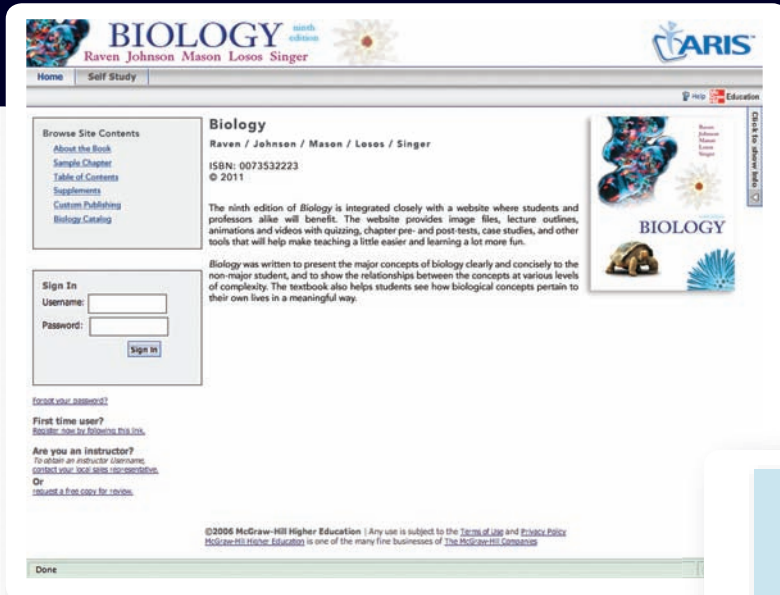

#### Learning Outcomes Review 22.1

Species are populations of organisms that are distinct from other, co-occurring species, and are interconnected geographically. The biological species concept therefore defines species based on their ability to interbreed. Reproductive isolating mechanisms prevent successful interbreeding between species. The ecological species concept relies on adaptation and natural selection as a force for maintaining separation of species.

- How does the ability to exchange genes explain why sympatric species remain distinct and geographic populations of one species remain connected?

### In Print and Online

The online eBook in Connect Plus™ provides students with clear understanding of concepts through a media-rich experience. Embedded animations bring key concepts to life. Also, the eBook provides an interactive experience with the Learning Outcome Review questions. Contact your McGraw-Hill/Glencoe sales representative for pricing information.

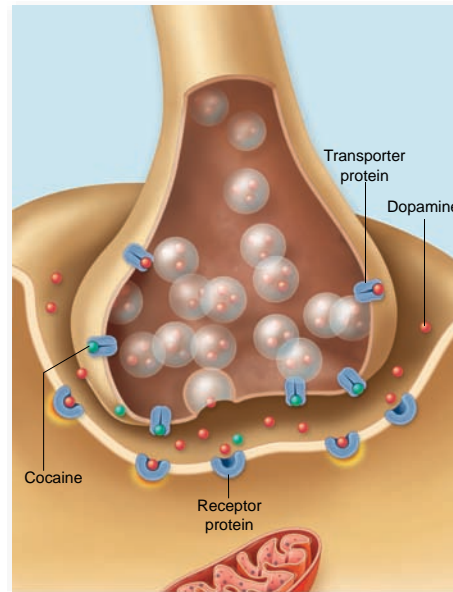

**Companion Website**

Students can enhance their understanding of the concepts with the rich study materials available to at [www.glencoe.com/raven9](http://www.glencoe.com/raven9). This open access website provides self-study options with chapter pretest quizzes to assess current understanding, animations that highlight topics students typically struggle with and textbook images that can be used for notetaking and study.

**A Consistent and Instructional Visual Program**

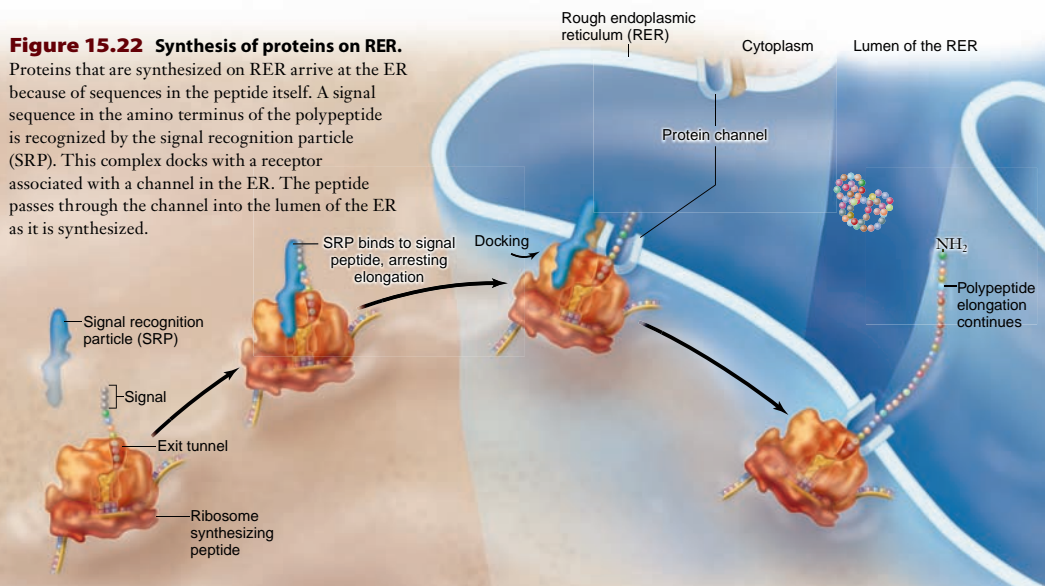

The author team collaborated with a team of medical and scientific illustrations to create the unsurpassed visual program. Focusing on consistency, accuracy, and instructional value, they created an art program that is intimately connected with the text narrative. The resulting realistic, 3-D illustrations will stimulate student interest and help teachers teach difficult concepts.

**Figure 44.18** How cocaine alters events at the synapse. When cocaine binds to the dopamine transporters, it prevents reuptake of dopamine so the neurotransmitter survives longer in the synapse and continues to stimulate the postsynaptic cell. Cocaine thus acts to intensify pleasurable sensations.

**Figure 15.22** Synthesis of proteins on RER.

Proteins that are synthesized on RER arrive at the ER because of sequences in the peptide itself. A signal sequence in the amino terminus of the polypeptide is recognized by the signal recognition particle (SRP). This complex docks with a receptor associated with a channel in the ER. The peptide passes through the channel into the lumen of the ER as it is synthesized.

The art is quite good! The colors are well saturated and the figures are clear and often compelling, particularly in showing the molecular complexity of these molecules and cells.

*Susan J Stamler  
College of DuPage*

## Apply Your Knowledge With...

### NEW Scientific Thinking Art

**Key illustrations** in every chapter highlight how the frontiers of knowledge are pushed forward by a combination of hypothesis and experiment. These figures begin with a hypothesis, then show how it makes explicit predictions, tests these by experiment and finally demonstrates what conclusions can be drawn, and where this leads. These provide a consistent framework to guide the student in the logic of scientific inquiry. Each illustration concludes with open-ended questions to promote scientific inquiry.

Knowing how scientists solve problems, and then using this knowledge to solve a problem (as an example) drives home the concept of induction and deduction — I applaud this highly!

Marc LaBella  
Ocean County College

#### SCIENTIFIC THINKING

**Hypothesis:** There are positive regulators of cell division.  
**Prediction:** Frog oocytes are arrested in  $G_2$  of meiosis I. They can be induced to mature (undergo meiosis) by progesterone treatment. If maturing oocytes contain a positive regulator of cell division, injection of cytoplasm should induce an immature oocyte to undergo meiosis.  
**Test:** Oocytes are induced with progesterone, then cytoplasm from these maturing cells is injected into immature oocytes.

**Result:** Injected oocytes progress  $G_2$  from into meiosis I.  
**Conclusion:** The progesterone treatment causes production of a positive regulator of maturation: Maturation Promoting Factor (MPF).  
**Prediction:** If mitosis is driven by positive regulators, then cytoplasm from a mitotic cell should cause a  $G_1$  cell to enter mitosis.  
**Test:** M phase cells are fused with  $G_1$  phase cells, then the nucleus from the  $G_1$  phase cell is monitored microscopically.

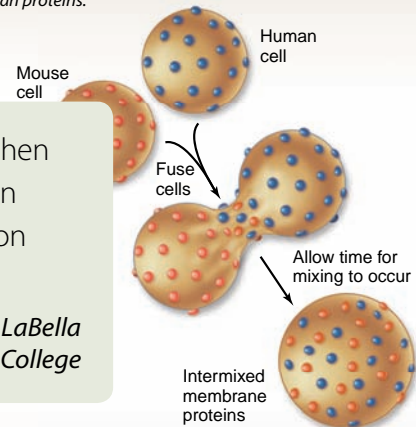

**Conclusion:** Cytoplasm from M phase cells contains a positive regulator that causes a cell to enter mitosis.  
**Further Experiments:** How can both of these experiments be rationalized? What would be the next step in characterizing these factors?

**Figure 10.16** Discovery of positive regulator of cell division.

#### SCIENTIFIC THINKING

**Hypothesis:** The plasma membrane is fluid, not rigid.  
**Prediction:** If the membrane is fluid, membrane proteins may diffuse laterally.  
**Test:** Fuse mouse and human cells, then observe the distribution of membrane proteins over time by labeling specific mouse and human proteins.

**Result:** Over time, hybrid cells show increasingly intermixed proteins.  
**Conclusion:** At least some membrane proteins can diffuse laterally in the membrane.  
**Further Experiments:** Can you think of any other explanation for these observations? What if newly synthesized proteins were inserted into the membrane during the experiment? How could you use this basic experimental design to rule out this or other possible explanations?

**Figure 5.4** Test of membrane fluidity.

### Inquiry question

? Based only on amino acid sequence, how would you recognize an integral membrane protein?

### Inquiry Questions

Questions that challenge students to think about and engage in what they are reading at a more sophisticated level.

## Review Questions

# Synthesize and Tie It All Together With . . .

## End-of-Chapter Conceptual Assessment Questions

Thought-provoking questions at the end of each chapter tie the concepts together by asking the student to go beyond the basics to achieve a higher level of cognitive thinking.

I think that the end-of-chapter summary and review questions are thorough and written well. I very much like the way that they are categorized into understanding, application, and synthesizing. I use these types of questions on my exams. So I think that these end-of-chapter questions can be used as homework or in class work to help prepare students for exams.

*Dr. Sharon K. Bullock  
UNC Charlotte*

### UNDERSTAND

- What property distinguished Mendel's investigation from previous studies?
  - Mendel used true-breeding pea plants.
  - Mendel quantified his results.
  - Mendel examined many different traits.
  - Mendel examined the segregation of traits.
- The  $F_1$  generation of the monohybrid cross purple ( $PP$ )  $\times$  white ( $pp$ ) flower pea plants should
  - all have white flowers.
  - all have a light purple or blended appearance.
  - all have purple flowers.
  - have  $(\frac{3}{4})$  purple flowers, and  $\frac{1}{4}$  white flowers.
- The  $F_1$  plants from the previous question are allowed to self-fertilize. The phenotypic ratio for the  $F_2$  should be
  - all purple.
  - 1 purple:1 white.
  - 3 purple:1 white.
  - 3 white:1 purple.
- Which of the following is *not* a part of Mendel's five-element model?
  - Traits have alternative forms (what we now call alleles).
  - Parents transmit discrete traits to their offspring.
  - If an allele is present it will be expressed.
  - Traits do not blend.
- An organism's \_\_\_\_\_ is/are determined by its \_\_\_\_\_.
  - genotype; phenotype
  - phenotype; genotype
  - alleles; phenotype
  - genes; alleles
- Phenotypes like height in humans, which show a continuous distribution, are usually the result of
  - an alteration of dominance for multiple alleles of a single gene.
  - the presence of multiple alleles for a single gene.
  - the action of one gene on multiple phenotypes.
  - the action of multiple genes on a single phenotype.

### APPLY

- A dihybrid cross between a plant with long smooth leaves and a plant with short hairy leaves produces a long smooth  $F_1$ . If this  $F_1$  is allowed to self-cross to produce an  $F_2$ , what would you predict for the ratio of  $F_2$  phenotypes?
  - 9 long smooth:3 long hairy:3 short smooth:1 short hairy
  - 9 long smooth:3 long hairy:3 short smooth:1 short hairy
  - 9 short hairy:3 long hairy:3 short smooth:1 long smooth
  - 1 long smooth:1 long hairy:1 short smooth:1 short hairy
- Consider a long smooth  $F_2$  plant from the previous question. This plant's genotype
  - must be homozygous for both long alleles and hairy alleles.
  - must be heterozygous at both the leaf length gene, and the leaf hair gene.
  - can only be inferred by another cross.
  - cannot be determined by any means.
- What is the probability of obtaining an individual with the genotype  $bb$  from a cross between two individuals with the genotype  $Bb$ ?
  - $\frac{1}{2}$
  - $\frac{1}{4}$
  - $\frac{1}{6}$
  - 0

238 part III Genetic and Molecular Biology

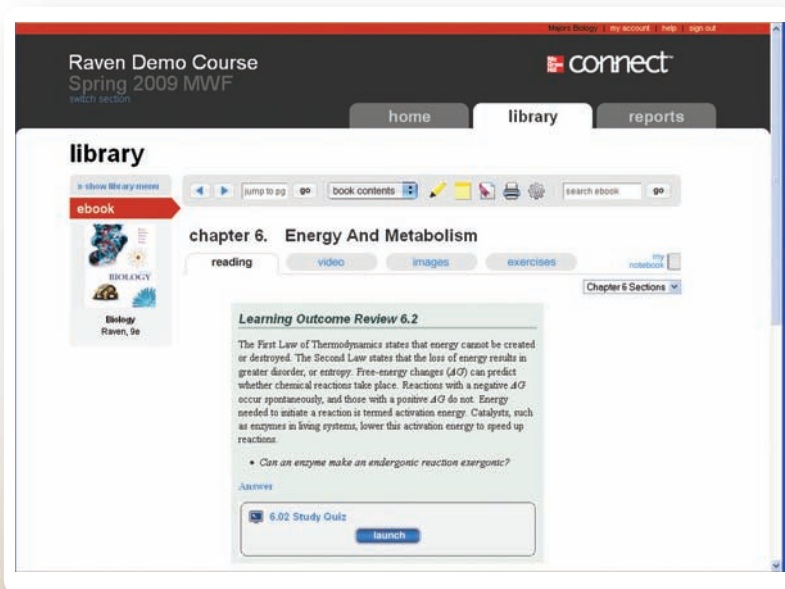

- What is the probability of obtaining an individual with the genotype  $CC$  from a cross between two individuals with the genotypes  $Cc$  and  $Cc$ ?
  - $\frac{1}{2}$
  - $\frac{1}{4}$
  - $\frac{1}{6}$
  - $\frac{1}{16}$
- You discover a new variety of plant with color varieties of purple and white. When you intercross these, the  $F_1$  is a lighter purple. You consider that this may be an example of blending and self-cross the  $F_1$ . If Mendel is correct, what would you predict for the  $F_2$ ?
  - 1 purple:2 white:1 light purple
  - 1 white:2 purple:1 light purple
  - 1 purple:2 light purple:1 white
  - 1 light purple:2 purple:1 white
- Mendel's model assumes that each trait is determined by a single factor with alternate forms. We now know that this is too simplistic and that
  - a single gene may affect more than one trait.
  - a single trait may be affected by more than one gene.
  - a single gene always affects only one trait, but traits may be affected by more than one gene.
  - a single gene can affect more than one trait, and traits may be affected by more than one gene.

### SYNTHESIZE

- Create a Punnett square for the following crosses and use this to predict phenotypic ratio for dominant and recessive traits. Dominant alleles are indicated by uppercase letters and recessive are indicated by lowercase letters. For parts b and c, predict ratios using probability and the product rule.
  - A monohybrid cross between individuals with the genotype  $Aa$  and  $Aa$
  - A dihybrid cross between two individuals with the genotype  $AaBb$
  - A dihybrid cross between individuals with the genotype  $AaBb$  and  $aabb$
- Explain how the events of meiosis can explain both segregation and independent assortment.
- In mice, there is a yellow strain that when crossed yields 2 yellow:1 black. How could you explain this observation? How could you test this with crosses?
- In mammals, a variety of genes affect coat color. One of these is a gene with mutant alleles that results in the complete loss of pigment, or albinism. Another controls the type of dark pigment with alleles that lead to black or brown colors. The albinistic trait is recessive, and black is dominant to brown. Two black mice are crossed and yield 9 black:4 albino:3 brown. How would you explain these results?

ONLINE RESOURCE [www.ravenbiology.com](http://www.ravenbiology.com)

Understand, Apply, and Synthesize—enhance your study with animations that bring concepts to life and practice tests to assess your understanding. Your instructor may also recommend the interactive eBook, individualized learning tools, and more.

## Integrated Study Quizzes

Study quizzes have been integrated into the Connect Plus eBook for students to assess their understanding of the information presented in each section. End of chapter questions are linked to the answer section of the text to provide for easy study. The notebook feature allows students to collect and manage notes and highlights from the eBook to create a custom study guide.

# Committed to Biology Educators

## McGraw-Hill Connect Biology

**Connect Biology™** is a web-based assignment and assessment platform that gives students the

means to better connect with their coursework, with their teachers, and with the important concepts that they will need to know for success now and in the future.

With Connect Biology you can deliver assignments, quizzes, and tests online. A robust set of questions and activities are presented and tied to the textbook's learning objectives. As a teacher, you can edit existing questions and author entirely new problems. Track individual student performance — by question, assignment, or in relation to the class overall — with detailed grade reports. Integrate grade reports easily with Learning Management Systems (LMS) such as WebCT and Blackboard. And much more.

ConnectPlus™ Biology provides students with all the advantages of Connect™ Biology, plus 24/7 access to an eBook. This media-rich version of the book includes animations, videos, and inline assessments placed appropriately throughout the chapter. Connect Plus Biology allows students to practice important skills at their own pace and on their own schedule. By purchasing eBooks from McGraw-Hill students can save as much as 50% on selected titles delivered on the most advanced eBook platforms available. Contact your Glencoe/McGraw-Hill sales representative to discuss eBook pricing and packaging options.

## Powerful Presentation Tools

Everything you need for outstanding presentation in one place!

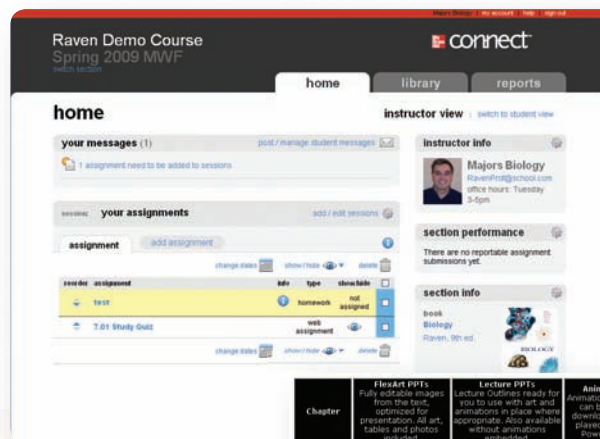

- **FlexArt Image PowerPoints** — including every piece of art that has been sized and cropped specifically for superior presentations as well as labels that you can edit, flexible art that can be picked up and moved, tables, and photographs
- **Animation PowerPoints** — Numerous full-color animations illustrating important processes. Harness the visual impact of concepts in motion by importing these slides into classroom presentations or online course materials
- **Lecture PowerPoints** — with fully embedded animations
- **Labeled and unlabeled JPEG images** — Full-color digital files of all illustrations, which can be readily incorporated into presentations, exams, or custom-made classroom materials

## Presentation Center

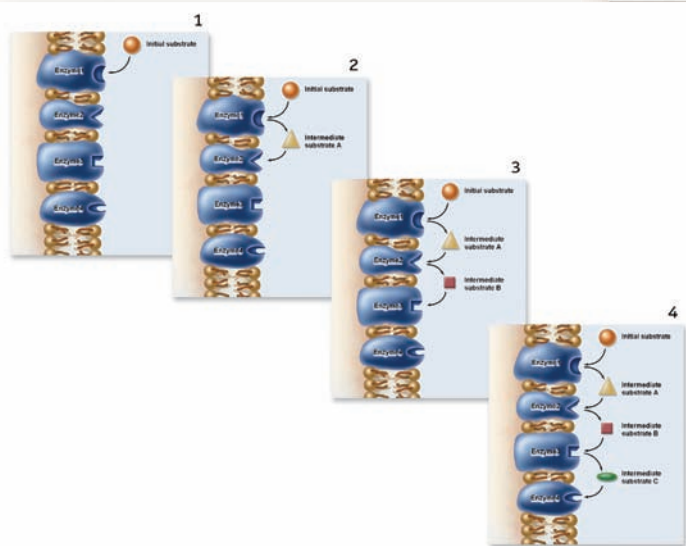

In addition to the images from your book, this **online digital library** contains photos, artwork, animations, and other media from an array of McGraw-Hill textbooks that can be used to create customized lectures, visually enhance tests and quizzes, and make compelling course websites or attractive printed support materials.

## Quality Test Bank

All questions have been written to fully align with the Learning Outcomes and content of the text. Provided within a computerized test bank powered by McGraw-Hill's flexible electronic testing program **EZ Test Online**, teachers can create paper and online tests or quizzes in this easy to use program! A new tagging scheme allows you to sort questions by difficulty level, topic, and section. Imagine being able to create and access your test or quiz anywhere, at any time, without installing the testing software. Now, with EZ Test Online, teachers can select questions from multiple McGraw-Hill test banks or author their own, and then either print the test for paper distribution or give it online.

Chapter	FlexArt PPTs Fully editable images from the text, optimized for presentation. All art, tables and photos included.	Lecture PPTs Lecture Outlines ready for you to use with art and animations in place where appropriate. Also available without animations embedded.	Animations Animations files that can be easily downloaded and played without PowerPoint.	Animation PPTs Animations placed into PowerPoint for easy presentation and custom slide shows.	JPEG Images Illustration files as they appear in the text.	Base Art Images Illustration files without labels and leader lines.

## Active Learning Exercises

Supporting biology faculty in their efforts to make introductory courses more active and student-centered is critical to improving undergraduate biological education. Active learning can broadly be described as strategies and techniques in which students are engaged in their own learning, and is typically characterized by the utilization of higher order critical thinking skills. The use of these techniques is critical to biological education because of their powerful impact on students' learning and development of scientific professional skills.

Active learning strategies are highly valued and have been shown to:

- Help make content relevant
- Be particularly adept at addressing common misconceptions
- Help students to think about their own learning (metacognition)
- Promote meaningful learning of content by emphasizing application
- Foster student interest in science

**Guided Activities** have been provided for teachers to use in their course for both in-class and out-of-class activities. The Guided Activities make it easy for you to incorporate active learning into your course and are flexible to fit your specific needs.

## Teacher's Manual for \*Advanced Placement Biology

This robust teacher's resource was developed specifically for Advanced Placement Biology courses using *Biology, 9<sup>th</sup> Edition* by Raven, Mason, Losos, and Singer. Each chapter includes a chapter discussion, pacing suggestions, "student misconceptions and common pitfalls", activities, web resources, lab suggestions and other resources as appropriate. Each chapter also includes sample multiple choice and free-response questions similar to questions on the AP Exam.

## AP\* Achiever Advanced Placement Exam Preparation Guide for Biology

The *AP\* Achiever* was written specifically for students enrolled in an Advanced Placement Biology course. The AP Achiever is designed to be used with one of the top selling college biology textbooks, *Biology, 9<sup>th</sup> Edition* by Raven, Mason, Losos, and Singer, although it can be used effectively with any college level biology textbook.

The AP\* Achiever includes:

- An introduction to the AP Biology Course and Exam; including comprehensive tips on writing essays for the free-response section of the exam.
- Each chapter includes a chapter summary and sections highlighting critical material required for the AP Biology Exam. Each chapter also includes sample multiple choice and free-response questions with answers and explanations.

- Two complete *practice exams* parallel the Advanced Placement Biology Exam in terms of question type, style, format and number of questions. Each practice exam includes answers and thorough explanations.

## Test Bank for \*Advanced Placement Biology

A test bank to accompany *Biology, 9<sup>th</sup> Edition* by Raven, Mason, Losos, and Singer has been adapted specifically for Advanced Placement courses. There are 5 choices for each multiple choice question and many questions refer to figures, diagrams and data sets. Free-response questions are included for each chapter.

## Laboratory Manuals

### Biology Laboratory Manual, Ninth Edition

Vodopich and Moore ISBN: 0-07-338306-6

This laboratory manual is designed for an introductory course for biology majors with a broad survey of basic laboratory techniques. The experiments and procedures are simple, safe, easy to perform, and especially appropriate for large classes.

Few experiments require a second class meeting to complete the procedure. Each exercise includes many photographs, traditional topics, and experiments that help students learn about life. Procedures within each exercise are numerous and discrete so that an exercise can be tailored to the needs of the students, the style of the instructor, and the facilities available.

### Biological Investigations Lab Manual, Ninth Edition

Dolphin ISBN: 0-07-338305-8

This independent lab manual can be used for a one- or two-semester majors' level general biology lab and can be used with any majors' level general biology textbook. The labs are investigative and ask students to use more critical thinking and hands-on learning. The author emphasizes investigative, quantitative, and comparative approaches to studying the life sciences.

## Focus on Evolution

### Understanding Evolution, Seventh Edition

Rosenbaum and Volpe ISBN: 0-07-338323-6

As an introduction to the principles of evolution, this paperback text is ideally suited as a main text for general evolution or as a supplement for general biology, genetics, zoology, botany, anthropology, or any life science course that utilizes evolution as the underlying theme of all life.

## 360° Development Process

McGraw-Hill's 360° Development Process is an ongoing, never-ending, education-oriented approach to building accurate and innovative print and digital products. It is dedicated to continual large-scale and incremental improvement, driven by multiple user feedback loops and checkpoints. This is initiated during the early planning

stages of our new products, intensifies during the development and production stages, then begins again after publication in anticipation of the next edition.

This process is designed to provide a broad, comprehensive spectrum of feedback for refinement and innovation of our learning tools, for both student and instructor. The 360° Development Process includes market research, content reviews, course- and product-specific symposia, accuracy checks, and art reviews. We appreciate the expertise of the many individuals involved in this process.

### General Biology Symposia

Every year McGraw-Hill conducts several General Biology Symposia, which are attended by instructors from across the country. These events are an opportunity for editors from McGraw-Hill to gather information about the needs and challenges of instructors teaching the major's biology course. It also offers a forum for the attendees to exchange ideas and experiences with colleagues they might not have otherwise met. The feedback we have received has been invaluable and has contributed to the development of Biology and its supplements. A special thank you to recent attendees:

## A Note From the Authors

A revision of this scope relies on the talents and efforts of many people working behind the scenes and we have benefited greatly from their assistance.

Jody Larson, our developmental copyeditor, labored many hours and provided countless suggestions for improving the organization and clarity of the text. She has made a tremendous contribution to the quality of the final product.

We were fortunate to again work with Electronic Publishing Services to update the art program and improve the layout of the pages. Our close collaboration resulted in a text that is pedagogically effective as well as more beautiful than any other biology text on the market.

We have the continued support of our McGraw-Hill team. Developmental editors Rose Koos and Lisa Brufodt kept the authors on track during the development process. Sheila Frank, project manager, and David Hash, designer, ensured our text was on time and elegantly designed. Patrick Reidy, marketing manager and many more people behind the scenes have all contributed to the success of our text.

Throughout this edition we have had the support of spouses and children, who have seen less of us than they might have liked because

of the pressures of getting this revision completed. They have adapted to the many hours this book draws us away from them, and, even more than us, looked forward to its completion.

As with every edition, acknowledgments would not be complete without thanking the generations of students who have used the many editions of this text. They have taught us as least as much as we have taught them, and their questions and suggestions continue to improve the text and supplementary materials.

Finally, we need to thank our reviewers and contributors. Instructors from across the country are continually invited to share their knowledge and experience with us through reviews and focus groups. The feedback we received shaped this edition, resulting in new chapters, reorganization of the table of contents, and expanded coverage in key areas. Several faculty members were asked to provide preliminary drafts of chapters to ensure that the content was as up to date and accurate as possible, and still others were asked to provide chapter outlines and assessment questions. All of these people took time out of their already busy lives to help us build a better edition of Biology for the next generation of introductory biology students, and they have our heartfelt thanks.

# Contents

Part

## The Molecular Basis of Life

### 1 The Science of Biology 1

- 1.1 The Science of Life 1
- 1.2 The Nature of Science 4
- 1.3 An Example of Scientific Inquiry: Darwin and Evolution 8
- 1.4 Unifying Themes in Biology 12

### 2 The Nature of Molecules and the Properties of Water 17

- 2.1 The Nature of Atoms 18
- 2.2 Elements Found in Living Systems 22
- 2.3 The Nature of Chemical Bonds 23
- 2.4 Water: A Vital Compound 25
- 2.5 Properties of Water 28
- 2.6 Acids and Bases 29

### 3 The Chemical Building Blocks of Life 33

- 3.1 Carbon: The Framework of Biological Molecules 34
- 3.2 Carbohydrates: Energy Storage and Structural Molecules 38
- 3.3 Nucleic Acids: Information Molecules 41
- 3.4 Proteins: Molecules with Diverse Structures and Functions 44
- 3.5 Lipids: Hydrophobic Molecules 53

Part

## Biology of the Cell

### 4 Cell Structure 59

- 4.1 Cell Theory 59
- 4.2 Prokaryotic Cells 63
- 4.3 Eukaryotic Cells 65
- 4.4 The Endomembrane System 69
- 4.5 Mitochondria and Chloroplasts: Cellular Generators 73
- 4.6 The Cytoskeleton 75
- 4.7 Extracellular Structures and Cell Movement 79
- 4.8 Cell-to-Cell Interactions 82

### 5 Membranes 88

- 5.1 The Structure of Membranes 88
- 5.2 Phospholipids: The Membrane's Foundation 92
- 5.3 Proteins: Multifunctional Components 93
- 5.4 Passive Transport Across Membranes 96
- 5.5 Active Transport Across Membranes 99
- 5.6 Bulk Transport by Endocytosis and Exocytosis 102

### 6 Energy and Metabolism 107

- 6.1 The Flow of Energy in Living Systems 108
- 6.2 The Laws of Thermodynamics and Free Energy 109
- 6.3 ATP: The Energy Currency of Cells 112
- 6.4 Enzymes: Biological Catalysts 113
- 6.5 Metabolism: The Chemical Description of Cell Function 117

### 7 How Cells Harvest Energy 122

- 7.1 Overview of Respiration 123
- 7.2 Glycolysis: Splitting Glucose 127
- 7.3 The Oxidation of Pyruvate to Produce Acetyl-CoA 130
- 7.4 The Krebs Cycle 131
- 7.5 The Electron Transport Chain and Chemiosmosis 134
- 7.6 Energy Yield of Aerobic Respiration 137
- 7.7 Regulation of Aerobic Respiration 138
- 7.8 Oxidation Without O<sub>2</sub> 139
- 7.9 Catabolism of Proteins and Fats 140
- 7.10 Evolution of Metabolism 142

### 8 Photosynthesis 147

- 8.1 Overview of Photosynthesis 147
- 8.2 The Discovery of Photosynthetic Processes 149
- 8.3 Pigments 151
- 8.4 Photosystem Organization 154
- 8.5 The Light-Dependent Reactions 156
- 8.6 Carbon Fixation: The Calvin Cycle 160
- 8.7 Photorespiration 163

### 9 Cell Communication 168

- 9.1 Overview of Cell Communication 168
- 9.2 Receptor Types 171
- 9.3 Intracellular Receptors 173
- 9.4 Signal Transduction Through Receptor Kinases 174
- 9.5 Signal Transduction Through G Protein-Coupled Receptors 179

## 10 How Cells Divide 186

- 10.1 Bacterial Cell Division 187
- 10.2 Eukaryotic Chromosomes 189
- 10.3 Overview of the Eukaryotic Cell Cycle 192
- 10.4 Interphase: Preparation for Mitosis 193
- 10.5 M Phase: Chromosome Segregation and the Division of Cytoplasmic Contents 194
- 10.6 Control of the Cell Cycle 198

- 15.5 Eukaryotic pre-mRNA Splicing 289
- 15.6 The Structure of tRNA and Ribosomes 291
- 15.7 The Process of Translation 293
- 15.8 Summarizing Gene Expression 297
- 15.9 Mutation: Altered Genes 299

## 16 Control of Gene Expression 304

- 16.1 Control of Gene Expression 304
- 16.2 Regulatory Proteins 305
- 16.3 Prokaryotic Regulation 308
- 16.4 Eukaryotic Regulation 312
- 16.5 Eukaryotic Chromatin Structure 316
- 16.6 Eukaryotic Posttranscriptional Regulation 317
- 16.7 Protein Degradation 322

## 17 Biotechnology 327

- 17.1 DNA Manipulation 327
- 17.2 Molecular Cloning 330
- 17.3 DNA Analysis 335
- 17.4 Genetic Engineering 341
- 17.5 Medical Applications 343
- 17.6 Agricultural Applications 346

## 18 Genomics 352

- 18.1 Mapping Genomes 352
- 18.2 Whole-Genome Sequencing 356
- 18.3 Characterizing Genomes 358
- 18.4 Genomics and Proteomics 362
- 18.5 Applications of Genomics 367

## 19 Cellular Mechanisms of Development 372

- 19.1 The Process of Development 372
- 19.2 Cell Division 373
- 19.3 Cell Differentiation 375
- 19.4 Nuclear Reprogramming 380
- 19.5 Pattern Formation 383
- 19.6 Morphogenesis 390

## 11 Sexual Reproduction and Meiosis 207

- 11.1 Sexual Reproduction Requires Meiosis 207
- 11.2 Features of Meiosis 209
- 11.3 The Process of Meiosis 210
- 11.4 Summing Up: Meiosis Versus Mitosis 215

## 12 Patterns of Inheritance 221

- 12.1 The Mystery of Heredity 221
- 12.2 Monohybrid Crosses: The Principle of Segregation 224
- 12.3 Dihybrid Crosses: The Principle of Independent Assortment 228
- 12.4 Probability: Predicting the Results of Crosses 230
- 12.5 The Testcross: Revealing Unknown Genotypes 231
- 12.6 Extensions to Mendel 232

## 13 Chromosomes, Mapping, and the Meiosis–Inheritance Connection 239

- 13.1 Sex Linkage and the Chromosomal Theory of Inheritance 240
- 13.2 Sex Chromosomes and Sex Determination 241
- 13.3 Exceptions to the Chromosomal Theory of Inheritance 244
- 13.4 Genetic Mapping 244
- 13.5 Selected Human Genetic Disorders 249

## 14 DNA: The Genetic Material 256

- 14.1 The Nature of the Genetic Material 256
- 14.2 DNA Structure 259
- 14.3 Basic Characteristics of DNA Replication 263
- 14.4 Prokaryotic Replication 266
- 14.5 Eukaryotic Replication 271
- 14.6 DNA Repair 273

## 15 Genes and How They Work 278

- 15.1 The Nature of Genes 278
- 15.2 The Genetic Code 282
- 15.3 Prokaryotic Transcription 284
- 15.4 Eukaryotic Transcription 287

## Part IV Evolution

### 20 Genes Within Populations 396

- 20.1 Genetic Variation and Evolution 396
- 20.2 Changes in Allele Frequency 398
- 20.3 Five Agents of Evolutionary Change 401
- 20.4 Fitness and Its Measurement 405
- 20.5 Interactions Among Evolutionary Forces 406
- 20.6 Maintenance of Variation 407
- 20.7 Selection Acting on Traits Affected by Multiple Genes 409
- 20.8 Experimental Studies of Natural Selection 411
- 20.9 The Limits of Selection 413

## Part III Genetic and

## Molecular Biology

## 21 The Evidence for Evolution 417

- 21.1 The Beaks of Darwin's Finches: Evidence of Natural Selection 418
- 21.2 Peppered Moths and Industrial Melanism: More Evidence of Selection 420
- 21.3 Artificial Selection: Human-Initiated Change 422
- 21.4 Fossil Evidence of Evolution 424
- 21.5 Anatomical Evidence for Evolution 428
- 21.6 Convergent Evolution and the Biogeographical Record 430
- 21.7 Darwin's Critics 432

## 22 The Origin of Species 436

- 22.1 The Nature of Species and the Biological Species Concept 437
- 22.2 Natural Selection and Reproductive Isolation 441
- 22.3 The Role of Genetic Drift and Natural Selection in Speciation 443
- 22.4 The Geography of Speciation 444
- 22.5 Adaptive Radiation and Biological Diversity 446
- 22.6 The Pace of Evolution 451
- 22.7 Speciation and Extinction Through Time 452

## 23 Systematics and the Phylogenetic Revolution 456

- 23.1 Systematics 456
- 23.2 Cladistics 458
- 23.3 Systematics and Classification 461
- 23.4 Phylogenetics and Comparative Biology 464
- 23.5 Phylogenetics and Disease Evolution 470

## 24 Genome Evolution 474

- 24.1 Comparative Genomics 474
- 24.2 Whole-Genome Duplications 477
- 24.3 Evolution Within Genomes 481
- 24.4 Gene Function and Expression Patterns 484
- 24.5 Nonprotein-Coding DNA and Regulatory Function 485
- 24.6 Genome Size and Gene Number 486
- 24.7 Genome Analysis and Disease Prevention and Treatment 487
- 24.8 Crop Improvement Through Genome Analysis 489

## 25 Evolution of Development 492

- 25.1 Overview of Evolutionary Developmental Biology 492
- 25.2 One or Two Gene Mutations, New Form 495
- 25.3 Same Gene, New Function 496
- 25.4 Different Genes, Convergent Function 498
- 25.5 Gene Duplication and Divergence 499
- 25.6 Functional Analysis of Genes Across Species 500
- 25.7 Diversity of Eyes in the Natural World: A Case Study 501

# Part V The Diversity of Life

## 26 The Tree of Life 507

- 26.1 Origins of Life 508
- 26.2 Classification of Organisms 512
- 26.3 Grouping Organisms 514
- 26.4 Making Sense of the Protists 520
- 26.5 Origin of Plants 520
- 26.6 Sorting out the Animals 522

## 27 Viruses 528

- 27.1 The Nature of Viruses 529
- 27.2 Bacteriophages: Bacterial Viruses 533
- 27.3 Human Immunodeficiency Virus (HIV) 535
- 27.4 Other Viral Diseases 539
- 27.5 Prions and Viroids: Subviral Particles 541

## 28 Prokaryotes 545

- 28.1 The First Cells 546
- 28.2 Prokaryotic Diversity 547
- 28.3 Prokaryotic Cell Structure 551
- 28.4 Prokaryotic Genetics 554
- 28.5 Prokaryotic Metabolism 559
- 28.6 Human Bacterial Disease 560
- 28.7 Beneficial Prokaryotes 563

## 29 Protists 567

- 29.1 Eukaryotic Origins and Endosymbiosis 568
- 29.2 Defining Protists 571
- 29.3 Diplomonads and Parabasalids: Flagellated Protists Lacking Mitochondria 572
- 29.4 Euglenozoa: A Diverse Group in Which Some Members Have Chloroplasts 573
- 29.5 Alveolata: Protists with Submembrane Vesicles 576
- 29.6 Stramenopila: Protists with Fine Hairs 580
- 29.7 Rhodophyta: Red Algae 582
- 29.8 Choanoflagellida: Possible Animal Ancestors 583
- 29.9 Protists Without a Clade 583

## 30 Green Plants 588

- 30.1 Defining Plants 588
- 30.2 Chlorophytes and Charophytes: Green Algae 591
- 30.3 Bryophytes: Dominant Gametophyte Generation 593
- 30.4 Tracheophyte Plants: Roots, Stems, and Leaves 596
- 30.5 Lycophytes: Dominant Sporophyte Generation and Vascular Tissue 598
- 30.6 Pterophytes: Ferns and Their Relatives 598
- 30.7 The Evolution of Seed Plants 602
- 30.8 Gymnosperms: Plants with "Naked Seeds" 603
- 30.9 Angiosperms: The Flowering Plants 606

## 31 Fungi 614

- 31.1 Defining Fungi 614
- 31.2 Microsporidia: Unicellular Parasites 618
- 31.3 Chytridiomycota and Relatives: Fungi with Flagellated Zoospores 619
- 31.4 Zygomycota: Fungi that Produce Zygotes 620
- 31.5 Glomeromycota: Asexual Plant Symbionts 622
- 31.6 Basidiomycota: The Club (Basidium) Fungi 622
- 31.7 Ascomycota: The Sac (Ascus) Fungi 623
- 31.8 Ecology of Fungi 625
- 31.9 Fungal Parasites and Pathogens 629

## 32 Overview of Animal Diversity 633

- 32.1 Some General Features of Animals 634
- 32.2 Evolution of the Animal Body Plan 636
- 32.3 The Classification of Animals 640
- 32.4 The Roots of the Animal Tree of Life 645

## 33 Noncoelomate Invertebrates 649

- 33.1 Parazoa: Animals That Lack Specialized Tissues 650
- 33.2 Eumetazoa: Animals with True Tissues 652
- 33.3 The Bilaterian Acoelomates 656
- 33.4 The Pseudocoelomates 661

## 34 Coelomate Invertebrates 666

- 34.1 Phylum Mollusca: The Mollusks 666
- 34.2 Phylum Nemertea: The Ribbon Worms 672
- 34.3 Phylum Annelida: The Annelids 673
- 34.4 The Lophophorates: Bryozoa and Brachiopoda 676
- 34.5 Phylum Arthropoda: The Arthropods 678
- 34.6 Phylum Echinodermata: The Echinoderms 687

## 35 Vertebrates 693

- 35.1 The Chordates 694
- 35.2 The Nonvertebrate Chordates 695
- 35.3 The Vertebrate Chordates 696
- 35.4 Fishes 698
- 35.5 Amphibians 703
- 35.6 Reptiles 706
- 35.7 Birds 712
- 35.8 Mammals 716
- 35.9 Evolution of the Primates 721

## 37 Vegetative Plant Development 753

- 37.1 Embryo Development 754
- 37.2 Seeds 760
- 37.3 Fruits 761
- 37.4 Germination 764

## 38 Transport in Plants 769

- 38.1 Transport Mechanisms 770
- 38.2 Water and Mineral Absorption 773
- 38.3 Xylem Transport 776
- 38.4 The Rate of Transpiration 778
- 38.5 Water-Stress Responses 780
- 38.6 Phloem Transport 781

## 39 Plant Nutrition and Soils 786

- 39.1 Soils: The Substrates on Which Plants Depend 787
- 39.2 Plant Nutrients 790
- 39.3 Special Nutritional Strategies 792
- 39.4 Carbon–Nitrogen Balance and Global Change 795
- 39.5 Phytoremediation 797

## 40 Plant Defense Responses 802

- 40.1 Physical Defenses 802
- 40.2 Chemical Defenses 805
- 40.3 Animals that Protect Plants 809
- 40.4 Systemic Responses to Invaders 810

## 41 Sensory Systems in Plants 814

- 41.1 Responses to Light 815
- 41.2 Responses to Gravity 819
- 41.3 Responses to Mechanical Stimuli 821
- 41.4 Responses to Water and Temperature 823
- 41.5 Hormones and Sensory Systems 825

## 42 Plant Reproduction 839

- 42.1 Reproductive Development 840
- 42.2 Flower Production 842
- 42.3 Structure and Evolution of Flowers 848
- 42.4 Pollination and Fertilization 851
- 42.5 Asexual Reproduction 857
- 42.6 Plant Life Spans 859

## Part VI Plant Form and Function

### 36 Plant Form 729

- 36.1 Organization of the Plant Body: An Overview 730
- 36.2 Plant Tissues 733
- 36.3 Roots: Anchoring and Absorption Structures 739
- 36.4 Stems: Support for Above-Ground Organs 743
- 36.5 Leaves: Photosynthetic Organs 747

## Part VII Animal Form and Function

### 43 The Animal Body and Principles of Regulation 863

- 43.1 Organization of the Vertebrate Body 864
- 43.2 Epithelial Tissue 865
- 43.3 Connective Tissue 868

43.4	Muscle Tissue	870		
43.5	Nerve Tissue	872		
43.6	Overview of Vertebrate Organ Systems	872		
43.7	Homeostasis	876		
43.8	Regulating Body Temperature	878		
<b>44</b>	<b>The Nervous System</b>	<b>887</b>		
44.1	Nervous System Organization	888		
44.2	The Mechanism of Nerve Impulse Transmission	890		
44.3	Synapses: Where Neurons Communicate with Other Cells	896		
44.4	The Central Nervous System: Brain and Spinal Cord	901		
44.5	The Peripheral Nervous System: Sensory and Motor Neurons	909		
<b>45</b>	<b>Sensory Systems</b>	<b>915</b>		
45.1	Overview of Sensory Receptors	916		
45.2	Mechanoreceptors: Touch and Pressure	917		
45.3	Hearing, Vibration, and Detection of Body Position	920		
45.4	Chemoreceptors: Taste, Smell, and pH	925		
45.5	Vision	928		
45.6	The Diversity of Sensory Experiences	933		
<b>46</b>	<b>The Endocrine System</b>	<b>937</b>		
46.1	Regulation of Body Processes by Chemical Messengers	938		
46.2	Actions of Lipophilic Versus Hydrophilic Hormones	943		
46.3	The Pituitary and Hypothalamus: The Body's Control Centers	946		
46.4	The Major Peripheral Endocrine Glands	951		
46.5	Other Hormones and Their Effects	955		
<b>47</b>	<b>The Musculoskeletal System</b>	<b>961</b>		
47.1	Types of Skeletal Systems	962		
47.2	A Closer Look at Bone	963		
47.3	Joints and Skeletal Movement	967		
47.4	Muscle Contraction	969		
47.5	Modes of Animal Locomotion	975		
<b>48</b>	<b>The Digestive System</b>	<b>981</b>		
48.1	Types of Digestive Systems	982		
48.2	The Mouth and Teeth: Food Capture and Bulk Processing	984		
48.3	The Esophagus and the Stomach: The Early Stages of Digestion	985		
48.4	The Intestines: Breakdown, Absorption, and Elimination	987		
48.5	Variations in Vertebrate Digestive Systems	990

54.4	Organogenesis	1116		
54.5	Vertebrate Axis Formation	1122		
54.6	Human Development	1125		

## Part VIII Ecology and Behavior

### 55 Behavioral Biology 1132

- 55.1 The Natural History of Behavior 1133
- 55.2 Nerve Cells, Neurotransmitters, Hormones, and Behavior 1134
- 55.3 Behavioral Genetics 1135
- 55.4 Learning 1137
- 55.5 The Development of Behavior 1139
- 55.6 Animal Cognition 1141
- 55.7 Orientation and Migratory Behavior 1142
- 55.8 Animal Communication 1144
- 55.9 Behavioral Ecology 1147
- 55.10 Reproductive Strategies and Sexual Selection 1150
- 55.11 Altruism 1154
- 55.12 The Evolution of Group Living and Animal Societies 1157

### 56 Ecology of Individuals and Populations 1162

- 56.1 The Environmental Challenges 1162
- 56.2 Populations: Groups of a Single Species in One Place 1165
- 56.3 Population Demography and Dynamics 1168
- 56.4 Life History and the Cost of Reproduction 1171
- 56.5 Environmental Limits to Population Growth 1173
- 56.6 Factors That Regulate Populations 1175
- 56.7 Human Population Growth 1178

### 57 Community Ecology 1185

- 57.1 Biological Communities: Species Living Together 1186
- 57.2 The Ecological Niche Concept 1188

- 57.3 Predator–Prey Relationships 1192
- 57.4 The Many Types of Species Interactions 1196
- 57.5 Ecological Succession, Disturbance, and Species Richness 1202

### 58 Dynamics of Ecosystems 1207

- 58.1 Biogeochemical Cycles 1208
- 58.2 The Flow of Energy in Ecosystems 1214
- 58.3 Trophic-Level Interactions 1219
- 58.4 Biodiversity and Ecosystem Stability 1223
- 58.5 Island Biogeography 1226

### 59 The Biosphere 1230

- 59.1 Ecosystem Effects of Sun, Wind, and Water 1230
- 59.2 Earth's Biomes 1235
- 59.3 Freshwater Habitats 1238
- 59.4 Marine Habitats 1241
- 59.5 Human Impacts on the Biosphere: Pollution and Resource Depletion 1245
- 59.6 Human Impacts on the Biosphere: Climate Change 1250

### 60 Conservation Biology 1256

- 60.1 Overview of the Biodiversity Crisis 1257
- 60.2 The Value of Biodiversity 1261
- 60.3 Factors Responsible for Extinction 1264
- 60.4 Approaches for Preserving Endangered Species and Ecosystems 1275

# The Science of Biology

## Chapter Outline

- 1.1 The Science of Life
- 1.2 The Nature of Science
- 1.3 An Example of Scientific Inquiry: Darwin and Evolution
- 1.4 Unifying Themes in Biology

## Introduction

You are about to embark on a journey—a journey of discovery about the nature of life. Nearly 180 years ago, a young English naturalist named Charles Darwin set sail on a similar journey on board H.M.S. Beagle; a replica of this ship is pictured here. What Darwin learned on his five-year voyage led directly to his development of the theory of evolution by natural selection, a theory that has become the core of the science of biology. Darwin's voyage seems a fitting place to begin our exploration of biology—the scientific study of living organisms and how they have evolved. Before we begin, however, let's take a moment to think about what biology is and why it's important.

### 1.1 The Science of Life

#### Learning Outcomes

1. Explain the importance of biology as a science.
2. Describe the characteristics of living systems.
3. Recognize the hierarchical organization of living systems.

This is the most exciting time to be studying biology in the history of the field. The amount of data available about the natural world has exploded in the last 25 years, and we are now in a position to ask and answer questions that previously were only dreamed of.

We have determined the entire sequence of the human genome and are in the process of sequencing the genomes of other species at an ever-increasing pace. We are closing in on a description of the molecular workings of the cell in unprecedented detail, and we are in the process of finally unveiling the mystery of how a single cell can give rise to the complex organization seen in multicellular organisms. With robotics, advanced imaging,

and analytical techniques, we have tools available that were formerly the stuff of science fiction.

In this text, we attempt to draw a contemporary picture of the science of biology, as well as provide some history and experimental perspective on this exciting time in the discipline. In this introductory chapter, we examine the nature of biology and the foundations of science in general to put into context the information presented in the rest of the text.

## Biology unifies much of natural science

The study of biology is a point of convergence for the information and tools from all of the natural sciences. Biological systems are the most complex chemical systems on Earth, and their many functions are both determined and constrained by the principles of chemistry and physics. Put another way, no new laws of nature can be gleaned from the study of biology—but that study does illuminate and illustrate the workings of those natural laws.

The intricate chemical workings of cells are based on everything we have learned from the study of chemistry. And every level of biological organization is governed by the nature of energy transactions learned from the study of thermodynamics. Biological systems do not represent any new forms of matter, and yet they are the most complex organization of matter known. The complexity of living systems is made possible by a constant source of energy—the Sun. The conversion of this energy source into organic molecules by photosynthesis is one of the most beautiful and complex reactions known in chemistry and physics.

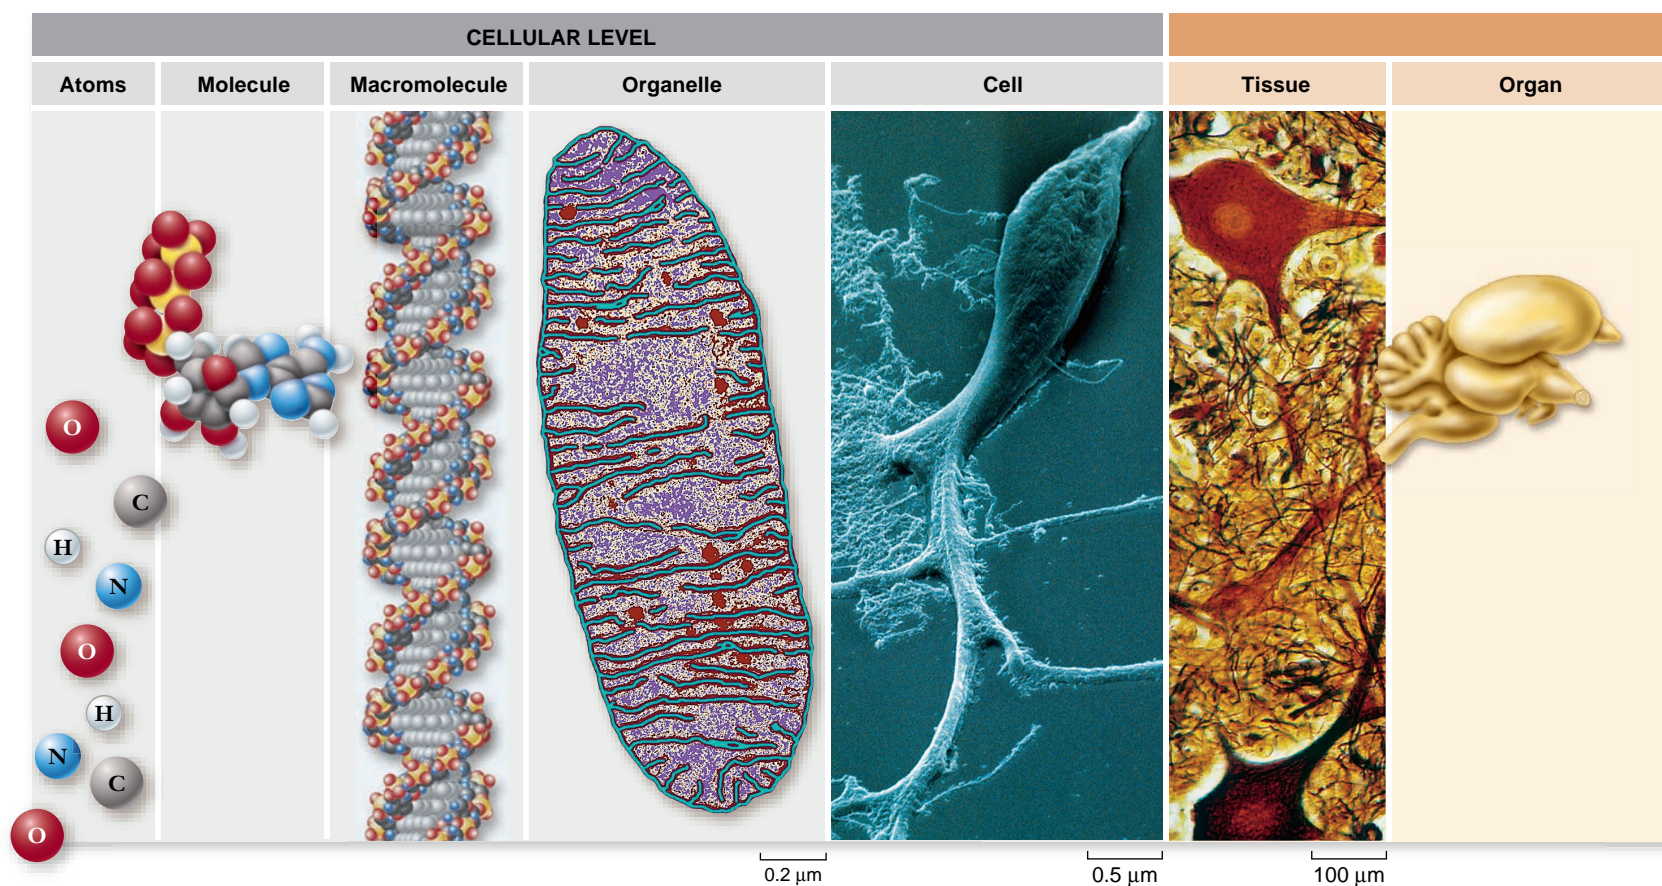

The way we do science is changing to grapple with increasingly difficult modern problems. Science is becoming more interdisciplinary, combining the expertise from a variety of exciting new fields such as nanotechnology. Biology is at the heart of this multidisciplinary approach because biological problems often require many different approaches to arrive at solutions.

## Life defies simple definition

In its broadest sense, biology is the study of living things—the *science of life*. Living things come in an astounding variety of shapes and forms, and biologists study life in many different ways. They live with gorillas, collect fossils, and listen to whales. They read the messages encoded in the long molecules of heredity and count how many times a hummingbird’s wings beat each second.

What makes something “alive”? Anyone could deduce that a galloping horse is alive and a car is not, but why? We cannot say, “If it moves, it’s alive,” because a car can move, and gelatin can wiggle in a bowl. They certainly are not alive. Although we cannot define life with a single simple sentence, we can come up with a series of seven characteristics shared by living systems:

- **Cellular organization.** All organisms consist of one or more cells. Often too tiny to see, cells carry out the basic activities of living. Each cell is bounded by a membrane that separates it from its surroundings.
- **Ordered complexity.** All living things are both complex and highly ordered. Your body is composed of many different kinds of cells, each containing many complex

molecular structures. Many nonliving things may also be complex, but they do not exhibit this degree of ordered complexity.

- **Sensitivity.** All organisms respond to stimuli. Plants grow toward a source of light, and the pupils of your eyes dilate when you walk into a dark room.
- **Growth, development, and reproduction.** All organisms are capable of growing and reproducing, and they all possess hereditary molecules that are passed to their offspring, ensuring that the offspring are of the same species.
- **Energy utilization.** All organisms take in energy and use it to perform many kinds of work. Every muscle in your body is powered with energy you obtain from the food you eat.
- **Homeostasis.** All organisms maintain relatively constant internal conditions that are different from their environment, a process called **homeostasis**.
- **Evolutionary adaptation.** All organisms interact with other organisms and the nonliving environment in ways that influence their survival, and as a consequence, organisms evolve adaptations to their environments.

## Living systems show hierarchical organization

The organization of the biological world is hierarchical—that is, each level builds on the level below it.

1. **The Cellular Level.** At the cellular level (figure 1.1), **atoms**, the fundamental elements of matter, are joined together into clusters called **molecules**. Complex

biological molecules are assembled into tiny structures called **organelles** within membrane-bounded units we call **cells**. The cell is the basic unit of life. Many independent organisms are composed only of single cells. Bacteria are single cells, for example. All animals and plants, as well as most fungi and algae, are multicellular—composed of more than one cell.

2. **The Organismal Level.** Cells in complex multicellular organisms exhibit three levels of organization. The most basic level is that of **tissues**, which are groups of similar cells that act as a functional unit. Tissues, in turn, are grouped into **organs**—body structures composed of several different tissues that act as a structural and functional unit. Your brain is an organ composed of nerve cells and a variety of associated tissues that form protective coverings and contribute blood. At the third level of organization, organs are grouped into **organ systems**. The nervous system, for example, consists of sensory organs, the brain and spinal cord, and neurons that convey signals.

### Figure 1.1 Hierarchical organization of living systems.

Life is highly organized from the simplest atoms to complex multicellular organisms. Along this hierarchy of structure, atoms form molecules that are used to form organelles, which in turn form the functional subsystems within cells. Cells are organized into tissues, and then into organs and organ systems such as the nervous system pictured. This organization extends beyond individual organisms to populations, communities, ecosystems, and finally the entire biosphere.

3. **The Populational Level.** Individual organisms can be categorized into several hierarchical levels within the living world. The most basic of these is the **population**—a group of organisms of the same species living in the same place. All populations of a particular kind of organism together form a **species**, its members similar in appearance and able to interbreed. At a higher level of biological organization, a **biological community** consists of all the populations of different species living together in one place.
4. **Ecosystem Level.** At the highest tier of biological organization, a biological community and the physical habitat within which it lives together constitute an ecological system, or **ecosystem**. For example, the soil, water, and atmosphere of a mountain ecosystem interact with the biological community of a mountain meadow in many important ways.
5. **The Biosphere.** The entire planet can be thought of as an ecosystem that we call the biosphere.

As you move up this hierarchy, novel properties emerge. These **emergent properties** result from the way in which components interact, and they often cannot be deduced just from looking at the parts themselves. Examining individual cells, for example, gives little hint about the whole animal. You, and all humans, have the same array of cell types as a giraffe. It is because the living world exhibits many emergent properties that it is difficult to define “life.”

The previous descriptions of the common features and organization of living systems begins to get at the nature of what it is to be alive. The rest of this book illustrates and expands on these basic ideas to try to provide a more complete account of living systems.

### Learning Outcomes Review 1.1

Biology is a unifying science that brings together other natural sciences, such as chemistry and physics, to study living systems. Life does not have a simple definition, but living systems share a number of properties that together describe life. Living systems can also be organized hierarchically, from the cellular level to the entire biosphere, with emerging properties that may exceed the sum of the parts.

- *Can you study biology without studying other sciences?*

## 1.2 The Nature of Science

### Learning Outcomes

1. *Describe the types of reasoning used by biologists.*
2. *Demonstrate how to formulate a hypothesis.*

Much like life itself, the nature of science defies simple description. For many years scientists have written about the “scien-

tific method” as though there is a single way of doing science. This oversimplification has contributed to confusion on the part of nonscientists about the nature of science.

At its core, science is concerned with developing an increasingly accurate understanding of the world around us using observation and reasoning. To begin with, we assume that natural forces acting now have always acted, that the fundamental nature of the universe has not changed since its inception, and that it is not changing now. A number of complementary approaches allow understanding of natural phenomena—there is no one “right way.”

Scientists also attempt to be as objective as possible in the interpretation of the data and observations they have collected. Because scientists themselves are human, this is not completely possible, but because science is a collective endeavor subject to scrutiny, it is self-correcting. One person’s results are verified by others, and if the results cannot be repeated, they are rejected.

### Much of science is descriptive

The classic vision of the scientific method is that observations lead to hypotheses that in turn make experimentally testable predictions. In this way, we dispassionately evaluate new ideas to arrive at an increasingly accurate view of nature. We discuss this way of doing science later in this chapter, but it is important to understand that much of science is purely descriptive: In order to understand anything, the first step is to describe it completely. Much of biology is concerned with arriving at an increasingly accurate description of nature.

The study of biodiversity is an example of descriptive science that has implications for other aspects of biology in addition to societal implications. Efforts are currently underway to classify all life on Earth. This ambitious project is purely descriptive, but it will lead to a much greater understanding of biodiversity as well as the effect our species has on biodiversity.

One of the most important accomplishments of molecular biology at the dawn of the 21st century was the completion of the sequence of the human genome. Many new hypotheses about human biology will be generated by this knowledge, and many experiments will be needed to test these hypotheses, but the determination of the sequence itself was descriptive science.

### Science uses both deductive and inductive reasoning

The study of logic recognizes two opposite ways of arriving at logical conclusions: deductive and inductive reasoning. Science makes use of both of these methods, although induction is the primary way of reasoning in hypothesis-driven science.

#### Deductive reasoning

**Deductive reasoning** applies general principles to predict specific results. More than 2200 years ago, the Greek scientist Eratosthenes used Euclidean geometry and deductive reasoning to accurately estimate the circumference of the Earth (figure 1.2). Deductive reasoning is the reasoning of mathematics and

**Figure 1.2 Deductive reasoning: how Eratosthenes estimated the circumference of the earth using deductive reasoning.** 1. On a day when sunlight shone straight down a deep well at Syene in Egypt, Eratosthenes measured the length of the shadow cast by a tall obelisk in the city of Alexandria, about 800 kilometers (km) away. 2. The shadow's length and the obelisk's height formed two sides of a triangle. Using the recently developed principles of Euclidean geometry, Eratosthenes calculated the angle,  $a$ , to be  $7^\circ$  and  $12'$ , exactly  $\frac{1}{50}$  of a circle ( $360^\circ$ ). 3. If angle  $a$  is  $\frac{1}{50}$  of a circle, then the distance between the obelisk (in Alexandria) and the well (in Syene) must be equal to  $\frac{1}{50}$  the circumference of the Earth. 4. Eratosthenes had heard that it was a 50-day camel trip from Alexandria to Syene. Assuming that a camel travels about 18.5 km per day, he estimated the distance between obelisk and well as 925 km (using different units of measure, of course). 5. Eratosthenes thus deduced the circumference of the Earth to be  $50 \times 925 = 46,250$  km. Modern measurements put the distance from the well to the obelisk at just over 800 km. Employing a distance of 800 km, Eratosthenes's value would have been  $50 \times 800 = 40,000$  km. The actual circumference is 40,075 km.

philosophy, and it is used to test the validity of general ideas in all branches of knowledge. For example, if all mammals by definition have hair, and you find an animal that does not have hair, then you may conclude that this animal is not a mammal. A biologist uses deductive reasoning to infer the species of a specimen from its characteristics.

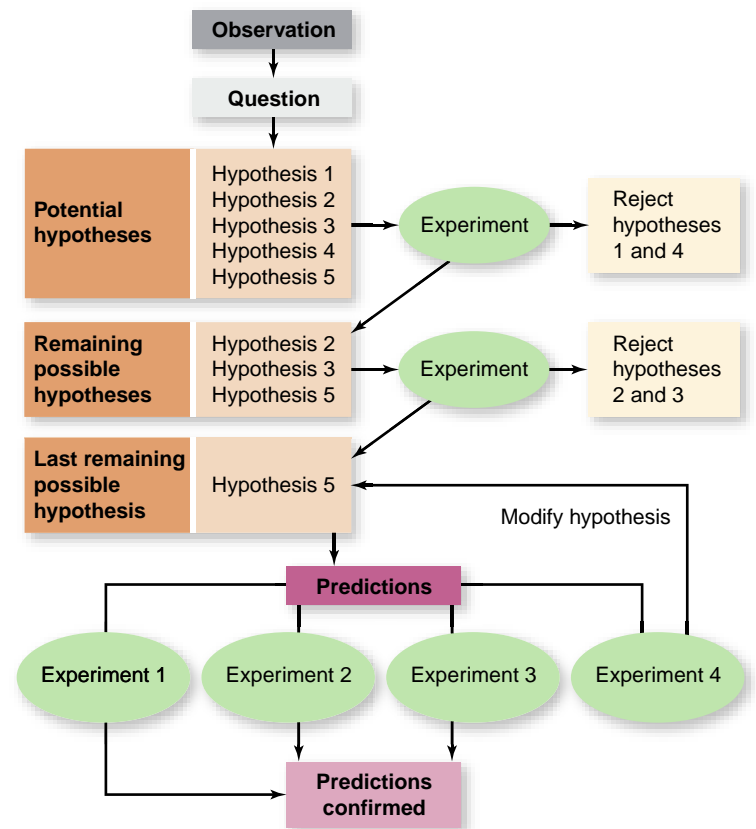

### Inductive reasoning

In **inductive reasoning**, the logic flows in the opposite direction, from the specific to the general. Inductive reasoning uses specific observations to construct general scientific principles. For example, if poodles have hair, and terriers have hair, and every dog that you observe has hair, then you may conclude that all dogs have hair. Inductive reasoning leads to generalizations that can then be tested. Inductive reasoning first became important to science in the 1600s in Europe, when Francis Bacon, Isaac Newton, and others began to use the results of particular experiments to infer general principles about how the world operates.

An example from modern biology is the role of homeobox genes in development. Studies in the fruit fly, *Drosophila melanogaster*, identified genes that could cause dramatic changes in developmental fate, such as a leg appearing in the place of an antenna. When the genes themselves were isolated and their DNA sequence determined, it was found that similar genes were found in many animals, including humans. This led to the general idea that the homeobox genes act as switches to control developmental fate.

### Hypothesis-driven science makes and tests predictions

Scientists establish which general principles are true from among the many that might be true through the process of systematically testing alternative proposals. If these proposals prove inconsistent with experimental observations, they are rejected as untrue. Figure 1.3 illustrates the process.

**Figure 1.3 How science is done.** This diagram illustrates how scientific investigations proceed. First, scientists make observations that raise a particular question. They develop a number of potential explanations (hypotheses) to answer the question. Next, they carry out experiments in an attempt to eliminate one or more of these hypotheses. Then, predictions are made based on the remaining hypotheses, and further experiments are carried out to test these predictions. The process can also be iterative. As experimental results are performed, the information can be used to modify the original hypothesis to fit each new observation.

After making careful observations, scientists construct a **hypothesis**, which is a suggested explanation that accounts for those observations. A hypothesis is a proposition that might be true. Those hypotheses that have not yet been disproved are retained. They are useful because they fit the known facts, but they are always subject to future rejection if, in the light of new information, they are found to be incorrect.

This process can also be *iterative*, that is, a hypothesis can be changed and refined with new data. For instance, geneticists George Beadle and Edward Tatum studied the nature of genetic information to arrive at their “one-gene/one-enzyme” hypothesis (see chapter 15). This hypothesis states that a gene represents the genetic information necessary to make a single enzyme. As investigators learned more about the molecular nature of genetic information, the hypothesis was refined to “one-gene/one-polypeptide” because enzymes can be made up of more than one polypeptide. With still more information about the nature of genetic information, other investigators found that a single gene can specify more than one polypeptide, and the hypothesis was refined again.

### Testing hypotheses

We call the test of a hypothesis an **experiment**. Suppose that a room appears dark to you. To understand why it appears dark, you propose several hypotheses. The first might be, “There is no light in the room because the light switch is turned off.” An alternative hypothesis might be, “There is no light in the room because the light-bulb is burned out.” And yet another hypothesis might be, “I am going blind.” To evaluate these hypotheses, you would conduct an experiment designed to eliminate one or more of the hypotheses.

For example, you might test your hypotheses by flipping the light switch. If you do so and the room is still dark, you have disproved the first hypothesis: Something other than the setting of the light switch must be the reason for the darkness. Note that a test such as this does not prove that any of the other hypotheses are true; it merely demonstrates that the one being tested is not. A successful experiment is one in which one or more of the alternative hypotheses is demonstrated to be inconsistent with the results and is thus rejected.

As you proceed through this text, you will encounter many hypotheses that have withstood the test of experiment. Many will continue to do so; others will be revised as new observations are made by biologists. Biology, like all science, is in a constant state of change, with new ideas appearing and replacing or refining old ones.

### Establishing controls

Often scientists are interested in learning about processes that are influenced by many factors, or **variables**. To evaluate alternative hypotheses about one variable, all other variables must be kept constant. This is done by carrying out two experiments in parallel: a test experiment and a control experiment. In the **test experiment**, one variable is altered in a known way to test a particular hypothesis. In the **control experiment**, that variable is left unaltered. In all other respects the two experiments are identical, so any difference in the outcomes of the two experiments must result from the influence of the variable that was changed.

Much of the challenge of experimental science lies in designing control experiments that isolate a particular variable from other factors that might influence a process.

### Using predictions

A successful scientific hypothesis needs to be not only valid but also useful—it needs to tell us something we want to know. A hypothesis is most useful when it makes predictions because those predictions provide a way to test the validity of the hypothesis. If an experiment produces results inconsistent with the predictions, the hypothesis must be rejected or modified. In contrast, if the predictions are supported by experimental testing, the hypothesis is supported. The more experimentally supported predictions a hypothesis makes, the more valid the hypothesis is.

As an example, in the early history of microbiology it was known that nutrient broth left sitting exposed to air becomes contaminated. Two hypotheses were proposed to explain this observation: spontaneous generation and the germ hypothesis. Spontaneous generation held that there was an inherent property in organic molecules that could lead to the spontaneous generation of life. The germ hypothesis proposed that preexisting microorganisms that were present in the air could contaminate the nutrient broth.

These competing hypotheses were tested by a number of experiments that involved filtering air and boiling the broth to kill any contaminating germs. The definitive experiment was performed by Louis Pasteur, who constructed flasks with curved necks that could be exposed to air, but that would trap any contaminating germs. When such flasks were boiled to sterilize them, they remained sterile, but if the curved neck was broken off, they became contaminated (figure 1.4).

### SCIENTIFIC THINKING

**Question:** What is the source of contamination that occurs in a flask of nutrient broth left exposed to the air?

**Germ Hypothesis:** Preexisting microorganisms present in the air contaminate nutrient broth.

**Prediction:** Sterilized broth will remain sterile if microorganisms are prevented from entering flask.

**Spontaneous Generation Hypothesis:** Living organisms will spontaneously generate from nonliving organic molecules in broth.

**Prediction:** Organisms will spontaneously generate from organic molecules in broth after sterilization.

**Test:** Use swan-necked flasks to prevent entry of microorganisms. To ensure that broth can still support life, break swan-neck after sterilization.

Flask is sterilized by boiling the broth.

Unbroken flask remains sterile.

Broken flask becomes contaminated after exposure to germ-laden air.

**Result:** No growth occurs in sterile swan-necked flasks. When the neck is broken off, and the broth is exposed to air, growth occurs.

**Conclusion:** Growth in broth is of preexisting microorganisms.

**Figure 1.4** Experiment to test spontaneous generation versus germ hypothesis.

This result was predicted by the germ hypothesis—that when the sterile flask is exposed to air, airborne germs are deposited in the broth and grow. The spontaneous generation hypothesis predicted no difference in results with exposure to air. This experiment disproved the hypothesis of spontaneous generation and supported the hypothesis of airborne germs under the conditions tested.

## Reductionism breaks larger systems into their component parts

Scientists often use the philosophical approach of **reductionism** to understand a complex system by reducing it to its working parts. Reductionism has been the general approach of biochemistry, which has been enormously successful at unraveling the complexity of cellular metabolism by concentrating on individual pathways and specific enzymes. By analyzing all of the pathways and their components, scientists now have an overall picture of the metabolism of cells.

Reductionism has limits when applied to living systems, however—one of which is that enzymes do not always behave exactly the same in isolation as they do in their normal cellular context. A larger problem is that the complex interworking of many interconnected functions leads to emergent properties that cannot be predicted based on the workings of the parts. For example, an examination of all of the proteins and RNAs in a ribosome in isolation would not lead to predictions about the nature of protein synthesis. On a higher level, understanding the physiology of a single Canada goose, would not lead to predictions about flocking behavior. Biologists are just beginning to come to grips with this problem and to think about ways of dealing with the whole as well as the workings of the parts. The emerging field of systems biology focuses on this different approach.

## Biologists construct models to explain living systems

Biologists construct models in many different ways for a variety of uses. Geneticists construct models of interacting networks of proteins that control gene expression, often even drawing cartoon figures to represent that which we cannot see. Population biologists build models of how evolutionary change occurs. Cell biologists build models of signal transduction pathways and the events leading from an external signal to internal events. Structural biologists build actual models of the structure of proteins and macromolecular complexes in cells.

Models provide a way to organize how we think about a problem. Models can also get us closer to the larger picture and away from the extreme reductionist approach. The working parts are provided by the reductionist analysis, but the model shows how they fit together. Often these models suggest other experiments that can be performed to refine or test the model.

As researchers gain more knowledge about the actual flow of molecules in living systems, more sophisticated kinetic models can be used to apply information about isolated enzymes to their cellular context. In systems biology, this

modeling is being applied on a large scale to regulatory networks during development, and even to modeling an entire bacterial cell.

## The nature of scientific theories

Scientists use the word **theory** in two main ways. The first meaning of *theory* is a proposed explanation for some natural phenomenon, often based on some general principle. Thus, we speak of the principle first proposed by Newton as the “theory of gravity.” Such theories often bring together concepts that were previously thought to be unrelated.

The second meaning of *theory* is the body of interconnected concepts, supported by scientific reasoning and experimental evidence, that explains the facts in some area of study. Such a theory provides an indispensable framework for organizing a body of knowledge. For example, quantum theory in physics brings together a set of ideas about the nature of the universe, explains experimental facts, and serves as a guide to further questions and experiments.

To a scientist, theories are the solid ground of science, expressing ideas of which we are most certain. In contrast, to the general public, the word *theory* usually implies the opposite—a *lack* of knowledge, or a guess. Not surprisingly, this difference often results in confusion. In this text, *theory* will always be used in its scientific sense, in reference to an accepted general principle or body of knowledge.

Some critics outside of science attempt to discredit evolution by saying it is “just a theory.” The hypothesis that evolution has occurred, however, is an accepted scientific fact—it is supported by overwhelming evidence. Modern evolutionary theory is a complex body of ideas, the importance of which spreads far beyond explaining evolution. Its ramifications permeate all areas of biology, and it provides the conceptual framework that unifies biology as a science. Again, the key is how well a hypothesis fits the observations. Evolutionary theory fits the observations very well.

## Research can be basic or applied

In the past it was fashionable to speak of the “scientific method” as consisting of an orderly sequence of logical, either-or steps. Each step would reject one of two mutually incompatible alternatives, as though trial-and-error testing would inevitably lead a researcher through the maze of uncertainty to the ultimate scientific answer. If this were the case, a computer would make a good scientist. But science is not done this way.

As the British philosopher Karl Popper has pointed out, successful scientists without exception design their experiments with a pretty fair idea of how the results are going to come out. They have what Popper calls an “imaginative preconception” of what the truth might be. Because insight and imagination play such a large role in scientific progress, some scientists are better at science than others—just as Bruce Springsteen stands out among songwriters or Claude Monet stands out among Impressionist painters.

Some scientists perform *basic research*, which is intended to extend the boundaries of what we know. These individuals typically work at universities, and their research is usually supported by grants from various agencies and foundations.

The information generated by basic research contributes to the growing body of scientific knowledge, and it provides the scientific foundation utilized by *applied research*. Scientists who conduct applied research are often employed in some kind of industry. Their work may involve the manufacture of food additives, the creation of new drugs, or the testing of environmental quality.

Research results are written up and submitted for publication in scientific journals, where the experiments and conclusions are reviewed by other scientists. This process of careful evaluation, called *peer review*, lies at the heart of modern science. It helps to ensure that faulty research or false claims are not given the authority of scientific fact. It also provides other scientists with a starting point for testing the reproducibility of experimental results. Results that cannot be reproduced are not taken seriously for long.

### Learning Outcomes Review 1.2

Much of science is descriptive, amassing observations to gain an accurate view. Both deductive reasoning and inductive reasoning are used in science. Scientific hypotheses are suggested explanations for observed phenomena. When a hypothesis has been extensively tested and no contradictory information has been found, it becomes an accepted theory. Theories are coherent explanations of observed data, but they may be modified by new information.

- How does a scientific theory differ from a hypothesis?

## 1.3 An Example of Scientific Inquiry: Darwin and Evolution

### Learning Outcomes

1. Describe Darwin's theory of evolution by natural selection.
2. List evidence that supports the theory of evolution.

Darwin's theory of evolution explains and describes how organisms on Earth have changed over time and acquired a diversity of new forms. This famous theory provides a good example of how a scientist develops a hypothesis and how a scientific theory grows and wins acceptance.

Charles Robert Darwin (1809–1882; figure 1.5) was an English naturalist who, after 30 years of study and observation, wrote one of the most famous and influential books of all time. This book, *On the Origin of Species by Means of Natural Selection*, created a sensation when it was published, and the ideas Darwin expressed in it have played a central role in the development of human thought ever since.

### The idea of evolution existed prior to Darwin

In Darwin's time, most people believed that the different kinds of organisms and their individual structures resulted from di-

**Figure 1.5 Charles Darwin.** This newly rediscovered photograph taken in 1881, the year before Darwin died, appears to be the last ever taken of the great biologist.

rect actions of a Creator (many people still believe this). Species were thought to have been specially created and to be unchangeable over the course of time.

In contrast to these ideas, a number of earlier naturalists and philosophers had presented the view that living things must have changed during the history of life on Earth. That is, **evolution** has occurred, and living things are now different from how they began. Darwin's contribution was a concept he called *natural selection*, which he proposed as a coherent, logical explanation for this process, and he brought his ideas to wide public attention.

### Darwin observed differences in related organisms

The story of Darwin and his theory begins in 1831, when he was 22 years old. He was part of a five-year navigational mapping expedition around the coasts of South America (figure 1.6), aboard H.M.S. *Beagle*. During this long voyage, Darwin had the chance to study a wide variety of plants and animals on continents and islands and in distant seas. Darwin observed a number of phenomena that were of central importance to his reaching his ultimate conclusion.

Repeatedly, Darwin saw that the characteristics of similar species varied somewhat from place to place. These geographical patterns suggested to him that lineages change gradually as species migrate from one area to another. On the Galápagos Islands, 960 km (600 miles) off the coast of Ecuador, Darwin encountered a variety of different finches on the various islands. The 14 species, although related, differed slightly in appearance, particularly in their beaks (figure 1.7).

Darwin thought it was reasonable to assume that all these birds had descended from a common ancestor arriving from the South American mainland several million years ago. Eating different foods on different islands, the finches' beaks had changed during their descent—"descent with modification," or evolution. (These finches are discussed in more detail in chapters 21 and 22.)

**Figure 1.6 The five-year voyage of H.M.S. Beagle.** Most of the time was spent exploring the coasts and coastal islands of South America, such as the Galápagos Islands. Darwin's studies of the animals of the Galápagos Islands played a key role in his eventual development of the concept of evolution by means of natural selection.

In a more general sense, Darwin was struck by the fact that the plants and animals on these relatively young volcanic islands resembled those on the nearby coast of South America. If each one of these plants and animals had been created independently and simply placed on the Galápagos Islands, why didn't they resemble the plants and animals of islands with similar climates—such as those off the coast of Africa, for example? Why did they resemble those of the adjacent South American coast instead?

## Darwin proposed natural selection as a mechanism for evolution

It is one thing to observe the results of evolution, but quite another to understand how it happens. Darwin's great achievement lies in his ability to move beyond all the individual observations to formulate the hypothesis that evolution occurs because of natural selection.

**Figure 1.7 Three Galápagos finches and what they eat.** On the Galápagos Islands, Darwin observed 14 different species of finches differing mainly in their beaks and feeding habits. These three finches eat very different food items, and Darwin surmised that the different shapes of their bills represented evolutionary adaptations that improved their ability to eat the foods available in their specific habitats.

## Darwin and Malthus

Of key importance to the development of Darwin's insight was his study of Thomas Malthus's *An Essay on the Principle of Population* (1798). In this book, Malthus stated that populations of plants and animals (including human beings) tend to increase geometrically, while humans are able to increase their food supply only arithmetically. Put another way, population increases by a multiplying factor—for example, in the series 2, 6, 18, 54, the starting number is multiplied by 3. Food supply increases by an additive factor—for example, the series 2, 4, 6, 8 adds 2 to each starting number. Figure 1.8 shows the difference that these two types of relationships produce over time.

Because populations increase geometrically, virtually any kind of animal or plant, if it could reproduce unchecked, would cover the entire surface of the world surprisingly quickly. Instead, populations of species remain fairly constant year after year, because death limits population numbers.

Sparked by Malthus's ideas, Darwin saw that although every organism has the potential to produce more offspring than can survive, only a limited number actually do survive and produce further offspring. Combining this observation with what he had seen on the voyage of the *Beagle*, as well as with his own experiences in breeding domestic animals, Darwin made an important association: Individuals possessing physical, behavioral, or

**Figure 1.8 Geometric and arithmetic progressions.** A geometric progression increases by a constant factor (for example, the curve shown increases  $\times 3$  for each step), whereas an arithmetic progression increases by a constant difference (for example, the line shown increases  $+2$  for each step). Malthus contended that the human growth curve was geometric, but the human food production curve was only arithmetic.

### Inquiry question

? What is the effect of reducing the constant factor by which the geometric progression increases? Might this effect be achieved with humans? How?

other attributes that give them an advantage in their environment are more likely to survive and reproduce than those with less advantageous traits. By surviving, these individuals gain the opportunity to pass on their favorable characteristics to their offspring. As the frequency of these characteristics increases in the population, the nature of the population as a whole will gradually change. Darwin called this process *selection*.

### Natural selection

Darwin was thoroughly familiar with variation in domesticated animals, and he began *On the Origin of Species* with a detailed discussion of pigeon breeding. He knew that animal breeders selected certain varieties of pigeons and other animals, such as dogs, to produce certain characteristics, a process Darwin called **artificial selection**.

Artificial selection often produces a great variation in traits. Domestic pigeon breeds, for example, show much greater variety than all of the wild species found throughout the world. Darwin thought that this type of change could occur in nature, too. Surely if pigeon breeders could foster variation by artificial selection, nature could do the same—a process Darwin called **natural selection**.

### Darwin drafts his argument

Darwin drafted the overall argument for evolution by natural selection in a preliminary manuscript in 1842. After showing the manuscript to a few of his closest scientific friends, however, Darwin put it in a drawer, and for 16 years turned to other research. No one knows for sure why Darwin did not publish his initial manuscript—it is very thorough and outlines his ideas in detail.

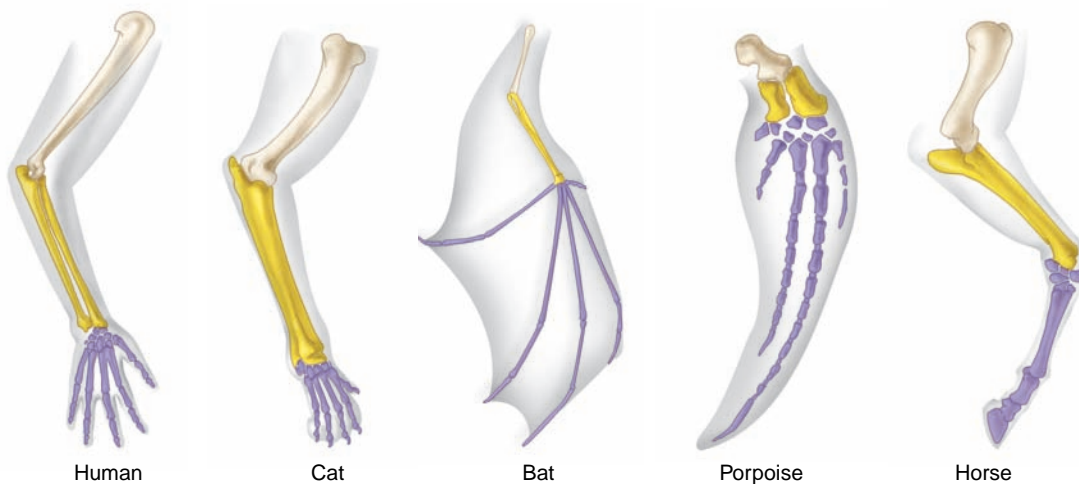

The stimulus that finally brought Darwin's hypothesis into print was an essay he received in 1858. A young English naturalist named Alfred Russel Wallace (1823–1913) sent the essay to Darwin from Indonesia; it concisely set forth the hypothesis of evolution by means of natural selection, a hypothesis Wallace had developed independently of Darwin. After receiving Wallace's essay, friends of Darwin arranged for a joint presentation of their ideas at a seminar in London. Darwin then completed his own book, expanding the 1842 manuscript he had written so long ago, and submitted it for publication.

### The predictions of natural selection have been tested

More than 120 years have elapsed since Darwin's death in 1882. During this period, the evidence supporting his theory has grown progressively stronger. We briefly explore some of this evidence here; in chapter 22, we will return to the theory of evolution by natural selection and examine the evidence in more detail.

### The fossil record

Darwin predicted that the fossil record would yield intermediate links between the great groups of organisms—for example, between fishes and the amphibians thought to have arisen from them, and between reptiles and birds. Furthermore, natural selection predicts the relative positions in time of such transitional forms. We now know the fossil record to a degree that was unthinkable in the 19th century, and although truly “intermediate”

**Figure 1.9 Homology among vertebrate limbs.**

The forelimbs of these five vertebrates show the ways in which the relative proportions of the forelimb bones have changed in relation to the particular way of life of each organism.

organisms are hard to determine, paleontologists have found what appear to be transitional forms and found them at the predicted positions in time.

Recent discoveries of microscopic fossils have extended the known history of life on Earth back to about 3.5 billion years ago (BYA). The discovery of other fossils has supported Darwin's predictions and has shed light on how organisms have, over this enormous time span, evolved from the simple to the complex. For vertebrate animals especially, the fossil record is rich and exhibits a graded series of changes in form, with the evolutionary sequence visible for all to see.

### The age of the Earth

Darwin's theory predicted the Earth must be very old, but some physicists argued that the Earth was only a few thousand years old. This bothered Darwin, because the evolution of all living things from some single original ancestor would have required a great deal more time. Using evidence obtained by studying the rates of radioactive decay, we now know that the physicists of Darwin's time were very wrong: The Earth was formed about 4.5 BYA.

### The mechanism of heredity

Darwin received some of his sharpest criticism in the area of heredity. At that time, no one had any concept of genes or how heredity works, so it was not possible for Darwin to explain completely how evolution occurs.

Even though Gregor Mendel was performing his experiments with pea plants in Brunn, Austria (now Brno, the Czech Republic), during roughly the same period, genetics was established as a science only at the start of the 20th century. When scientists began to understand the laws of inheritance (discussed in chapters 12 and 13), this problem with Darwin's theory vanished.

### Comparative anatomy

Comparative studies of animals have provided strong evidence for Darwin's theory. In many different types of vertebrates, for example, the same bones are present, indicating their evolutionary past. Thus, the forelimbs shown in figure 1.9 are all constructed from the same basic array of bones, modified for different purposes.

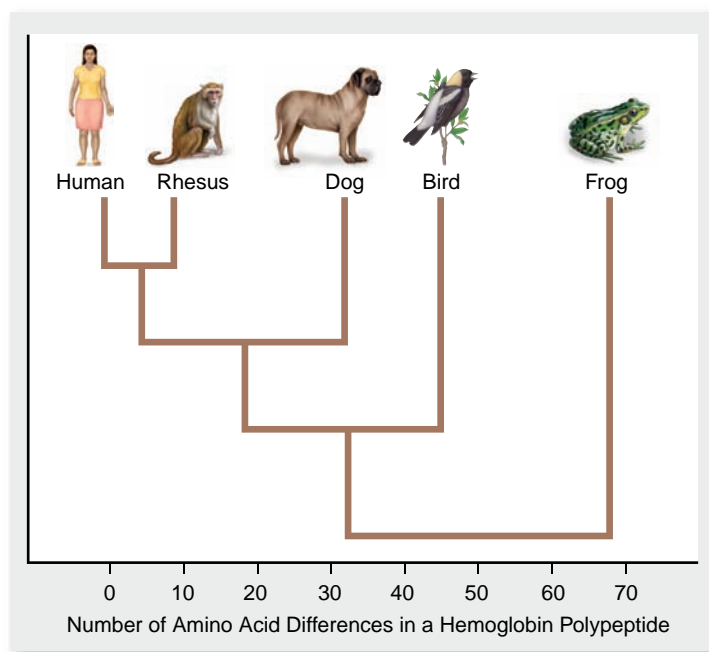

These bones are said to be **homologous** in the different vertebrates; that is, they have the same evolutionary origin, but they now differ in structure and function. They are contrasted with

**analogous** structures, such as the wings of birds and butterflies, which have similar function but different evolutionary origins.

### Molecular evidence

Evolutionary patterns are also revealed at the molecular level. By comparing the genomes (that is, the sequences of all the genes) of different groups of animals or plants, we can more precisely specify the degree of relationship among the groups. A series of evolutionary changes over time should involve a continual accumulation of genetic changes in the DNA.

This difference can be seen clearly in the protein hemoglobin (figure 1.10). Rhesus monkeys, which like humans

**Figure 1.10 Molecules reflect evolutionary patterns.**

Vertebrates that are more distantly related to humans have a greater number of amino acid differences in the hemoglobin polypeptide.

### Inquiry question

? Where do you imagine a snake might fall on the graph? Why?

are primates, have fewer differences from humans in the 146-amino-acid hemoglobin  $\beta$ -chain than do more distantly related mammals, such as dogs. Nonmammalian vertebrates, such as birds and frogs, differ even more.

The sequences of some genes, such as the ones specifying the hemoglobin proteins, have been determined in many organisms, and the entire time course of their evolution can be laid out with confidence by tracing the origins of particular nucleotide changes in the gene sequence. The pattern of descent obtained is called a **phylogenetic tree**. It represents the evolutionary history of the gene, its “family tree.” Molecular phylogenetic trees agree well with those derived from the fossil record, which is strong direct evidence of evolution. The pattern of accumulating DNA changes represents, in a real sense, the footprints of evolutionary history.

### Learning Outcomes Review 1.3

Darwin observed differences in related organisms and proposed the hypothesis of evolution by natural selection to explain these differences. The predictions generated by natural selection have been tested and continue to be tested by analysis of the fossil record, genetics, comparative anatomy, and even the DNA of living organisms.

- Does Darwin’s theory of evolution by natural selection explain the origin of life?

## 1.4 Unifying Themes in Biology

### Learning Outcomes

1. Describe the unifying themes in biology.
2. Contrast living and nonliving systems.

The study of biology encompasses a large number of different subdisciplines, ranging from biochemistry to ecology. In all of these, however, unifying themes can be identified. Among these are cell theory, the molecular basis of inheritance, the relationship between structure and function, evolution, and the emergence of novel properties.

### Cell theory describes the organization of living systems

As was stated at the beginning of this chapter, all organisms are composed of cells, life’s basic units (figure 1.11). Cells were discovered by Robert Hooke in England in 1665, using one of the first microscopes, one that magnified 30 times. Not long after that, the Dutch scientist Anton van Leeuwenhoek used microscopes capable of magnifying 300 times and discovered an amazing world of single-celled life in a drop of pond water.

In 1839, the German biologists Matthias Schleiden and Theodor Schwann, summarizing a large number of observations by themselves and others, concluded that all living organ-

b.

568  $\mu\text{m}$

**Figure 1.11 Cellular basis of life.** All organisms are composed of cells. Some organisms, including the protists, shown in part (a) are single-celled. Others, such as the plant shown in cross section in part (b) consist of many cells.

isms consist of cells. Their conclusion has come to be known as the **cell theory**. Later, biologists added the idea that all cells come from preexisting cells. The cell theory, one of the basic ideas in biology, is the foundation for understanding the reproduction and growth of all organisms.

### The molecular basis of inheritance explains the continuity of life

Even the simplest cell is incredibly complex—more intricate than any computer. The information that specifies what a cell is like—its detailed plan—is encoded in **deoxyribonucleic acid (DNA)**, a long, cablelike molecule. Each DNA molecule is

formed from two long chains of building blocks, called nucleotides, wound around each other (see chapter 14). Four different nucleotides are found in DNA, and the sequence in which they occur encodes the cell's information. Specific sequences of several hundred to many thousand nucleotides make up a **gene**, a discrete unit of information.

The continuity of life from one generation to the next—heredity—depends on the faithful copying of a cell's DNA into daughter cells. The entire set of DNA instructions that specifies a cell is called its *genome*. The sequence of the human genome, 3 billion nucleotides long, was decoded in rough draft form in 2001, a triumph of scientific investigation.

## The relationship between structure and function underlies living systems

One of the unifying themes of molecular biology is the relationship between structure and function. Function in molecules, and larger macromolecular complexes, is dependent on their structure.

Although this observation may seem trivial, it has far-reaching implications. We study the structure of molecules and macromolecular complexes to learn about their function. When we know the function of a particular structure, we can infer the function of similar structures found in different contexts, such as in different organisms.

Biologists study both aspects, looking for the relationships between structure and function. On the one hand, this allows similar structures to be used to infer possible similar functions. On the other hand, this knowledge also gives clues as to what kinds of structures may be involved in a process if we know about the functionality.

For example, suppose that we know the structure of a human cell's surface receptor for insulin, the hormone that controls uptake of glucose. We then find a similar molecule in the membrane of a cell from a different species—perhaps even a very different organism, such as a worm. We might conclude that this membrane molecule acts as a receptor for an insulin-like molecule produced by the worm. In this way, we might be able to discern the evolutionary relationship between glucose uptake in worms and in humans.

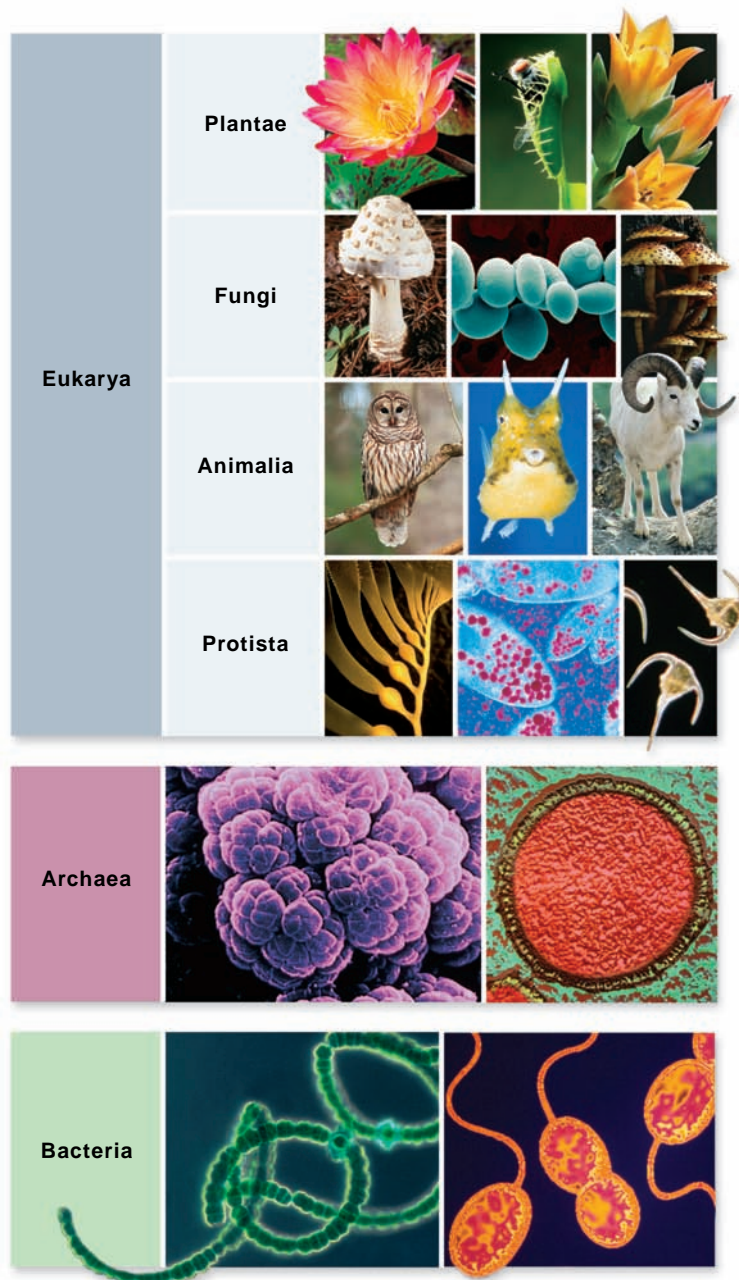

## The diversity of life arises by evolutionary change

The unity of life that we see in certain key characteristics shared by many related life-forms contrasts with the incredible diversity of living things in the varied environments of Earth. The underlying unity of biochemistry and genetics argues that all life has evolved from the same origin event. The diversity of life arises by evolutionary change leading to the present biodiversity we see.

Biologists divide life's great diversity into three great groups, called domains: Bacteria, Archaea, and Eukarya (figure 1.12). The domains Bacteria and Archaea are composed of single-celled organisms (*prokaryotes*) with little internal structure, and the domain Eukarya is made up of organisms (*eukaryotes*) composed of a complex, organized cell or multiple complex cells.

Within Eukarya are four main groups called kingdoms (figure 1.12). Kingdom Protista consists of all the unicellular eukaryotes except yeasts (which are fungi), as well as the multicellular algae. Because of the great diversity among the protists, many biologists feel kingdom Protista should be split into several kingdoms.

Kingdom Plantae consists of organisms that have cell walls of cellulose and obtain energy by photosynthesis. Organisms in the kingdom Fungi have cell walls of chitin and obtain energy by secreting digestive enzymes and then absorbing the products they release from the external environment. Kingdom Animalia contains organisms that lack cell walls and obtain energy by first ingesting other organisms and then digesting them internally.

**Figure 1.12 The diversity of life.** Biologists categorize all living things into three overarching groups called domains: Bacteria, Archaea, and Eukarya. Domain Eukarya is composed of four kingdoms: Plantae, Fungi, Animalia, and Protista.

## Evolutionary conservation explains the unity of living systems

Biologists agree that all organisms alive today have descended from some simple cellular creature that arose about 3.5 BYA. Some of the characteristics of that earliest organism have been preserved. The storage of hereditary information in DNA, for example, is common to all living things.

The retention of these conserved characteristics in a long line of descent usually reflects that they have a fundamental role in the biology of the organism—one not easily changed once adopted. A good example is provided by the homeodomain proteins, which play critical roles in early development in eukaryotes. Conserved characteristics can be seen in approximately 1850 homeodomain proteins, distributed among three different kingdoms of organisms (figure 1.13). The homeodomain proteins are powerful developmental tools that evolved early, and for which no better alternative has arisen.

### Cells are information-processing systems

One way to think about cells is as highly complex nanomachines that process information. The information stored in DNA is used to direct the synthesis of cellular components, and the particular set of components can differ from cell to cell. The way that proteins fold in space is a form of information that is three-dimensional, and interesting properties emerge from the interaction of these shapes in macromolecular complexes. The control of gene expression allows differentiation of

**Figure 1.13** Tree of homeodomain proteins.

Homeodomain proteins are found in fungi (*brown*), plants (*green*), and animals (*blue*). Based on their sequence similarities, these 11 different homeodomain proteins (uppercase letters at the ends of branches) fall into two groups, with representatives from each kingdom in each group. That means, for example, the mouse homeodomain protein PAX6 is more closely related to fungal and flowering plant proteins, such as PHO2 and GL2, than it is to the mouse protein MEIS.

cell types in time and space, leading to changes over developmental time into different tissue types—even though all cells in an organism carry the same genetic information.

Cells also process information that they receive about the environment. Cells sense their environment through proteins in their membranes, and this information is transmitted across the membrane to elaborate signal-transduction chemical pathways that can change the functioning of a cell.

This ability of cells to sense and respond to their environment is critical to the function of tissues and organs in multicellular organisms. A multicellular organism can regulate its internal environment, maintaining constant temperature, pH, and concentrations of vital ions. This homeostasis is possible because of elaborate signaling networks that coordinate the activities of different cells in different tissues.

### Living systems exist in a nonequilibrium state

A key feature of living systems is that they are open systems that function far from thermodynamic equilibrium. This has a number of implications for their behavior. A constant supply of energy is necessary to maintain a stable nonequilibrium state. Consider the state of the nucleic acids, and proteins in all of your cells: at equilibrium they are not polymers, they would all be hydrolyzed to monomer nucleotides and amino acids. Second, nonequilibrium systems exhibit self-organizing properties not seen in equilibrium systems.

These self-organizing properties of living systems show up at different levels of the hierarchical organization. At the cellular level, macromolecular complexes such as the spindle necessary for chromosome separation can self-organize. At the population level, a flock of birds, a school of fish, or the bacteria in a biofilm are all also self-organizing. This kind of interacting behavior of individual units leads to emergent properties that are not predictable from the nature of the units themselves.

Emergent properties are properties of collections of molecules, cells, individuals, that are distinct from the categorical properties that can be described by such statistics as mean and standard deviation. The mathematics necessary to describe these kind of interacting systems is nonlinear dynamics. The emerging field of systems biology is beginning to model biological systems in this way. The kinds of feedback and feedforward loops that exist between molecules in cells, or neurons in a nervous system, lead to emergent behaviors like human consciousness.

#### Learning Outcomes Review 1.4

Biography is a broad and complex field, but we can identify unifying themes in this complexity. Cells are the basic unit of life, and they are information-processing machines. The structures of molecules, macromolecular complexes, cells, and even higher levels of organization are related to their functions. The diversity of life can be classified and organized based on similar features; biologists identify three large domains that encompass six kingdoms. Living organisms are able to use energy to construct complex molecules from simple ones, and are thus not in a state of thermodynamic equilibrium.

- How do viruses fit into our definitions of living systems?

## Chapter Review

### 1.1 The Science of Life

#### **Biology unifies much of the natural sciences.**

The study of biological systems is interdisciplinary because solutions require many different approaches to solve a problem.

#### **Life defies simple definition.**

Although life is difficult to define, living systems have seven characteristics in common. They are composed of one or more cells; are complex and highly ordered; can respond to stimuli; can grow, reproduce, and transmit genetic information to their offspring; need energy to accomplish work; can maintain relatively constant internal conditions (homeostasis); and are capable of evolutionary adaptation to the environment.

#### **Living systems show hierarchical organization.**

The hierarchical organization of living systems progresses from atoms to the biosphere. At each higher level, emergent properties arise that are greater than the sum of the parts.

### 1.2 The Nature of Science

At its core, science is concerned with understanding the nature of the world by using observation and reasoning.

#### **Much of science is descriptive.**

Science is concerned with developing an increasingly accurate description of nature through observation and experimentation.

#### **Science uses both deductive and inductive reasoning.**

Deductive reasoning applies general principles to predict specific results. Inductive reasoning uses specific observations to construct general scientific principles.

#### **Hypothesis-driven science makes and tests predictions.**

A hypothesis is constructed based on observations, and it must generate experimentally testable predictions. Experiments involve a test in which a variable is manipulated, and a control in which the variable is not manipulated. Hypotheses are rejected if their predictions cannot be verified by observation or experiment.

#### **Reductionism breaks larger systems into their component parts.**

Reductionism attempts to understand a complex system by breaking it down into its component parts. It is limited because parts may act differently when isolated from the larger system.

#### **Biologists construct models to explain living systems.**

A model provides a way of organizing our thinking about a problem; models may also suggest experimental approaches.

#### **The nature of scientific theories.**

Scientists use the word *theory* in two main ways: as a proposed explanation for some natural phenomenon and as a body of concepts that explains facts in an area of study.

#### **Research can be basic or applied.**

Basic research extends the boundaries of what we know; applied research seeks to use scientific findings in practical areas such as agriculture, medicine, and industry.

### 1.3 An Example of Scientific Inquiry

Darwin's theory of evolution shows how a scientist develops a hypothesis and sets forth evidence, as well as how a scientific theory grows and gains acceptance.

#### **The idea of evolution existed prior to Darwin.**

A number of naturalists and philosophers had suggested living things had changed during Earth's history. Darwin's contribution was the concept of natural selection.

#### **Darwin observed differences in related organisms.**

During the voyage of the H.M.S. *Beagle*, Darwin had an opportunity to observe worldwide patterns of diversity.

#### **Darwin proposed natural selection as a mechanism for evolution.**

Darwin noted that species produce many offspring, but only a limited number survive and reproduce. He observed that the traits of offspring can be changed by artificial selection. Darwin proposed that individuals possessing traits that increase survival and reproductive success become more numerous in populations over time. This is the essence of descent with modification (natural selection). Alfred Russel Wallace independently came to the same conclusions from his own studies.

#### **The predictions of natural selection have been tested.**

Natural selection has been tested using data from many fields. Among these are the fossil record; the age of the Earth, determined by rates of radioactive decay to be 4.5 billion years; genetic experiments such as those of Gregor Mendel, showing that traits can be inherited as discrete units; comparative anatomy and the study of homologous structures; and molecular data that provides evidence for changes in DNA and proteins over time.

Taken together, these findings strongly support evolution by natural selection. No data to conclusively disprove evolution has been found.

### 1.4 Unifying Themes in Biology

#### **Cell theory describes the organization of living systems.**

The cell is the basic unit of life and is the foundation for understanding growth and reproduction in all organisms.

#### **The molecular basis of inheritance explains the continuity of life.**

Hereditary information, encoded in genes found in the DNA molecule, is passed on from one generation to the next.

#### **The relationship between structure and function underlies living systems.**

The function of macromolecules and their complexes is dictated by and dependent on their structure. Similarity of structure and function from one life form to another may indicate an evolutionary relationship.

#### **The diversity of life arises by evolutionary change.**

Living organisms appear to have had a common origin from which a diversity of life arose by evolutionary change. They can be grouped into three domains comprising six kingdoms based on their differences.

#### **Evolutionary conservation explains the unity of living systems.**

The underlying similarities in biochemistry and genetics support the contention that all life evolved from a single source.

#### **Cells are information-processing systems.**

Cells can sense and respond to environmental changes through proteins located on their cell membranes. Differential expression of stored genetic information is the basis for different cell types.

#### **Living systems exist in a nonequilibrium state.**

Organisms are open systems that need a constant supply of energy to maintain their stable nonequilibrium state. Living things are able to self-organize, creating levels of complexity that may exhibit emergent properties.

## Review Questions

### UNDERSTAND

- Which of the following is NOT a property of life?
  - Energy utilization
  - Movement
  - Order
  - Homeostasis
- The process of inductive reasoning involves
  - the use of general principles to predict a specific result.
  - the generation of specific predictions based on a belief system.
  - the use of specific observations to develop general principles.
  - the use of general principles to support a hypothesis.
- A hypothesis in biology is best described as
  - a possible explanation of an observation.
  - an observation that supports a theory.
  - a general principle that explains some aspect of life.
  - an unchanging statement that correctly predicts some aspect of life.
- A scientific theory is
  - a guess about how things work in the world.
  - a statement of how the world works that is supported by experimental data.
  - a belief held by many scientists.
  - both a and c.
- The cell theory states that
  - cells are small.
  - cells are highly organized.
  - there is only one basic type of cell.
  - all living things are made up of cells.
- The molecule DNA is important to biological systems because
  - it can be replicated.
  - it encodes the information for making a new individual.
  - it forms a complex, double-helical structure.
  - nucleotides form genes.
- The organization of living systems is
  - linear with cells at one end and the biosphere at the other.
  - circular with cells in the center.
  - hierarchical with cells at the base, and the biosphere at the top.
  - chaotic and beyond description.
- The idea of evolution
  - was original to Darwin.
  - was original to Wallace.
  - predated Darwin and Wallace.
  - both a and b.

### APPLY

- What is the significance of Pasteur's experiment to test the germ hypothesis?
  - It proved that heat can sterilize a broth.
  - It demonstrated that cells can arise spontaneously.
  - It demonstrated that some cells are germs.
  - It demonstrated that cells can only arise from other cells.
- Which of the following is NOT an example of reductionism?
  - Analysis of an isolated enzyme's function in an experimental assay

- Investigation of the effect of a hormone on cell growth in a Petri dish
  - Observation of the change in gene expression in response to specific stimulus
  - An evaluation of the overall behavior of a cell
- How is the process of natural selection different from that of artificial selection?
    - Natural selection produces more variation.
    - Natural selection makes an individual better adapted.
    - Artificial selection is a result of human intervention.
    - Artificial selection results in better adaptations.
  - How does the fossil record help support the theory of evolution by natural selection?
    - It demonstrates that simple organisms predate more complex organisms.
    - It provides evidence of change in the form of organisms over time.
    - It shows that diversity existed millions of years ago.
    - Both a and b.
  - The theory of evolution by natural selection is a good example of how science proceeds because
    - it rationalizes a large body of observations.
    - it makes predictions that have been tested by a variety of approaches.
    - it represents Darwin's belief of how life has changed over time.
    - both a and b.
  - In which domain of life would you find only single-celled organisms?
    - Eukarya
    - Bacteria
    - Archaea
    - Both b and c
  - Evolutionary conservation occurs when a characteristic is
    - important to the life of the organism.
    - not influenced by evolution.
    - reduced to its least complex form.
    - found in more primitive organisms.

### SYNTHESIZE

- Exobiology is the study of life on other planets. In recent years, scientists have sent various spacecraft out into the galaxy in search for extraterrestrial life. Assuming that all life shares common properties, what should exobiologists be looking for as they explore other worlds?
- The classic experiment by Pasteur (see figure 1.4) tested the hypothesis that cells arise from other cells. In this experiment cell growth was measured following sterilization of broth in a swan-neck flask or in a flask with a broken neck.
  - Which variables were kept the same in these two experiments?
  - How does the shape of the flask affect the experiment?
  - Predict the outcome of each experiment based on the two hypotheses.
  - Some bacteria (germs) are capable of producing heat-resistant spores that protect the cell and allow it to continue to grow after the environment cools. How would the outcome of this experiment have been affected if spore-forming bacteria were present in the broth?

# The Nature of Molecules and the Properties of Water

## Chapter Outline

- 2.1 The Nature of Atoms
- 2.2 Elements Found in Living Systems
- 2.3 The Nature of Chemical Bonds
- 2.4 Water: A Vital Compound
- 2.5 Properties of Water
- 2.6 Acids and Bases

## Introduction

About 12.5 billion years ago, an enormous explosion probably signalled the beginning of the universe. This explosion started a process of star building and planetary formation that eventually led to the formation of Earth, about 4.5 billion years ago (BYA). Around 3.5 BYA, life began on Earth and started to diversify. To understand the nature of life on Earth, we first need to understand the nature of the matter that forms the building blocks of all life.

The earliest speculations about the world around us included this most basic question, "What is it made of?" The ancient Greeks recognized that larger things may be built of smaller parts. This concept was formed into a solid experimental scientific idea in the early 20th century, when physicists began trying to break atoms apart. From those humble beginnings to the huge particle accelerators used by the modern physicists of today, the picture of the atomic world emerges as fundamentally different from the tangible, macroscopic world around us.

To understand how living systems are assembled, we must first understand a little about atomic structure, about how atoms can be linked together by chemical bonds to make molecules, and about the ways in which these small molecules are joined together to make larger molecules, until finally we arrive at the structures of cells and then of organisms. Our study of life on Earth therefore begins with physics and chemistry. For many of you, this chapter will be a review of material encountered in other courses.

## 2.1 The Nature of Atoms

### Learning Outcomes

1. Define element, atomic number, atomic mass, and isotope.
2. Describe atomic structure, the relationships of subatomic particles, and how these relationships determine chemical properties.
3. Explain the discrete energy levels in which electrons orbit the nucleus of an atom.

Any substance in the universe that has mass and occupies space is defined as *matter*. All matter is composed of extremely small particles called **atoms**. Because of their size, atoms are difficult to study. Not until early in the 20th century did scientists carry

### SCIENTIFIC THINKING

**Hypothesis:** Atoms are composed of diffuse positive charge with embedded negative charge (electrons).

**Prediction:** If alpha particles ( $\alpha$ ), which are helium nuclei, are shot at a thin foil of gold, the  $\alpha$ -particles will not be deflected much by the diffuse positive charge or by the light electrons.

**Test:**  $\alpha$ -Particles are shot at a thin sheet of gold foil surrounded by a detector screen, which shows flashes of light when hit by the particles.

**Result:** Most particles are not deflected at all, but a small percentage of particles are deflected at angles of  $90^\circ$  or more.

**Conclusion:** The hypothesis is not supported. The large deflections observed led to a view of the atom as composed of a very small central region containing positive charge (the nucleus) surrounded by electrons.

**Further Experiments:** How does the Bohr atom with its quantized energy for electrons extend this model?

### Figure 2.1 Rutherford scattering experiment.

Large-angle scattering of  $\alpha$  particles led Rutherford to propose the existence of the nucleus.

out the first experiments revealing the physical nature of atoms (figure 2.1).

### Atomic structure includes a central nucleus and orbiting electrons

Objects as small as atoms can be “seen” only indirectly, by using complex technology such as tunneling microscopy (figure 2.2). We now know a great deal about the complexities of atomic structure, but the simple view put forth in 1913 by the Danish physicist Niels Bohr provides a good starting point for understanding atomic theory. Bohr proposed that every atom possesses an orbiting cloud of tiny subatomic particles called *electrons* whizzing around a core, like the planets of a miniature solar system. At the center of each atom is a small, very dense nucleus formed of two other kinds of subatomic particles: *protons* and *neutrons* (figure 2.3).

### Atomic number and the elements

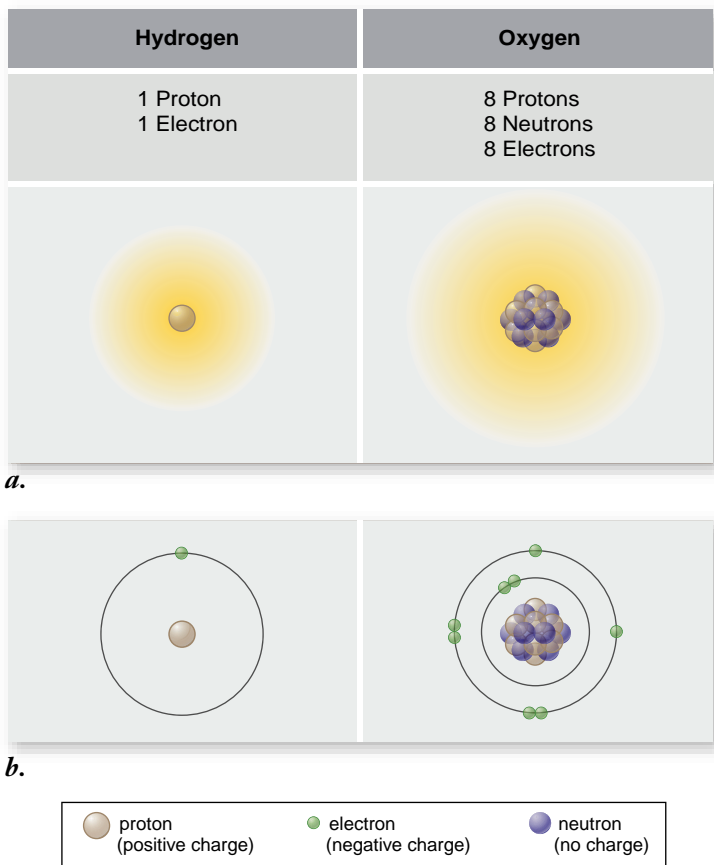

Within the nucleus, the cluster of protons and neutrons is held together by a force that works only over short, subatomic distances. Each proton carries a positive (+) charge, and each neutron has no charge. Each electron carries a negative (–) charge. Typically, an atom has one electron for each proton and is, thus, electrically neutral. Different atoms are defined by the number of protons, a quantity called the *atomic number*. The chemical behavior of an atom is due to the number and configuration of electrons, as we will see later in this chapter. Atoms with the same atomic number (that is, the same number of protons) have the same chemical properties and are said to belong to the same element. Formally speaking, an *element* is any substance that cannot be broken down to any other substance by ordinary chemical means.

### Atomic mass

The terms *mass* and *weight* are often used interchangeably, but they have slightly different meanings. *Mass* refers to the amount of a substance, but *weight* refers to the force gravity exerts on a substance. An object has the same mass whether it is on the Earth or the Moon, but its weight will be greater on the Earth because the Earth’s gravitational force is greater than the Moon’s. The *atomic mass* of an atom is equal to the sum of the masses of

**Figure 2.2 Scanning tunneling microscope image.** The scanning tunneling microscope is a nonoptical way of imaging that allows atoms to be visualized. This image shows a lattice of oxygen atoms (dark blue) on a rhodium crystal (light blue).

**Figure 2.3 Basic structure of atoms.** All atoms have a nucleus consisting of protons and neutrons, except hydrogen, the smallest atom, which usually has only one proton and no neutrons in its nucleus. Oxygen typically has eight protons and eight neutrons in its nucleus. In the simple “Bohr model” of atoms pictured here, electrons spin around the nucleus at a relatively far distance. **a.** Atoms are depicted as a nucleus with a cloud of electrons (not shown to scale). **b.** The electrons are shown in discrete energy levels. These are described in greater detail in the text.

its protons and neutrons. Atoms that occur naturally on Earth contain from 1 to 92 protons and up to 146 neutrons.

The mass of atoms and subatomic particles is measured in units called *daltons*. To give you an idea of just how small these units are, note that it takes 602 million million billion ( $6.02 \times 10^{23}$ ) daltons to make 1 gram (g). A proton weighs approximately 1 dalton (actually 1.007 daltons), as does a neutron (1.009 dal-

tons). In contrast, electrons weigh only 1/1840 of a dalton, so they contribute almost nothing to the overall mass of an atom.

### Electrons

The positive charges in the nucleus of an atom are neutralized, or counterbalanced, by negatively charged electrons, which are located in regions called **orbitals** that lie at varying distances around the nucleus. Atoms with the same number of protons and electrons are electrically neutral; that is, they have no net charge, and are therefore called *neutral atoms*.

Electrons are maintained in their orbitals by their attraction to the positively charged nucleus. Sometimes other forces overcome this attraction, and an atom loses one or more electrons. In other cases, atoms gain additional electrons. Atoms in which the number of electrons does not equal the number of protons are known as *ions*, and they are charged particles. An atom having more protons than electrons has a net positive charge and is called a **cation**. For example, an atom of sodium (Na) that has lost one electron becomes a sodium ion ( $\text{Na}^+$ ), with a charge of +1. An atom having fewer protons than electrons carries a net negative charge and is called an **anion**. A chlorine atom (Cl) that has gained one electron becomes a chloride ion ( $\text{Cl}^-$ ), with a charge of -1.

### Isotopes

Although all atoms of an element have the same number of protons, they may not all have the same number of neutrons. Atoms of a single element that possess different numbers of neutrons are called **isotopes** of that element.

Most elements in nature exist as mixtures of different isotopes. Carbon (C), for example, has three isotopes, all containing six protons (figure 2.4). Over 99% of the carbon found in nature exists as an isotope that also contains six neutrons. Because the total mass of this isotope is 12 daltons (6 from protons plus 6 from neutrons), it is referred to as carbon-12 and is symbolized  $^{12}\text{C}$ . Most of the rest of the naturally occurring carbon is carbon-13, an isotope with seven neutrons. The rarest carbon isotope is carbon-14, with eight neutrons. Unlike the other two isotopes, carbon-14 is unstable: This means that its nucleus tends to break up into elements with lower atomic numbers. This nuclear breakup, which emits a significant amount of energy, is called *radioactive decay*, and isotopes that decay in this fashion are **radioactive isotopes**.

Some radioactive isotopes are more unstable than others, and therefore they decay more readily. For any given isotope, however, the rate of decay is constant. The decay time is usually expressed as the *half-life*, the time it takes for one-half of the

**Figure 2.4 The three most abundant isotopes of carbon.** Isotopes of a particular element have different numbers of neutrons.

atoms in a sample to decay. Carbon-14, for example, often used in the carbon dating of fossils and other materials, has a half-life of 5730 years. A sample of carbon containing 1 g of carbon-14 today would contain 0.5 g of carbon-14 after 5730 years, 0.25 g 11,460 years from now, 0.125 g 17,190 years from now, and so on. By determining the ratios of the different isotopes of carbon and other elements in biological samples and in rocks, scientists are able to accurately determine when these materials formed.

Radioactivity has many useful applications in modern biology. Radioactive isotopes are one way to label, or “tag,” a specific molecule and then follow its progress, either in a chemical reaction or in living cells and tissue. The downside, however, is that the energetic subatomic particles emitted by radioactive substances have the potential to severely damage living cells, producing genetic mutations and, at high doses, cell death. Consequently, exposure to radiation is carefully controlled and regulated. Scientists who work with radioactivity follow strict handling protocols and wear radiation-sensitive badges to monitor their exposure over time to help ensure a safe level of exposure.

## Electrons determine the chemical behavior of atoms

The key to the chemical behavior of an atom lies in the number and arrangement of its electrons in their orbitals. The Bohr model of the atom shows individual electrons as following discrete, or distinct, circular orbits around a central nucleus. The trouble with this simple picture is that it doesn't reflect reality. Modern physics indicates that we cannot pinpoint the position of any individual electron at any given time. In fact, an electron could be anywhere, from close to the nucleus to infinitely far away from it.

A particular electron, however, is more likely to be in some areas than in others. An orbital is defined as the area around a nucleus where an electron is most likely to be found. These orbitals represent probability distributions for electrons, that is, regions more likely to contain an electron. Some electron orbitals near the nucleus are spherical (*s* orbitals), while others are dumbbell-shaped (*p* orbitals) (figure 2.5). Still other orbitals, farther away from the nucleus, may have different shapes. Regardless of its shape, no orbital can contain more than two electrons.

Almost all of the volume of an atom is empty space. This is because the electrons are usually far away from the nucleus, relative to its size. If the nucleus of an atom were the size of a golf ball, the orbit of the nearest electron would be a mile away. Consequently, the nuclei of two atoms never come close enough in nature to interact with each other. It is for this reason that an atom's electrons, not its protons or neutrons, determine its chemical behavior, and it also explains why the isotopes of an element, all of which have the same arrangement of electrons, behave the same way chemically.

a.

b.

c.

**Figure 2.5 Electron orbitals.** *a.* The lowest energy level, or electron shell—the one nearest the nucleus—is level K. It is occupied by a single *s* orbital, referred to as 1s. *b.* The next highest energy level, L, is occupied by four orbitals: one *s* orbital (referred to as the 2s orbital) and three *p* orbitals (each referred to as a 2p orbital). Each orbital holds two paired electrons with opposite spin. Thus, the K level is populated by two electrons, and the L level is populated by a total of eight electrons. *c.* The neon atom shown has the L and K energy levels completely filled with electrons and is thus unreactive.

## Atoms contain discrete energy levels

Because electrons are attracted to the positively charged nucleus, it takes work to keep them in their orbitals, just as it takes work to hold a grapefruit in your hand against the pull of gravity. The formal definition of energy is the ability to do work.

The grapefruit held above the ground is said to possess *potential energy* because of its position. If you release it, the grapefruit falls, and its potential energy is reduced. On the other hand, if you carried the grapefruit to the top of a building, you would increase its potential energy. Electrons also have a potential energy that is related to their position. To oppose the attraction of the nucleus and move the electron to a more distant orbital requires an input of energy, which results in an electron with greater potential energy. The chlorophyll that makes plants green captures energy from light during photosynthesis in this way. As you'll see in chapter 8—light energy excites electrons in the chlorophyll molecule. Moving an electron closer to the nucleus has the opposite effect: Energy is released, usually as radiant energy (heat or light), and the electron ends up with less potential energy (figure 2.6).

One of the initially surprising aspects of atomic structure is that electrons within the atom have discrete **energy levels**. These discrete levels correspond to quanta (sing., quantum), which means specific amount of energy. To use the grapefruit analogy again, it is as though a grapefruit could only be raised to particular floors of a building. Every atom exhibits a ladder of potential energy values, a discrete set of orbitals at particular energetic “distances” from the nucleus.

Because the amount of energy an electron possesses is related to its distance from the nucleus, electrons that are the same distance from the nucleus have the same energy, even if they occupy different orbitals. Such electrons are said to occupy the same energy level. The energy levels are denoted with letters K, L, M, and so on (see figure 2.6). Be careful not to confuse energy levels, which are drawn as rings to indicate an electron's *energy*, with orbitals, which have a variety of three-dimensional shapes and indicate an electron's most likely *location*. Electron orbitals are arranged so that as they are filled, this fills each energy level in successive order. This filling of orbitals

and energy levels is what is responsible for the chemical reactivity of elements.

During some chemical reactions, electrons are transferred from one atom to another. In such reactions, the loss of an electron is called **oxidation**, and the gain of an electron is called *reduction*.

Notice that when an electron is transferred in this way, it keeps its energy of position. In organisms, chemical energy is stored in high-energy electrons that are transferred from one atom to another in reactions involving oxidation and reduction (described in chapter 7). When the processes of oxidation and reduction are coupled, which often happens, one atom or molecule is oxidized while another is reduced in the same reaction. We call these combinations *redox reactions*.

### Learning Outcomes Review 2.1

An atom consists of a nucleus of protons and neutrons surrounded by a cloud of electrons. For each atom, the number of protons is the atomic number; atoms with the same atomic number constitute an element. Atoms of a single element that have different numbers of neutrons are called isotopes. Electrons, which determine the chemical behavior of an element, are located about a nucleus in orbitals representing discrete energy levels. No orbital can contain more than two electrons, but many orbitals may have the same energy level, and thus contain electrons with the same energy.

- If the number of protons exceeds the number of neutrons, is the charge on the atom positive or negative?
- If the number of protons exceeds electrons?

**Figure 2.6 Atomic energy levels.** Electrons have energy of position. When an atom absorbs energy, an electron moves to a higher energy level, farther from the nucleus. When an electron falls to lower energy levels, closer to the nucleus, energy is released. The first two energy levels are the same as shown in the previous figure.

## 2.2 Elements Found in Living Systems

### Learning Outcomes

1. Relate atomic structure to the periodic table of the elements.
2. List the important elements found in living systems.

Ninety elements occur naturally, each with a different number of protons and a different arrangement of electrons. When the 19th-century Russian chemist Dmitri Mendeleev arranged the known elements in a table according to their atomic number, he discovered one of the great generalizations of science: The elements exhibit a pattern of chemical properties that repeats itself in groups of eight. This periodically repeating pattern lent the table its name: the periodic table of elements (figure 2.7).

### The periodic table displays elements according to atomic number and properties

The eight-element periodicity that Mendeleev found is based on the interactions of the electrons in the outermost energy level of the different elements. These electrons are called **valence electrons**, and their interactions are the basis for the elements' differing chemical properties. For most of the atoms important to life, the outermost energy level can contain no more than eight electrons; the chemical behavior of an element reflects how many of the eight positions are filled. Elements

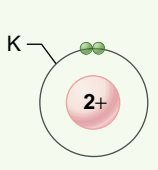

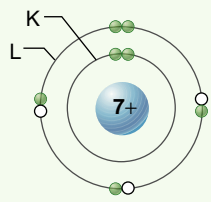

possessing all eight electrons in their outer energy level (two for helium) are *inert*, or nonreactive. These elements, which include helium (He), neon (Ne), argon (Ar), and so on, are termed the *noble gases*. In sharp contrast, elements with seven electrons (one fewer than the maximum number of eight) in their outer energy level, such as fluorine (F), chlorine (Cl), and bromine (Br), are highly reactive. They tend to gain the extra electron needed to fill the energy level. Elements with only one electron in their outer energy level, such as lithium (Li), sodium (Na), and potassium (K), are also very reactive. They tend to lose the single electron in their outer level.

Mendeleev's periodic table leads to a useful generalization, the **octet rule**, or *rule of eight* (Latin *octo*, "eight"): Atoms tend to establish completely full outer energy levels. For the main group elements of the periodic table, the rule of eight is accomplished by one filled *s* orbital and three filled *p* orbitals (figure 2.8). The exception to this is He, in the first row, which needs only two electrons to fill the 1*s* orbital. Most chemical behavior of biological interest can be predicted quite accurately from this simple rule, combined with the tendency of atoms to balance positive and negative charges. For instance, you read earlier that sodium ion (Na<sup>+</sup>) has lost an electron, and chloride ion (Cl<sup>-</sup>) has gained an electron. In the following section, we describe how these ions react to form table salt.

Of the 90 naturally occurring elements on Earth, only 12 (C, H, O, N, P, S, Na, K, Ca, Mg, Fe, Cl) are found in living systems in more than trace amounts (0.01% or higher). These elements all have atomic numbers less than 21, and thus, have low atomic masses. Of these 12, the first 4 elements (carbon, hydrogen, oxygen, and nitrogen) constitute 96.3% of the weight of your body. The majority of molecules that make up your body are compounds of carbon, which we call *organic* compounds.

**Figure 2.7** Periodic table of the elements. *a.* In this representation, the frequency of elements that occur in the Earth's crust is indicated by the height of the block. Elements shaded in green are found in living systems in more than trace amounts. *b.* Common elements found in living systems are shown in colors that will be used throughout the text.

Nonreactive	Reactive
2 protons 2 neutrons 2 electrons	7 protons 7 neutrons 7 electrons
 Helium	 Nitrogen

**Figure 2.8** Electron energy levels for helium and nitrogen. Green balls represent electrons, blue ball represents the nucleus with number of protons indicated by number of (+) charges. Note that the helium atom has a filled K shell and is thus unreactive, whereas the nitrogen atom has five electrons in the L shell, three of which are unpaired, making it reactive.

These organic compounds contain primarily these four elements (CHON), explaining their prevalence in living systems. Some trace elements, such as zinc (Zn) and iodine (I), play crucial roles in living processes even though they are present in tiny amounts. Iodine deficiency, for example, can lead to enlargement of the thyroid gland, causing a bulge at the neck called a goiter.

### Learning Outcomes Review 2.2

The periodic table shows the elements in terms of atomic number and repeating chemical properties. Only 12 elements are found in significant amounts in living organisms: C, H, O, N, P, S, Na, K, Ca, Mg, Fe, and Cl.

- Why are the noble gases more stable than other elements in the periodic table?

## 2.3 The Nature of Chemical Bonds

### Learning Outcomes

1. Relate position in the periodic table to the formation of ions.
2. Explain how complex molecules can be built from many atoms by covalent bonds.
3. Contrast polar and nonpolar covalent bonds.

A group of atoms held together by energy in a stable association is called a *molecule*. When a molecule contains atoms of more than one element, it is called a *compound*. The atoms in a molecule are joined by *chemical bonds*; these bonds can result when atoms with opposite charges attract each other (ionic bonds), when two atoms share one or more pairs of electrons

TABLE 2.1 Bonds and Interactions		
Name	Basis of Interaction	Strength
Covalent bond	Sharing of electron pairs	Strong
Ionic bond	Attraction of opposite charges	↑ ↓
Hydrogen bond	Sharing of H atom	
Hydrophobic interaction	Forcing of hydrophobic portions of molecules together in presence of polar substances	
van der Waals attraction	Weak attractions between atoms due to oppositely polarized electron clouds	Weak

(covalent bonds), or when atoms interact in other ways (table 2.1). We will start by examining *ionic bonds*, which form when atoms with opposite electrical charges (ions) attract.

### Ionic bonds form crystals

Common table salt, the molecule sodium chloride (NaCl), is a lattice of ions in which the atoms are held together by ionic bonds (figure 2.9). Sodium has 11 electrons: 2 in the inner

**Figure 2.9** The formation of ionic bonds by sodium chloride. *a.* When a sodium atom donates an electron to a chlorine atom, the sodium atom becomes a positively charged sodium ion, and the chlorine atom becomes a negatively charged chloride ion. *b.* The electrostatic attraction of oppositely charged ions leads to the formation of a lattice of  $\text{Na}^+$  and  $\text{Cl}^-$ .

energy level (K), 8 in the next level (L), and 1 in the outer (valence) level (M). The single, unpaired valence electron has a strong tendency to join with another unpaired electron in another atom. A stable configuration can be achieved if the valence electron is lost to another atom that also has an unpaired electron. The loss of this electron results in the formation of a positively charged sodium ion,  $\text{Na}^+$ .

The chlorine atom has 17 electrons: 2 in the K level, 8 in the L level, and 7 in the M level. As you can see in the figure, one of the orbitals in the outer energy level has an unpaired electron (red circle). The addition of another electron fills that level and causes a negatively charged chloride ion,  $\text{Cl}^-$ , to form.

When placed together, metallic sodium and gaseous chlorine react swiftly and explosively, as the sodium atoms donate electrons to chlorine to form  $\text{Na}^+$  and  $\text{Cl}^-$  ions. Because opposite charges attract, the  $\text{Na}^+$  and  $\text{Cl}^-$  remain associated in an *ionic compound*,  $\text{NaCl}$ , which is electrically neutral. The electrical attractive force holding  $\text{NaCl}$  together, however, is not directed specifically between individual  $\text{Na}^+$  and  $\text{Cl}^-$  ions, and no individual sodium chloride molecules form. Instead, the force exists between any one ion and *all* neighboring ions of the opposite charge. The ions aggregate in a crystal matrix with a precise geometry. Such aggregations are what we know as salt crystals. If a salt such as  $\text{NaCl}$  is placed in water, the electrical attraction of the water molecules, for reasons we will point out later in this chapter, disrupts the forces holding the ions in their crystal matrix, causing the salt to dissolve into a roughly equal mixture of free  $\text{Na}^+$  and  $\text{Cl}^-$  ions.

Because living systems always include water, ions are more important than ionic crystals. Important ions in biological systems include  $\text{Ca}^{2+}$ , which is involved in cell signaling,  $\text{K}^+$  and  $\text{Na}^+$ , which are involved in the conduction of nerve impulses.

## Covalent bonds build stable molecules

*Covalent bonds* form when two atoms share one or more pairs of valence electrons. Consider gaseous hydrogen ( $\text{H}_2$ ) as an example. Each hydrogen atom has an unpaired electron and an unfilled outer energy level; for these reasons, the hydrogen atom is unstable. However, when two hydrogen atoms are in close association, each atom's electron is attracted to both nuclei. In effect, the nuclei are able to share their electrons. The result is a diatomic (two-atom) molecule of hydrogen gas.

The molecule formed by the two hydrogen atoms is stable for three reasons:

1. **It has no net charge.** The diatomic molecule formed as a result of this sharing of electrons is not charged because it still contains two protons and two electrons.
2. **The octet rule is satisfied.** Each of the two hydrogen atoms can be considered to have two orbiting electrons in its outer energy level. This state satisfies the octet rule, because each shared electron orbits both nuclei and is included in the outer energy level of both atoms.
3. **It has no unpaired electrons.** The bond between the two atoms also pairs the two free electrons.

Unlike ionic bonds, covalent bonds are formed between two individual atoms, giving rise to true, discrete molecules.

## The strength of covalent bonds

The strength of a covalent bond depends on the number of shared electrons. Thus *double bonds*, which satisfy the octet rule by allowing two atoms to share two pairs of electrons, are stronger than *single bonds*, in which only one electron pair is shared. In practical terms, more energy is required to break a double bond than a single bond. The strongest covalent bonds are *triple bonds*, such as those that link the two nitrogen atoms of nitrogen gas molecules ( $\text{N}_2$ ).

Covalent bonds are represented in chemical formulas as lines connecting atomic symbols. Each line between two bonded atoms represents the sharing of one pair of electrons. The *structural formulas* of hydrogen gas and oxygen gas are  $\text{H}-\text{H}$  and  $\text{O}=\text{O}$ , respectively, and their *molecular formulas* are  $\text{H}_2$  and  $\text{O}_2$ . The structural formula for  $\text{N}_2$  is  $\text{N}\equiv\text{N}$ .

## Molecules with several covalent bonds

A vast number of biological compounds are composed of more than two atoms. An atom that requires two, three, or four additional electrons to fill its outer energy level completely may acquire them by sharing its electrons with two or more other atoms.

For example, the carbon atom (C) contains six electrons, four of which are in its outer energy level and are unpaired. To satisfy the octet rule, a carbon atom must form four covalent bonds. Because four covalent bonds may form in many ways, carbon atoms are found in many different kinds of molecules.  $\text{CO}_2$  (carbon dioxide),  $\text{CH}_4$  (methane), and  $\text{C}_2\text{H}_5\text{OH}$  (ethanol) are just a few examples.

## Polar and nonpolar covalent bonds

Atoms differ in their affinity for electrons, a property called **electronegativity**. In general, electronegativity increases left to right across a row of the periodic table and decreases down the column. Thus the elements in the upper-right corner have the highest electronegativity.

For bonds between identical atoms, for example, between two hydrogen or two oxygen atoms, the affinity for electrons is obviously the same, and the electrons are equally shared. Such

bonds are termed **nonpolar**. The resulting compounds (H<sub>2</sub> or O<sub>2</sub>) are also referred to as nonpolar.

For atoms that differ greatly in electronegativity, electrons are not shared equally. The shared electrons are more likely to be closer to the atom with greater electronegativity, and less likely to be near the atom of lower electronegativity. In this case, although the molecule is still electrically neutral (same number of protons as electrons), the distribution of charge is not uniform. This unequal distribution results in regions of partial negative charge near the more electronegative atom, and regions of partial positive charge near the less electronegative atom. Such bonds are termed **polar covalent bonds**, and the molecules polar molecules. When drawing polar molecules, these partial charges are usually symbolized by the lowercase Greek letter delta ( $\delta$ ). The partial charge seen in a polar covalent bond is relatively small—far less than the unit charge of an ion. For biological molecules, we can predict polarity of bonds by knowing the relative electronegativity of a small number of important atoms (table 2.2). Notice that although C and H differ slightly in electronegativity, this small difference is negligible, and C–H bonds are considered nonpolar.

Because of its importance in the chemistry of water, we will explore the nature of polar and nonpolar molecules in the following section on water. Water (H<sub>2</sub>O) is a polar molecule with electrons more concentrated around the oxygen atom.

## Chemical reactions alter bonds

The formation and breaking of chemical bonds, which is the essence of chemistry, is termed a *chemical reaction*. All chemical reactions involve the shifting of atoms from one molecule or ionic compound to another, without any change in the number or identity of the atoms. For convenience, we refer to the original molecules before the reaction starts as *reactants*, and the molecules resulting from the chemical reaction as *products*. For example:

You may recognize this reaction as a simplified form of the photosynthesis reaction, in which water and carbon dioxide are combined to produce glucose and oxygen. Most animal life ultimately depends on this reaction, which takes place in plants. (Photosynthetic reactions will be discussed in detail in chapter 8.)

<b>TABLE 2.2</b>		<b>Relative Electronegativities of Some Important Atoms</b>
<b>Atom</b>	<b>Electronegativity</b>	
O	3.5	
N	3.0	
C	2.5	
H	2.1	

The extent to which chemical reactions occur is influenced by three important factors:

- 1. Temperature.** Heating the reactants increases the rate of a reaction because the reactants collide with one another more often. (Care must be taken that the temperature is not so high that it destroys the molecules.)
- 2. Concentration of reactants and products.** Reactions proceed more quickly when more reactants are available, allowing more frequent collisions. An accumulation of products typically slows the reaction and, in reversible reactions, may speed the reaction in the reverse direction.
- 3. Catalysts.** A catalyst is a substance that increases the rate of a reaction. It doesn't alter the reaction's equilibrium between reactants and products, but it does shorten the time needed to reach equilibrium, often dramatically. In living systems, proteins called enzymes catalyze almost every chemical reaction.

Many reactions in nature are reversible. This means that the products may themselves be reactants, allowing the reaction to proceed in reverse. We can write the preceding reaction in the reverse order:

This reaction is a simplified version of the oxidation of glucose by cellular respiration, in which glucose is broken down into water and carbon dioxide in the presence of oxygen. Virtually all organisms carry out forms of glucose oxidation; details are covered later, in chapter 7.

### Learning Outcomes Review 2.3

An ionic bond is an attraction between ions of opposite charge in an ionic compound. A covalent bond is formed when two atoms share one or more pairs of electrons. Complex biological compounds are formed in large part by atoms that can form one or more covalent bonds: C, H, O, and N. A polar covalent bond is formed by unequal sharing of electrons. Nonpolar bonds exhibit equal sharing of electrons.

- **How is a polar covalent bond different from an ionic bond?**

## 2.4 Water: A Vital Compound

### Learning Outcomes

- 1. Relate how the structure of water leads to hydrogen bonds.**
- 2. Describe water's cohesive and adhesive properties.**

Of all the common molecules, only water exists as a liquid at the relatively low temperatures that prevail on the Earth's surface. Three-fourths of the Earth is covered by liquid water

a. Solid

b. Liquid

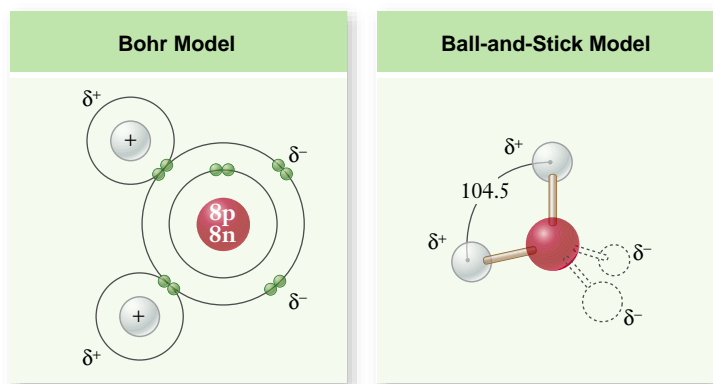

c. Gas

**Figure 2.10 Water takes many forms.** a. When water cools below 0°C, it forms beautiful crystals, familiar to us as snow and ice. b. Ice turns to liquid when the temperature is above 0°C. c. Liquid water becomes steam when the temperature rises above 100°C, as seen in this hot spring at Yellowstone National Park.

(figure 2.10). When life was beginning, water provided a medium in which other molecules could move around and interact, without being held in place by strong covalent or ionic bonds. Life evolved in water for 2 billion years before spreading to land. And even today, life is inextricably tied to water. About two-thirds of any organism's body is composed of water, and all organisms require a water-rich environment, either inside or outside it, for growth and reproduction. It is no accident that tropical rain forests are bursting with life, while dry deserts appear almost lifeless except when water becomes temporarily plentiful, such as after a rainstorm.

### Water's structure facilitates hydrogen bonding

Water has a simple molecular structure, consisting of an oxygen atom bound to two hydrogen atoms by two single covalent bonds (figure 2.11). The resulting molecule is stable: It satisfies the octet rule, has no unpaired electrons, and carries no net electrical charge.

a.

b.

**Figure 2.11 Water has a simple molecular structure.**

a. Each water molecule is composed of one oxygen atom and two hydrogen atoms. The oxygen atom shares one electron with each hydrogen atom.

b. The greater electronegativity of the oxygen atom makes the water molecule polar: Water carries two partial negative charges ( $\delta^-$ ) near the oxygen atom and two partial positive charges ( $\delta^+$ ), one on each hydrogen atom. c. Space-filling model shows what the molecule would look like if it were visible.

c.

The single most outstanding chemical property of water is its ability to form weak chemical associations, called **hydrogen bonds**. These bonds form between the partially negative O atoms and the partially positive H atoms of two water molecules. Although these bonds have only 5–10% of the strength of covalent bonds, they are important to DNA and protein structure, and thus responsible for much of the chemical organization of living systems.

The electronegativity of O is much greater than that of H (see table 2.2), and so the bonds between these atoms are highly polar. *The polarity of water underlies water's chemistry and the chemistry of life.*

If we consider the shape of a water molecule, we see that its two covalent bonds have a partial charge at each end:  $\delta^-$  at the oxygen end and  $\delta^+$  at the hydrogen end. The most stable arrangement of these charges is a *tetrahedron* (a pyramid with a triangle as its base), in which the two negative and two positive charges are approximately equidistant from one another. The oxygen atom lies at the center of the tetrahedron, the hydrogen atoms occupy two of the apexes (corners), and the partial negative charges occupy the other two apexes (figure 2.11b). The bond angle between the two covalent oxygen–hydrogen bonds is 104.5°. This value is slightly less than the bond angle of a regular tetrahedron, which would be 109.5°. In water, the partial negative charges occupy more space than the partial positive regions, so the oxygen–hydrogen bond angle is slightly compressed.

### Water molecules are cohesive

The polarity of water allows water molecules to be attracted to one another: that is, water is *cohesive*. The oxygen end of each water molecule, which is  $\delta^-$ , is attracted to the hydrogen end, which is  $\delta^+$ , of other molecules. The attraction produces hydrogen bonds among water molecules (figure 2.12). Each hydrogen bond is individually very weak and transient, lasting on average only a hundred-billionth ( $10^{-11}$ ) of a second. The cumulative effects of large numbers of these bonds, however, can be enormous. Water forms an abundance of hydrogen bonds, which are responsible for many of its important physical properties (table 2.3).

Water's cohesion is responsible for its being a liquid, not a gas, at moderate temperatures. The cohesion of liquid water is also responsible for its **surface tension**. Small insects can walk on water (figure 2.13) because at the air–water interface, all the surface water molecules are hydrogen-bonded to molecules below them.

**Figure 2.12 Structure of a hydrogen bond.** *a.* Hydrogen bond between two water molecules. *b.* Hydrogen bond between an organic molecule (*n*-butanol) and water. H in *n*-butanol forms a hydrogen bond with oxygen in water. This kind of hydrogen bond is possible any time H is bound to a more electronegative atom (see table 2.2).

### Water molecules are adhesive

The polarity of water causes it to be attracted to other polar molecules as well. This attraction for other polar substances is called *adhesion*. Water adheres to any substance with which it can form hydrogen bonds. This property explains why substances containing polar molecules get “wet” when they are immersed in water, but those that are composed of nonpolar molecules (such as oils) do not.

The attraction of water to substances that have electrical charges on their surface is responsible for capillary action. If a glass tube with a narrow diameter is lowered into a beaker of water, the water will rise in the tube above the level of the water in the beaker,

**Figure 2.13 Cohesion.** Some insects, such as this water strider, literally walk on water. Because the surface tension of the water is greater than the force of one foot, the strider glides atop the surface of the water rather than sinking. The high surface tension of water is due to hydrogen bonding between water molecules.

because the adhesion of water to the glass surface, drawing it upward, is stronger than the force of gravity, pulling it downward. The narrower the tube, the greater the electrostatic forces between the water and the glass, and the higher the water rises (figure 2.14).

**Figure 2.14 Adhesion.** Capillary action causes the water within a narrow tube to rise above the surrounding water level; the adhesion of the water to the glass surface, which draws water upward, is stronger than the force of gravity, which tends to pull it down. The narrower the tube, the greater the surface area available for adhesion for a given volume of water, and the higher the water rises in the tube.

TABLE 2.3 The Properties of Water		
Property	Explanation	Example of Benefit to Life
Cohesion	Hydrogen bonds hold water molecules together.	Leaves pull water upward from the roots; seeds swell and germinate.
High specific heat	Hydrogen bonds absorb heat when they break and release heat when they form, minimizing temperature changes.	Water stabilizes the temperature of organisms and the environment.
High heat of vaporization	Many hydrogen bonds must be broken for water to evaporate.	Evaporation of water cools body surfaces.
Lower density of ice	Water molecules in an ice crystal are spaced relatively far apart because of hydrogen bonding.	Because ice is less dense than water, lakes do not freeze solid, allowing fish and other life in lakes to survive the winter.
Solubility	Polar water molecules are attracted to ions and polar compounds, making these compounds soluble.	Many kinds of molecules can move freely in cells, permitting a diverse array of chemical reactions.

### Learning Outcomes Review 2.4

Because of its polar covalent bonds, water can form hydrogen bonds with itself and with other polar molecules. Hydrogen bonding is responsible for water's cohesion, the force that holds water molecules together, and its adhesion, which is its ability to "stick" to other polar molecules. Capillary action results from both of these properties.

- If water were made of C and H instead of H and O, would it still be cohesive and adhesive?

## 2.5 Properties of Water

### Learning Outcomes

1. Describe how hydrogen bonding determines many properties of water.
2. Explain the relevance of water's unusual properties for living systems.
3. Understand the dissociation products of water.

Water moderates temperature through two properties: its high specific heat and its high heat of vaporization. Water also has the unusual property of being less dense in its solid form, ice, than as a liquid. Water acts as a solvent for polar molecules and exerts an organizing effect on nonpolar molecules. All these properties result from its polar nature.

### Water's high specific heat helps maintain temperature

The temperature of any substance is a measure of how rapidly its individual molecules are moving. In the case of water, a large input of thermal energy is required to break the many hydrogen bonds that keep individual water molecules from moving about. Therefore, water is said to have a high **specific heat**, which is defined as the amount of heat 1 g of a substance must absorb or lose to change its temperature by 1 degree Celsius ( $^{\circ}\text{C}$ ). Specific heat measures the extent to which a substance resists changing its temperature when it absorbs or loses heat. Because polar substances tend to form hydrogen bonds, the more polar it is, the higher is its specific heat. The specific heat of water (1 calorie/ $\text{g}/^{\circ}\text{C}$ ) is twice that of most carbon compounds and nine times that of iron. Only ammonia, which is more polar than water and forms very strong hydrogen bonds, has a higher specific heat than water (1.23 cal/ $\text{g}/^{\circ}\text{C}$ ). Still, only 20% of the hydrogen bonds are broken as water heats from  $0^{\circ}$  to  $100^{\circ}\text{C}$ .

Because of its high specific heat, water heats up more slowly than almost any other compound and holds its temperature longer. Because organisms have a high water content, water's high specific heat allows them to maintain a relatively constant internal temperature. The heat generated by the chemical reactions inside cells would destroy the cells if not for the absorption of this heat by the water within them.

### Water's high heat of vaporization facilitates cooling

The **heat of vaporization** is defined as the amount of energy required to change 1 g of a substance from a liquid to a gas. A considerable amount of heat energy (586 cal) is required to accomplish this change in water. As water changes from a liquid to a gas it requires energy (in the form of heat) to break its many hydrogen bonds. The evaporation of water from a surface cools that surface. Many organisms dispose of excess body heat by evaporative cooling, for example, through sweating in humans and many other vertebrates.

### Solid water is less dense than liquid water

At low temperatures, water molecules are locked into a crystal-like lattice of hydrogen bonds, forming solid ice (see figure 2.10a). Interestingly, ice is less dense than liquid water because the hydrogen bonds in ice space the water molecules relatively far apart. This unusual feature enables icebergs to float. If water did not have this property, nearly all bodies of water would be ice, with only the shallow surface melting every year. The buoyancy of ice is important ecologically because it means bodies of water freeze from the top down and not the bottom up. Because ice floats on the surface of lakes in the winter and the water beneath the ice remains liquid, fish and other animals keep from freezing.

### The solvent properties of water help move ions and polar molecules

Water molecules gather closely around any substance that bears an electrical charge, whether that substance carries a full charge (ion) or a charge separation (polar molecule). For example, sucrose (table sugar) is composed of molecules that contain polar hydroxyl (OH) groups. A sugar crystal dissolves rapidly in water because water molecules can form hydrogen bonds with individual hydroxyl groups of the sucrose molecules. Therefore, sucrose is said to be *soluble* in water. Water is termed the *solvent*, and sugar is called the *solute*. Every time a sucrose molecule dissociates, or breaks away, from a solid sugar crystal, water molecules surround it in a cloud, forming a *hydration shell* that prevents it from associating with other sucrose molecules. Hydration shells also form around ions such as  $\text{Na}^+$  and  $\text{Cl}^-$  (figure 2.15).

### Water organizes nonpolar molecules

Water molecules always tend to form the maximum possible number of hydrogen bonds. When nonpolar molecules such as oils, which do not form hydrogen bonds, are placed in water, the water molecules act to exclude them. The nonpolar molecules aggregate, or clump together, thus minimizing their disruption of the hydrogen bonding of water. In effect, they shrink from contact with water, and for this reason they are referred to as **hydrophobic** (Greek *hydros*, "water," and *phobos*, "fearing"). In contrast, polar molecules, which readily form hydrogen bonds with water, are said to be **hydrophilic** ("water-loving").

The tendency of nonpolar molecules to aggregate in water is known as **hydrophobic exclusion**. By forcing the hydrophobic portions of molecules together, water causes these molecules to

**Figure 2.15 Why salt dissolves in water.** When a crystal of table salt dissolves in water, individual  $\text{Na}^+$  and  $\text{Cl}^-$  ions break away from the salt lattice and become surrounded by water molecules. Water molecules orient around  $\text{Na}^+$  so that their partial negative poles face toward the positive  $\text{Na}^+$ ; water molecules surrounding  $\text{Cl}^-$  orient in the opposite way, with their partial positive poles facing the negative  $\text{Cl}^-$ . Surrounded by hydration shells,  $\text{Na}^+$  and  $\text{Cl}^-$  never reenter the salt lattice.

assume particular shapes. This property can also affect the structure of proteins, DNA, and biological membranes. In fact, the interaction of nonpolar molecules and water is critical to living systems.

## Water can form ions

The covalent bonds of a water molecule sometimes break spontaneously. In pure water at  $25^\circ\text{C}$ , only 1 out of every 550 million water molecules undergoes this process. When it happens, a proton (hydrogen atom nucleus) dissociates from the molecule. Because the dissociated proton lacks the negatively charged electron it was sharing, its positive charge is no longer counterbalanced, and it becomes a hydrogen ion,  $\text{H}^+$ . The rest of the dissociated water molecule, which has retained the shared electron from the covalent bond, is negatively charged and forms a hydroxide ion,  $\text{OH}^-$ . This process of spontaneous ion formation is called *ionization*:

At  $25^\circ\text{C}$ , 1 liter (L) of water contains one ten-millionth (or  $10^{-7}$ ) mole of  $\text{H}^+$  ions. A **mole** (mol) is defined as the weight of a substance in grams that corresponds to the atomic masses of all of the atoms in a molecule of that substance. In the case of  $\text{H}^+$ , the atomic mass is 1, and a mole of  $\text{H}^+$  ions would weigh 1 g. One mole of any substance always contains  $6.02 \times 10^{23}$  molecules of the substance. Therefore, the **molar concentration** of hydrogen ions in pure water, represented as  $[\text{H}^+]$ , is  $10^{-7}$  mol/L. (In reality, the  $\text{H}^+$  usually associates with another water molecule to form a hydronium ion,  $\text{H}_3\text{O}^+$ .)

## Learning Outcomes Review 2.5

Water has a high specific heat so it does not change temperature rapidly, which helps living systems maintain a near-constant temperature. Water's high heat of vaporization allows cooling by evaporation. Solid water is less dense than liquid water because the hydrogen bonds space the molecules farther apart. Polar molecules are soluble in a water solution, but water tends to exclude nonpolar molecules. Water dissociates to form  $\text{H}^+$  and  $\text{OH}^-$ .

- How does the fact that ice floats affect life in a lake?

## 2.6 Acids and Bases

### Learning Outcomes

1. Explain the nature of acids and bases, and their relationship to the pH scale.
2. Relate changes in pH to changes in  $[\text{H}^+]$ .

The concentration of hydrogen ions, and concurrently of hydroxide ions, in a solution is described by the terms *acidity* and *basicity*, respectively. Pure water, having an  $[\text{H}^+]$  of  $10^{-7}$  mol/L, is considered to be neutral, that is, neither acidic nor basic. Recall that for every  $\text{H}^+$  ion formed when water dissociates, an  $\text{OH}^-$  ion is also formed, meaning that the dissociation of water produces  $\text{H}^+$  and  $\text{OH}^-$  in equal amounts.

### The pH scale measures hydrogen ion concentration

The *pH scale* (figure 2.16) is a more convenient way to express the hydrogen ion concentration of a solution. This scale defines *pH*, which stands for “partial hydrogen,” as the negative logarithm of the hydrogen ion concentration in the solution:

$$\text{pH} = -\log [\text{H}^+]$$

Because the logarithm of the hydrogen ion concentration is simply the exponent of the molar concentration of  $\text{H}^+$ , the pH equals the exponent times  $-1$ . For water, therefore, an  $[\text{H}^+]$  of  $10^{-7}$  mol/L corresponds to a pH value of 7. This is the neutral point—a balance between  $\text{H}^+$  and  $\text{OH}^-$ —on the pH scale. This balance occurs because the dissociation of water produces equal amounts of  $\text{H}^+$  and  $\text{OH}^-$ .

Note that, because the pH scale is *logarithmic*, a difference of 1 on the scale represents a 10-fold change in  $[\text{H}^+]$ . A solution with a pH of 4 therefore has 10 times the  $[\text{H}^+]$  of a solution with a pH of 5 and 100 times the  $[\text{H}^+]$  of a solution with a pH of 6.

### Acids

Any substance that dissociates in water to increase the  $[\text{H}^+]$  (and lower the pH) is called an **acid**. The stronger an acid is, the more hydrogen ions it produces and the lower its pH. For example, hydrochloric acid (HCl), which is abundant in your stomach, ionizes completely in water. A dilution of  $10^{-1}$  mol/L of HCl dissociates to form  $10^{-1}$  mol/L of  $\text{H}^+$ , giving the solution

**Figure 2.16 The pH scale.** The pH value of a solution indicates its concentration of hydrogen ions. Solutions with a pH less than 7 are acidic, whereas those with a pH greater than 7 are basic. The scale is logarithmic, which means that a pH change of 1 represents a 10-fold change in the concentration of hydrogen ions. Thus, lemon juice is 100 times more acidic than tomato juice, and seawater is 10 times more basic than pure water, which has a pH of 7.

a pH of 1. The pH of champagne, which bubbles because of the carbonic acid dissolved in it, is about 2.

### Bases

A substance that combines with H<sup>+</sup> when dissolved in water, and thus lowers the [H<sup>+</sup>], is called a **base**. Therefore, basic (or alkaline) solutions have pH values above 7. Very strong bases, such as sodium hydroxide (NaOH), have pH values of 12 or more. Many common cleaning substances, such as ammonia and bleach, accomplish their action because of their high pH.

### Buffers help stabilize pH

The pH inside almost all living cells, and in the fluid surrounding cells in multicellular organisms, is fairly close to neutral, 7. Most of the enzymes in living systems are extremely sensitive to pH. Often even a small change in pH will alter their shape, thereby disrupting their activities. For this reason, it is important that a cell maintain a constant pH level.

But the chemical reactions of life constantly produce acids and bases within cells. Furthermore, many animals eat substances that are acidic or basic. Cola drinks, for example, are moderately strong (although dilute) acidic solutions. Despite such variations in the concentrations of H<sup>+</sup> and OH<sup>-</sup>, the pH of an organism is kept at a relatively constant level by buffers (figure 2.17).

A **buffer** is a substance that resists changes in pH. Buffers act by releasing hydrogen ions when a base is added and absorbing hydrogen ions when acid is added, with the overall effect of keeping [H<sup>+</sup>] relatively constant.

Within organisms, most buffers consist of pairs of substances, one an acid and the other a base. The key buffer in human blood is an acid–base pair consisting of carbonic acid

**Figure 2.17 Buffers minimize changes in pH.** Adding a base to a solution neutralizes some of the acid present, and so raises the pH. Thus, as the curve moves to the right, reflecting more and more base, it also rises to higher pH values. A buffer makes the curve rise or fall very slowly over a portion of the pH scale, called the “buffering range” of that buffer.

### Inquiry question

**?** For this buffer, adding base raises pH more rapidly below pH 4 than above it. What might account for this behavior?

(acid) and bicarbonate (base). These two substances interact in a pair of reversible reactions. First, carbon dioxide (CO<sub>2</sub>) and H<sub>2</sub>O join to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>), which in a second reaction dissociates to yield bicarbonate ion (HCO<sub>3</sub><sup>-</sup>) and H<sup>+</sup>.

If some acid or other substance adds H<sup>+</sup> to the blood, the HCO<sub>3</sub><sup>-</sup> acts as a base and removes the excess H<sup>+</sup> by forming H<sub>2</sub>CO<sub>3</sub>. Similarly, if a basic substance removes H<sup>+</sup> from the blood, H<sub>2</sub>CO<sub>3</sub> dissociates, releasing more H<sup>+</sup> into the blood. The forward and reverse reactions that interconvert H<sub>2</sub>CO<sub>3</sub> and HCO<sub>3</sub><sup>-</sup> thus stabilize the blood’s pH.

The reaction of carbon dioxide and water to form carbonic acid is a crucial one because it permits carbon, essential to life, to enter water from the air. The Earth’s oceans are rich in carbon because of the reaction of carbon dioxide with water.

In a condition called blood acidosis, human blood, which normally has a pH of about 7.4, drops to a pH of about 7.1. This condition is fatal if not treated immediately. The reverse condition, blood alkalosis, involves an increase in blood pH of a similar magnitude and is just as serious.

### Learning Outcomes Review 2.6

Acid solutions have a high [H<sup>+</sup>], and basic solutions have a low [H<sup>+</sup>] (and therefore a high [OH<sup>-</sup>]). The pH of a solution is the negative logarithm of its [H<sup>+</sup>]. Low pH values indicate acids, and high pH values indicate bases. Even small changes in pH can be harmful to life. Buffer systems in organisms help to maintain pH within a narrow range.

■ A change of 2 pH units indicates what change in [H<sup>+</sup>]?

## Chapter Review

### 2.1 The Nature of Atoms

*All matter is composed of atoms (see figure 2.3).*

**Atomic structure includes a central nucleus and orbiting electrons.**

Electrically neutral atoms have the same number of protons as electrons. Atoms that gain or lose electrons are called ions.

Each element is defined by its atomic number, the number of protons in the nucleus. Atomic mass is the sum of the mass of protons and neutrons in an atom. Isotopes are forms of a single element with different numbers of neutrons, and thus different atomic mass. Radioactive isotopes are unstable.

**Electrons determine the chemical behavior of atoms.**

The potential energy of electrons increases as distance from the nucleus increases. Electron orbitals are probability distributions. *s*-orbitals are spherical; other orbitals have different shapes, such as the dumbbell-shaped *p*-orbitals.

**Atoms contain discrete energy levels.**

Energy levels correspond to quanta (sing. quantum) of energy, a “ladder” of energy levels that an electron may have.

The loss of electrons from an atom is called oxidation. The gain of electrons is called reduction. Electrons can be transferred from one atom to another in coupled redox reactions.

### 2.2 Elements Found in Living Systems

*The periodic table displays elements according to atomic number and properties.*

Atoms tend to establish completely full outer energy levels (the octet rule). Elements with filled outermost orbitals are inert.

Ninety elements occur naturally in the Earth’s crust. Twelve of these elements are found in living organisms in greater than trace amounts: C, H, O, N, P, S, Na, K, Ca, Mg, Fe, and Cl.

Compounds of carbon are called organic compounds. The majority of molecules in living systems are composed of C bound to H, O, and N.

### 2.3 The Nature of Chemical Bonds

Molecules contain two or more atoms joined by chemical bonds. Compounds contain two or more different elements.

**Ionic bonds form crystals.**

Ions with opposite electrical charges form ionic bonds, such as NaCl (see figure 2.9*b*).

**Covalent bonds build stable molecules.**

A molecule formed by a covalent bond is stable because it has no net charge, the octet rule is satisfied, and it has no unpaired electrons. Covalent bonds may be single, double, or triple, depending on the number of pairs of electrons shared. Nonpolar covalent bonds involve equal sharing of electrons between atoms. Polar covalent bonds involve unequal sharing of electrons.

**Chemical reactions alter bonds.**

Temperature, reactant concentration, and the presence of catalysts affect reaction rates. Most biological reactions are reversible, such as the conversion of carbon dioxide and water into carbohydrates.

### 2.4 Water: A Vital Compound

**Water’s structure facilitates hydrogen bonding.**

Hydrogen bonds are weak interactions between a partially positive H in one molecule and a partially negative O in another molecule (see figure 2.11).

**Water molecules are cohesive.**

Cohesion is the tendency of water molecules to adhere to one another due to hydrogen bonding. The cohesion of water is responsible for its surface tension.

**Water molecules are adhesive.**

Adhesion occurs when water molecules adhere to other polar molecules. Capillary action results from water’s adhesion to the sides of narrow tubes, combined with its cohesion.

### 2.5 Properties of Water

**Water’s high specific heat helps maintain temperature.**

The specific heat of water is high because it takes a considerable amount of energy to disrupt hydrogen bonds.

**Water’s high heat of vaporization facilitates cooling.**

Breaking hydrogen bonds to turn liquid water into vapor takes a lot of energy. Many organisms lose excess heat through evaporative cooling, such as sweating.

**Solid water is less dense than liquid water.**

Hydrogen bonds are spaced farther apart in the solid phase of water than in the liquid phase. As a result, ice floats.

**The solvent properties of water help move ions and polar molecules.**

Water’s polarity makes it a good solvent for polar substances and ions. Polar molecules or portions of molecules are attracted to water (hydrophilic). Molecules that are nonpolar are repelled by water (hydrophobic). Water makes nonpolar molecules clump together.

**Water organizes nonpolar molecules.**

Nonpolar molecules will aggregate to avoid water. This maximizes the hydrogen bonds that water can make. This hydrophobic exclusion can affect the structure of DNA, proteins and biological membranes.

**Water can form ions.**

Water dissociates into  $H^+$  and  $OH^-$ . The concentration of  $H^+$ , shown as  $[H^+]$ , in pure water is  $10^{-7}$  mol/L.

### 2.6 Acids and Bases (see figure 2.16)

**The pH scale measures hydrogen ion concentration.**

pH is defined as the negative logarithm of  $[H^+]$ . Pure water has a pH of 7. A difference of 1 pH unit means a 10-fold change in  $[H^+]$ .

Acids have a greater  $[H^+]$  and therefore a lower pH; bases have a lower  $[H^+]$  and therefore a higher pH.

**Buffers help stabilize pH.**

Carbon dioxide and water react reversibly to form carbonic acid. A buffer resists changes in pH by absorbing or releasing  $H^+$ . The key buffer in the human blood is the carbonic acid/bicarbonate pair.

## Review Questions

### UNDERSTAND

- The property that distinguishes an atom of one element (carbon, for example) from an atom of another element (oxygen, for example) is
  - the number of electrons.
  - the number of protons.
  - the number of neutrons.
  - the combined number of protons and neutrons.
- If an atom has one valence electron, that is, a single electron in its outer energy level, it will most likely form
  - one polar, covalent bond.
  - two nonpolar, covalent bonds.
  - two covalent bonds.
  - an ionic bond.
- An atom with a net positive charge must have more
  - protons than neutrons.
  - protons than electrons.
  - electrons than neutrons.
  - electrons than protons.
- The isotopes carbon-12 and carbon-14 differ in
  - the number of neutrons.
  - the number of protons.
  - the number of electrons.
  - both b and c.
- Which of the following is NOT a property of the elements most commonly found in living organisms?
  - The elements have a low atomic mass.
  - The elements have an atomic number less than 21.
  - The elements possess eight electrons in their outer energy level.
  - The elements are lacking one or more electrons from their outer energy level.
- Ionic bonds arise from
  - shared valence electrons.
  - attractions between valence electrons.
  - charge attractions between valence electrons.
  - attractions between ions of opposite charge.
- A substance with a high concentration of hydrogen ions
  - is called a base.
  - is called an acid.
  - has a high pH.
  - both b and c.

### APPLY

- Using the periodic table on page 22, which of the following atoms would you predict could form a positively charged ion (cation)?
  - Fluorine (F)
  - Neon (Ne)
  - Potassium (K)
  - Sulfur (S)
- Refer to the element pictured. How many covalent bonds could this atom form?
  - Two
  - Three
  - Four
  - None

- A molecule with polar covalent bonds would
  - be soluble in water.
  - not be soluble in water.
  - contain atoms with very similar electronegativity.
  - contain atoms that have gained or lost electrons.
- Hydrogen bonds are formed
  - between any molecules that contain hydrogen.
  - only between water molecules.
  - when hydrogen is part of a polar bond.
  - when two atoms of hydrogen share an electron.
- Which of the following properties of water is NOT a consequence of its ability to form hydrogen bonds?
  - Cohesiveness
  - High specific heat
  - Ability to function as a solvent
  - Neutral pH
- The decay of radioactive isotopes involves changes to the nucleus of atoms. Explain how this differs from the changes in atoms that occur during chemical reactions.

### SYNTHESIZE

- Elements that form ions are important for a range of biological processes. You have learned something about the cations sodium ( $\text{Na}^+$ ), calcium ( $\text{Ca}^{2+}$ ) and potassium ( $\text{K}^+$ ) in this chapter. Use your knowledge of the definition of a cation to identify other examples from the periodic table.
- A popular theme in science fiction literature has been the idea of silicon-based life-forms in contrast to our carbon-based life. Evaluate the possibility of silicon-based life based on the chemical structure and potential for chemical bonding of a silicon atom.
- Recent efforts by NASA to search for signs of life on Mars have focused on the search for evidence of liquid water rather than looking directly for biological organisms (living or fossilized). Use your knowledge of the influence of water on life on Earth to construct an argument justifying this approach.

# Chapter 3

## The Chemical Building Blocks of Life

### Chapter Outline

- 3.1 Carbon: The Framework of Biological Molecules
- 3.2 Carbohydrates: Energy Storage and Structural Molecules
- 3.3 Nucleic Acids: Information Molecules
- 3.4 Proteins: Molecules with Diverse Structures and Functions
- 3.5 Lipids: Hydrophobic Molecules

### Introduction

A cup of water contains more molecules than there are stars in the sky. But many molecules are much larger than water molecules. Many thousands of distinct biological molecules are long chains made of thousands or even billions of atoms. These enormous assemblages, which are almost always synthesized by living things, are macromolecules. As you may know, biological macromolecules can be divided into four categories: carbohydrates, nucleic acids, proteins, and lipids, and they are the basic chemical building blocks from which all organisms are composed.

We take the existence of these classes of macromolecules for granted now, but as late as the 19th century many theories of “vital forces” were associated with living systems. One such theory held that cells contained a substance, protoplasm, that was responsible for the chemical reactions in living systems. Any disruption of cells was thought to disturb the protoplasm. Such a view makes studying the chemical reactions of cells in the lab (*in vitro*) impossible. The demonstration of fermentation in a cell-free system marked the beginning of modern biochemistry (figure 3.1). This approach involves studying biological molecules outside of cells to infer their role inside cells. Because these biological macromolecules all involve carbon-containing compounds, we begin with a brief summary of carbon and its chemistry.

## SCIENTIFIC THINKING

**Hypothesis:** Chemical reactions, such as the fermentation reaction in yeast, are controlled by enzymes and do not require living cells.

**Prediction:** If yeast cells are broken open, these enzymes should function outside of the cell.

**Test:** Yeast is mixed with quartz sand and diatomaceous earth and then ground in a mortar and pestle. The resulting paste is wrapped in canvas and subjected to 400–500 atm pressure in a press. Fermentable and nonfermentable substrates are added to the resulting fluid, with fermentation being measured by the production of  $\text{CO}_2$ .

**Result:** When a fermentable substrate (cane sugar, glucose) is used,  $\text{CO}_2$  is produced, when a nonfermentable substrate (lactose, mannose) is used, no  $\text{CO}_2$  is produced. In addition, visual inspection of the fluid shows no visible yeast cells.

**Conclusion:** The hypothesis is supported. The fermentation reaction can occur in the absence of live yeast.

**Historical Significance:** Although this is not precisely the intent of the original experiment, it represents the first use of a cell-free system. Such systems allow for the study of biochemical reactions *in vitro* and the purification of proteins involved. We now know that the “fermentation reaction” is actually a complex series of reactions. Would such a series of reactions be your first choice for this kind of demonstration?

**Figure 3.1** The demonstration of cell-free fermentation. Eduard Buchner’s (1860–1917) demonstration of fermentation by fluid produced from yeast, but not containing any live cells both argued against the protoplasm theory and provided a method for future biochemists to examine the chemistry of life outside of cells.

## 3.1 Carbon: The Framework of Biological Molecules

### Learning Outcomes

1. Describe the relationship between functional groups and macromolecules.
2. Recognize the different kinds of isomers.
3. List the different kinds of biological macromolecules.

In chapter 2, we reviewed the basics of chemistry. Biological systems obey all the laws of chemistry. Thus, chemistry forms the basis of living systems.

The framework of biological molecules consists predominantly of carbon atoms bonded to other carbon atoms or to atoms of oxygen, nitrogen, sulfur, phosphorus, or hydrogen. Because carbon atoms can form up to four covalent bonds, molecules containing carbon can form straight chains, branches, or even rings, balls, tubes, and coils.

Molecules consisting only of carbon and hydrogen are called *hydrocarbons*. Because carbon–hydrogen covalent bonds store considerable energy, hydrocarbons make good fuels. Gasoline, for example, is rich in hydrocarbons, and propane gas, an-

other hydrocarbon, consists of a chain of three carbon atoms, with eight hydrogen atoms bound to it. The chemical formula for propane is  $\text{C}_3\text{H}_8$ . Its structural formula is

Theoretically speaking, the length of a chain of carbon atoms is unlimited. As described in the rest of this chapter, the four main types of biological molecules often consist of huge chains of carbon-containing compounds.

### Functional groups account for differences in molecular properties

Carbon and hydrogen atoms both have very similar electronegativities. Electrons in  $\text{C}-\text{C}$  and  $\text{C}-\text{H}$  bonds are therefore evenly distributed, with no significant differences in charge over the molecular surface. For this reason, hydrocarbons are nonpolar. Most biological molecules produced by cells, however, also contain other atoms. Because these other atoms frequently have different electronegativities, molecules containing them exhibit regions of partial positive or negative charge. They are polar. These molecules can be thought of as a  $\text{C}-\text{H}$

core to which specific molecular groups, called **functional groups**, are attached. One such common functional group is  $\text{—OH}$ , called a *hydroxyl group*.

Functional groups have definite chemical properties that they retain no matter where they occur. Both the hydroxyl and carbonyl ( $\text{C=O}$ ) groups, for example, are polar because of the

Functional Group	Structural Formula	Example	Found In
Hydroxyl	$\text{—OH}$	$\begin{array}{c} \text{H} \quad \text{H} \\   \quad   \\ \text{H—C—C—OH} \\   \quad   \\ \text{H} \quad \text{H} \end{array}$ Ethanol	carbohydrates, proteins, nucleic acids, lipids
Carbonyl	$\begin{array}{c} \text{O} \\    \\ \text{—C—} \end{array}$	$\begin{array}{c} \text{H} \quad \text{O} \\   \quad    \\ \text{H—C—C—H} \\   \\ \text{H} \end{array}$ Acetaldehyde	carbohydrates, nucleic acids
Carboxyl	$\begin{array}{c} \text{O} \\ // \\ \text{—C} \\ \backslash \\ \text{OH} \end{array}$	$\begin{array}{c} \text{H} \quad \text{O} \\   \quad // \\ \text{H—C—C—OH} \\   \\ \text{H} \end{array}$ Acetic acid	proteins, lipids
Amino	$\begin{array}{c} \text{H} \\ \backslash \\ \text{—N} \\ / \\ \text{H} \end{array}$	$\begin{array}{c} \text{O} \quad \text{H} \\    \quad   \\ \text{HO—C—C—N} \\ \quad \quad   \quad \quad \backslash \\ \quad \quad \text{CH}_3 \quad \quad \text{H} \\ \quad \quad \quad \quad \quad \quad \quad \quad / \\ \quad \quad \quad \quad \quad \quad \quad \quad \text{H} \end{array}$ Alanine	proteins, nucleic acids
Sulfhydryl	$\text{—S—H}$	$\begin{array}{c} \text{COOH} \\   \\ \text{H—C—CH}_2\text{—S—H} \\   \\ \text{NH}_2 \end{array}$ Cysteine	proteins
Phosphate	$\begin{array}{c} \text{O}^- \\   \\ \text{—O—P—O}^- \\    \\ \text{O} \end{array}$	$\begin{array}{c} \text{OH} \quad \text{OH} \quad \text{H} \quad \text{O} \\   \quad   \quad   \quad    \\ \text{H—C—C—C—O—P—O}^- \\   \quad   \quad   \quad \quad   \\ \text{H} \quad \text{H} \quad \text{H} \quad \quad \text{O}^- \end{array}$ Glycerol phosphate	nucleic acids
Methyl	$\begin{array}{c} \text{H} \\   \\ \text{—C—H} \\   \\ \text{H} \end{array}$	$\begin{array}{c} \text{O} \quad \text{H} \\    \quad   \\ \text{HO—C—C—NH}_2 \\ \quad \quad   \\ \quad \quad \text{H—C—H} \\ \quad \quad   \\ \quad \quad \text{H} \end{array}$ Alanine	proteins

**Figure 3.2** The primary functional chemical groups.

These groups tend to act as units during chemical reactions and give specific chemical properties to the molecules that possess them. Amino groups, for example, make a molecule more basic, and carboxyl groups make a molecule more acidic. These functional groups are also not limited to the examples in the “Found In” column but are widely distributed in biological molecules.

electronegativity of the oxygen atoms (see chapter 2). Other common functional groups are the acidic carboxyl ( $\text{COOH}$ ), phosphate ( $\text{PO}_4$ ), and the basic amino ( $\text{NH}_2$ ) group. Many of these functional groups can also participate in hydrogen bonding. Hydrogen bond donors and acceptors can be predicted based on their electronegativities shown in table 2.2. Figure 3.2 illustrates these biologically important functional groups and lists the macromolecules in which they are found.

### Isomers have the same molecular formulas but different structures

Organic molecules having the same molecular or empirical formula can exist in different forms called **isomers**. If there are differences in the actual structure of their carbon skeleton, we call them *structural isomers*. Later you will see that glucose and fructose are structural isomers of  $\text{C}_6\text{H}_{12}\text{O}_6$ . Another form of isomers, called *stereoisomers*, have the same carbon skeleton but differ in how the groups attached to this skeleton are arranged in space.

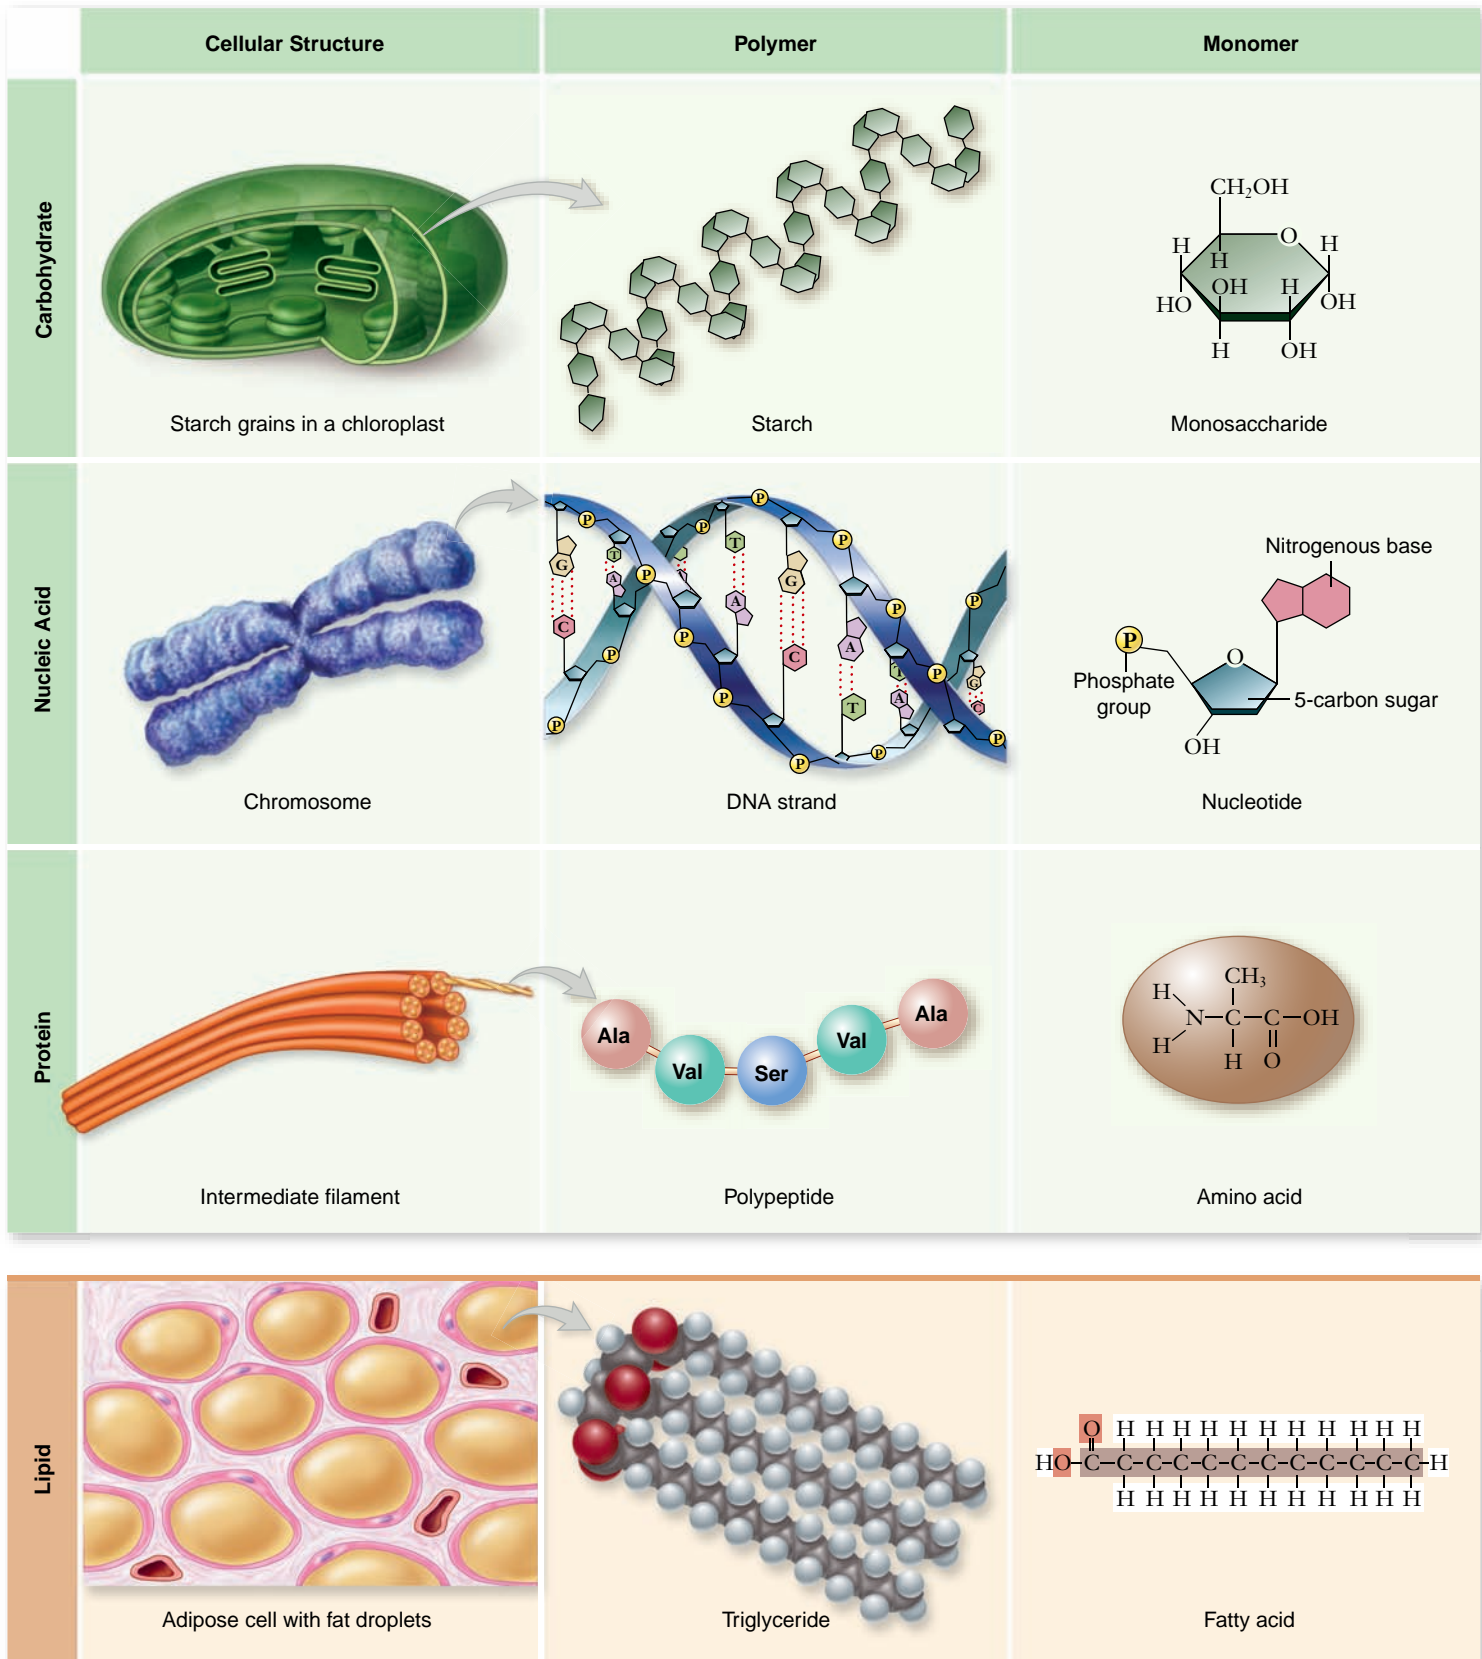

Enzymes in biological systems usually recognize only a single, specific stereoisomer. A subcategory of stereoisomers, called *enantiomers*, are actually mirror images of each other. A molecule that has mirror-image versions is called a *chiral* molecule. When carbon is bound to four different molecules, this inherent asymmetry exists (figure 3.3).

Chiral compounds are characterized by their effect on polarized light. Polarized light has a single plane, and chiral molecules rotate this plane either to the right (Latin, *dextro*) or left (Latin, *levo*). We therefore call the two chiral forms *D* for *dextrorotatory* and *L* for *levorotatory*. Living systems tend to produce only a single enantiomer of the two possible forms; for example, in most organisms we find primarily D-sugars and L-amino acids.

**Figure 3.3** Chiral molecules. When carbon is bound to four different groups, the resulting molecule is said to be chiral (from Greek *cheir*, meaning “hand.”). A chiral molecule will have stereoisomers that are mirror images. The two molecules shown have the same four groups but cannot be superimposed, much like your two hands cannot be superimposed but must be flipped to match. These types of stereoisomers are called *enantiomers*.

**Figure 3.4 Polymer macromolecules.** The four major biological macromolecules are shown. Carbohydrates, nucleic acids, and proteins all form polymers and are shown with the monomers used to make them. Lipids do not fit this simple monomer–polymer relationship, however, because they are constructed from glycerol and fatty acids. All four types of macromolecules are also shown in their cellular context.

TABLE 3.1		Macromolecules	
Macromolecule	Subunit	Function	Example
<b>C A R B O H Y D R A T E S</b>			
Starch, glycogen	Glucose	Energy storage	Potatoes
Cellulose	Glucose	Structural support in plant cell walls	Paper; strings of celery
Chitin	Modified glucose	Structural support	Crab shells
<b>N U C L E I C A C I D S</b>			
DNA	Nucleotides	Encodes genes	Chromosomes
RNA	Nucleotides	Needed for gene expression	Messenger RNA
<b>P R O T E I N S</b>			
Functional	Amino acids	Catalysis; transport	Hemoglobin
Structural	Amino acids	Support	Hair; silk
<b>L I P I D S</b>			
Fats	Glycerol and three fatty acids	Energy storage	Butter; corn oil; soap
Phospholipids	Glycerol, two fatty acids, phosphate, and polar R groups	Cell membranes	Phosphatidylcholine
Prostaglandins	Five-carbon rings with two nonpolar tails	Chemical messengers	Prostaglandin E (PGE)
Steroids	Four fused carbon rings	Membranes; hormones	Cholesterol; estrogen
Terpenes	Long carbon chains	Pigments; structural support	Carotene; rubber

## Biological macromolecules include carbohydrates, nucleic acids, proteins, and lipids

Remember that biological macromolecules are traditionally grouped into carbohydrates, nucleic acids, proteins, and lipids (table 3.1). In many cases, these macromolecules are polymers. A **polymer** is a long molecule built by linking together a large number of small, similar chemical subunits called **monomers**. They are like railroad cars coupled to form a train. The nature of a polymer is determined by the monomers used to build the polymer. Here are some examples. Complex carbohydrates such as starch are polymers composed of simple ring-shaped sugars. Nucleic acids (DNA and RNA) are polymers of nucleotides (figure 3.4). Proteins are polymers of amino acids, and lipids are polymers of fatty acids (see figure 3.4). These long chains are built via chemical reactions termed *dehydration reactions* and are broken down by *hydrolysis reactions*.

### The dehydration reaction

Despite the differences between monomers of these major polymers, the basic chemistry of their synthesis is similar: To form a covalent bond between two monomers, an —OH group is removed from one monomer, and a hydrogen atom (H) is removed from the other (figure 3.5*a*). For example, this simple chemistry is the same for linking amino acids together to make a protein or assembling glucose units together to make starch. This reaction is also used to link fatty acids to glycerol in lipids. This chemical reaction is called condensation, or a **dehydration reaction**, because the removal of —OH and —H is the same as the removal

of a molecule of water ( $H_2O$ ). For every subunit added to a macromolecule, one water molecule is removed. These and other biochemical reactions require that the reacting substances are held close together and that the correct chemical bonds are stressed and broken. This process of positioning and stressing, termed *catalysis*, is carried out within cells by enzymes.

### The hydrolysis reaction

Cells disassemble macromolecules into their constituent subunits through reactions that are the reverse of dehydration—a molecule of water is added instead of removed (figure 3.5*b*). In this process, called **hydrolysis**, a hydrogen atom is attached to one subunit and a hydroxyl group to the other, breaking a specific covalent bond in the macromolecule.

## Figure 3.5 Making and breaking macromolecules.

**a.** Biological macromolecules are polymers formed by linking monomers together through dehydration reactions. This process releases a water molecule for every bond formed. **b.** Breaking the bond between subunits involves hydrolysis, which reverses the loss of a water molecule by dehydration.

### Learning Outcomes Review 3.1

Functional groups account for differences in chemical properties in organic molecules. Isomers are compounds with the same empirical formula but different structures. This difference may affect biological function. Macromolecules are polymers consisting of long chains of similar subunits that are joined by dehydration reactions and are broken down by hydrolysis reactions.

- What is the relationship between dehydration and hydrolysis?

## 3.2 Carbohydrates: Energy Storage and Structural Molecules

### Learning Outcomes

1. Describe the structure of a sugar.
2. Name the different forms of carbohydrate molecules.
3. Relate the structure of polysaccharides to their functions

### Monosaccharides are simple sugars

Carbohydrates are a loosely defined group of molecules that all contain carbon, hydrogen, and oxygen in the molar ratio 1:2:1. Their empirical formula (which lists the number of atoms in the molecule with subscripts) is  $(\text{CH}_2\text{O})_n$ , where  $n$  is the number of carbon atoms. Because they contain many carbon-hydrogen (C—H) bonds, which release energy when oxidation occurs, carbohydrates are well suited for energy storage. Sugars are among the most important energy-storage molecules, and they exist in several different forms.

The simplest of the carbohydrates are the **monosaccharides** (Greek *mono*, “single,” and Latin *saccharum*, “sugar”). Simple sugars contain as few as three carbon atoms, but those that play the central role in energy storage have six (figure 3.6). The empirical formula of six-carbon sugars is:

**Figure 3.6 Monosaccharides.** Monosaccharides, or simple sugars, can contain as few as three carbon atoms and are often used as building blocks to form larger molecules. The five-carbon sugars ribose and deoxyribose are components of nucleic acids (see figure 3.15). The carbons are conventionally numbered from the more oxidized end.

Six-carbon sugars can exist in a straight-chain form, but dissolved in water (an aqueous environment) they almost always form rings.

The most important of the six-carbon monosaccharides for energy storage is glucose, which you first encountered in the examples of chemical reactions in chapter 2. Glucose has seven energy-storing C—H bonds (figure 3.7). Depending on the orientation of the carbonyl group (C=O) when the ring is closed, glucose can exist in two different forms: alpha ( $\alpha$ ) or beta ( $\beta$ ).

### Sugar isomers have structural differences

Glucose is not the only sugar with the formula  $\text{C}_6\text{H}_{12}\text{O}_6$ . Both structural isomers and stereoisomers of this simple six-carbon skeleton exist in nature. Fructose is a structural isomer that differs in the position of the carbonyl carbon (C=O); galactose is a stereoisomer that differs in the position of —OH and —H groups relative to the ring (figure 3.8). These differences often account for substantial functional differences between the isomers. Your taste buds can discern them: Fructose tastes much sweeter than glucose, despite the fact that both sugars have identical chemical composition. Enzymes that act on different sugars can distinguish both the structural and stereoisomers of this basic six-carbon skeleton. The different stereoisomers of glucose are also important in the polymers that can be made using glucose as a monomer, as you will see later in this chapter.

### Disaccharides serve as transport molecules in plants and provide nutrition in animals

Most organisms transport sugars within their bodies. In humans, the glucose that circulates in the blood does so as a simple monosaccharide. In plants and many other organisms, however, glucose is converted into a transport form before it is moved from place to place within the organism. In such a form, it is less readily metabolized during transport.

Transport forms of sugars are commonly made by linking two monosaccharides together to form a **disaccharide** (Greek *di*, “two”). Disaccharides serve as effective reservoirs of glucose because the enzymes that normally use glucose in the organism cannot break the bond linking the two monosaccharide subunits. Enzymes that can do so are typically present only in the tissue that uses glucose.

**Figure 3.7 Structure of the glucose molecule.** Glucose is a linear, six-carbon molecule that forms a six-membered ring in solution. Ring closure occurs such that two forms can result:  $\alpha$ -glucose and  $\beta$ -glucose. These structures differ only in the position of the  $\text{—OH}$  bound to carbon 1. The structure of the ring can be represented in many ways; shown here are the most common, with the carbons conventionally numbered (in blue) so that the forms can be compared easily. The heavy lines in the ring structures represent portions of the molecule that are projecting out of the page toward you.

Transport forms differ depending on which monosaccharides are linked to form the disaccharide. Glucose forms transport disaccharides with itself and with many other monosaccharides, including fructose and galactose. When glucose forms a disaccharide with the structural isomer fructose, the resulting disaccharide is *sucrose*, or table sugar (figure 3.9*a*). Sucrose is the form most plants use to transport glucose and is the sugar that most humans and other animals eat. Sugarcane and sugar beets are rich in sucrose.

When glucose is linked to the stereoisomer galactose, the resulting disaccharide is *lactose*, or milk sugar. Many mammals supply energy to their young in the form of lactose. Adults often have greatly reduced levels of lactase, the enzyme required to cleave lactose into its two monosaccharide components, and thus they cannot metabolize lactose efficiently. This can result in lactose intolerance in humans. Most of the energy that is channeled into lactose production is therefore reserved for offspring. For this reason, lactose as an energy source is primarily for offspring in mammals.

**Figure 3.8 Isomers and stereoisomers.** Glucose, fructose, and galactose are isomers with the empirical formula  $\text{C}_6\text{H}_{12}\text{O}_6$ . A structural isomer of glucose, such as fructose, has identical chemical groups bonded to different carbon atoms. Notice that this results in a five-membered ring in solution (see figure 3.6). A stereoisomer of glucose, such as galactose, has identical chemical groups bonded to the same carbon atoms but in different orientations (the  $\text{—OH}$  at carbon 4).

## Polysaccharides provide energy storage and structural components

**Polysaccharides** are longer polymers made up of monosaccharides that have been joined through dehydration reactions. **Starch**, a storage polysaccharide, consists entirely of  $\alpha$ -glucose molecules linked in long chains. **Cellulose**, a structural polysaccharide, also consists of glucose molecules linked in chains, but these molecules are  $\beta$ -glucose. Because starch is built from  $\alpha$ -glucose we call the linkages  $\alpha$  linkages; cellulose has  $\beta$  linkages.

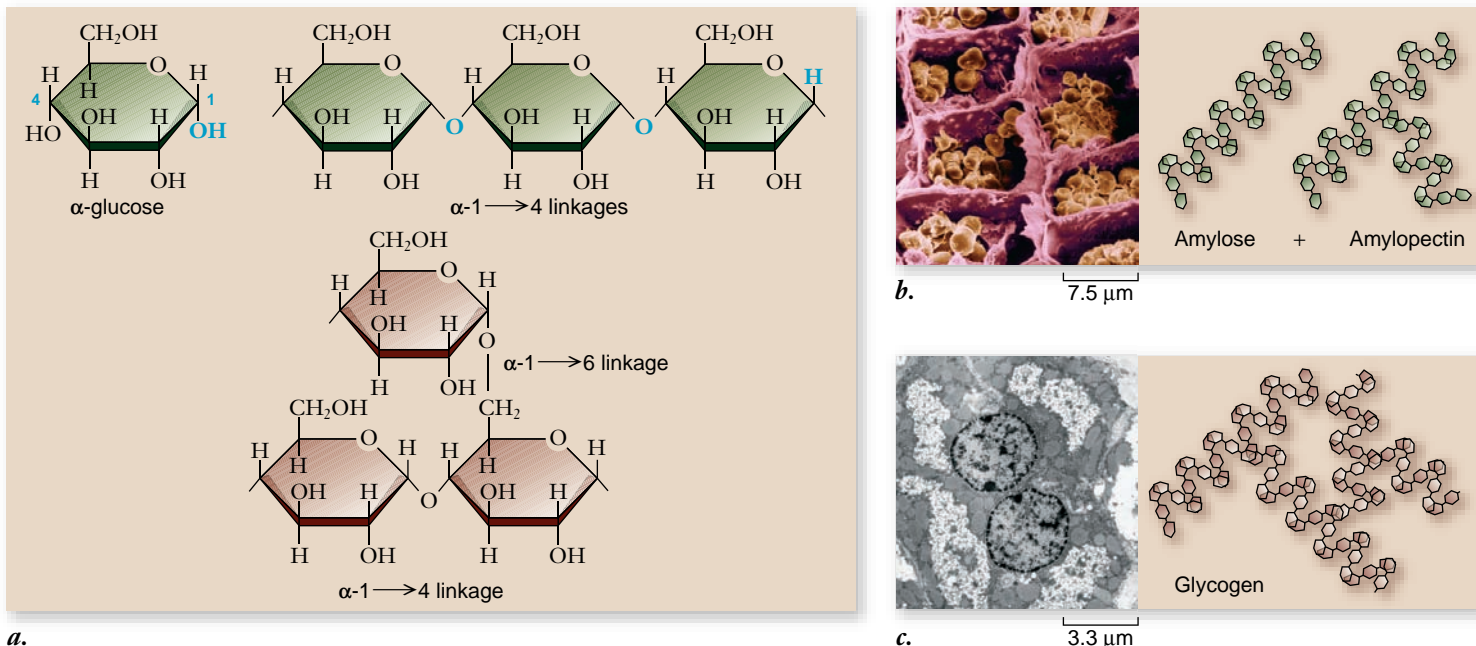

### Starches and Glycogen

Organisms store the metabolic energy contained in monosaccharides by converting them into disaccharides, such as *maltose* (figure 3.9*b*). These are then linked together into the insoluble polysaccharides called *starches*. These polysaccharides differ mainly in how the polymers branch.

The starch with the simplest structure is *amylose*. It is composed of many hundreds of  $\alpha$ -glucose molecules linked together in long, unbranched chains. Each linkage occurs between the carbon 1

**Figure 3.9 How disaccharides form.** Some disaccharides are used to transport glucose from one part of an organism's body to another; one example is sucrose (*a*), which is found in sugarcane. Other disaccharides, such as maltose (*b*), are used in grain for storage.

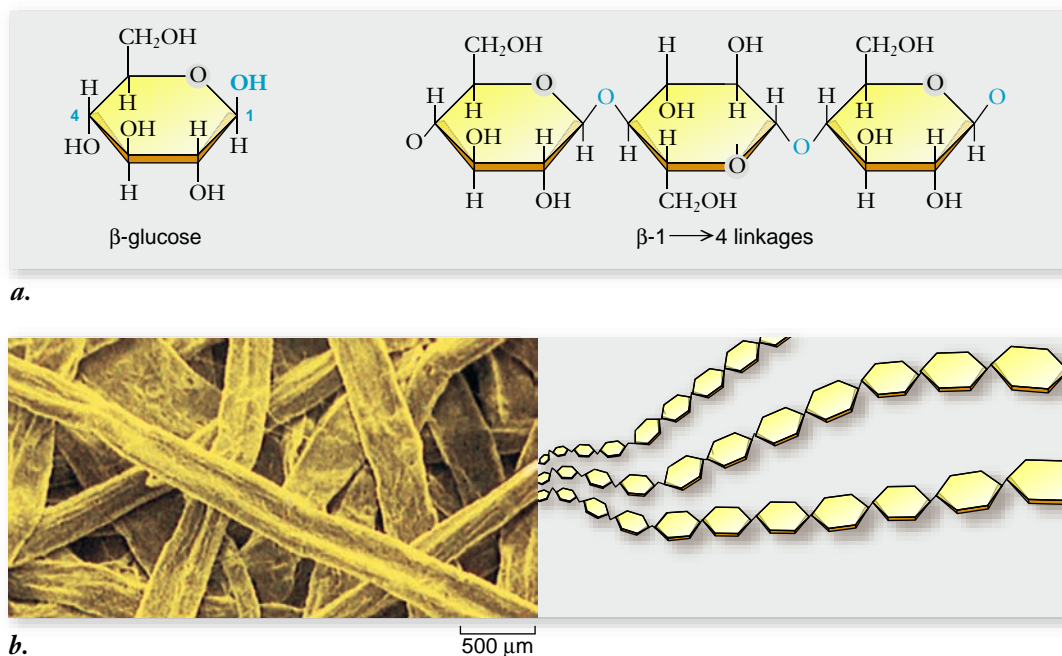

**Figure 3.10 Polymers of glucose: Starch and glycogen.** *a.* Starch chains consist of polymers of  $\alpha$ -glucose subunits joined by  $\alpha$ -(1 $\rightarrow$ 4) glycosidic linkages. These chains can be branched by forming similar  $\alpha$ -(1 $\rightarrow$ 6) glycosidic bonds. These storage polymers then differ primarily in their degree of branching. *b.* Starch is found in plants and is composed of amylose and amylopectin, which are unbranched and branched, respectively. The branched form is insoluble and forms starch granules in plant cells. *c.* Glycogen is found in animal cells and is highly branched and also insoluble, forming glycogen granules.

(C-1) of one glucose molecule and the C-4 of another, making them  $\alpha$ -(1 $\rightarrow$ 4) linkages (figure 3.10*a*). The long chains of amylose tend to coil up in water, a property that renders amylose insoluble. Potato starch is about 20% amylose (figure 3.10*b*).

Most plant starch, including the remaining 80% of potato starch, is a somewhat more complicated variant of amylose called *amylopectin*. Pectins are branched polysaccharides with the branches occurring due to bonds between the C-1 of one molecule and the C-6 of another [ $\alpha$ -(1 $\rightarrow$ 6) linkages]. These short amylose branches consist of 20 to 30 glucose subunits (figure 3.10*b*).

**Figure 3.11 Polymers of glucose: Cellulose.**

Starch chains consist of  $\alpha$ -glucose subunits, and cellulose chains consist of  $\beta$ -glucose subunits. *a.* Thus the bonds between adjacent glucose molecules in cellulose are  $\beta$ -(1 $\rightarrow$ 4) glycosidic linkages. *b.* Cellulose is unbranched and forms long fibers. Cellulose fibers can be very strong and are quite resistant to metabolic breakdown, which is one reason wood is such a good building material.

The comparable molecule to starch in animals is **glycogen**. Like amylopectin, glycogen is an insoluble polysaccharide containing branched amylose chains. Glycogen has a much longer average chain length and more branches than plant starch (figure 3.10*c*).

**Cellulose**

Although some chains of sugars store energy, others serve as structural material for cells. For two glucose molecules to link together, the glucose subunits must be of the same form. *Cellulose* is a polymer of  $\beta$ -glucose (figure 3.11). The bonds between

## 3.3 Nucleic Acids: Information Molecules

adjacent glucose molecules still exist between the C-1 of the first glucose and the C-4 of the next glucose, but these are  $\beta$ -(1 $\rightarrow$ 4) linkages.

The properties of a chain of glucose molecules consisting of all  $\beta$ -glucose are very different from those of starch. These long, unbranched  $\beta$ -linked chains make tough fibers. Cellulose is the chief component of plant cell walls (see figure 3.11*b*). It is chemically similar to amylose, with one important difference: The starch-hydrolyzing enzymes that occur in most organisms cannot break the bond between two  $\beta$ -glucose units because they only recognize  $\alpha$  linkages.

Because cellulose cannot be broken down readily by most creatures, it works well as a biological structural material. But some animals, such as cows, are able to break down cellulose by means of symbiotic bacteria and protists in their digestive tracts. These organisms provide the necessary enzymes for cleaving the  $\beta$ -(1 $\rightarrow$ 4) linkages, thus enabling access to a rich source of energy.

### Chitin

**Chitin**, the structural material found in arthropods and many fungi, is a polymer of *N*-acetylglucosamine, a substituted version of glucose. When cross-linked by proteins, it forms a tough, resistant surface material that serves as the hard exoskeleton of insects and crustaceans (figure 3.12; see chapter 34). Few organisms are able to digest chitin, but most possess a chitinase enzyme, probably to protect against fungi.

### Learning Outcomes Review 3.2

Monosaccharides have three to six or more carbon atoms typically arranged in a ring form. Disaccharides consist of two linked monosaccharides; polysaccharides are long chains of monosaccharides. Structural differences between sugar isomers can lead to functional differences. Starches are branched polymers of  $\alpha$ -glucose used for energy storage. Cellulose in plants consists of unbranched chains of  $\beta$ -glucose that are not easily digested.

- How do the structures of starch, glycogen, and cellulose affect their function?

**Figure 3.12 Chitin.** Chitin is the principal structural element in the external skeletons of many invertebrates, such as this lobster.

### Learning Outcomes

1. Describe the structure of nucleotides.
2. Compare and contrast the structures of DNA and RNA.
3. Explain the functions of DNA and RNA.
4. Recognize other nucleotides involved in energy metabolism.

The biochemical activity of a cell depends on production of a large number of proteins, each with a specific sequence. The information necessary to produce the correct proteins is passed through generations of organisms, even though the protein molecules themselves are not.

Nucleic acids carry information inside cells, just as disks contain the information in a computer or road maps display information needed by travelers. Two main varieties of nucleic acids are **deoxyribonucleic acid (DNA)** (figure 3.13) and **ribonucleic acid (RNA)**.

DNA encodes the genetic information used to assemble proteins (as discussed in detail in chapter 15) similar to the way the letters on this page encode information. Unique among macromolecules, nucleic acids are able to serve as templates to produce precise copies of themselves. This characteristic allows genetic information to be preserved during cell division and

**Figure 3.13 Images of DNA.** *a.* A scanning-tunneling micrograph of DNA (false color; 2,000,000 $\times$ ) showing approximately three turns of the DNA double helix. *b.* A space-filling model for comparison to the image of actual DNA in (*a*).

during the reproduction of organisms. DNA, found primarily in the nuclear region of cells, contains the genetic information necessary to build specific organisms.

Cells use a type of RNA called messenger RNA (mRNA) to direct the synthesis of proteins. mRNA consists of transcribed single-stranded copies of portions of the DNA. These transcripts serve as blueprints specifying the amino acid sequences of proteins. This process will be described in detail in chapter 15.

## Nucleic acids are nucleotide polymers

Nucleic acids are long polymers of repeating subunits called **nucleotides**. Each nucleotide consists of three components: a pentose, or five-carbon sugar (ribose in RNA and deoxyribose in DNA); a phosphate ( $-\text{PO}_4$ ) group; and an organic nitrogenous (nitrogen-containing) base (figure 3.14). When a nucleic acid polymer forms, the phosphate group of one nucleotide binds to the hydroxyl group from the pentose sugar of another, releasing water and forming a *phosphodiester bond* by a dehydration reaction. A **nucleic acid**, then, is simply a chain of five-carbon sugars linked together by phosphodiester bonds with a nitrogenous base protruding from each sugar (see figure 3.15a). These chains of nucleotides, *polynucleotides*, have different ends: a phosphate on one end and an  $-\text{OH}$  from a sugar on the other end. We conventionally refer to these ends as 5' ("five-prime,"  $-\text{PO}_4$ ) and 3' ("three-prime,"  $-\text{OH}$ ) taken from the carbon numbering of the sugar (figure 3.15a).

Two types of nitrogenous bases occur in nucleotides (3.15b). The first type, *purines*, are large, double-ring molecules found in both DNA and RNA; the two types of purines are adenine (A) and guanine (G). The second type, *pyrimidines*, are smaller, single-ring molecules; they include cytosine (C, in both

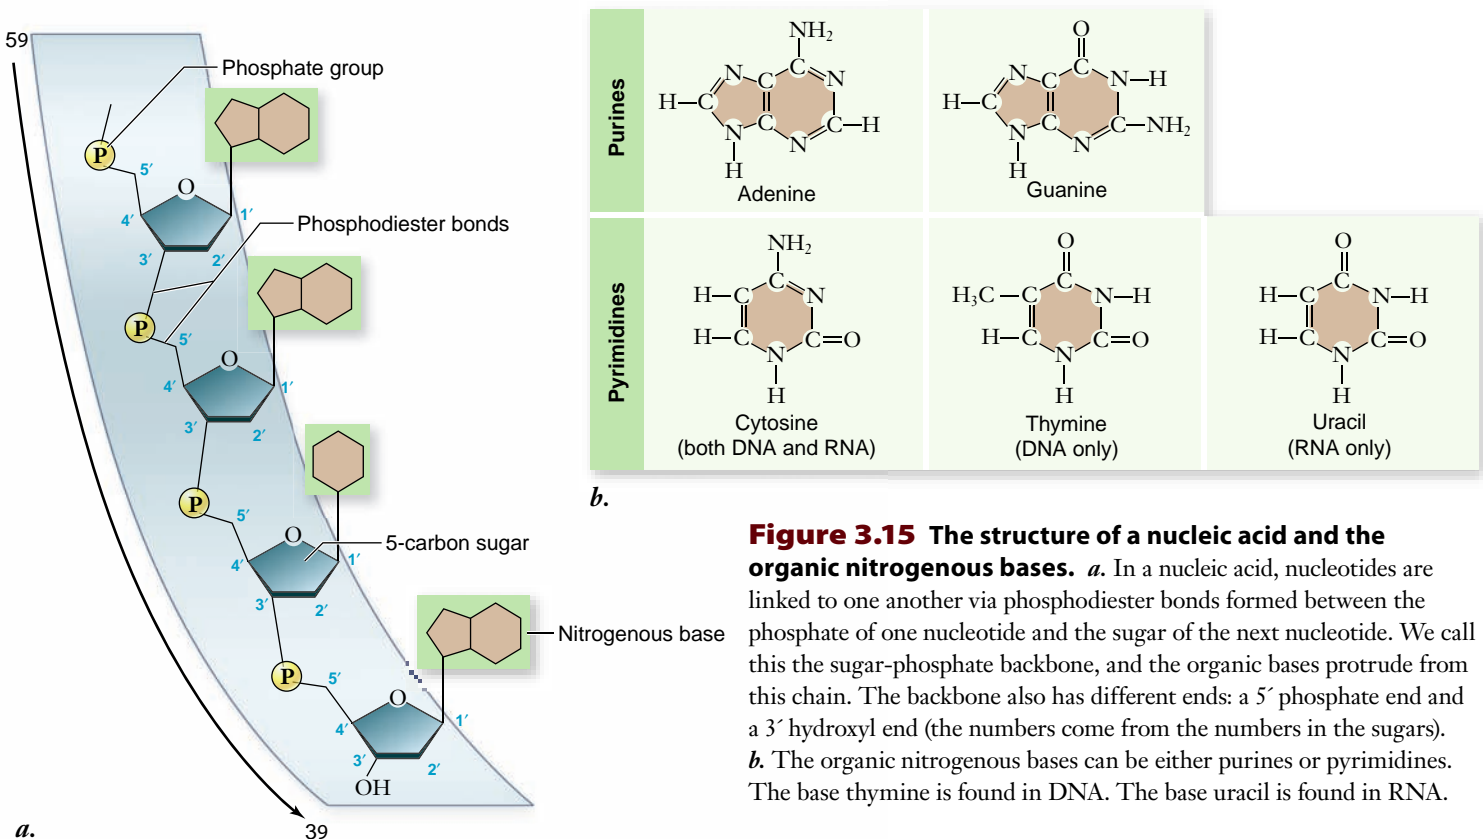

**Figure 3.14 Structure of a nucleotide.** The nucleotide subunits of DNA and RNA are made up of three elements: a five-carbon sugar (ribose or deoxyribose), an organic nitrogenous base (adenine is shown here), and a phosphate group. Notice that all the numbers on the sugar are given as "primes" (1', 2', etc.) to distinguish them from the numbering on the rings of the bases.

DNA and RNA), thymine (T, in DNA only), and uracil (U, in RNA only).

## DNA carries the genetic code

Organisms use sequences of nucleotides in DNA to encode the information specifying the amino acid sequences of their proteins. This method of encoding information is very similar to the way in which sequences of letters encode information in a sentence.

**Figure 3.15 The structure of a nucleic acid and the organic nitrogenous bases.** *a.* In a nucleic acid, nucleotides are linked to one another via phosphodiester bonds formed between the phosphate of one nucleotide and the sugar of the next nucleotide. We call this the sugar-phosphate backbone, and the organic bases protrude from this chain. The backbone also has different ends: a 5' phosphate end and a 3' hydroxyl end (the numbers come from the numbers in the sugars). *b.* The organic nitrogenous bases can be either purines or pyrimidines. The base thymine is found in DNA. The base uracil is found in RNA.

**Figure 3.16 The structure of DNA.** DNA consists of two polynucleotide chains running in opposite directions wrapped about a single helical axis. Hydrogen bond formation (dashed lines) between the nitrogenous bases, called base-pairing, causes the two chains of DNA to bind to each other and form a double helix.

A sentence written in English consists of a combination of the 26 different letters of the alphabet in a certain order; the code of a DNA molecule consists of different combinations of the four types of nucleotides in specific sequences, such as CGCTTACG. The information encoded in DNA is used in the everyday functioning of the organism and is passed on to the organism's descendants.

DNA molecules in organisms exist not as single chains folded into complex shapes, like proteins, but rather as two chains wrapped about each other in a long linear molecule in eukaryotes, and a circular molecule in most prokaryotes. The two strands of a DNA polymer wind around each other like the outside and inside rails of a spiral staircase. Such a spiral shape is called a helix, and a helix composed of two chains is called a **double helix**. Each step of DNA's helical staircase is composed of a base-pair. The pair consists of a base in one chain attracted by hydrogen bonds to a base opposite it on the other chain (figure 3.16).

The base-pairing rules are rigid: Adenine can pair only with thymine (in DNA) or with uracil (in RNA), and cytosine can pair only with guanine. The bases that participate in base-pairing are said to be **complementary** to each other. Additional details of the structure of DNA and how it interacts with RNA in the production of proteins are presented in chapters 14 and 15.

### RNA is a transcript of a DNA strand

RNA is similar to DNA, but with two major chemical differences. First, RNA molecules contain ribose sugars, in which the C-2 is bonded to a hydroxyl group. (In DNA, this hydroxyl

group is replaced by a hydrogen atom.) Second, RNA molecules use uracil in place of thymine. Uracil has the same structure as thymine, except that one of its carbons lacks a methyl ( $-\text{CH}_3$ ) group.

Transcribing the DNA message into a chemically different molecule such as RNA allows the cell to distinguish between the original information-storage molecule and the transcript. DNA molecules are always double-stranded (except for a few single-stranded DNA viruses), whereas the RNA molecules transcribed from DNA are typically single-stranded (figure 3.17). These differences allow DNA to store hereditary information and RNA to use this information to specify the sequence of amino acids in proteins.

### Other nucleotides are vital components of energy reactions

In addition to serving as subunits of DNA and RNA, nucleotide bases play other critical roles in the life of a cell. For example, adenine is a key component of the molecule **adenosine**

**Figure 3.17 DNA versus RNA.** DNA forms a double helix, uses deoxyribose as the sugar in its sugar-phosphate backbone, and uses thymine among its nitrogenous bases. RNA is usually single-stranded, uses ribose as the sugar in its sugar-phosphate backbone, and uses uracil in place of thymine.

**Figure 3.18 ATP.** Adenosine triphosphate (ATP) contains adenine, a five-carbon sugar, and three phosphate groups.

**triphosphate (ATP; figure 3.18)**—the energy currency of the cell. Cells use ATP as energy in a variety of transactions, the way we use money in society. ATP is used to drive energetically unfavorable chemical reactions, to power transport across membranes, and to power the movement of cells.

Two other important nucleotide-containing molecules are **nicotinamide adenine dinucleotide (NAD<sup>+</sup>)** and **flavin adenine dinucleotide (FAD)**. These molecules function as electron carriers in a variety of cellular processes. You will see the action of these molecules in detail when we discuss photosynthesis and respiration (chapters 7–8).

### Learning Outcomes Review 3.3

A nucleic acid is a polymer composed of alternating phosphate and five-carbon sugar groups with a nitrogenous base protruding from each sugar. In DNA, this sugar is deoxyribose. In RNA, the sugar is ribose. RNA also contains the base uracil instead of thymine. DNA is a double-stranded helix that stores hereditary information as a specific sequence of nucleotide bases. RNA is a single-stranded molecule consisting of a transcript of a DNA sequence that directs protein synthesis.

- *If an RNA molecule is copied from a DNA strand, what is the relationship between the sequence of bases in RNA and each DNA strand?*

Proteins are the most diverse group of biological macromolecules, both chemically and functionally. Because proteins have so many different functions in cells we could not begin to list them all. We can, however, group these functions into the following seven categories. This list is a summary only, however; details are covered in later chapters.

- 1. Enzyme catalysis.** Enzymes are biological catalysts that facilitate specific chemical reactions. Because of this property, the appearance of enzymes was one of the most important events in the evolution of life. Enzymes are three-dimensional globular proteins that fit snugly around the molecules they act on. This fit facilitates chemical reactions by stressing particular chemical bonds.
- 2. Defense.** Other globular proteins use their shapes to “recognize” foreign microbes and cancer cells. These cell-surface receptors form the core of the body’s endocrine and immune systems.
- 3. Transport.** A variety of globular proteins transport small molecules and ions. The transport protein hemoglobin, for example, transports oxygen in the blood. Membrane transport proteins help move ions and molecules across the membrane.
- 4. Support.** Protein fibers play structural roles. These fibers include keratin in hair, fibrin in blood clots, and collagen. The last one, collagen, forms the matrix of skin, ligaments, tendons, and bones and is the most abundant protein in a vertebrate body.
- 5. Motion.** Muscles contract through the sliding motion of two kinds of protein filaments: actin and myosin. Contractile proteins also play key roles in the cell’s cytoskeleton and in moving materials within cells.
- 6. Regulation.** Small proteins called hormones serve as intercellular messengers in animals. Proteins also play many regulatory roles within the cell—turning on and shutting off genes during development, for example. In addition, proteins receive information, acting as cell-surface receptors.
- 7. Storage.** Calcium and iron are stored in the body by binding as ions to storage proteins.

Table 3.2 summarizes these functions and includes examples of the proteins that carry them out in the human body.

## 3.4 Proteins: Molecules with Diverse Structures and Functions

### Learning Outcomes

- 1. Describe the possible levels of protein structure.**
- 2. Explain how motifs and domains contribute to protein structure.**
- 3. Understand the relationship between amino acid sequence and their three-dimensional structure.**

### Proteins are polymers of amino acids

Proteins are linear polymers made with 20 different amino acids. **Amino acids**, as their name suggests, contain an amino group ( $-\text{NH}_2$ ) and an acidic carboxyl group ( $-\text{COOH}$ ). The specific order of amino acids determines the protein’s structure and function. Many scientists believe amino acids were among the first molecules formed on the early Earth. It seems highly likely that the oceans that existed early in the history of the Earth contained a wide variety of amino acids.

#### Amino acid structure

The generalized structure of an amino acid is shown here as amino and carboxyl groups bonded to a central carbon atom, with an additional hydrogen and a functional side group

TABLE 3.2

The Many Functions of Protein

Function	Class of Protein	Examples	Examples of Use
Enzyme catalysis	Enzymes	Glycosidases	Cleave polysaccharides
		Proteases	Break down proteins
		Polymerases	Synthesize nucleic acids
		Kinases	Phosphorylate sugars and proteins
Defense	Immunoglobulins	Antibodies	Mark foreign proteins for elimination
	Toxins	Snake venom	Blocks nerve function
	Cell-surface antigens	MHC* proteins	"Self" recognition
Transport	Circulating transporters	Hemoglobin	Carries O <sub>2</sub> and CO <sub>2</sub> in blood
		Myoglobin	Carries O <sub>2</sub> and CO <sub>2</sub> in muscle
		Cytochromes	Electron transport
	Membrane transporters	Sodium–potassium pump	Excitable membranes
		Proton pump	Chemiosmosis
Support	Fibers	Collagen	Forms cartilage
		Keratin	Forms hair, nails
		Fibrin	Forms blood clots
Motion	Muscle	Actin	Contraction of muscle fibers
		Myosin	Contraction of muscle fibers
Regulation	Osmotic proteins	Serum albumin	Maintains osmotic concentration of blood
	Gene regulators	<i>lac</i> Repressor	Regulates transcription
	Hormones	Insulin	Controls blood glucose levels
		Vasopressin	Increases water retention by kidneys
Storage	Ion-binding	Oxytocin	Regulates uterine contractions and milk production
		Ferritin	Stores iron, especially in spleen
		Casein	Stores ions in milk
		Calmodulin	Binds calcium ions

\*MHC, major histocompatibility complex.

indicated by R. These components completely fill the bonds of the central carbon:

The unique character of each amino acid is determined by the nature of the R group. Notice that unless the R group is an H atom, as in glycine, amino acids are chiral and can exist as two enantiomeric forms: D or L. In living systems, only the L-amino acids are found in proteins, and D-amino acids are rare.

The R group also determines the chemistry of amino acids. Serine, in which the R group is —CH<sub>2</sub>OH, is a polar molecule. Alanine, which has —CH<sub>3</sub> as its R group, is nonpolar.

The 20 common amino acids are grouped into five chemical classes, based on their R group:

1. Nonpolar amino acids, such as leucine, often have R groups that contain —CH<sub>2</sub> or —CH<sub>3</sub>.
2. Polar uncharged amino acids, such as threonine, have R groups that contain oxygen (or —OH).
3. Charged amino acids, such as glutamic acid, have R groups that contain acids or bases that can ionize.
4. Aromatic amino acids, such as phenylalanine, have R groups that contain an organic (carbon) ring with alternating single and double bonds. These are also nonpolar.
5. Amino acids that have special functions have unique properties. Some examples are methionine, which is often the first amino acid in a chain of amino acids; proline, which causes kinks in chains; and cysteine, which links chains together.

Each amino acid affects the shape of a protein differently, depending on the chemical nature of its side group. For example, portions of a protein chain with numerous nonpolar amino acids tend to fold into the interior of the protein by hydrophobic exclusion.

### Peptide bonds

In addition to its R group, each amino acid, when ionized, has a positive amino ( $\text{NH}_3^+$ ) group at one end and a negative carboxyl ( $\text{COO}^-$ ) group at the other. The amino and carboxyl groups on a pair of amino acids can undergo a dehydration reaction to form a covalent bond. The covalent bond that links two amino acids is called a **peptide bond** (figure 3.19). The two amino acids linked by such a bond are not free to rotate around the N—C linkage because the peptide bond has a partial double-bond character. This is different from the N—C and C—C bonds to the central carbon of the amino acid. This lack of rotation about the peptide bond is one factor that determines the structural character of the coils and other regular shapes formed by chains of amino acids.

A protein is composed of one or more long unbranched chains. Each chain is called a **polypeptide** and is composed of amino acids linked by peptide bonds. The terms *protein* and *polypeptide* tend to be used loosely and may be confusing. For proteins that include only a single polypeptide chain, the two terms are synonymous.

The pioneering work of Frederick Sanger in the early 1950s provided the evidence that each kind of protein has a specific amino acid sequence. Using chemical methods to remove successive amino acids and then identify them, Sanger succeeded in determining the amino acid sequence of insulin. In so doing he demonstrated clearly that this protein had a defined sequence, which was the same for all insulin molecules in

the solution. Although many different amino acids occur in nature, only 20 commonly occur in proteins. Figure 3.20 illustrates these 20 amino acids and their side groups.

## Proteins have levels of structure

The shape of a protein determines its function. One way to study the shape of something as small as a protein is to look at it with very short wavelength energy—in other words, with X-rays. X-rays can be passed through a crystal of protein to produce a diffraction pattern. This pattern can then be analyzed by a painstaking procedure that allows the investigator to build up a three-dimensional picture of the position of each atom. The first protein to be analyzed in this way was myoglobin, and the related protein hemoglobin was analyzed soon thereafter.

As more and more proteins were studied, a general principle became evident: In every protein studied, essentially all the internal amino acids are nonpolar ones—amino acids such as leucine, valine, and phenylalanine. Water's tendency to hydrophobically exclude nonpolar molecules literally shoves the nonpolar portions of the amino acid chain into the protein's interior (figure 3.21). This tendency forces the nonpolar amino acids into close contact with one another, leaving little empty space inside. Polar and charged amino acids are restricted to the surface of the protein, except for the few that play key functional roles.

The structure of proteins is usually discussed in terms of a hierarchy of four levels: *primary*, *secondary*, *tertiary*, and *quaternary* (figure 3.22). We will examine this view and then integrate it with a more modern approach arising from our increasing knowledge of protein structure.

### Primary structure: amino acid sequence

The **primary structure** of a protein is its amino acid sequence. Because the R groups that distinguish the amino acids play no role in the peptide backbone of proteins, a protein can consist of any sequence of amino acids. Thus, because any of 20 different amino acids might appear at any position, a protein containing 100 amino acids could form any of  $20^{100}$  different amino acid sequences (that's the same as  $10^{130}$ , or 1 followed by 130 zeros—more than the number of atoms known in the universe). This important property of proteins permits great diversity.

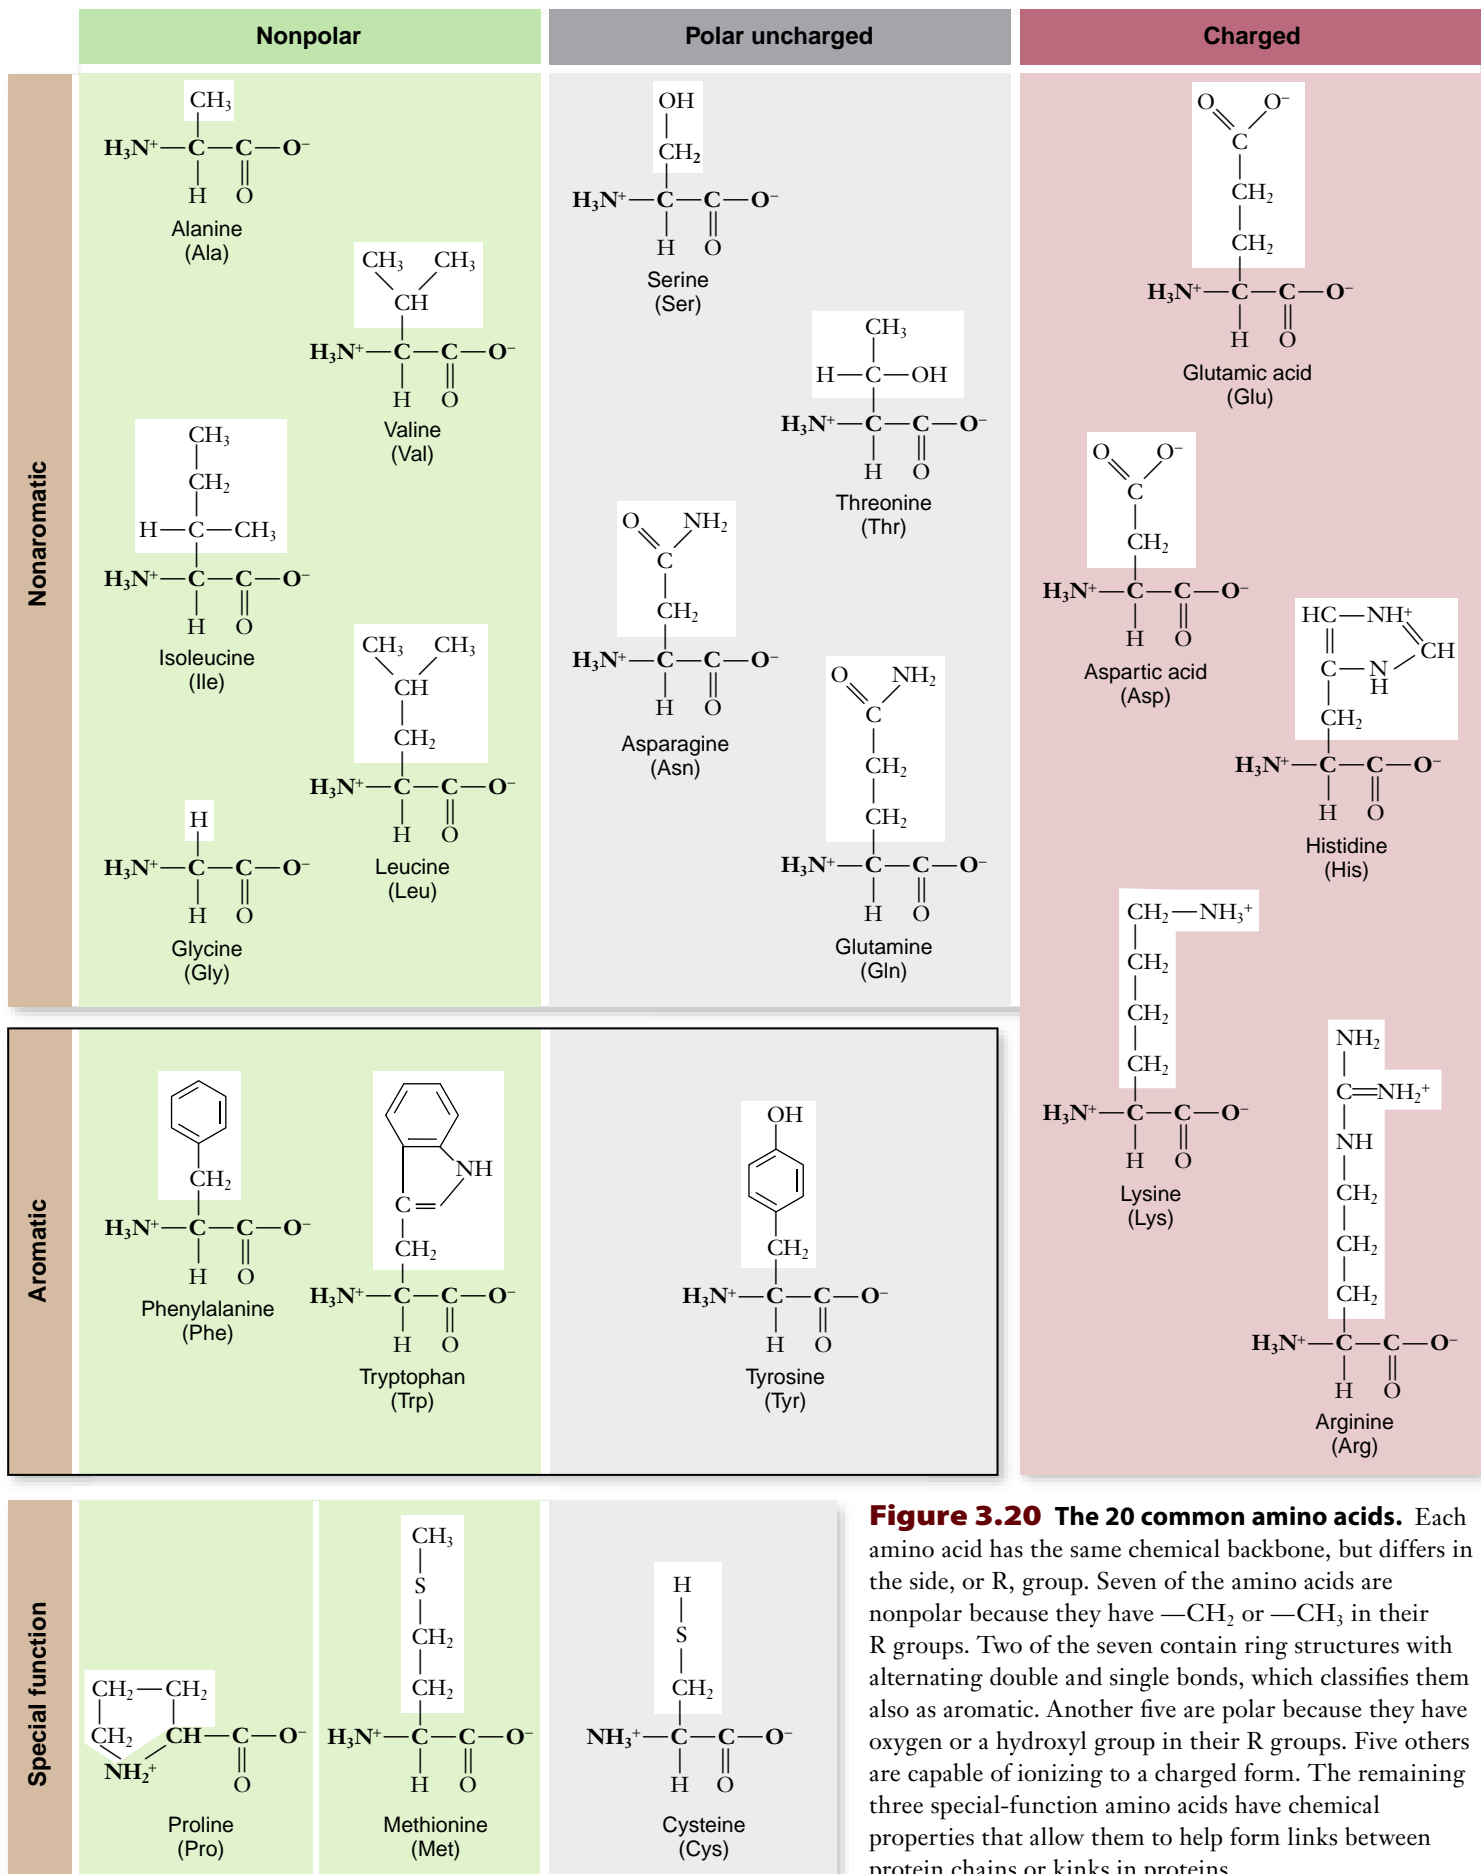

Consider the protein hemoglobin, the protein your blood uses to transport oxygen. Hemoglobin is composed of two  $\alpha$ -globin peptide chains and two  $\beta$ -globin peptide chains. The  $\alpha$ -globin chains differ from the  $\beta$ -globin ones in the sequence of amino acids. Furthermore, any alteration in the normal sequence of either of the types of globin proteins, even by a single amino acid, can have drastic effects on how the protein functions.

### Secondary structure: Hydrogen bonding patterns

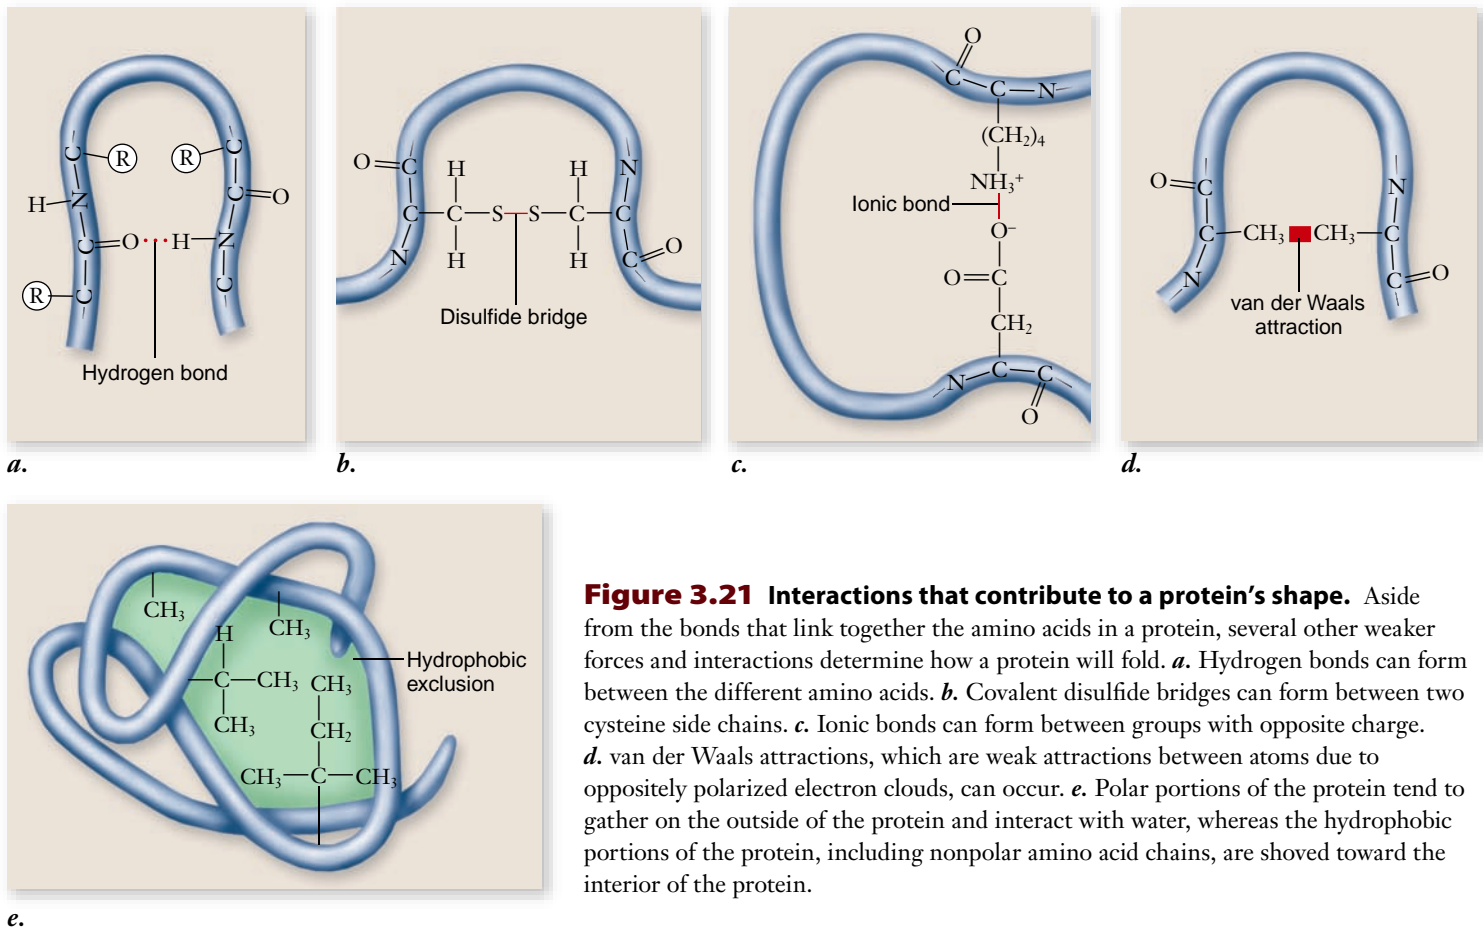

The amino acid side groups are not the only portions of proteins that form hydrogen bonds. The peptide groups of the main chain can also do so. These hydrogen bonds can be with water or with other peptide groups. If the peptide groups formed too many hydrogen bonds with water, the proteins would tend to behave like a random coil and wouldn't produce

**Figure 3.19 The peptide bond.** A peptide bond forms when the amino end of one amino acid joins to the carboxyl end of another. Reacting amino and carboxyl groups are shown in red and nonreacting groups are highlighted in green. Notice that the resulting dipeptide still has an amino end and a carboxyl end. Because of the partial double-bond nature of peptide bonds, the resulting peptide chain cannot rotate freely around these bonds.

**Figure 3.20 The 20 common amino acids.** Each amino acid has the same chemical backbone, but differs in the side, or R, group. Seven of the amino acids are nonpolar because they have  $-\text{CH}_2$  or  $-\text{CH}_3$  in their R groups. Two of the seven contain ring structures with alternating double and single bonds, which classifies them also as aromatic. Another five are polar because they have oxygen or a hydroxyl group in their R groups. Five others are capable of ionizing to a charged form. The remaining three special-function amino acids have chemical properties that allow them to help form links between protein chains or kinks in proteins.

**Figure 3.21 Interactions that contribute to a protein's shape.** Aside from the bonds that link together the amino acids in a protein, several other weaker forces and interactions determine how a protein will fold. **a.** Hydrogen bonds can form between the different amino acids. **b.** Covalent disulfide bridges can form between two cysteine side chains. **c.** Ionic bonds can form between groups with opposite charge. **d.** van der Waals attractions, which are weak attractions between atoms due to oppositely polarized electron clouds, can occur. **e.** Polar portions of the protein tend to gather on the outside of the protein and interact with water, whereas the hydrophobic portions of the protein, including nonpolar amino acid chains, are shoved toward the interior of the protein.

the kinds of globular structures that are common in proteins. Linus Pauling suggested that the peptide groups could interact with one another if the peptide was coiled into a spiral that he called the  **$\alpha$  helix**. We now call this sort of regular interaction of groups in the peptide backbone **secondary structure**. Another form of secondary structure can occur between regions of peptide aligned next to each other to form a planar structure called a  **$\beta$  sheet**. These can be either parallel or antiparallel depending on whether the adjacent sections of peptide are oriented in the same direction, or opposite direction.

These two kinds of secondary structure create regions of the protein that are cylindrical ( $\alpha$  helices) and planar ( $\beta$  sheets). A protein's final structure can include regions of each type of secondary structure. For example, DNA-binding proteins usually have regions of  $\alpha$  helix that can lay across DNA and interact directly with the bases of DNA. Porin proteins that form holes in membranes are composed of  $\beta$  sheets arranged to form a pore in the membrane. Finally in hemoglobin, the  $\alpha$ - and  $\beta$ -globin peptide chains that make up the final molecule each have characteristic regions of secondary structure.

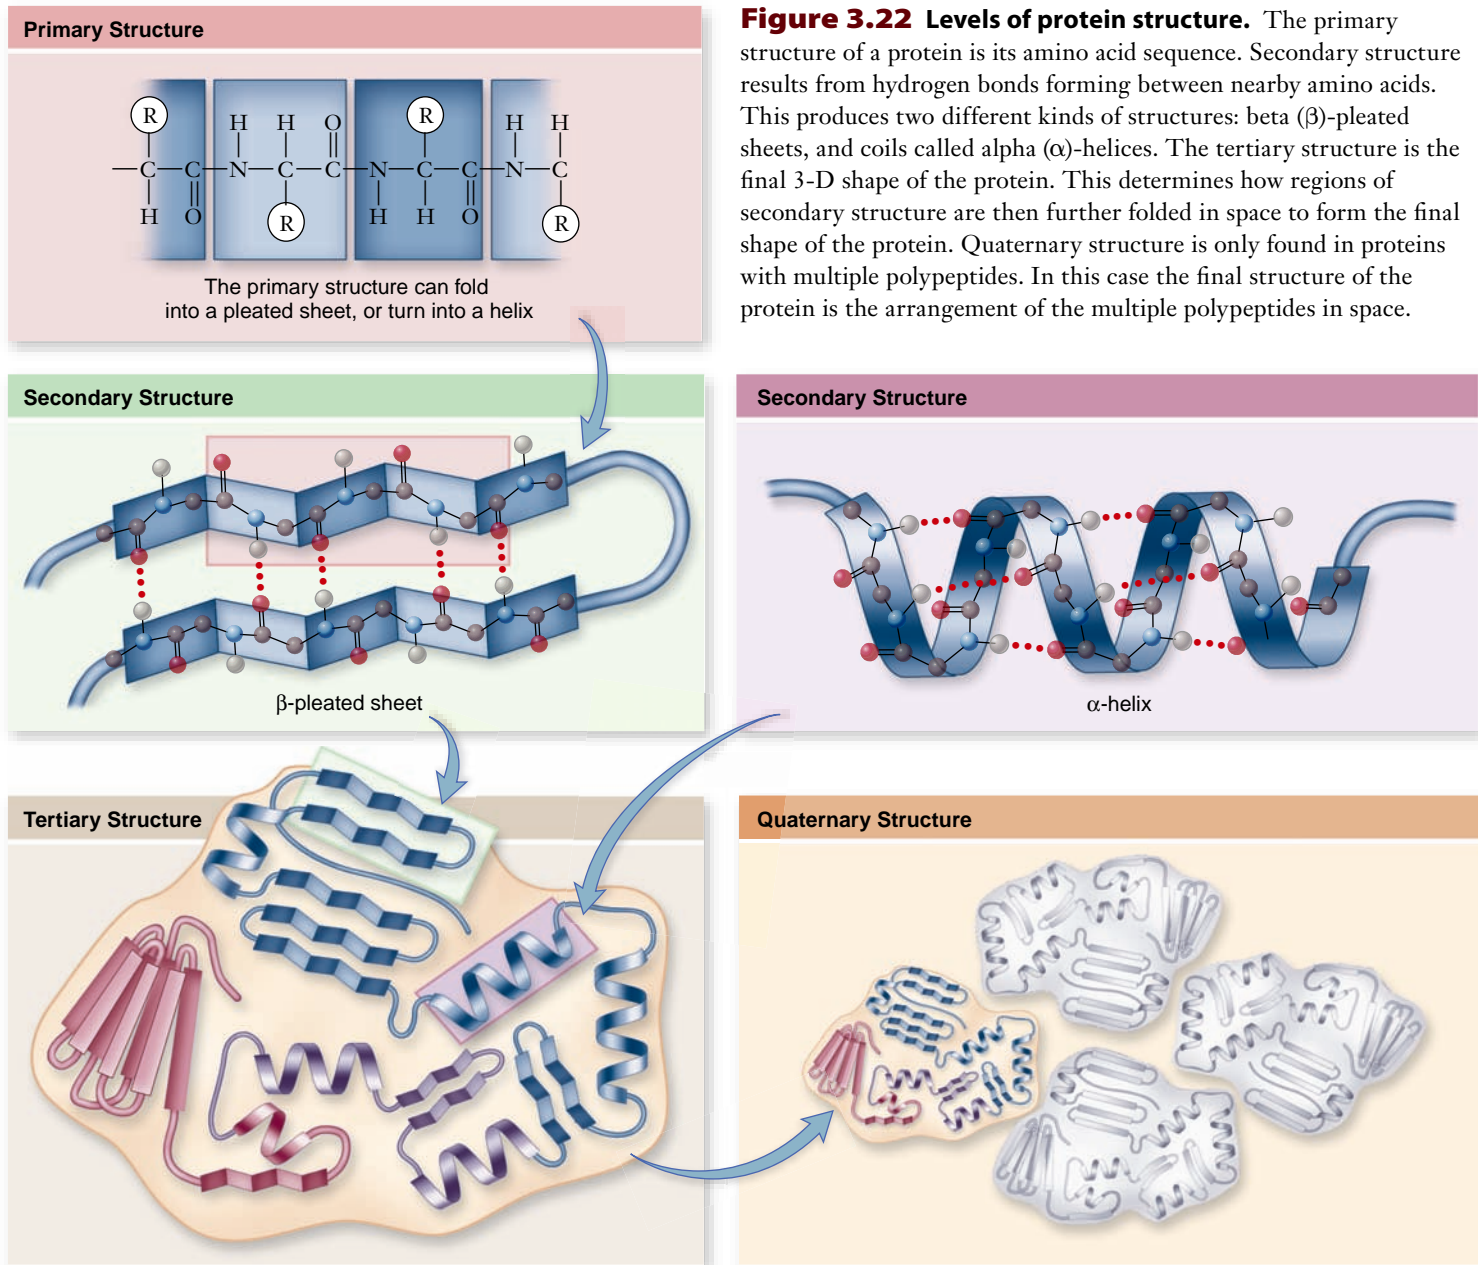

### Tertiary structure: Folds and links

The final folded shape of a globular protein is called its **tertiary structure**. This tertiary structure contains regions that have secondary structure and determines how these are further arranged in space to produce the overall structure. A protein is initially driven into its tertiary structure by hydrophobic exclusion from water. Ionic bonds between oppositely charged

R groups bring regions into close proximity, and disulfide bonds (covalent links between two cysteine R groups) lock particular regions together. The final folding of a protein is determined by its primary structure—the chemical nature of its side groups (see figure 3.21 and 3.22). Many small proteins can be fully unfolded (“denatured”) and will spontaneously refold into their characteristic shape. Other larger proteins tend to associate together and form insoluble clumps when denatured, such as the film that can form when you heat milk for hot chocolate.

The tertiary structure is stabilized by a number of forces including hydrogen bonding between R groups of different amino acids, electrostatic attraction between R groups with opposite charge (also called salt bridges), hydrophobic exclusion of nonpolar R groups, and covalent bonds in the form of disulfides. The stability of a protein, once it has folded into its tertiary shape, is strongly influenced by how well its interior fits together. When two nonpolar chains in the interior are very close together, they experience a form of molecular attraction called van der Waals forces. Individually quite weak, these forces can add up to a strong attraction when many of them come into play, like the combined strength of hundreds of hooks and loops on a strip of Velcro. These forces are effective only over short distances, however. No “holes” or cavities exist in the interior of proteins. The variety of different nonpolar amino acids, with a different-sized R group with its own distinctive shape, allows nonpolar chains to fit very precisely within the protein interior.

It is therefore not surprising that changing a single amino acid can drastically alter the structure, and thus the function of a

**Figure 3.22 Levels of protein structure.** The primary structure of a protein is its amino acid sequence. Secondary structure results from hydrogen bonds forming between nearby amino acids. This produces two different kinds of structures: beta ( $\beta$ )-pleated sheets, and coils called alpha ( $\alpha$ )-helices. The tertiary structure is the final 3-D shape of the protein. This determines how regions of secondary structure are then further folded in space to form the final shape of the protein. Quaternary structure is only found in proteins with multiple polypeptides. In this case the final structure of the protein is the arrangement of the multiple polypeptides in space.

protein. The sickle cell version of hemoglobin (HbS), for example, is a change of a single glutamic acid for a valine in the  $\beta$ -globin chain. This change substitutes a charged amino acid for a nonpolar one on the surface of the protein, leading the protein to become sticky and form clumps. Another variant of hemoglobin called HbE, actually the most common in human populations, causes a change from glutamic acid to lysine at a different site in the  $\beta$ -globin chain. In this case the structural change is not as dramatic, but it still impairs function, resulting in blood disorders called anemia and thalassemia. More than 700 structural variants of hemoglobin are known, with up to 7% of the world's population being carriers of forms that are medically important.

#### **Quaternary structure: Subunit arrangements**

When two or more polypeptide chains associate to form a functional protein, the individual chains are referred to as subunits of

the protein. The arrangement of these subunits is termed its **quaternary structure**. In proteins composed of subunits, the interfaces where the subunits touch one another are often nonpolar, and they play a key role in transmitting information between the subunits about individual subunit activities.

Remember that the protein hemoglobin is composed of two  $\alpha$ -chain subunits and two  $\beta$ -chain subunits. Each  $\alpha$ - and  $\beta$ -globin chain has a primary structure consisting of a specific sequence of amino acids. This then assumes a characteristic secondary structure consisting of  $\alpha$  helices and  $\beta$  sheets that are then arranged into a specific tertiary structure for each  $\alpha$ - and  $\beta$ -globin subunit. Lastly, these subunits are then arranged into their final quaternary structure. This is the final structure of the protein. For proteins that consist of only a single peptide chain, the enzyme lysozyme for example, the tertiary structure is the final structure of the protein.

## Motifs and domains are additional structural characteristics

To directly determine the sequence of amino acids in a protein is a laborious task. Although the process has been automated, it remains slow and difficult.

The ability to sequence DNA changed this situation rather suddenly. Sequencing DNA was a much simpler process, and even before it was automated, the number of known sequences rose quickly. With the advent of automation, the known sequences increased even more dramatically. Today the entire sequence of hundreds of bacterial genomes and more than a dozen animal genomes, including that of humans, has been determined. Because the DNA sequence is directly related to amino acid sequence in proteins, biologists now have a large database of protein sequences to compare and analyze. This new information has also stimulated thought about the logic of the genetic code and whether underlying patterns exist in protein structure. Our view of protein structure has evolved with this new information. Researchers still view the four-part hierarchical structure as important, but two new terms have entered the biologist's vocabulary: motif and domain.

### Motifs

As biologists discovered the 3-D structure of proteins (an even more laborious task than determining the sequence), they noticed similarities between otherwise dissimilar proteins. These similar structures are called **motifs**, or sometimes “supersecondary structure.” The term *motif* is borrowed from the arts and refers to a recurring thematic element in music or design.

One very common protein motif is the  $\beta$ - $\alpha$ - $\beta$  motif, which creates a fold or crease; the so-called “Rossmann fold” at the core of nucleotide-binding sites in a wide variety of proteins. A second motif that occurs in many proteins is the  $\beta$  barrel, which is a  $\beta$  sheet folded around to form a tube. A third type

of motif, the helix-turn-helix, consists of two  $\alpha$  helices separated by a bend. This motif is important because many proteins use it to bind to the DNA double helix (figure 3.23; see also chapter 16).

Motifs indicate a logic to structure that investigators still do not understand. Do they simply represent a reuse by evolution of something that already works, or are they an optimal solution to a problem, such as how to bind a nucleotide? One way to think about it is that if amino acids are letters in the language of proteins, then motifs represent repeated words or phrases. Motifs have been useful in determining the function of unknown proteins. Databases of protein motifs are used to search new unknown proteins. Finding motifs with known functions may allow an investigator to infer the function of a new protein.

### Domains

**Domains** of proteins are functional units within a larger structure. They can be thought of as substructure within the tertiary structure of a protein (see figure 3.23). To continue the metaphor: Amino acids are letters in the protein language, motifs are words or phrases, and domains are paragraphs.

Most proteins are made up of multiple domains that perform different parts of the protein's function. In many cases, these domains can be physically separated. For example, transcription factors (discussed in chapter 16) are proteins that bind to DNA and initiate its transcription. If the DNA-binding region is exchanged with a different transcription factor, then the specificity of the factor for DNA can be changed without changing its ability to stimulate transcription. Such “domain-swapping” experiments have been performed with many transcription factors, and they indicate, among other things, that the DNA-binding and activation domains are functionally separate.

These functional domains of proteins may also help the protein to fold into its proper shape. As a polypeptide chain

**Figure 3.23 Motifs and domains.** The elements of secondary structure can combine, fold, or crease to form motifs. These motifs are found in different proteins and can be used to predict function. Proteins also are made of larger domains, which are functionally distinct parts of a protein. The arrangement of these domains in space is the tertiary structure of a protein.

fold, the domains take their proper shape, each more or less independently of the others. This action can be demonstrated experimentally by artificially producing the fragment of a polypeptide that forms the domain in the intact protein, and showing that the fragment folds to form the same structure as it exhibits in the intact protein. A single polypeptide chain connects the domains of a protein, like a rope tied into several adjacent knots.

Domains can also correspond to the structure of the genes that encode them. Later, in chapter 15, you will see that genes in eukaryotes are often in pieces within the genome, and these pieces, called *exons*, sometimes encode the functional domains of a protein. This finding led to the idea of evolution acting by shuffling protein-encoding domains.

## The process of folding relies on chaperone proteins

Until recently, scientific investigators thought that newly made proteins fold spontaneously, randomly trying out different configurations as hydrophobic interactions with water shoved nonpolar amino acids into the protein's interior until the final structure was arrived at. We now know this view is too simple. Protein chains can fold in so many different ways that trial and error would simply take too long. In addition, as the open chain folds its way toward its final form, nonpolar "sticky" interior portions are exposed during intermediate stages. If these intermediate forms are placed in a test tube in an environment identical to that inside a cell, they stick to other, unwanted protein partners, forming a gluey mess.

How do cells avoid having their proteins clump into a mass? A vital clue came in studies of unusual mutations that prevent viruses from replicating in bacterial cells. It turns out that the virus proteins produced inside the cells could not fold properly. Further study revealed that normal cells contain **chaperone proteins**, which help other proteins to fold correctly.

Molecular biologists have now identified many proteins that act as molecular chaperones. This class of proteins has

multiple subclasses, and representatives have been found in essentially every organism that has been examined. Furthermore, these proteins seem to be essential for viability as well, illustrating their fundamental importance. Many are heat shock proteins, produced in greatly increased amounts when cells are exposed to elevated temperature. High temperatures cause proteins to unfold, and heat shock chaperone proteins help the cell's proteins to refold properly.

One class of these proteins, called chaperonins, has been extensively studied. In the bacterium *Escherichia coli* (*E. coli*), one example is the essential protein GroE chaperonin. In mutants in which the GroE chaperonin is inactivated, fully 30% of the bacterial proteins fail to fold properly. Chaperonins associate to form a large macromolecular complex that resembles a cylindrical container. Proteins can move into the container, and the container itself can change its shape considerably (figure 3.24). Experiments have shown that an improperly folded protein can enter the chaperonin and be refolded. Although we don't know exactly how this happens, it seems to involve changes in the hydrophobicity of the interior of the chamber.

The flexibility of the structure of chaperonins is amazing. We tend to think of proteins as being fixed structures, but this is clearly not the case for chaperonins and this flexibility is necessary for their function. It also illustrates that even domains that may be very widely separated in a very large protein are still functionally connected. The folding process within a chaperonin harnesses the hydrolysis of ATP to power these changes in structure necessary for function. This entire process can occur in a cyclic manner until the appropriate structure is achieved. Cells use these chaperonins both to accomplish the original folding of some proteins and to restore the structure of incorrectly folded ones.

## Some diseases may result from improper folding

Chaperone protein deficiencies may be implicated in certain diseases in which key proteins are improperly folded. Cystic fibrosis

**Figure 3.24** How one type of chaperone protein works. This barrel-shaped chaperonin is from the GroE family of chaperone proteins. It is composed of two identical rings each with seven identical subunits, each of which has three distinct domains. An incorrectly folded protein enters one chamber of the barrel, and a cap seals the chamber. Energy from the hydrolysis of ATP fuels structural alterations to the chamber, changing it from hydrophobic to hydrophilic. This change allows the protein to refold. After a short time, the protein is ejected, either folded or unfolded, and the cycle can repeat itself.

is a hereditary disorder in which a mutation disables a vital protein that moves ions across cell membranes. As a result, people with cystic fibrosis have thicker than normal mucus. This results in breathing problems, lung disease, and digestive difficulties, among other things. One interesting feature of the molecular analysis of this disease has been the number of different mutations found in human populations. One diverse class of mutations all result in problems with protein folding. The number of different mutations that can result in improperly folded proteins may be related to the fact that the native protein often fails to fold properly.

### Denaturation inactivates proteins

If a protein's environment is altered, the protein may change its shape or even unfold completely. This process is called **denaturation** (figure 3.25). Proteins can be denatured when the pH, temperature, or ionic concentration of the surrounding solution changes.

Denatured proteins are usually biologically inactive. This action is particularly significant in the case of enzymes. Because practically every chemical reaction in a living organism is catalyzed by a specific enzyme, it is vital that a cell's enzymes work properly.

The traditional methods of food preservation, salt curing and pickling, involve denaturation of proteins. Prior to the general availability of refrigerators and freezers, the only practical

**Figure 3.25 Protein denaturation.** Changes in a protein's environment, such as variations in temperature or pH, can cause a protein to unfold and lose its shape in a process called denaturation. In this denatured state, proteins are biologically inactive.

### SCIENTIFIC THINKING

**Hypothesis:** *The 3-D structure of a protein is the thermodynamically stable structure. It depends only on the primary structure of the protein and the solution conditions.*

**Prediction:** *If a protein is denatured and allowed to renature under native conditions, it will refold into the native structure.*

**Test:** *Ribonuclease is treated with a reducing agent to break disulfide bonds and is then treated with urea to completely unfold the protein. The disulfide bonds are reformed under nondenaturing conditions to see if the protein refolds properly.*

**Result:** *Denatured Ribonuclease refolds properly under nondenaturing conditions.*

**Conclusion:** *The hypothesis is supported. The information in the primary structure (amino acid sequence) is sufficient for refolding to occur. This implies that protein folding results in the thermodynamically stable structure.*

**Further Experiments:** *If the disulfide bonds were allowed to reform under denaturing conditions, would we get the same result? How can we rule out that the protein had not been completely denatured and therefore retained some structure?*

**Figure 3.26 Primary structure determines tertiary structure.**

## 3.5 Lipids: Hydrophobic Molecules

way to keep microorganisms from growing in food was to keep the food in a solution containing a high concentration of salt or vinegar, which denatured the enzymes of most microorganisms and prevented them from growing on the food.

Most enzymes function within a very narrow range of environmental conditions. Blood-borne enzymes that course through a human body at a pH of about 7.4 would rapidly become denatured in the highly acidic environment of the stomach. Conversely, the protein-degrading enzymes that function at a pH of 2 or less in the stomach would be denatured in the relatively basic pH of the blood. Similarly, organisms that live near oceanic hydrothermal vents have enzymes that work well at these extremes of temperature (over 100°C). They cannot survive in cooler waters, because their enzymes do not function properly at lower temperatures. Any given organism usually has a tolerance range of pH, temperature, and salt concentration. Within that range, its enzymes maintain the proper shape to carry out their biological functions.

When a protein's normal environment is reestablished after denaturation, a small protein may spontaneously refold into its natural shape, driven by the interactions between its nonpolar amino acids and water (figure 3.26). This process is termed *renaturation*, and it was first established for the enzyme ribonuclease (RNase). The renaturation of RNase led to the doctrine that primary structure determines tertiary structure. Larger proteins can rarely refold spontaneously, however, because of the complex nature of their final shape, so this simple idea needs to be qualified.

The fact that some proteins can spontaneously renature implies that tertiary structure is strongly influenced by primary structure. In an extreme example, the *E. coli* ribosome can be taken apart and put back together experimentally. Although this process requires temperature and ion concentration shifts, it indicates an amazing degree of self-assembly. That complex structures can arise by self-assembly is a key idea in the study of modern biology.

It is important to distinguish denaturation from **dissociation**. For proteins with quaternary structure, the subunits may be dissociated without losing their individual tertiary structure. For example, the four subunits of hemoglobin may dissociate into four individual molecules (two  $\alpha$ -globins and two  $\beta$ -globins) without denaturation of the folded globin proteins. They readily reassume their four-subunit quaternary structure.

### Learning Outcomes Review 3.4

Proteins are molecules with diverse functions. They are constructed from 20 different kinds of amino acids. Protein structure can be viewed at four levels: (1) the amino acid sequence, or primary structure; (2) coils and sheets, called secondary structure; (3) the three-dimensional shape, called tertiary structure; and (4) individual polypeptide subunits associated in a quaternary structure. Different proteins often have similar substructures called motifs and can be broken down into functional domains. Proteins have a narrow range of conditions in which they fold properly; outside that range, proteins tend to unfold (denaturation). Under some conditions, denatured proteins can refold and become functional again (renaturation).

- How does our knowledge of protein structure help us to predict the function of unknown proteins?

### Learning Outcomes

1. Understand the structure of triglycerides.
2. Explain how fats function as energy-storage molecules.
3. Apply knowledge of the structure of phospholipids to the formation of membranes.

**Lipids** are a somewhat loosely defined group of molecules with one main chemical characteristic: They are insoluble in water. Storage fats such as animal fat are one kind of lipid. Oils such as those from olives, corn, and coconut are also lipids, as are waxes such as beeswax and earwax. Even some vitamins are lipids!

Lipids have a very high proportion of nonpolar carbon-hydrogen (C—H) bonds, and so long-chain lipids cannot fold up like a protein to confine their nonpolar portions away from the surrounding aqueous environment. Instead, when they are placed in water, many lipid molecules spontaneously cluster together and expose what polar (hydrophilic) groups they have to the surrounding water, while confining the nonpolar (hydrophobic) parts of the molecules together within the cluster. You may have noticed this effect when you add oil to a pan containing water, and the oil beads up into cohesive drops on the water's surface. This spontaneous assembly of lipids is of paramount importance to cells, as it underlies the structure of cellular membranes.

### Fats consist of complex polymers of fatty acids attached to glycerol

Many lipids are built from a simple skeleton made up of two main kinds of molecules: fatty acids and glycerol. Fatty acids are long-chain hydrocarbons with a carboxylic acid (COOH) at one end. Glycerol is a three-carbon polyalcohol (three —OH groups). Many lipid molecules consist of a glycerol molecule with three fatty acids attached, one to each carbon of the glycerol backbone. Because it contains three fatty acids, a fat molecule is commonly called a **triglyceride** (the more accurate chemical name is *triacylglycerol*). This basic structure is depicted in figure 3.27. The three fatty acids of a triglyceride need not be identical, and often they are very different from one another. The hydrocarbon chains of fatty acids vary in length. The most common are even-numbered chains of 14 to 20 carbons. The many C—H bonds of fats serve as a form of long-term energy storage.

If all of the internal carbon atoms in the fatty acid chains are bonded to at least two hydrogen atoms, the fatty acid is said to be **saturated**, which refers to its having all the hydrogen atoms possible (see figure 3.27). A fatty acid that has double bonds between one or more pairs of successive carbon atoms is said to be **unsaturated**. Fatty acids with one double bond are called monounsaturated, and those with more than one double bond are termed **polyunsaturated**. Most naturally occurring unsaturated fatty acids have double bonds with a *cis* configuration where the carbon chain is on the same side before and after the double bond (double bonds in fatty acids in 3.27*b* are all *cis*).

*a.*

**Figure 3.27 Saturated and unsaturated fats.** *a.* A saturated fat is composed of triglycerides that contain three saturated fatty acids (the kind that have no double bonds). A saturated fat therefore has the maximum number of hydrogen atoms bonded to its carbon chain. Most animal fats are saturated. *b.* Unsaturated fat is composed of triglycerides that contain three unsaturated fatty acids (the kind that have one or more double bonds). These have fewer than the maximum number of hydrogen atoms bonded to the carbon chain. This example includes both a monounsaturated and two polyunsaturated fatty acids. Plant fats are typically unsaturated. The many kinks of the double bonds prevent the triglyceride from closely aligning, which makes them liquid oils at room temperature.

*b.*

When fats are partially hydrogenated industrially, this can produce double bonds with a *trans* configuration where the carbon chain is on opposite sides before and after the double bond. These are the so called *trans* fats. These have been linked to elevated levels of low-density lipoprotein (LDL) “bad cholesterol” and lowered levels of high-density lipoprotein (HDL) “good cholesterol.” This condition is thought to be associated with an increased risk for coronary heart disease.

Having double bonds changes the behavior of the molecule because free rotation cannot occur about a C=C double bond as it can with a C—C single bond. This characteristic mainly affects melting point: that is, whether the fatty acid is a solid fat or a liquid oil at room temperature. Fats containing polyunsaturated fatty acids have low melting points because their fatty acid chains bend at the double bonds, preventing the fat molecules from aligning closely with one another. Most saturated fats, such as animal fat or those in butter, are solid at room temperature.

Placed in water, triglycerides spontaneously associate together, forming fat globules that can be very large relative to the size of the individual molecules. Because fats are insoluble in water, they can be deposited at specific locations within an organism, such as in vesicles of adipose tissue.

Organisms contain many other kinds of lipids besides fats (figure 3.28). *Terpenes* are long-chain lipids that are components of many biologically important pigments, such as chlorophyll and the visual pigment retinal. Rubber is also a terpene. *Steroids*, another class of lipid, are composed of four carbon rings. Most animal cell membranes contain the steroid cholesterol. Other steroids, such as testosterone and estrogen, function as hormones in multicellular animals. *Prostaglandins* are a group of about 20 lipids that are modified fatty acids, with two nonpolar “tails” attached to a five-carbon ring. Prostaglandins act as local chemical messengers in many vertebrate tissues. Later chapters explore the effects of some of these complex fatty acids.

### Fats are excellent energy-storage molecules

Most fats contain over 40 carbon atoms. The ratio of energy-storing C—H bonds in fats is more than twice that of carbohydrates (see section 3.2), making fats much more efficient molecules for storing chemical energy. On average, fats yield about 9 kilocalories (kcal) of chemical energy per gram, as compared with about 4 kcal/g for carbohydrates.

Most fats produced by animals are saturated (except some fish oils), whereas most plant fats are unsaturated (see

a. Terpene (citronellol)

b. Steroid (cholesterol)

**Figure 3.28 Other kinds of lipids.** a. Terpenes are found in biological pigments, such as chlorophyll and retinal, and (b) steroids play important roles in membranes and as the basis for a class of hormones involved in chemical signaling.

figure 3.27). The exceptions are the tropical plant oils (palm oil and coconut oil), which are saturated even though they are liquid at room temperature. An oil may be converted into a solid fat by chemically adding hydrogen. Most peanut butter is usually artificially hydrogenated to make the peanut fats solidify, preventing them from separating out as oils while the jar sits on the store shelf. However, artificially hydrogenating unsaturated fats produces the *trans*-fatty acids described above.

When an organism consumes excess carbohydrate, it is converted into starch, glycogen, or fats reserved for future use. The reason that many humans in developed countries gain weight as

they grow older is that the amount of energy they need decreases with age, but their intake of food does not. Thus, an increasing proportion of the carbohydrates they ingest is converted into fat.

A diet heavy in fats is one of several factors thought to contribute to heart disease, particularly atherosclerosis. In atherosclerosis, sometimes referred to as “hardening of the arteries,” fatty substances called plaque adhere to the lining of blood vessels, blocking the flow of blood. Fragments of a plaque can break off from a deposit and clog arteries to the brain, causing a stroke.

## Phospholipids form membranes

Complex lipid molecules called **phospholipids** are among the most important molecules of the cell because they form the core of all biological membranes. An individual phospholipid can be thought of as a substituted triglyceride, that is, a triglyceride with a phosphate replacing one of the fatty acids. The basic structure of a phospholipid includes three kinds of subunits:

1. *Glycerol*, a three-carbon alcohol, in which each carbon bears a hydroxyl group. Glycerol forms the backbone of the phospholipid molecule.
2. *Fatty acids*, long chains of  $-\text{CH}_2$  groups (hydrocarbon chains) ending in a carboxyl ( $-\text{COOH}$ ) group. Two fatty acids are attached to the glycerol backbone in a phospholipid molecule.
3. A *phosphate group* ( $-\text{PO}_4^{2-}$ ) attached to one end of the glycerol. The charged phosphate group usually has a charged organic molecule linked to it, such as choline, ethanolamine, or the amino acid serine.

The phospholipid molecule can be thought of as having a polar “head” at one end (the phosphate group) and two long, very nonpolar “tails” at the other (figure 3.29). This structure is essential for how these molecules function, although it first

**Figure 3.29 Phospholipids.**

The phospholipid phosphatidylcholine is shown as (a) a schematic, (b) a formula, (c) a space-filling model, and (d) an icon used in depictions of biological membranes.

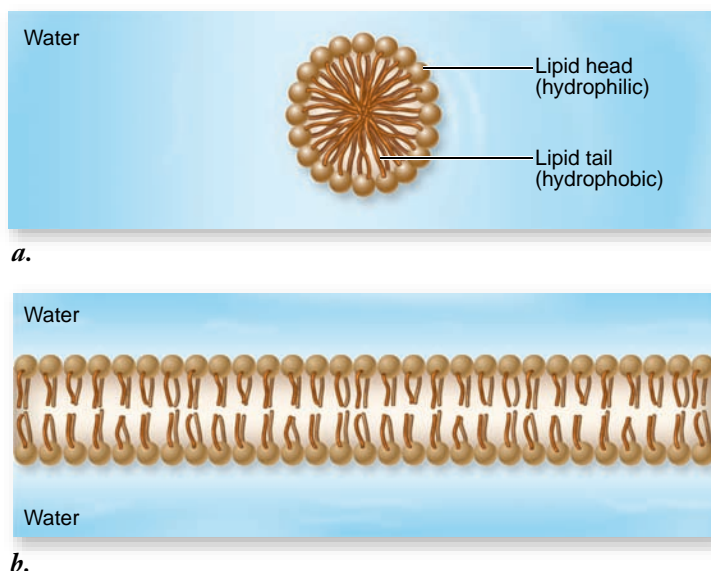

appears paradoxical. Why would a molecule need to be soluble in water, but also not soluble in water? The formation of a membrane shows the unique properties of such a structure.

In water, the nonpolar tails of nearby lipid molecules aggregate away from the water, forming spherical *micelles*, with the tails facing inward (figure 3.30*a*). This is actually how detergent molecules work to make grease soluble in water. The grease is soluble within the nonpolar interior of the micelle and the polar surface of the micelle is soluble in water. With phospholipids, a more complex structure forms in which two layers of molecules line up, with the hydrophobic tails of each layer pointing toward one another, or inward, leaving the hydrophilic heads oriented outward, forming a bilayer (figure 3.30*b*). Lipid bilayers are the basic framework of biological membranes, discussed in detail in chapter 5.

### Learning Outcomes Review 3.5

Triglycerides are made of fatty acids linked to glycerol. Fats can contain twice as many C—H bonds as carbohydrates and thus they store energy efficiently. Because the C—H bonds in lipids are nonpolar, they are not water-soluble and aggregate together in water. Phospholipids replace one fatty acid with a hydrophilic phosphate group. This allows them to spontaneously form bilayers, which are the basis of biological membranes.

- **Why do phospholipids form membranes while triglycerides form insoluble droplets?**

**Figure 3.30 Lipids spontaneously form micelles or lipid bilayers in water.** In an aqueous environment, lipid molecules orient so that their polar (hydrophilic) heads are in the polar medium, water, and their nonpolar (hydrophobic) tails are held away from the water. *a.* Droplets called micelles can form, or *(b)* phospholipid molecules can arrange themselves into two layers; in both structures, the hydrophilic heads extend outward and the hydrophobic tails inward. This second example is called a phospholipid bilayer.

## Chapter Review

### 3.1 Carbon: The Framework of Biological Molecules

Carbon, the backbone of all biological molecules, can form four covalent bonds and make long chains. Hydrocarbons consist of carbon and hydrogen, and their bonds store considerable energy.

#### Functional groups account for differences in molecular properties.

Functional groups are small molecular entities that confer specific chemical characteristics when attached to a hydrocarbon.

Carbon and hydrogen have similar electronegativity so C—H bonds are not polar. Oxygen and nitrogen have greater electronegativity, leading to polar bonds.

#### Isomers have the same molecular formulas but different structures.

Structural isomers are molecules with the same formula but different structures; stereoisomers differ in how groups are attached. Enantiomers are mirror-image stereoisomers.

#### Biological macromolecules include carbohydrates, nucleic acids, proteins, and lipids.

Most important biological macromolecules are polymers—long chains of monomer units. Biological polymers are formed by elimination of water (H and OH) from two monomers (dehydration reaction). They are broken down by adding water (hydrolysis).

### 3.2 Carbohydrates: Energy Storage and Structural Molecules

The empirical formula of a carbohydrate is  $(\text{CH}_2\text{O})_n$ . Carbohydrates are used for energy storage and as structural molecules.

#### Monosaccharides are simple sugars.

Simple sugars contain three to six or more carbon atoms. Examples are glyceraldehyde (3 carbons), deoxyribose (5 carbons), and glucose (6 carbons).

#### Sugar isomers have structural differences.

The general formula for six-carbon sugars is  $\text{C}_6\text{H}_{12}\text{O}_6$ , and many isomeric forms are possible. Living systems often have enzymes for converting isomers from one to the other.

#### Disaccharides serve as transport molecules in plants and provide nutrition in animals.

Plants convert glucose into the disaccharide sucrose for transport within their bodies. Female mammals produce the disaccharide lactose to nourish their young.

#### Polysaccharides provide energy storage and structural components.

Glucose is used to make three important polymers: glycogen (in animals), and starch and cellulose (in plants). Chitin is a related structural material found in arthropods and many fungi.

### 3.3 Nucleic Acids: Information Molecules

Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are polymers composed of nucleotide monomers. Cells use nucleic acids for information storage and transfer.

#### **Nucleic acids are nucleotide polymers.**

Nucleic acids contain four different nucleotide bases. In DNA these are adenine, guanine, cytosine, and thymine. In RNA, thymine is replaced by uracil.

#### **DNA carries the genetic code.**

DNA exists as a double helix held together by specific base pairs: adenine with thymine and guanine with cytosine. The nucleic acid sequence constitutes the genetic code.

#### **RNA is a transcript of a DNA strand.**

RNA is made by copying DNA. This transcript is then used as a template to make proteins.

#### **Other nucleotides are vital components of energy reactions.**

Adenosine triphosphate (ATP) provides energy in cells; NAD<sup>+</sup> and FAD transport electrons in cellular processes.

### 3.4 Proteins: Molecules with Diverse Structures and Functions

Most enzymes are proteins. Proteins also provide defense, transport, motion, and regulation, among many other roles.

#### **Proteins are polymers of amino acids.**

Amino acids are joined by peptide bonds to make polypeptides. The 20 common amino acids are characterized by R groups that determine their properties.

#### **Proteins have levels of structure.**

Protein structure is defined by the following hierarchy: primary (amino acid sequence), secondary (hydrogen bonding patterns), tertiary (three-dimensional folding), and quaternary (associations between two or more polypeptides).

#### **Motifs and domains are additional structural characteristics.**

Motifs are similar structural elements found in dissimilar proteins. They can create folds, creases, or barrel shapes. Domains are functional subunits or sites within a tertiary structure.

#### **The process of folding relies on chaperone proteins.**

Chaperone proteins assist in the folding of proteins. Heat shock proteins are an example of chaperone proteins.

#### **Some diseases may result from improper folding.**

Some forms of cystic fibrosis and Alzheimer disease are associated with misfolded proteins.

#### **Denaturation inactivates proteins.**

Denaturation refers to an unfolding of tertiary structure, which usually destroys function. Some denatured proteins may recover function when conditions are returned to normal. This implies that primary structure strongly influences tertiary structure.

Disassociation refers to separation of quaternary subunits with no changes to their tertiary structure.

### 3.5 Lipids: Hydrophobic Molecules

Lipids are insoluble in water because they have a high proportion of nonpolar C—H bonds.

#### **Fats consist of complex polymers of fatty acids attached to glycerol.**

Many lipids exist as triglycerides, three fatty acids connected to a glycerol molecule. Saturated fatty acids contain the maximum number of hydrogen atoms. Unsaturated fatty acids contain one or more double bonds between carbon atoms.

#### **Fats are excellent energy-storage molecules.**

The energy stored in the C—H bonds of fats is more than twice that of carbohydrates: 9 kcal/g compared with 4 kcal/g. For this reason, excess carbohydrate is converted to fat for storage.

#### **Phospholipids form membranes**

Phospholipids contain two fatty acids and one phosphate attached to glycerol. In phospholipid-bilayer membranes, the phosphate heads are hydrophilic and cluster on the two faces of the membrane, and the hydrophobic tails are in the center.

## Review Questions

### UNDERSTAND

- How is a polymer formed from multiple monomers?
  - From the growth of the chain of carbon atoms
  - By the removal of an —OH group and a hydrogen atom
  - By the addition of an —OH group and a hydrogen atom
  - Through hydrogen bonding
- Why are carbohydrates important molecules for energy storage?
  - The C—H bonds found in carbohydrates store energy.
  - The double bonds between carbon and oxygen are very strong.
  - The electronegativity of the oxygen atoms means that a carbohydrate is made up of many polar bonds.
  - They can form ring structures in the aqueous environment of a cell.
- Plant cells store energy in the form of \_\_\_\_\_, and animal cells store energy in the form of \_\_\_\_\_.
  - fructose; glucose
  - disaccharides; monosaccharides
  - cellulose; chitin
  - starch; glycogen
- Which carbohydrate would you find as part of a molecule of RNA?
  - Galactose
  - Deoxyribose
  - Ribose
  - Glucose
- A molecule of DNA or RNA is a polymer of
  - monosaccharides.
  - nucleotides.
  - amino acids.
  - fatty acids.

6. What makes cellulose different from starch?
  - a. Starch is produced by plant cells, and cellulose is produced by animal cells.
  - b. Cellulose forms long filaments, and starch is highly branched.
  - c. Starch is insoluble, and cellulose is soluble.
  - d. All of the above.
7. What monomers make up a protein?
  - a. Monosaccharides
  - b. Nucleotides
  - c. Amino acids
  - d. Fatty acids
8. A triglyceride is a form of \_\_\_\_\_ composed of \_\_\_\_\_.
  - a. lipid; fatty acids and glucose
  - b. lipid; fatty acids and glycerol
  - c. carbohydrate; fatty acids
  - d. lipid; cholesterol
9. What are the functions of lipids?
  - c. very different functions.
  - d. the same primary structure but different function.
6. What chemical property of lipids accounts for their insolubility in water?
  - a. The COOH group of fatty acids
  - b. The large number of nonpolar C—H bonds
  - c. The branching of saturated fatty acids
  - d. The C=C bonds found in unsaturated fatty acids
7. The spontaneous formation of a lipid bilayer in an aqueous environment occurs because
  - a. the polar head groups of the phospholipids can interact with water.
  - b. the long fatty acid tails of the phospholipids can interact with water.
  - c. the fatty acid tails of the phospholipids are hydrophobic.
  - d. both a and c.

## APPLY

1. Amino acids are linked together to form a protein by
  - a. phosphodiester bonds.
  - b.  $\beta$ -(1 $\rightarrow$ 4) linkages.
  - c. peptide bonds.
  - d. hydrogen bonds.
2. Which of the following is NOT a difference between DNA and RNA?
  - a. Deoxyribose sugar versus ribose sugar
  - b. Thymine versus uracil
  - c. Double-stranded versus single-stranded
  - d. Phosphodiester versus hydrogen bonds
3. Which part of an amino acid has the greatest influence on the overall structure of a protein?
  - a. The ( $-\text{NH}_2$ ) amino group
  - b. The R group
  - c. The ( $-\text{COOH}$ ) carboxyl group
  - d. Both a and c
4. A mutation that alters a single amino acid within a protein can alter
  - a. the primary level of protein structure.
  - b. the secondary level of protein structure.
  - c. the tertiary level of protein structure.
  - d. all of the above.
5. Two different proteins have the same domain in their structure. From this we can infer that they have
  - a. the same primary structure.
  - b. similar function.

## SYNTHESIZE

1. How do the four biological macromolecules differ from one another? How does the structure of each relate to its function?
2. Hydrogen bonds and hydrophobic interactions each play an important role in stabilizing and organizing biological macromolecules. Consider the four macromolecules discussed in this chapter. Describe how these affect the form and function of each type of macromolecule. Would a disruption in the hydrogen bonds affect form and function? Hydrophobic interactions?
3. Plants make both starch and cellulose. Would you predict that the enzymes involved in starch synthesis could also be used by the plant for cellulose synthesis? Construct an argument to explain this based on the structure and function of the enzymes and the polymers synthesized.

## Chapter 4

## Cell Structure

## Chapter Outline

- 4.1 Cell Theory
- 4.2 Prokaryotic Cells
- 4.3 Eukaryotic Cells
- 4.4 The Endomembrane System
- 4.5 Mitochondria and Chloroplasts: Cellular Generators
- 4.6 The Cytoskeleton
- 4.7 Extracellular Structures and Cell Movement
- 4.8 Cell-to-Cell Interactions

## Introduction

All organisms are composed of cells. The gossamer wing of a butterfly is a thin sheet of cells and so is the glistening outer layer of your eyes. The hamburger or tomato you eat is composed of cells, and its contents soon become part of your cells. Some organisms consist of a single cell too small to see with the unaided eye. Others, such as humans, are composed of many specialized cells, such as the fibroblast cell shown in the striking fluorescence micrograph on this page. Cells are so much a part of life that we cannot imagine an organism that is not cellular in nature. In this chapter, we take a close look at the internal structure of cells. In chapters 4 to 10, we will focus on cells in action—how they communicate with their environment, grow, and reproduce.

## 4.1 Cell Theory

## Learning Outcomes

1. Explain the cell theory.
2. Describe the factors that limit cell size.
3. Categorize structural and functional similarities in cells.

Cells are characteristically microscopic in size. Although there are exceptions, a typical eukaryotic cell is 10 to 100 micrometers ( $\mu\text{m}$ ) (10 to 100 millionths of a meter) in diameter, while most prokaryotic cells are only 1 to 10  $\mu\text{m}$  in diameter.

Because cells are so small, they were not discovered until the invention of the microscope in the 17th century. Robert Hooke was the first to observe cells in 1665, naming the shapes he saw in cork *cellulae* (Latin, “small rooms”). This is known to us as *cells*. Another early microscopist, Anton van Leeuwenhoek first observed living cells, which he termed “animalcules,” or little animals. After these early efforts, a century and a half

passed before biologists fully recognized the importance of cells. In 1838, botanist Matthias Schleiden stated that all plants “are aggregates of fully individualized, independent, separate beings, namely the cells themselves.” In 1839, Theodor Schwann reported that all animal tissues also consist of individual cells. Thus, the cell theory was born.

## Cell theory is the unifying foundation of cell biology

The cell theory was proposed to explain the observation that all organisms are composed of cells. It sounds simple, but it is a far-reaching statement about the organization of life.

In its modern form, the *cell theory* includes the following three principles:

1. All organisms are composed of one or more cells, and the life processes of metabolism and heredity occur within these cells.
2. Cells are the smallest living things, the basic units of organization of all organisms.
3. Cells arise only by division of a previously existing cell.

Although life likely evolved spontaneously in the environment of early Earth, biologists have concluded that no additional cells are originating spontaneously at present. Rather, life on Earth represents a continuous line of descent from those early cells.

## Cell size is limited

Most cells are relatively small for reasons related to the diffusion of substances into and out of cells. The rate of diffusion is affected by a number of variables, including (1) surface area available for diffusion, (2) temperature, (3) concentration gradient of diffusing substance, and (4) the distance over which diffusion must occur. As the size of a cell increases, the length of time for diffusion from the outside membrane to the interior of the cell increases as well. Larger cells need to synthesize more macromolecules, have correspondingly higher energy requirements, and produce a greater quantity of waste. Molecules used for energy and biosynthesis must be transported through the membrane. Any metabolic waste produced must be removed, also passing through the membrane. The rate at which this transport occurs depends on both the distance to the membrane and the area of membrane available. For this reason, an organism made up of many relatively small cells has an advantage over one composed of fewer, larger cells.

The advantage of small cell size is readily apparent in terms of the **surface area-to-volume ratio**. As a cell’s size increases, its volume increases much more rapidly than its surface area. For a spherical cell, the surface area is proportional to the square of the radius, whereas the volume is proportional to the cube of the radius. Thus, if the radii of two cells differ by a factor of 10, the larger cell will have  $10^2$ , or 100 times, the surface area, but  $10^3$ , or 1000 times, the volume of the smaller cell (figure 4.1).

The cell surface provides the only opportunity for interaction with the environment, because all substances enter and exit a cell via this surface. The membrane surrounding the cell

**Figure 4.1 Surface area-to-volume ratio.** As a cell gets larger, its volume increases at a faster rate than its surface area. If the cell radius increases by 10 times, the surface area increases by 100 times, but the volume increases by 1000 times. A cell’s surface area must be large enough to meet the metabolic needs of its volume.

Cell radius ( $r$ )	1 unit	10 unit
Surface area ( $4\pi r^2$ )	12.57 unit <sup>2</sup>	1257 unit <sup>2</sup>
Volume ( $\frac{4}{3}\pi r^3$ )	4.189 unit <sup>3</sup>	4189 unit <sup>3</sup>
Surface Area / Volume	3	0.3

plays a key role in controlling cell function. Because small cells have more surface area per unit of volume than large ones, control over cell contents is more effective when cells are relatively small.

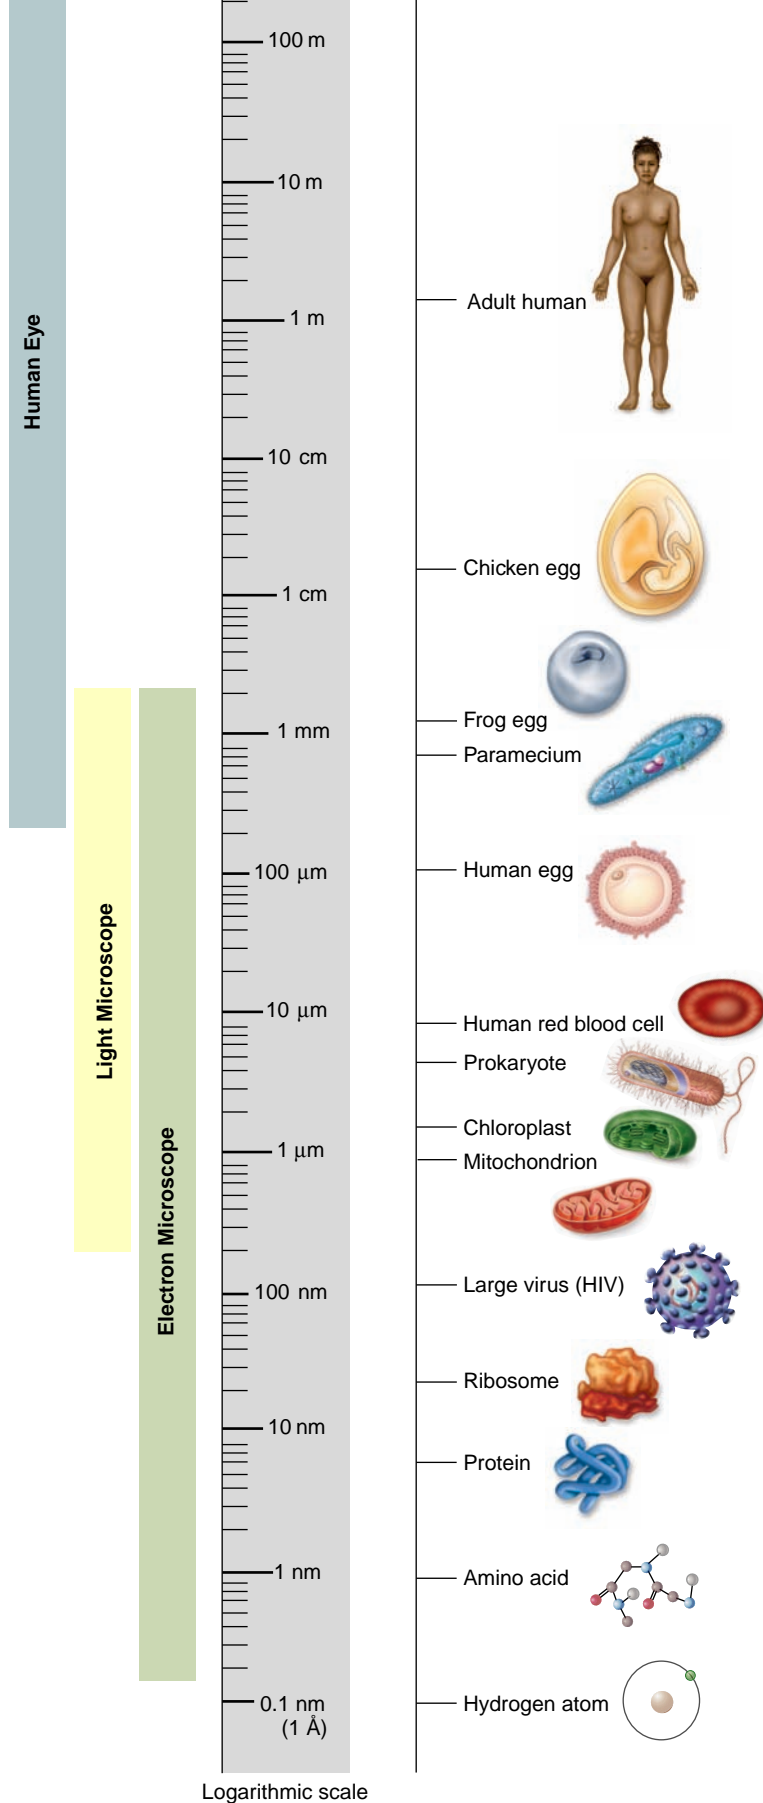

Although most cells are small, some quite large cells do exist. These cells have apparently overcome the surface area-to-volume problem by one or more adaptive mechanisms. For example, some cells, such as skeletal muscle cells, have more than one nucleus, allowing genetic information to be spread around a large cell. Some other large cells, such as neurons, are long and skinny, so that any given point within the cell is close to the plasma membrane. This permits diffusion between the inside and outside of the cell to still be rapid.

## Microscopes allow visualization of cells and components

Other than egg cells, not many cells are visible to the naked eye (figure 4.2). Most are less than 50  $\mu\text{m}$  in diameter, far smaller than the period at the end of this sentence. So, to visualize cells we need the aid of technology. The development of microscopes and their refinement over the centuries has allowed us to continually explore cells in greater detail.

### The resolution problem

How do we study cells if they are too small to see? The key is to understand why we can’t see them. The reason we can’t see such small objects is the limited resolution of the human eye. *Resolution* is the minimum distance two points can be apart and still be distinguished as two separate points. When two objects are closer together than about 100  $\mu\text{m}$ , the light reflected from each strikes the same photoreceptor cell at the rear of the eye. Only when the objects are farther than 100  $\mu\text{m}$  apart can the light from each strike different cells, allowing your eye to resolve them as two distinct objects rather than one.

**Figure 4.2 The size of cells and their contents.** Except for vertebrate eggs, which can typically be seen with the unaided eye, most cells are microscopic in size. Prokaryotic cells are generally 1 to 10  $\mu\text{m}$  across.  
 $1 \text{ m} = 10^2 \text{ cm} = 10^3 \text{ mm} = 10^6 \mu\text{m} = 10^9 \text{ nm}$

### Types of microscopes

One way to overcome the limitations of our eyes is to increase magnification so that small objects appear larger. The first microscopists used glass lenses to magnify small cells and cause them to appear larger than the 100- $\mu\text{m}$  limit imposed by the human eye. The glass lens increases focusing power. Because the glass lens makes the object appear closer, the image on the back of the eye is bigger than it would be without the lens.

Modern *light microscopes*, which operate with visible light, use two magnifying lenses (and a variety of correcting lenses) to achieve very high magnification and clarity (table 4.1). The first lens focuses the image of the object on the second lens, which magnifies it again and focuses it on the back of the eye. Microscopes that magnify in stages using several lenses are called *compound microscopes*. They can resolve structures that are separated by at least 200 nanometers (nm).

Light microscopes, even compound ones, are not powerful enough to resolve many of the structures within cells. For example, a cell membrane is only 5 nm thick. Why not just add another magnifying stage to the microscope to increase its resolving power? This doesn't work because when two objects are closer than a few hundred nanometers, the light beams reflecting from the two images start to overlap each other. The only way two light beams can get closer together and still be resolved is if their wavelengths are shorter. One way to avoid overlap is by using a beam of electrons rather than a beam of light. Electrons have a much shorter wavelength, and an *electron microscope*, employing electron beams, has 1000 times the resolving power of a light microscope. *Transmission electron microscopes*, so called because the electrons used to visualize the specimens are transmitted through the material, are capable of resolving objects only 0.2 nm apart—which is only twice the diameter of a hydrogen atom!

A second kind of electron microscope, the *scanning electron microscope*, beams electrons onto the surface of the specimen. The electrons reflected back from the surface, together with other electrons that the specimen itself emits as a result of the bombardment, are amplified and transmitted to a screen, where the image can be viewed and photographed. Scanning electron microscopy yields striking three-dimensional images. This technique has improved our understanding of many biological and physical phenomena (see table 4.1).

### Using stains to view cell structure

Although resolution remains a physical limit, we can improve the images we see by altering the sample. Certain chemical stains increase the contrast between different cellular components. Structures within the cell absorb or exclude the stain differentially, producing contrast that aids resolution.

Stains that bind to specific types of molecules have made these techniques even more powerful. This method uses antibodies that bind, for example, to a particular protein. This process, called *immunohistochemistry*, uses antibodies generated in animals such as rabbits or mice. When these animals are injected with specific proteins, they produce antibodies that bind to the injected protein. The antibodies are then purified and chemically bonded to enzymes, to stains, or to fluorescent molecules. When cells are incubated in a solution containing the antibodies, the antibodies

**TABLE 4.1**

**Microscopes**

**L I G H T M I C R O S C O P E S**

**Bright-field microscope:**

Light is transmitted through a specimen, giving little contrast. Staining specimens improves contrast but requires that cells be fixed (not alive), which can distort or alter components.

**Dark-field microscope:**

Light is directed at an angle toward the specimen. A condenser lens transmits only light reflected off the specimen. The field is dark, and the specimen is light against this dark background.

**Phase-contrast microscope:**

Components of the microscope bring light waves out of phase, which produces differences in contrast and brightness when the light waves recombine.

**Differential-interference-contrast microscope:**

Polarized light is split into two beams that have slightly different paths through the sample. Combining these two beams produces greater contrast, especially at the edges of structures.

**Fluorescence microscope:**

Fluorescent stains absorb light at one wavelength, then emit it at another. Filters transmit only the emitted light.

**Confocal microscope:**

Light from a laser is focused to a point and scanned across the fluorescently stained specimen in two directions. This produces clear images of one plane of the specimen. Other planes of the specimen are excluded to prevent the blurring of the image. Multiple planes can be used to reconstruct a 3-D image.

**E L E C T R O N M I C R O S C O P E S**

**Transmission electron microscope:**

A beam of electrons is passed through the specimen. Electrons that pass through are used to expose film. Areas of the specimen that scatter electrons appear dark. False coloring enhances the image.

**Scanning electron microscope:**

An electron beam is scanned across the surface of the specimen, and electrons are knocked off the surface. Thus, the topography of the specimen determines the contrast and the content of the image. False coloring enhances the image.

bind to cellular structures that contain the target molecule and can be seen with light microscopy. This approach has been used extensively in the analysis of cell structure and function.

**All cells exhibit basic structural similarities**

The general plan of cellular organization varies between different organisms, but despite these modifications, all cells resemble one another in certain fundamental ways. Before we begin a detailed examination of cell structure, let's first summarize four major features all cells have in common: (1) a nucleoid or nucleus where genetic material is located, (2) cytoplasm, (3) *ribosomes* to synthesize proteins, and (4) a plasma membrane.

**Centrally located genetic material**

Every cell contains DNA, the hereditary molecule. In **prokaryotes**, the simplest organisms, most of the genetic material lies in a single circular molecule of DNA. It typically resides near the center of the cell in an area called the **nucleoid**. This area is not segregated, however, from the rest of the cell's interior by membranes.

By contrast, the DNA of eukaryotes, which are more complex organisms, is contained in the nucleus, which is surrounded by a double-membrane structure called the nuclear envelope. In both types of organisms, the DNA contains the genes that code for the proteins synthesized by the cell. (Details of nucleus structure are described later in the chapter.)

**The cytoplasm**

A semifluid matrix called the **cytoplasm** fills the interior of the cell. The cytoplasm contains all of the sugars, amino acids, and proteins the cell uses to carry out its everyday activities. Although it is an aqueous medium, cytoplasm is more like jello than water due to the high concentration of proteins and other macromolecules. We call any discrete macromolecular structure in the cytoplasm specialized for a particular function an **organelle**. The part of the cytoplasm that contains organic molecules and ions in solution is called the **cytosol** to distinguish it from the larger organelles suspended in this fluid.

**The plasma membrane**

The **plasma membrane** encloses a cell and separates its contents from its surroundings. The plasma membrane is a phospholipid bilayer about 5 to 10 nm (5 to 10 billionths of a meter) thick, with proteins embedded in it. Viewed in cross section with the electron microscope, such membranes appear as two dark lines separated by a lighter area. This distinctive appearance arises from the tail-to-tail packing of the phospholipid molecules that make up the membrane (see chapter 5).

The proteins of the plasma membrane are generally responsible for a cell's ability to interact with the environment. *Transport proteins* help molecules and ions move across the plasma membrane, either from the environment to the interior of the cell or vice versa. *Receptor proteins* induce changes within the cell when they come in contact with specific molecules in the environment, such as hormones, or with molecules on the surface of neighboring cells. These molecules can function as *markers* that identify the cell as a particular type. This interaction between cell surface molecules is especially important in multicellular organisms, whose cells must be able to recognize one another as they form tissues.

We'll examine the structure and function of cell membranes more thoroughly in chapter 5.

### Learning Outcomes Review 4.1

All organisms are single cells or aggregates of cells, and all cells arise from preexisting cells. Cell size is limited primarily by the efficiency of diffusion across the plasma membrane. As a cell becomes larger, its volume increases more quickly than its surface area. Past a certain point, diffusion cannot support the cell's needs. All cells are bounded by a plasma membrane and filled with cytoplasm. The genetic material is found in the central portion of the cell; and in eukaryotic cells, it is contained in a membrane-bounded nucleus.

- *Would finding life on Mars change our view of cell theory?*

## 4.2 Prokaryotic Cells

### Learning Outcomes

1. Describe the organization of prokaryotic cells.
2. Distinguish between bacterial and archaeal cell types.

When cells were visualized with microscopes, two basic cellular architectures were recognized: eukaryotic and prokaryotic. These terms refer to the presence or absence, respectively, of a membrane-bounded nucleus that contains genetic material. We have already mentioned that in addition to lacking a nucleus, prokaryotic cells do not have an internal membrane system or numerous membrane-bounded organelles.

### Prokaryote cells have relatively simple organization

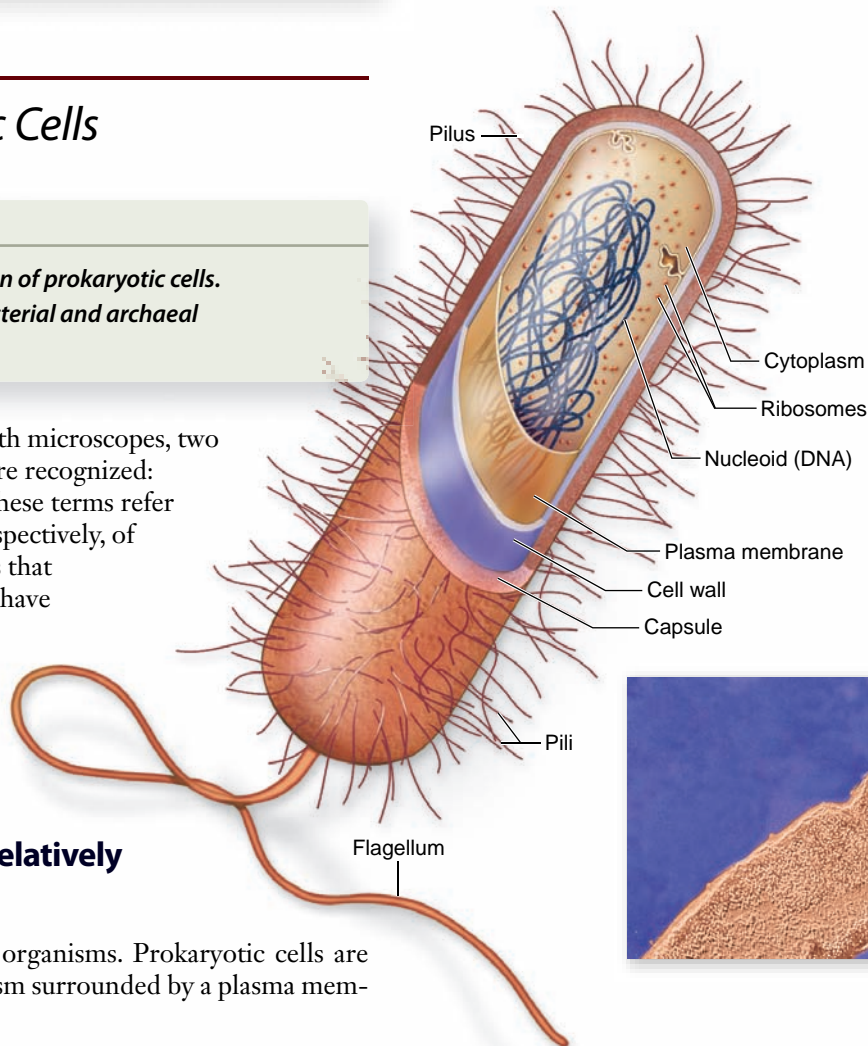

Prokaryotes are the simplest organisms. Prokaryotic cells are small. They consist of cytoplasm surrounded by a plasma mem-

brane and are encased within a rigid **cell wall**. They have no distinct interior compartments (figure 4.3). A prokaryotic cell is like a one-room cabin in which eating, sleeping, and watching TV all occur.

Prokaryotes are very important in the ecology of living organisms. Some harvest light by photosynthesis, others break down dead organisms and recycle their components. Still others cause disease or have uses in many important industrial processes. There are two main domains of prokaryotes: archaea and bacteria. Chapter 28 covers prokaryotic diversity in more detail.

Although prokaryotic cells do contain organelles like **ribosomes**, which carry out protein synthesis, most lack the membrane-bounded organelles characteristic of eukaryotic cells. It was long thought that prokaryotes also lack the elaborate cytoskeleton found in eukaryotes, but we have now found they have molecules related to both actin and tubulin, which form two of the cytoskeletal elements described later in the chapter. The actin-like proteins form supporting fibrils near the surface of the cell, but the cytoplasm of a prokaryotic cell does not appear to have an extensive internal support structure. Consequently, the strength of the cell comes primarily from its rigid cell wall (see figure 4.3).

The plasma membrane of a prokaryotic cell carries out some of the functions organelles perform in eukaryotic cells. For example, some photosynthetic bacteria, such as the

**Figure 4.3**  
**Structure of a prokaryotic cell.**

Generalized cell organization of a prokaryote. The nucleoid is visible as a dense central region segregated from the cytoplasm. Some prokaryotes have hairlike growths (called pili [singular, pilus]) on the outside of the cell.

**Figure 4.4 Electron micrograph of a photosynthetic bacterial cell.** Extensive folded photosynthetic membranes are shown in green in this false color electron micrograph of a *Prochloron* cell.

### Inquiry question

? What modifications would you include if you wanted to make a cell as large as possible?

cyanobacterium *Prochloron* (figure 4.4), have an extensively folded plasma membrane, with the folds extending into the cell's interior. These membrane folds contain the bacterial pigments connected with photosynthesis. In eukaryotic plant cells, photosynthetic pigments are found in the inner membrane of the chloroplast.

Because a prokaryotic cell contains no membrane-bounded organelles, the DNA, enzymes, and other cytoplasmic constituents have access to all parts of the cell. Reactions are not compartmen-

talized as they are in eukaryotic cells, and the whole prokaryote operates as a single unit.

## Bacterial cell walls consist of peptidoglycan

Most bacterial cells are encased by a strong cell wall. This cell wall is composed of *peptidoglycan*, which consists of a carbohydrate matrix (polymers of sugars) that is cross-linked by short polypeptide units. Details about the structure of this cell wall are discussed in chapter 28. Cell walls protect the cell, maintain its shape, and prevent excessive uptake or loss of water. The exception is the class Mollicutes, which includes the common genus *Mycoplasma*, which lack a cell wall. Plants, fungi, and most protists also have cell walls but with a chemical structure different from peptidoglycan.

The susceptibility of bacteria to antibiotics often depends on the structure of their cell walls. The drugs penicillin and vancomycin, for example, interfere with the ability of bacteria to cross-link the peptides in their peptidoglycan cell wall. Like removing all the nails from a wooden house, this destroys the integrity of the structural matrix, which can no longer prevent water from rushing in and swelling the cell to bursting.

Some bacteria also secrete a jelly-like protective capsule of polysaccharide around the cell. Many disease-causing bacteria have such a capsule, which enables them to adhere to teeth, skin, food—or to practically any surface that will support their growth.

## Archaea lack peptidoglycan

We are still learning about the physiology and structure of archaea. Many of these organisms are difficult to culture in the laboratory, and so this group has not yet been studied in detail. More is known about their genetic makeup than about any other feature.

The cell walls of archaea are composed of various chemical compounds, including polysaccharides and proteins, and possibly even inorganic components. A common feature

## Figure 4.5 Some prokaryotes move by rotating their flagella.

*a.* The photograph shows *Vibrio cholerae*, the microbe that causes the serious disease cholera. *b.* The bacterial flagellum is a complex structure. The motor proteins, powered by a proton gradient, are anchored in the plasma membrane. Two rings are found in the cell wall. The motor proteins cause the entire structure to rotate. *c.* As the flagellum rotates it creates a spiral wave down the structure. This powers the cell forward.

distinguishing archaea from bacteria is the nature of their membrane lipids. The chemical structure of archaeal lipids is distinctly different from that of lipids in bacteria and can include saturated hydrocarbons that are covalently attached to glycerol at both ends, such that their membrane is a monolayer. These features seem to confer greater thermal stability to archaeal membranes, although the tradeoff seems to be an inability to alter the degree of saturation of the hydrocarbons—meaning that archaea with this characteristic cannot adapt to changing environmental temperatures.

The cellular machinery that replicates DNA and synthesized proteins in archaea is more closely related to eukaryotic systems than to bacterial systems. Even though they share a similar overall cellular architecture with prokaryotes, archaea appear to be more closely related on a molecular basis to eukaryotes.

### Some prokaryotes move by means of rotating flagella

**Flagella** (singular, *flagellum*) are long, threadlike structures protruding from the surface of a cell that are used in locomotion. Prokaryotic flagella are protein fibers that extend out from the cell. There may be one or more per cell, or none, depending on the species. Bacteria can swim at speeds of up to 70 cell lengths per second by rotating their flagella like screws (figure 4.5). The rotary motor uses the energy stored in a gradient that transfers protons across the plasma membrane to power the movement of the flagellum. Interestingly, the same principle, in which a proton gradient powers the rotation of a molecule, is used in eukaryotic mitochondria and chloroplasts by an enzyme that synthesizes ATP (see chapters 7 and 8).

#### Learning Outcomes Review 4.2

Prokaryotes are small cells that lack complex interior organization. The two domains of prokaryotes are archaea and bacteria. The cell wall of bacteria is composed of peptidoglycan, which is not found in archaea. Archaea have cell walls made from a variety of polysaccharides and peptides, as well as membranes containing unusual lipids. Some bacteria move using a rotating flagellum.

- What features do bacteria and archaea share?

## 4.3 Eukaryotic Cells

#### Learning Outcomes

1. Compare the organization of eukaryotic and prokaryotic cells.
2. Discuss the role of the nucleus in eukaryotic cells.
3. Describe the role of ribosomes in protein synthesis.

Eukaryotic cells (figures 4.6 and 4.7) are far more complex than prokaryotic cells. The hallmark of the eukaryotic cell is compartmentalization. This is achieved through a combination of an extensive **endomembrane system** that weaves through the cell interior and by numerous *organelles*. These organelles include membrane-bounded structures that form compartments within which multiple biochemical processes can proceed simultaneously and independently.

Plant cells often have a large, membrane-bounded sac called a **central vacuole**, which stores proteins, pigments, and waste materials. Both plant and animal cells contain **vesicles**—smaller sacs that store and transport a variety of materials. Inside the nucleus, the DNA is wound tightly around proteins and packaged into compact units called **chromosomes**.

All eukaryotic cells are supported by an internal protein scaffold, the **cytoskeleton**. Although the cells of animals and some protists lack cell walls, the cells of fungi, plants, and many protists have strong cell walls composed of cellulose or chitin fibers embedded in a matrix of other polysaccharides and proteins. Through the rest of this chapter, we will examine the internal components of eukaryotic cells in more detail.

### The nucleus acts as the information center

The largest and most easily seen organelle within a eukaryotic cell is the **nucleus** (Latin, “kernel” or “nut”), first described by the botanist Robert Brown in 1831. Nuclei are roughly spherical in shape, and in animal cells, they are typically located in the central region of the cell (figure 4.8a). In some cells, a network of fine cytoplasmic filaments seems to cradle the nucleus in this position.

The nucleus is the repository of the genetic information that enables the synthesis of nearly all proteins of a living eukaryotic cell. Most eukaryotic cells possess a single nucleus, although the cells of fungi and some other groups may have several to many nuclei. Mammalian erythrocytes (red blood cells) lose their nuclei when they mature. Many nuclei exhibit a dark-staining zone called the **nucleolus**, which is a region where intensive synthesis of ribosomal RNA is taking place.

#### The nuclear envelope

The surface of the nucleus is bounded by *two* phospholipid bilayer membranes, which together make up the **nuclear envelope** (see figure 4.8). The outer membrane of the nuclear envelope is continuous with the cytoplasm’s interior membrane system, called the *endoplasmic reticulum* (described later).

Scattered over the surface of the nuclear envelope are what appear as shallow depressions in the electron micrograph but are in fact structures called **nuclear pores** (see figure 4.8b, c). These pores form 50 to 80 nm apart at locations where the two membrane layers of the nuclear envelope pinch together. They have a complex structure with a cytoplasmic face, a nuclear face, and a central ring embedded in the membrane. The proteins that make up this nuclear pore complex are arranged in a circle with a large central hole. The complex allows small molecules to diffuse freely between nucleoplasm and cytoplasm while controlling the passage of proteins and RNA–protein complexes. Passage is restricted primarily to two kinds

**Figure 4.6 Structure of an animal cell.** In this generalized diagram of an animal cell, the plasma membrane encases the cell, which contains the cytoskeleton and various cell organelles and interior structures suspended in a semifluid matrix called the cytoplasm. Some kinds of animal cells possess finger-like projections called microvilli. Other types of eukaryotic cells—for example, many protist cells—may possess flagella, which aid in movement, or cilia, which can have many different functions.

**Figure 4.7 Structure of a plant cell.** Most mature plant cells contain a large central vacuole, which occupies a major portion of the internal volume of the cell, and organelles called chloroplasts, within which photosynthesis takes place. The cells of plants, fungi, and some protists have cell walls, although the composition of the walls varies among the groups. Plant cells have cytoplasmic connections to one another through openings in the cell wall called plasmodesmata. Flagella occur in sperm of a few plant species, but are otherwise absent from plant and fungal cells. Centrioles are also usually absent.

of molecules: (1) proteins moving into the nucleus to be incorporated into nuclear structures or to catalyze nuclear activities and (2) RNA and RNA–protein complexes formed in the nucleus and exported to the cytoplasm.

The inner surface of the nuclear envelope is covered with a network of fibers that make up the nuclear lamina (see figure 4.8*d*). This is composed of intermediate filament fibers called *nuclear lamins*. This structure gives the nucleus its shape and is also involved in the deconstruction and reconstruction of the nuclear envelope that accompanies cell division.

### Chromatin: DNA packaging

In both prokaryotes and eukaryotes, DNA contains the hereditary information specifying cell structure and function. In most prokaryotes, the DNA is organized into a single circular chromosome. In eukaryotes, the DNA is divided into multiple linear chromosomes. The DNA in these chromosomes is organized with proteins into a complex structure called **chromatin**.

Chromatin is usually in a more extended form that allows regulatory proteins to attach to specific nucleotide sequences along the DNA and regulate gene expression. Without this access, DNA could not direct the day-to-day activities of the cell. When cells divide, the chromatin must be further compacted into a more highly condensed form.

### The nucleolus: Ribosomal subunit manufacturing

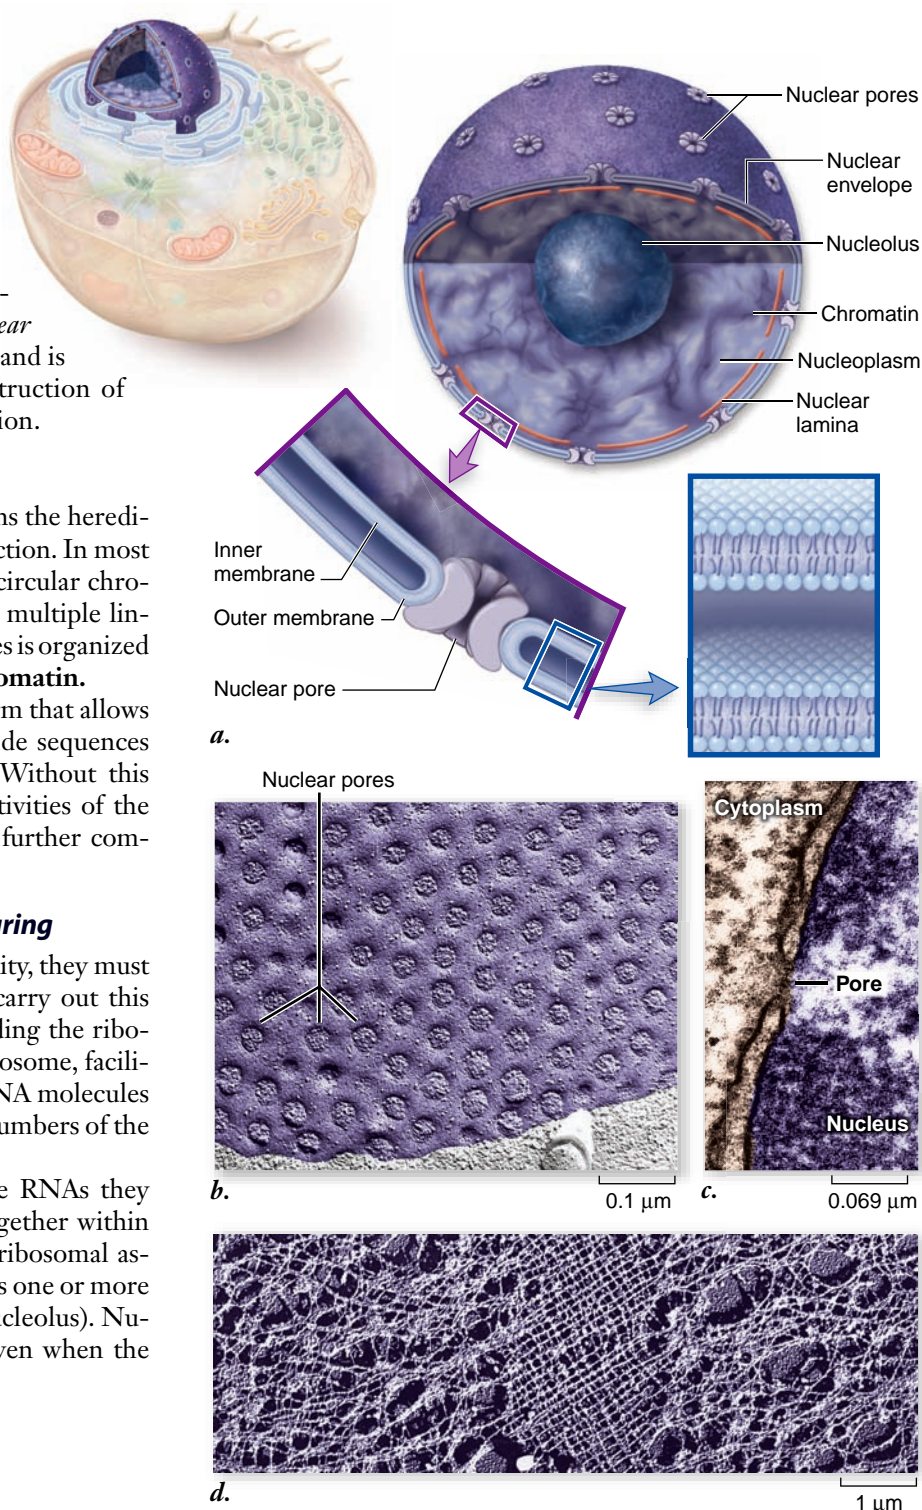

Before cells can synthesize proteins in large quantity, they must first construct a large number of ribosomes to carry out this synthesis. Hundreds of copies of the genes encoding the ribosomal RNAs are clustered together on the chromosome, facilitating ribosome construction. By transcribing RNA molecules from this cluster, the cell rapidly generates large numbers of the molecules needed to produce ribosomes.

The clusters of ribosomal RNA genes, the RNAs they produce, and the ribosomal proteins all come together within the nucleus during ribosome production. These ribosomal assembly areas are easily visible within the nucleus as one or more dark-staining regions called nucleoli (singular, nucleolus). Nucleoli can be seen under the light microscope even when the chromosomes are uncoiled.

## Ribosomes are the cell's protein synthesis machinery

Although the DNA in a cell's nucleus encodes the amino acid sequence of each protein in the cell, the proteins are not assembled there. A simple experiment demonstrates this: If a brief pulse of radioactive amino acid is administered to a cell, the radioactivity shows up associated with newly made protein in the cytoplasm, not in the nucleus. When investigators first carried out these experiments, they found that protein synthesis is associated with large RNA–protein complexes (called ribosomes) outside the nucleus.

Ribosomes are among the most complex molecular assemblies found in cells. Each ribosome is composed of two

**Figure 4.8 The nucleus.** *a.* The nucleus is composed of a double membrane called the nuclear envelope, enclosing a fluid-filled interior containing chromatin. The individual nuclear pores extend through the two membrane layers of the envelope. *b.* A freeze-fracture electron micrograph (see figure 5.3) of a cell nucleus, showing many nuclear pores. *c.* A transmission electron micrograph of the nuclear membrane showing a single nuclear pore. The dark material within the pore is protein, which acts to control access through the pore. *d.* The nuclear lamina is visible as a dense network of fibers made of intermediate filaments. The nucleus has been colored purple in the micrographs. (b): © Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited

**Figure 4.9 A ribosome.** Ribosomes consist of a large and a small subunit composed of rRNA and protein. The individual subunits are synthesized in the nucleolus and then move through the nuclear pores to the cytoplasm, where they assemble to translate mRNA. Ribosomes serve as sites of protein synthesis.

subunits (figure 4.9), and each subunit is composed of a combination of RNA, called **ribosomal RNA (rRNA)**, and proteins. The subunits join to form a functional ribosome only when they are actively synthesizing proteins. This complicated process requires the two other main forms of RNA: **messenger RNA (mRNA)**, which carries coding information from DNA, and **transfer RNA (tRNA)**, which carries amino acids. Ribosomes use the information in mRNA to direct the synthesis of a protein. This process will be described in more detail in chapter 15.

Ribosomes are found either free in the cytoplasm or associated with internal membranes, as described in the following section. Free ribosomes synthesize proteins that are found in the cytoplasm, nuclear proteins, mitochondrial proteins, and proteins found in other organelles not derived from the endomembrane system. Membrane-associated ribosomes synthesize membrane proteins, proteins found in the endomembrane system, and proteins destined for export from the cell.

Ribosomes can be thought of as “universal organelles” because they are found in all cell types from all three domains of life. As we build a picture of the minimal essential functions for cellular life, ribosomes will be on the short list. Life is protein-based, and ribosomes are the factories that make proteins.

### Learning Outcomes Review 4.3

In contrast to prokaryotic cells, eukaryotic cells exhibit compartmentalization. Eukaryotic cells contain an endomembrane system and organelles that carry out specialized functions. The nucleus, composed of a double membrane connected to the endomembrane system, contains the cell's genetic information. Material moves between the nucleus and cytoplasm through nuclear pores. Ribosomes translate mRNA, which is transcribed from DNA in the nucleus, into polypeptides that make up proteins. Ribosomes are a universal organelle found in all known cells.

- **Would you expect cells in different organs in complex animals to have the same structure?**

## 4.4 The Endomembrane System

### Learning Outcomes

1. **Identify the different parts of the endomembrane system.**
2. **Contrast the different functions of internal membranes and compartments.**
3. **Evaluate the importance of each step in the protein processing pathway.**

The interior of a eukaryotic cell is packed with membranes so thin that they are invisible under the low resolving power of light microscopes. This endomembrane system fills the cell, dividing it into compartments, channeling the passage of molecules through the interior of the cell, and providing surfaces for the synthesis of lipids and some proteins. The presence of these membranes in eukaryotic cells marks one of the fundamental distinctions between eukaryotes and prokaryotes.

The largest of the internal membranes is called the **endoplasmic reticulum (ER)**. *Endoplasmic* means “within the cytoplasm,” and *reticulum* is Latin for “a little net.” Like the plasma membrane, the ER is composed of a phospholipid bilayer embedded with proteins. It weaves in sheets through the interior of the cell, creating a series of channels between its folds (figure 4.10). Of the many compartments in eukaryotic cells, the two largest are the inner region of the ER, called the **cisternal space** or **lumen**, and the region exterior to it, the cytosol, which is the fluid component of the cytoplasm containing dissolved organic molecules such as proteins and ions.

### The rough ER is a site of protein synthesis

The **rough ER (RER)** gets its name from its surface appearance, which is pebbly due to the presence of ribosomes. The RER is not easily visible with a light microscope, but it can be seen using the electron microscope. It appears to be composed of flattened sacs, the surfaces of which are bumpy with ribosomes (see figure 4.10).

The proteins synthesized on the surface of the RER are destined to be exported from the cell, sent to lysosomes or vacuoles (described in a later section), or embedded in the plasma membrane. These proteins enter the cisternal space as a first step in the pathway that will sort proteins to their eventual destinations. This pathway also involves vesicles and the Golgi apparatus, described later. The sequence of the protein being synthesized determines whether the ribosome will become associated with the ER or remain a cytoplasmic ribosome.

In the ER, newly synthesized proteins can be modified by the addition of short-chain carbohydrates to form **glycoproteins**. Those proteins destined for secretion are separated from other products and later packaged into vesicles. The ER also manufactures membranes by producing membrane proteins and phospholipid molecules. The membrane

**Figure 4.10** The endoplasmic reticulum.

Rough ER (RER), blue in the drawing, is composed more of flattened sacs and forms a compartment throughout the cytoplasm. Ribosomes associated with the cytoplasmic face of the RER extrude newly made proteins into the interior, or lumen. The smooth ER (SER), green in the drawing, is a more tubelike structure connected to the RER. The micrograph has been colored to match the drawing.

proteins are inserted into the ER's own membrane, which can then expand and pinch off in the form of vesicles to be transferred to other locations.

### The smooth ER has multiple roles

Regions of the ER with relatively few bound ribosomes are referred to as **smooth ER (SER)**. The SER appears more like a network of tubules than the flattened sacs of the RER. The membranes of the SER contain many embedded enzymes. Enzymes anchored within the ER, for example, catalyze the synthesis of a variety of carbohydrates and lipids. Steroid hormones are synthesized in the SER as well. The majority of membrane lipids are assembled in the SER and then sent to whatever parts of the cell need membrane components.

The SER is used to store  $\text{Ca}^{2+}$  in cells. This keeps the cytoplasmic level low, allowing  $\text{Ca}^{2+}$  to be used as a signaling molecule. In muscle cells, for example,  $\text{Ca}^{2+}$  is used to trigger muscle contraction. In other cells,  $\text{Ca}^{2+}$  release from SER stores is involved in diverse signaling pathways.

The ratio of SER to RER depends on a cell's function. In multicellular animals such as ourselves, great variation exists in this ratio. Cells that carry out extensive lipid synthesis, such as those in the testes, intestine, and brain, have abundant SER. Cells that synthesize proteins that are secreted, such as antibodies, have much more extensive RER.

Another role of the SER is the modification of foreign substances to make them less toxic. In the liver, the enzymes of the SER carry out this detoxification. This action can include neutralizing substances that we have taken for a therapeutic reason, such as penicillin. Thus, relatively high doses are prescribed for some drugs to offset our body's efforts to

remove them. Liver cells have extensive SER as well as enzymes that can process a variety of substances by chemically modifying them.

### The Golgi apparatus sorts and packages proteins

Flattened stacks of membranes, often interconnected with one another, form a complex called the **Golgi body**. These structures are named for Camillo Golgi, the 19th-century physician who first identified them. The number of stacked membranes within the Golgi body ranges from 1 or a few in protists, to 20 or more in animal cells and to several hundred in plant cells. They are especially abundant in glandular cells, which manufacture and secrete substances. The Golgi body is often referred to as the **Golgi apparatus** (figure 4.11).

The Golgi apparatus functions in the collection, packaging, and distribution of molecules synthesized at one location and used at another within the cell or even outside of it. A Golgi body has a front and a back, with distinctly different membrane compositions at these opposite ends. The front, or receiving end, is called the *cis* face and is usually located near ER. Materials move to the *cis* face in transport vesicles that bud off the ER. These vesicles fuse with the *cis* face, emptying their contents into the interior, or lumen, of the Golgi apparatus. The ER-synthesized molecules then pass through the channels of the Golgi apparatus until they reach the back, or discharging end,

**Figure 4.11** The Golgi apparatus. The Golgi apparatus is a smooth, concave, membranous structure. It receives material for processing in transport vesicles on the *cis* face and sends the material packaged in transport or secretory vesicles off the *trans* face. The substance in a vesicle could be for export out of the cell or for distribution to another region within the same cell.

called the *trans* face, where they are discharged in secretory vesicles (figure 4.12).

Proteins and lipids manufactured on the rough and smooth ER membranes are transported into the Golgi apparatus and modified as they pass through it. The most common alteration is the addition or modification of short sugar chains, forming glycoproteins and glycolipids. In many instances, enzymes in the Golgi apparatus modify existing glycoproteins and glycolipids made in the ER by cleaving a sugar from a chain or by modifying one or more of the sugars.

The newly formed or altered glycoproteins and glycolipids collect at the ends of the Golgi bodies in flattened, stacked membrane folds called **cisternae** (Latin, “collecting vessels”). Periodically, the membranes of the cisternae push together, pinching off small, membrane-bounded secretory vesicles containing the glycoprotein and glycolipid molecules. These vesicles then diffuse to other locations in the cell, distributing the newly synthesized molecules to their appropriate destinations.

Another function of the Golgi apparatus is the synthesis of cell wall components. Noncellulose polysaccharides that form part of the cell wall of plants are synthesized in the Golgi apparatus and sent to the plasma membrane where they can be added to the cellulose that is assembled on the exterior of the cell. Other polysaccharides secreted by plants are also synthesized in the Golgi apparatus.

### Lysosomes contain digestive enzymes

Membrane-bounded digestive vesicles, called **lysosomes**, are also components of the endomembrane system. They arise from the Golgi apparatus. They contain high levels of degrading enzymes, which catalyze the rapid breakdown of proteins, nucleic acids, lipids, and carbohydrates. Throughout the lives of eukaryotic cells, lysosomal enzymes break down old organelles and recycle their component molecules. This makes room for newly formed organelles. For example, mitochondria are replaced in some tissues every 10 days.

The digestive enzymes in the lysosome are optimally active at acid pH. Lysosomes are activated by fusing with a food vesicle produced by *phagocytosis* (a specific type of endocytosis; see chapter 5) or by fusing with an old or worn-out organelle. The fusion event activates proton pumps in the lysosomal membrane, resulting in a lower internal pH. As the interior pH falls, the arsenal of digestive enzymes contained in the lysosome is activated. This leads to the degradation of macromolecules in the food vesicle or the destruction of the old organelle.

A number of human genetic disorders, collectively called lysosomal storage disorders, affect lysosomes. For example, the genetic abnormality called Tay–Sachs disease is caused by the loss of function of a single lysosomal enzyme. This enzyme is necessary to break down a membrane glycolipid found in nerve cells. Accumulation of glycolipid in lysosomes affects nerve cell function, leading to a variety of clinical symptoms such as seizures and muscle rigidity.

In addition to breaking down organelles and other structures within cells, lysosomes eliminate other cells that

**Figure 4.12 Protein transport through the endomembrane system.** Proteins synthesized by ribosomes on the RER are translocated into the internal compartment of the ER. These proteins may be used at a distant location within the cell or secreted from the cell. They are transported within vesicles that bud off the rough ER. These transport vesicles travel to the *cis* face of the Golgi apparatus. There they can be modified and packaged into vesicles that bud off the *trans* face of the Golgi apparatus. Vesicles leaving the *trans* face transport proteins to other locations in the cell, or fuse with the plasma membrane, releasing their contents to the extracellular environment.

the cell has engulfed by phagocytosis. When a white blood cell, for example, phagocytizes a passing pathogen, lysosomes fuse with the resulting “food vesicle,” releasing their enzymes into the vesicle and degrading the material within (figure 4.13).

**Figure 4.13 Lysosomes.** Lysosomes are formed from vesicles budding off the Golgi. They contain hydrolytic enzymes that digest particles or cells taken into the cell by phagocytosis, and break down old organelles.

## Microbodies are a diverse category of organelles

Eukaryotic cells contain a variety of enzyme-bearing, membrane-enclosed vesicles called **microbodies**. These are found in the cells of plants, animals, fungi, and protists. The distribution of enzymes into microbodies is one of the principal ways eukaryotic cells organize their metabolism.

### **Peroxisomes: Peroxide utilization**

An important type of microbody is the **peroxisome** (figure 4.14), which contains enzymes involved in the oxidation of fatty acids. If these oxidative enzymes were not isolated within microbodies, they would tend to short-circuit the metabolism of the cytoplasm, which often involves adding hydrogen atoms to oxygen. Because many peroxisomal proteins are synthesized by cytoplasmic ribosomes, the organelles themselves were long thought to form by the addition of lipids and proteins, leading to growth. As they grow larger, they divide to produce new peroxisomes. Although division of peroxisomes still appears to occur, it is now clear that peroxisomes can form from the fusion of ER-derived vesicles. These vesicles then import peroxisomal proteins to form a mature peroxisome. Genetic screens have isolated some 32 genes that encode proteins involved in biogenesis and maintenance of peroxisomes. The human genetic diseases called peroxisome biogenesis disorders (PBDs) appear to be caused by mutations in some of these genes.

Peroxisomes get their name from the hydrogen peroxide produced as a by-product of the activities of oxidative enzymes. Hydrogen peroxide is dangerous to cells because of its violent

**Figure 4.14 A peroxisome.** Peroxisomes are spherical organelles that may contain a large crystal structure composed of protein. Peroxisomes contain digestive and detoxifying enzymes that produce hydrogen peroxide as a by-product. A peroxisome has been colored green in the electron micrograph.

chemical reactivity. However, peroxisomes also contain the enzyme catalase, which breaks down hydrogen peroxide into its harmless constituents—water and oxygen.

## Plants use vacuoles for storage and water balance

Plant cells have specialized membrane-bounded structures called **vacuoles**. The most conspicuous example is the large central vacuole seen in most plant cells (figure 4.15). In fact, *vacuole* actually means blank space, referring to its appearance in the light microscope. The membrane surrounding this vacuole is called the **tonoplast** because it contains channels for water that are used to help the cell maintain its tonicity, or osmotic balance (see osmosis in chapter 5).

For many years biologists assumed that only one type of vacuole existed and that it served multiple functions. The functions assigned to this vacuole included water balance and storage of both useful molecules (such as sugars, ions and pigments) and waste products. The vacuole was also thought to store enzymes involved in the breakdown of macromolecules and those used in detoxifying foreign substances. Old textbooks of plant physiology referred to vacuoles as the attic of the cell for the variety of substances thought to be stored there.

Studies of tonoplast transporters and the isolation of vacuoles from a variety of cell types have led to a more complex view of vacuoles. These studies have made it clear that different vacuolar types can be found in different cells. These vacuoles are specialized, depending on the function of the cell.

The central vacuole is clearly important for a number of roles in all plant cells. The central vacuole and the water

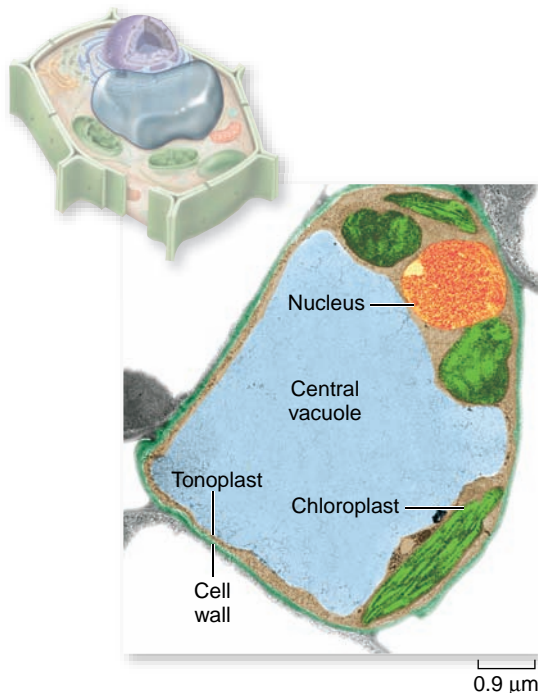

channels of the tonoplast maintain the tonicity of the cell, allowing the cell to expand and contract depending on conditions. The central vacuole is also involved in cell growth by occupying most of the volume of the cell. Plant cells grow by expanding the vacuole, rather than by increasing cytoplasmic volume.

Vacuoles with a variety of functions are also found in some types of fungi and protists. One form is the contractile vacuole, found in some protists, which can pump water and is used to maintain water balance in the cell. Other vacuoles are used for storage or to segregate toxic materials from the rest of the cytoplasm. The number and kind of vacuoles found in a cell depends on the needs of the particular cell type.

### Learning Outcomes Review 4.4

The endoplasmic reticulum (ER) is an extensive system of folded membranes that spatially organize the cell's biosynthetic activities. Smooth ER (SER) is the site of lipid and membrane synthesis and is used to store  $\text{Ca}^{2+}$ . Rough ER (RER) is covered with ribosomes and is a site of protein synthesis. Proteins from the RER are transported by vesicles to the Golgi apparatus where they are modified, packaged, and distributed to their final location. Lysosomes are vesicles that contain digestive enzymes used to degrade materials such as invaders or worn-out components. Peroxisomes carry out oxidative metabolism that generates peroxides. Vacuoles are membrane-bounded structures that have roles ranging from storage to cell growth in plants. They are also found in some fungi and protists.

- How do ribosomes on the RER differ from cytoplasmic ribosomes?

**Figure 4.15 The central vacuole.** A plant's central vacuole stores dissolved substances and can expand in size to increase the tonicity of a plant cell. Micrograph shown with false color.

## 4.5 Mitochondria and Chloroplasts: Cellular Generators

### Learning Outcomes

1. Describe the structure of mitochondria and chloroplasts.
2. Compare the function of mitochondria and chloroplasts.
3. Explain the probable origin of mitochondria and chloroplasts.

Mitochondria and chloroplasts share structural and functional similarities. Structurally, they are both surrounded by a double membrane, and both contain their own DNA and protein synthesis machinery. Functionally, they are both involved in energy metabolism, as we will explore in detail in later chapters on energy metabolism and photosynthesis.

**Figure 4.16 Mitochondria.** The inner membrane of a mitochondrion is shaped into folds called cristae that greatly increase the surface area for oxidative metabolism. A mitochondrion in cross section and cut lengthwise is shown colored red in the micrograph.

## Mitochondria metabolize sugar to generate ATP

**Mitochondria** (singular, *mitochondrion*) are typically tubular or sausage-shaped organelles about the size of bacteria that are found in all types of eukaryotic cells (figure 4.16). Mitochondria are bounded by two membranes: a smooth outer membrane, and an inner folded membrane with numerous contiguous layers called **cristae** (singular, *crista*).

The cristae partition the mitochondrion into two compartments: a **matrix**, lying inside the inner membrane; and an outer compartment, or **intermembrane space**, lying between the two mitochondrial membranes. On the surface of the inner membrane, and also embedded within it, are proteins that carry out oxidative metabolism, the oxygen-requiring process by which energy in macromolecules is used to produce ATP (chapter 7).

Mitochondria have their own DNA; this DNA contains several genes that produce proteins essential to the mitochondrion's role in oxidative metabolism. Thus, the mitochondrion, in many respects, acts as a cell within a cell, containing its own genetic information specifying proteins for its unique functions. The mitochondria are not fully autonomous, however, because most of the genes that encode the enzymes used in oxidative metabolism are located in the cell nucleus.

A eukaryotic cell does not produce brand-new mitochondria each time the cell divides. Instead, the mitochondria themselves divide in two, doubling in number, and these are partitioned between the new cells. Most of the components required for mitochondrial division are encoded by genes in the nucleus and are translated into proteins by cytoplasmic ribosomes. Mitochondrial replication is, therefore, impossible without nuclear participation, and mitochondria thus cannot be grown in a cell-free culture.

## Chloroplasts use light to generate ATP and sugars

Plant cells and cells of other eukaryotic organisms that carry out photosynthesis typically contain from one to several hundred **chloroplasts**. Chloroplasts bestow an obvious advantage on the organisms that possess them: They can manufacture their own food. Chloroplasts contain the photosynthetic pigment chlorophyll that gives most plants their green color.

The chloroplast, like the mitochondrion, is surrounded by two membranes (figure 4.17). However, chloroplasts are larger and more complex than mitochondria. In addition to the outer and inner membranes, which lie in close association with each other, chloroplasts have closed compartments of stacked membranes called **grana** (singular, *granum*), which lie inside the inner membrane.

A chloroplast may contain a hundred or more grana, and each granum may contain from a few to several dozen disk-shaped structures called **thylakoids**. On the surface of the thylakoids are the light-capturing photosynthetic pigments, to be discussed in depth in chapter 8. Surrounding the thylakoid is a fluid matrix called the *stroma*. The enzymes used to synthesize glucose during photosynthesis are found in the stroma.

Like mitochondria, chloroplasts contain DNA, but many of the genes that specify chloroplast components are also located in the nucleus. Some of the elements used in photosynthesis, including the specific protein components necessary to accomplish the reaction, are synthesized entirely within the chloroplast.

**Figure 4.17 Chloroplast structure.** The inner membrane of a chloroplast surrounds a membrane system of stacks of closed chlorophyll-containing vesicles called thylakoids, within which photosynthesis occurs. Thylakoids are typically stacked one on top of the other in columns called grana. The chloroplast has been colored green in the micrograph.

Other DNA-containing organelles in plants, called *leucoplasts*, lack pigment and a complex internal structure. In root cells and some other plant cells, leucoplasts may serve as starch storage sites. A leucoplast that stores starch (amylose) is sometimes termed an **amyloplast**. These organelles—chloroplasts, leucoplasts, and amyloplast—are collectively called **plastids**. All plastids are produced by the division of existing plastids.

### Inquiry question

? Mitochondria and chloroplasts both generate ATP. What structural features do they share?

## Mitochondria and chloroplasts arose by endosymbiosis

Symbiosis is a close relationship between organisms of different species that live together. As noted in chapter 29, the theory of **endosymbiosis** proposes that some of today's eukaryotic organelles evolved by a symbiosis arising between two cells that

**Figure 4.18 Possible origins of eukaryotic cells.** Both mitochondria and chloroplasts are thought to have arisen by endosymbiosis where a free-living cell is taken up but not digested. The nature of the engulfing cell is unknown. Two possibilities are shown. The engulfing cell (*top*) is an archaeon that gave rise to the nuclear genome and cytoplasmic contents. The engulfing cell (*bottom*) consists of a nucleus derived from an archaeon in a bacterial cell. This could arise by a fusion event or by engulfment of the archaeon by the bacterium.

were each free-living. One cell, a prokaryote, was engulfed by and became part of another cell, which was the precursor of modern eukaryotes (figure 4.18).

According to the endosymbiont theory, the engulfed prokaryotes provided their hosts with certain advantages associated with their special metabolic abilities. Two key eukaryotic organelles are believed to be the descendants of these endosymbiotic prokaryotes: mitochondria, which are thought to have originated as bacteria capable of carrying out oxidative metabolism, and chloroplasts, which apparently arose from photosynthetic bacteria. This is discussed in detail in chapter 29.

### Learning Outcomes Review 4.5

Mitochondria and chloroplasts have similar structures, with an outer membrane and an extensive inner membrane compartment. Both mitochondria and chloroplasts have their own DNA, but both also depend on nuclear genes for some functions. Mitochondria and chloroplasts are both involved in energy conversion: Mitochondria metabolize sugar to produce ATP, whereas chloroplasts harness light energy to produce ATP and synthesize sugars. Endosymbiosis theory proposes that both mitochondria and chloroplasts arose as prokaryotic cells engulfed by a eukaryotic precursor.

- Many proteins in mitochondria and chloroplasts are encoded by nuclear genes. In light of the endosymbiont hypothesis, how might this come about?

## 4.6 The Cytoskeleton

### Learning Outcomes

1. Contrast the structure and function of different fibers in the cytoskeleton.
2. Illustrate the role of microtubules in intracellular transport.

The cytoplasm of all eukaryotic cells is crisscrossed by a network of protein fibers that supports the shape of the cell and anchors organelles to fixed locations. This network, called the cytoskeleton, is a dynamic system, constantly assembling and disassembling. Individual fibers consist of polymers of identical protein subunits that attract one another and spontaneously assemble into long chains. Fibers disassemble in the same way, as one subunit after another breaks away from one end of the chain.

### Three types of fibers compose the cytoskeleton

Eukaryotic cells may contain the following three types of cytoskeletal fibers, each formed from a different kind of subunit: (1) actin filaments, sometimes called microfilaments, (2) microtubules, and (3) intermediate filaments.

## Actin filaments (microfilaments)

**Actin filaments** are long fibers about 7 nm in diameter. Each filament is composed of two protein chains loosely twined together like two strands of pearls (figure 4.19). Each “pearl,” or subunit, on the chain is the globular protein **actin**. Actin filaments exhibit polarity, that is, they have plus (+) and minus (–) ends. These designate the direction of growth of the filaments.

a. Actin filaments

b. Microtubules

c. Intermediate filament

### Figure 4.19 Molecules that make up the cytoskeleton.

**a. Actin filaments:** Actin filaments, also called *microfilaments*, are made of two strands of the globular protein actin twisted together. They are often found in bundles or in a branching network. Actin filaments in many cells are concentrated below the plasma membrane in bundles known as stress fibers, which may have a contractile function. **b. Microtubules:** Microtubules are composed of  $\alpha$ - and  $\beta$ -tubulin protein subunits arranged side by side to form a tube. Microtubules are comparatively stiff cytoskeletal elements and have many functions in the cell including intracellular transport and the separation of chromosomes during mitosis. **c. Intermediate filaments:** Intermediate filaments are composed of overlapping staggered tetramers of protein. These tetramers are then bundled into cables. This molecular arrangement allows for a ropelike structure that imparts tremendous mechanical strength to the cell.

Actin molecules spontaneously form these filaments, even in a test tube.

Cells regulate the rate of actin polymerization through other proteins that act as switches, turning on polymerization when appropriate. Actin filaments are responsible for cellular movements such as contraction, crawling, “pinching” during division, and formation of cellular extensions.

## Microtubule

**Microtubules**, the largest of the cytoskeletal elements, are hollow tubes about 25 nm in diameter, each composed of a ring of 13 protein protofilaments (see figure 4.19). Globular proteins consisting of dimers of  $\alpha$ - and  $\beta$ -tubulin subunits polymerize to form the 13 protofilaments. The protofilaments are arrayed side by side around a central core, giving the microtubule its characteristic tube shape.

In many cells, microtubules form from nucleation centers near the center of the cell and radiate toward the periphery. They are in a constant state of flux, continually polymerizing and depolymerizing. The average half-life of a microtubule ranges from as long as 10 minutes in a nondividing animal cell to as short as 20 seconds in a dividing animal cell. The ends of the microtubule are designated as plus (+) (away from the nucleation center) or minus (–) (toward the nucleation center).

Along with facilitating cellular movement, microtubules organize the cytoplasm and are responsible for moving materials within the cell itself, as described shortly.

## Intermediate filaments

The most durable element of the cytoskeleton in animal cells is a system of tough, fibrous protein molecules twined together in an overlapping arrangement (see figure 4.19). These *intermediate filaments* are characteristically 8 to 10 nm in diameter—between the size of actin filaments and microtubules. Once formed, intermediate filaments are stable and usually do not break down.

Intermediate filaments constitute a mixed group of cytoskeletal fibers. The most common type, composed of protein subunits called *vimentin*, provides structural stability for many kinds of cells. *Keratin*, another class of intermediate filament, is found in epithelial cells (cells that line organs and body cavities) and associated structures such as hair and fingernails. The intermediate filaments of nerve cells are called *neurofilaments*.

## Centrosomes are microtubule-organizing centers

**Centrioles** are barrel-shaped organelles found in the cells of animals and most protists. They occur in pairs, usually located at right angles to each other near the nuclear membranes (figure 4.20). The region surrounding the pair in almost all animal cells is referred to as a *centrosome*. Surrounding the centrioles in the centrosome is the **pericentriolar material**, which contains ring-shaped structures composed of tubulin. The pericentriolar material can nucleate the assembly of microtubules in animal cells. Structures with this function are called *microtubule-organizing centers*. The centrosome is also responsible for the reorganization of microtubules that occurs during

**Figure 4.20 Centrioles.** Each centriole is composed of nine triplets of microtubules. Centrioles are usually not found in plant cells. In animal cells they help to organize microtubules.

cell division. The centrosomes of plants and fungi lack centrioles, but still contain microtubule-organizing centers. You will learn more about the actions of the centrosomes when we describe the process of cell division in chapter 10.

## The cytoskeleton helps move materials within cells

Actin filaments and microtubules often orchestrate their activities to affect cellular processes. For example, during cell reproduction (see chapter 10), newly replicated chromosomes move to opposite sides of a dividing cell because they are attached to shortening microtubules. Then, in animal cells, a belt of actin pinches the cell in two by contracting like a purse string.

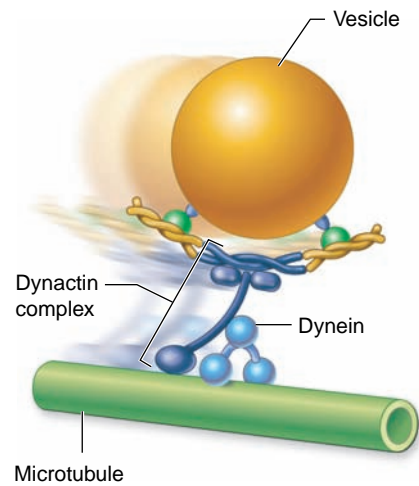

Muscle cells also use actin filaments, which slide along filaments of the motor protein myosin when a muscle contracts. The fluttering of an eyelash, the flight of an eagle, and the awkward crawling of a baby all depend on these cytoskeletal movements within muscle cells.

Not only is the cytoskeleton responsible for the cell's shape and movement, but it also provides a scaffold that holds certain enzymes and other macromolecules in defined areas of the cytoplasm. For example, many of the enzymes involved in cell metabolism bind to actin filaments, as do ribosomes. By moving and anchoring particular enzymes near one another, the cytoskeleton, like the endoplasmic reticulum, helps organize the cell's activities.

### Molecular motors

All eukaryotic cells must move materials from one place to another in the cytoplasm. One way cells do this is by using the channels of the endoplasmic reticulum as an intracellular highway. Material can also be moved using vesicles loaded with cargo that can move along the cytoskeleton like a railroad track. For example, in a nerve cell with an axon that may extend far from the cell body, vesicles can be moved along tracks of microtubules from the cell body to the end of the axon.

Four components are required to move material along microtubules: (1) a vesicle or organelle that is to be transported, (2) a motor protein that provides the energy-driven motion, (3) a connector molecule that connects the vesicle to the motor molecule, and (4) microtubules on which the vesicle will ride like a train on a rail (figure 4.21).

**Figure 4.21 Molecular motors.** Vesicles can be transported along microtubules using motor proteins that use ATP to generate force. The vesicles are attached to motor proteins by connector molecules, such as the dynalectin complex shown here. The motor protein dynein moves the connected vesicle along microtubules.

The direction a vesicle is moved depends on the type of motor protein involved and the fact that microtubules are organized with their plus ends toward the periphery of the cell. In one case, a protein called kinectin binds vesicles to the motor protein *kinesin*. Kinesin uses ATP to power its movement toward the cell periphery, dragging the vesicle with it as it travels along the microtubule toward the plus end (figure 4.22). As nature's tiniest motors, these proteins pull the transport vesicles along the microtubular tracks. Another set of vesicle proteins, called the dynalectin complex, binds vesicles to the motor protein *dynein* (see figure 4.22), which directs movement in the opposite

### SCIENTIFIC THINKING

**Hypothesis:** *Kinesin molecules can act as molecular motors and move along microtubules using energy from ATP.*

**Test:** *A microscope slide is covered with purified kinesin. Purified microtubules are added in a buffer containing ATP. The microtubules are monitored under a microscope using a video recorder to capture any movement.*

**Result:** *Over time, the movement of individual microtubules can be observed in the microscope. This is shown schematically in the figure by the movement of specific microtubules shown in color.*

**Conclusion:** *Kinesin acts as a molecular motor moving along (in this case actually moving) microtubules.*

**Further Experiments:** *Are there any further controls that are not shown in this experiment? What additional conclusions could be drawn by varying the amount of kinesin sticking to the slide?*

**Figure 4.22 Demonstration of kinesin as molecular motor.** Microtubules can be observed moving over a slide coated with kinesin.

**TABLE 4.2**
**Eukaryotic Cell Structures and their Functions**

Structure		Description	Function
Plasma membrane		Phospholipid bilayer with embedded proteins	Regulates what passes into and out of cell; cell-to-cell recognition; connection and adhesion; cell communication
Nucleus		Structure (usually spherical) that contains chromosomes and is surrounded by double membrane	Instructions for protein synthesis and cell reproduction; contains genetic information
Chromosomes		Long threads of DNA that form a complex with protein	Contain hereditary information used to direct synthesis of proteins
Nucleolus		Site of genes for rRNA synthesis	Synthesis of rRNA and ribosome assembly
Ribosomes		Small, complex assemblies of protein and RNA, often bound to ER	Sites of protein synthesis
Endoplasmic reticulum (ER)		Network of internal membranes	Intracellular compartment forms transport vesicles; participates in lipid synthesis and synthesis of membrane or secreted proteins
Golgi apparatus		Stacks of flattened vesicles	Packages proteins for export from cell; forms secretory vesicles
Lysosomes		Vesicles derived from Golgi apparatus that contain hydrolytic digestive enzymes	Digest worn-out organelles and cell debris; digest material taken up by endocytosis
Microbodies		Vesicles that are formed from incorporation of lipids and proteins and that contain oxidative and other enzymes	Isolate particular chemical activities from rest of cell
Mitochondria		Bacteria-like elements with double membrane	"Power plants" of the cell; sites of oxidative metabolism
Chloroplasts		Bacteria-like elements with double membrane surrounding a third, thylakoid membrane containing chlorophyll, a photosynthetic pigment	Sites of photosynthesis
Cytoskeleton		Network of protein filaments	Structural support; cell movement; movement of vesicles within cells
Flagella (cilia)		Cellular extensions with 9 + 2 arrangement of pairs of microtubules	Motility or moving fluids over surfaces
Cell wall		Outer layer of cellulose or chitin; or absent	Protection; support

direction along microtubules toward the minus end, inward toward the cell's center. (Dynein is also involved in the movement of eukaryotic flagella, as discussed later.) The destination of a particular transport vesicle and its content is thus determined by the nature of the linking protein embedded within the vesicle's membrane.

The major eukaryotic cell structures and their respective functions are summarized in table 4.2.

### Learning Outcomes Review 4.6

The three principal fibers of the cytoskeleton are actin filaments (microfilaments), microtubules, and intermediate filaments. These fibers interact to modulate cell shape and permit cell movement. They also act to move materials within the cytoplasm. Material is also moved in large cells using vesicles and molecular motors. The motor proteins move vesicles along tracks of microtubules.

- **What advantage does the cytoskeleton give to large eukaryotic cells?**

## 4.7 Extracellular Structures and Cell Movement

### Learning Outcomes

1. Describe how cells move.
2. Identify the different cytoskeletal elements involved in cell movement.
3. Classify the elements of extracellular matrix in animal cells.

Essentially all cell motion is tied to the movement of actin filaments, microtubules, or both. Intermediate filaments act as intracellular tendons, preventing excessive stretching of cells. Actin filaments play a major role in determining the shape of cells. Because actin filaments can form and dissolve so readily, they enable some cells to change shape quickly.

### Some cells crawl

The arrangement of actin filaments within the cell cytoplasm allows cells to crawl, literally! Crawling is a significant cellular phenomenon, essential to such diverse processes as inflammation, clotting, wound healing, and the spread of cancer. White blood cells in particular exhibit this ability. Produced in the bone marrow, these cells are released into the circulatory system and then eventually crawl out of venules and into the tissues to destroy potential pathogens.

At the leading edge of a crawling cell, actin filaments rapidly polymerize, and their extension forces the edge of the cell

forward. This extended region is stabilized when microtubules polymerize into the newly formed region. Overall forward movement of the cell is then achieved through the action of the protein **myosin**, which is best known for its role in muscle contraction. Myosin motors along the actin filaments contract, pulling the contents of the cell toward the newly extended front edge.

Cells crawl when these steps occur continuously, with a leading edge extending and stabilizing, and then motors contracting to pull the remaining cell contents along. Receptors on the cell surface can detect molecules outside the cell and stimulate extension in specific directions, allowing cells to move toward particular targets.

### Flagella and cilia aid movement

Earlier in this chapter, we described the structure of prokaryotic flagella. Eukaryotic cells have a completely different kind of flagellum, consisting of a circle of nine microtubule pairs surrounding two central microtubules. This arrangement is referred to as the *9 + 2 structure* (figure 4.23).

As pairs of microtubules move past each other using arms composed of the motor protein dynein, the eukaryotic flagellum *undulates*, rather than rotates. When examined carefully, each flagellum proves to be an outward projection of the cell's interior, containing cytoplasm and enclosed by the plasma membrane. The microtubules of the flagellum are derived from a **basal body**, situated just below the point where the flagellum protrudes from the surface of the cell.

The flagellum's complex microtubular apparatus evolved early in the history of eukaryotes. Today the cells of many

**Figure 4.23 Flagella and cilia.** A eukaryotic flagellum originates directly from a basal body. The flagellum has two microtubules in its core connected by radial spokes to an outer ring of nine paired microtubules with dynein arms (*9 + 2 structure*). The basal body consists of nine microtubule triplets connected by short protein segments. The structure of cilia is similar to that of flagella, but cilia are usually shorter.

multicellular and some unicellular eukaryotes no longer possess flagella and are nonmotile. Other structures, called **cilia** (singular, *cilium*), with an organization similar to the 9 + 2 arrangement of microtubules can still be found within them. Cilia are short cellular projections that are often organized in rows. They are more numerous than flagella on the cell surface, but have the same internal structure.

In many multicellular organisms, cilia carry out tasks far removed from their original function of propelling cells through water. In several kinds of vertebrate tissues, for example, the beating of rows of cilia move water over the tissue surface. The sensory cells of the vertebrate ear also contain conventional cilia surrounded by actin-based stereocilia; sound waves bend these structures and provide the initial sensory input for hearing. Thus, the 9 + 2 structure of flagella and cilia appears to be a fundamental component of eukaryotic cells (figure 4.24).

**a.** 40  $\mu\text{m}$

**b.** 66.6  $\mu\text{m}$

**Figure 4.24 Flagella and cilia.** *a.* A green alga with numerous flagella that allow it to move through the water. *b.* Paramecia are covered with many cilia, which beat in unison to move the cell. The cilia can also be used to move fluid into the paramecium's mouth to ingest material.

### Inquiry question

? The passageways of the human trachea (the path of airflow into and out of the lungs) are known to be lined with ciliated cells. What function could these cilia perform?

## Plant cell walls provide protection and support

The cells of plants, fungi, and many types of protists have cell walls, which protect and support the cells. The cell walls of these eukaryotes are chemically and structurally different from prokaryotic cell walls. In plants and protists, the cell walls are composed of fibers of the polysaccharide cellulose, whereas in fungi, the cell walls are composed of chitin.

In plants, **primary walls** are laid down when the cell is still growing. Between the walls of adjacent cells a sticky substance, called the **middle lamella**, glues the cells together (figure 4.25). Some plant cells produce strong **secondary walls**, which are deposited inside the primary walls of fully expanded cells.

## Animal cells secrete an extracellular matrix

Animal cells lack the cell walls that encase plants, fungi, and most protists. Instead, animal cells secrete an elaborate mixture of glycoproteins into the space around them, forming

**Figure 4.25 Cell walls in plants.** Plant cell walls are thick, strong, and rigid. Primary cell walls are laid down when the cell is young. Thicker secondary cell walls may be added later when the cell is fully grown.

**Figure 4.26 The extracellular matrix.** Animal cells are surrounded by an extracellular matrix composed of various glycoproteins that give the cells support, strength, and resilience.

the *extracellular matrix (ECM)* (figure 4.26). The fibrous protein collagen, the same protein found in cartilage, tendons, and ligaments may be abundant in the ECM. Strong fibers of collagen and another fibrous protein, elastin, are embedded within a complex web of other glycoproteins, called proteoglycans, that form a protective layer over the cell surface.

The ECM of some cells is attached to the plasma membrane by a third kind of glycoprotein, *fibronectin*. Fibronectin molecules bind not only to ECM glycoproteins but also to proteins called **integrins**. Integrins are an integral part of the plasma membrane, extending into the cytoplasm, where they are attached to the microfilaments and intermediate filaments of the cytoskeleton. Linking ECM and cytoskeleton, integrins allow the ECM to influence cell behavior in important ways. They can alter gene expression and cell migration patterns by a combination of mechanical and chemical signaling pathways. In this way, the ECM can help coordinate the behavior of all the cells in a particular tissue.

Table 4.3 compares and reviews the features of three types of cells.

<b>TABLE 4.3</b>		<b>A Comparison of Prokaryotic, Animal, and Plant Cells</b>		
	<b>Prokaryote</b>	<b>Animal</b>	<b>Plant</b>	
<i>E X T E R I O R   S T R U C T U R E S</i>				
Cell wall	Present (protein-polysaccharide)	Absent	Present (cellulose)	
Cell membrane	Present	Present	Present	
Flagella/cilia	Flagella may be present	May be present (9 + 2 structure)	Absent except in sperm of a few species (9 + 2 structure)	
<i>I N T E R I O R   S T R U C T U R E S</i>				
Endoplasmic reticulum	Absent	Usually present	Usually present	
Ribosomes	Present	Present	Present	
Microtubules	Absent	Present	Present	
Centrioles	Absent	Present	Absent	
Golgi apparatus	Absent	Present	Present	
Nucleus	Absent	Present	Present	
Mitochondria	Absent	Present	Present

Chromosomes	Single; circle of DNA	Multiple; DNA–protein complex	Multiple; DNA–protein complex	
Lysosomes	Absent	Usually present	Present	
Vacuoles	Absent	Absent or small	Usually a large single vacuole	

## Learning Outcomes Review 4.7

Cell movement involves proteins. These can either be internal in the case of crawling cells that use actin and myosin, or external in the case of cells powered by cilia or flagella. Eukaryotic cilia and flagella are different from prokaryotic flagella because they are composed of bundles of microtubules in a 9 + 2 array. They undulate rather than rotate.

Plant cells have a cellulose-based cell wall. Animal cells lack a cell wall. In animal cells, the cytoskeleton is linked to a web of glycoproteins called the extracellular matrix.

- What cellular roles are performed by microtubules and microfilaments and not intermediate filaments?

## 4.8 Cell-to-Cell Interactions

### Learning Outcomes

1. Differentiate between types of cell junctions.
2. Describe the roles of surface proteins.

In multicellular organisms, not only must cells be able to communicate with one another, they must also be organized in specific ways. With the exception of a few primitive types of organisms, the hallmark of multicellular life is the organization of highly specialized groups of cells into *tissues*, such as blood and muscle. Remarkably, each cell within a tissue performs the functions of that tissue and no other, even though all cells of the body

are derived from a single fertilized cell and contain the same genetic information—all of the genes found in the genome.

This kind of tissue organization requires that cells have both identity and specific kinds of cell-to-cell connections. As an organism develops, the cells acquire their identities by carefully controlling the *expression* of those genes, turning on the specific set of genes that encode the functions of each cell type. How do cells sense where they are? How do they “know” which type of tissue they belong to? Table 4.4 provides a summary of the kinds of connections seen between cells that are explored in the following sections.

### Surface proteins give cells identity

One key set of genes functions to mark the surfaces of cells, identifying them as being of a particular type. When cells make contact, they “read” each other’s cell surface markers and react accordingly. Cells that are part of the same tissue type recognize each other, and they frequently respond by forming connections between their surfaces to better coordinate their functions.

#### Glycolipids

Most tissue-specific cell surface markers are glycolipids, that is, lipids with carbohydrate heads. The glycolipids on the surface of red blood cells are also responsible for the A, B, and O blood types.

#### MHC proteins

One example of the function of cell surface markers is the recognition of “self” and “nonself” cells by the immune system. This function is vital for multicellular organisms, which need to defend themselves against invading or malignant cells. The immune system of vertebrates uses a particular set of markers to distinguish self from nonself cells, encoded by genes of the

TABLE 4.4

Cell-to-Cell Connections and Cell Identity

Type of Connection	Structure	Function	Example
Surface markers	Variable, integral proteins or glycolipids in plasma membrane	Identify the cell	MHC complexes, blood groups, antibodies
Tight junctions	Tightly bound, leakproof, fibrous protein seal that surrounds cell	Organizing junction; holds cells together such that materials pass <i>through</i> but not <i>between</i> the cells	Junctions between epithelial cells in the gut
Anchoring junction (Desmosome)	Intermediate filaments of cytoskeleton linked to adjoining cells through cadherins	Anchoring junction; binds cells together	Epithelium
Anchoring junction (Adherens junction)	Transmembrane fibrous proteins	Anchoring junction; connects extracellular matrix to cytoskeleton	Tissues with high mechanical stress, such as the skin
Communicating junction (Gap junction)	Six transmembrane connexon proteins creating a pore that connects cells	Communicating junction; allows passage of small molecules from cell to cell in a tissue	Excitable tissue such as heart muscle
Communicating junction (Plasmodesmata)	Cytoplasmic connections between gaps in adjoining plant cell walls	Communicating junction between plant cells	Plant tissues

major histocompatibility complex (MHC). Cell recognition in the immune system is covered in chapter 52.

## Cell connections mediate cell-to-cell adhesion

Most cells in a multicellular organism are in physical contact with other cells at all times, usually as members of organized tissues such as those in a leaf or those in your lungs, heart, or gut. These cells and the mass of other cells clustered around them form long-lasting or permanent connections with one another called *cell junctions*.

The nature of the physical connections between the cells of a tissue in large measure determines what the tissue is like. Indeed, a tissue's proper functioning often depends critically on how the individual cells are arranged within it. Just as a house

cannot maintain its structure without nails and cement, so a tissue cannot maintain its characteristic architecture without the appropriate cell junctions.

Cell junctions are divided into three categories, based on their functions: tight, anchoring, and communicating junctions (figure 4.27).

### Tight junctions

**Tight junctions** connect the plasma membranes of adjacent cells in a sheet. This sheet of cells acts as a wall within the organ, keeping molecules on one side or the other (figure 4.27a).

**Creating sheets of cells.** The cells that line an animal's digestive tract are organized in a sheet only one cell thick. One surface of the sheet faces the inside of the tract, and the other

**Figure 4.27 An overview of cell junction types.** Here, the diagram of gut epithelial cells on the right illustrates the comparative structures and locations of common cell junctions. The detailed models on the left show the structures of the three major types of cell junctions: (a) tight junction; (b) anchoring junction, the example shown is a desmosome; (c) communicating junction, the example shown is a gap junction.

faces the extracellular space, where blood vessels are located. Tight junctions encircle each cell in the sheet, like a belt cinched around a person's waist. The junctions between neighboring cells are so securely attached that there is no space between them for leakage. Hence, nutrients absorbed from the food in the digestive tract must pass directly through the cells in the sheet to enter the bloodstream because they cannot pass through spaces between cells.

**Partitioning the sheet.** The tight junctions between the cells lining the digestive tract also partition the plasma membranes of these cells into separate compartments. Transport proteins in the membrane facing the inside of the tract carry nutrients from that side to the cytoplasm of the cells. Other proteins, located in the membrane on the opposite side of the cells, transport those nutrients from the cytoplasm to the extracellular fluid, where they can enter the bloodstream.

For the sheet to absorb nutrients properly, these proteins must remain in the correct locations within the fluid membrane. Tight junctions effectively segregate the proteins on opposite sides of the sheet, preventing them from drifting within the membrane from one side of the sheet to the other. When tight junctions are experimentally disrupted, just this sort of migration occurs.

### Anchoring junctions

**Anchoring junctions** mechanically attach the cytoskeleton of a cell to the cytoskeletons of other cells or to the extracellular matrix. These junctions are most common in tissues subject to mechanical stress, such as muscle and skin epithelium.

**Cadherin and intermediate filaments.** *Desmosomes* connect the cytoskeletons of adjacent cells (figure 4.27b), and *hemidesmosomes* anchor epithelial cells to a basement membrane. Proteins called **cadherins**, most of which are single-pass transmembrane glycoproteins, create the critical link. Proteins link the short cytoplasmic end of a cadherin to the intermediate filaments in the cytoskeleton. The other end of the cadherin molecule projects outward from the plasma membrane, joining directly with a cadherin protruding from an adjacent cell similar to a firm handshake, binding the cells together. Connections between proteins tethered to the intermediate filaments are much more secure than connections between free-floating membrane proteins.

**Cadherin and actin filaments.** Cadherins can also connect the actin frameworks of cells in cadherin-mediated junctions (figure 4.28). When they do, they form less stable links between cells than when they connect intermediate filaments. Many kinds of actin-linking cadherins occur in different tissues. For example, during vertebrate development, the migration of neurons in the embryo is associated with changes in the type of cadherin expressed on their plasma membranes.

**Integrin-mediated links.** Anchoring junctions called **adherens junctions** connect the actin filaments of one cell with those of neighboring cells or with the extracellular matrix. The linking proteins in these junctions are members of a large superfamily of cell-surface receptors called integrins that bind to a protein component of the extracellular matrix. At least 20 different integrins exist each with a differently shaped binding domain.

**Figure 4.28 A cadherin-mediated junction.** The cadherin molecule is anchored to actin in the cytoskeleton and passes through the membrane to interact with the cadherin of an adjoining cell.

### Communicating junctions

Many cells communicate with adjacent cells through direct connections called *communicating junctions*. In these junctions, a chemical or electrical signal passes directly from one cell to an adjacent one. Communicating junctions permit small molecules or ions to pass from one cell to the other. In animals, these direct communication channels between cells are called *gap junctions*, and in plants, *plasmodesmata*.

**Gap junctions in animals.** **Gap junctions** are composed of structures called connexons, complexes of six identical transmembrane proteins (see figure 4.27c). The proteins in a connexon are arranged in a circle to create a channel through the plasma membrane that protrudes several nanometers from the cell surface. A gap junction forms when the connexons of two cells align perfectly, creating an open channel that spans the plasma membranes of both cells.

Gap junctions provide passageways large enough to permit small substances, such as simple sugars and amino acids, to pass from one cell to the next. Yet the passages are small enough to prevent the passage of larger molecules, such as proteins.

Gap junction channels are dynamic structures that can open or close in response to a variety of factors, including  $\text{Ca}^{2+}$  and  $\text{H}^+$  ions. This gating serves at least one important function. When a cell is damaged, its plasma membrane often becomes leaky. Ions in high concentrations outside the cell, such as  $\text{Ca}^{2+}$ , flow into the damaged cell and close its gap junction channels. This isolates the cell and so prevents the damage from spreading to other cells.

**Plasmodesmata in plants.** In plants, cell walls separate every cell from all others. Cell-cell junctions occur only at holes or gaps in the walls, where the plasma membranes of adjacent cells can come into contact with one another. Cytoplasmic connections that form across the touching plasma membranes are called **plasmodesmata** (singular, *plasmodesma*) (figure 4.29). The majority of living cells within a higher plant are connected to their neighbors by these junctions.

**Figure 4.29 Plasmodesmata.** Plant cells can communicate through specialized openings in their cell walls, called plasmodesmata, where the cytoplasm of adjoining cells are connected.

Plasmodesmata function much like gap junctions in animal cells, although their structure is more complex. Unlike gap junctions, plasmodesmata are lined with plasma membrane and contain a central tubule that connects the endoplasmic reticulum of the two cells.

### Learning Outcomes Review 4.8

Cell connections fall into three basic categories: (1) Tight junctions help to make sheets of cells that form watertight seals; (2) anchoring junctions provide strength and flexibility; and (3) communicating junctions, including gap junctions in animals and plasmodesmata in plants, allow passage of some materials between cells. Cells in multicellular organisms are usually organized into tissues, requiring that cells have distinct identity and connections. Cell identity is conferred by surface glycoproteins, which include the MHC proteins that are important in the immune system.

- How do cell junctions help to form tissues?

## Chapter Review

### 4.1 Cell Theory

**Cell theory is the unifying foundation of cell biology.**

All organisms are composed of one or more cells. Cells arise only by division of preexisting cells.

**Cell size is limited.**

Cell size is constrained by the diffusion distance. As cell size increases, diffusion becomes inefficient.

**Microscopes allow visualization of cells and components.**

Magnification gives better resolution than is possible with the naked eye. Staining with chemicals enhances contrast of structures.

**All cells exhibit basic structural similarities.**

All cells have centrally located DNA, a semifluid cytoplasm, and an enclosing plasma membrane.

### 4.2 Prokaryotic Cells (see figure 4.3)

**Prokaryotic cells have relatively simple organization.**

Prokaryotic cells contain DNA and ribosomes, but they lack a nucleus, an internal membrane system, and membrane-bounded organelles. A rigid cell wall surrounds the plasma membrane.

**Bacterial cell walls consist of peptidoglycan.**

Peptidoglycan is composed of carbohydrate cross-linked with short peptides.

**Archaea lack peptidoglycan.**

Archaeal cell walls do not contain peptidoglycan, and they have unique plasma membranes.

**Some prokaryotes move by means of rotating flagella.**

Prokaryotic flagella rotate because of proton transfer across the plasma membrane.

### 4.3 Eukaryotic Cells (see figures 4.6 and 4.7)

Eukaryotic cells have a membrane-bounded nucleus, an endomembrane system, and many different organelles.

**The nucleus acts as the information center.**

The nucleus is surrounded by an envelope of two phospholipid bilayers; the outer layer is contiguous with the ER. Pores allow exchange of small molecules. The nucleolus is a region of the nucleoplasm where rRNA is transcribed and ribosomes are assembled.

In most prokaryotes, DNA is organized into a single circular chromosome. In eukaryotes, numerous chromosomes are present.

**Ribosomes are the cell's protein synthesis machinery.**

Ribosomes translate mRNA to produce polypeptides. They are found in all cell types.

### 4.4 The Endomembrane System

The endoplasmic reticulum (ER) creates channels and passages within the cytoplasm (see figure 4.10).

**The rough ER is a site of protein synthesis.**

The rough ER (RER), studded with ribosomes, synthesizes and modifies proteins and manufactures membranes.

**The smooth ER has multiple roles.**

The smooth endoplasmic reticulum (SER) lacks ribosomes; it is involved in carbohydrate and lipid synthesis and detoxification.

**The Golgi apparatus sorts and packages proteins.**

The Golgi apparatus receives vesicles from the ER, modifies and packages macromolecules, and transports them (see figure 4.11).

**Lysosomes contain digestive enzymes.**

Lysosomes break down macromolecules and recycle the components of old organelles (see figure 4.13).

**Microbodies are a diverse category of organelles.**

**Plants use vacuoles for storage and water balance.**

## 4.5 Mitochondria and Chloroplasts: Cellular Generators

Mitochondria and chloroplasts have a double-membrane structure, contain their own DNA, and can divide independently.

**Mitochondria metabolize sugar to generate ATP.**

The inner membrane of mitochondria is extensively folded into layers called cristae. Proteins on the surface and in the inner membrane carry out metabolism to produce ATP (see figure 4.16).

**Chloroplasts use light to generate ATP and sugars.**

Chloroplasts capture light energy via thylakoid membranes arranged in stacks called grana, and use it to synthesize glucose (see figure 4.17).

**Mitochondria and chloroplasts arose by endosymbiosis.**

The endosymbiont theory proposes that mitochondria and chloroplasts were once prokaryotes engulfed by another cell.

## 4.6 The Cytoskeleton

The cytoskeleton consists of crisscrossed protein fibers that support the shape of the cell and anchor organelles (see figure 4.19).

**Three types of fibers compose the cytoskeleton.**

Actin filaments, or microfilaments, are long, thin polymers involved in cellular movement. Microtubules are hollow structures that move materials within a cell. Intermediate filaments serve a wide variety of functions.

**Centrosomes are microtubule-organizing centers.**

Centrosomes help assemble the nuclear division apparatus of animal cells (see figure 4.20).

**The cytoskeleton helps move materials within cells.**

Molecular motors move vesicles along microtubules, like a train on a railroad track. Kinesin and dynein are two motor proteins.

## 4.7 Extracellular Structures and Cell Movement

**Some cells crawl.**

Cell crawling occurs as actin polymerization forces the cell membrane forward, while myosin pulls the cell body forward.

**Flagella and cilia aid movement.**

Eukaryotic flagella have a 9 + 2 structure and arise from a basal body. Cilia are shorter and more numerous than flagella.

**Plant cell walls provide protection and support.**

Plants have cell walls composed of cellulose fibers. The middle lamella, between cell walls, holds adjacent cells together.

**Animal cells secrete an extracellular matrix.**

Glycoproteins are the main component of the extracellular matrix (ECM) of animal cells.

## 4.8 Cell-to-Cell Interactions (see figure 4.27)

**Surface proteins give cells identity.**

Glycolipids and MHC proteins on cell surfaces help distinguish self from nonself.

**Cell connections mediate cell-to-cell adhesion.**

Cell junctions include tight junctions, anchoring junctions, and communicating junctions. In animals, gap junctions allow the passage of small molecules between cells. In plants, plasmodesmata penetrate the cell wall and connect cells.

## Review Questions

### UNDERSTAND

- Which of the following statements is NOT part of the cell theory?
  - All organisms are composed of one or more cells.
  - Cells come from other cells by division.
  - Cells are the smallest living things.
  - Eukaryotic cells have evolved from prokaryotic cells.
- All cells have all of the following except
  - plasma membrane.
  - genetic material.
  - cytoplasm.
  - cell wall.
- Eukaryotic cells are more complex than prokaryotic cells. Which of the following are found only in a eukaryotic cell?
  - Cell wall
  - Plasma membrane
  - Endoplasmic reticulum
  - Ribosomes
- Which of the following are differences between bacteria and archaea?
  - The molecular architecture of their cell walls
  - The type of ribosomes found in each
  - Archaea have an internal membrane system that bacteria lack.
  - Both a and b
- The cytoskeleton includes
  - microtubules made of actin filaments.
  - microfilaments made of tubulin.
  - intermediate filaments made of twisted fibers of vimentin and keratin.
  - smooth endoplasmic reticulum.
- The smooth endoplasmic reticulum is
  - involved in protein synthesis.
  - a site of protein glycosylation.
  - used to store a variety of ions.
  - the site of lipid and membrane synthesis.

7. Plasmodesmata in plants and gap junctions in animals are functionally similar in that
  - a. each is used to anchor layers of cells.
  - b. they form channels between cells that allow diffusion of small molecules.
  - c. they form tight junctions between cells.
  - d. they are anchored to the extracellular matrix.

## APPLY

1. The most important factor that limits the size of a cell is the
  - a. quantity of proteins and organelles a cell can make.
  - b. rate of diffusion of small molecules.
  - c. surface area-to-volume ratio of the cell.
  - d. amount of DNA in the cell.
2. All eukaryotic cells possess each of the following except
  - a. mitochondria.
  - b. cell wall.
  - c. cytoskeleton.
  - d. nucleus.
3. Which of these organelles is NOT associated with the production or sorting of proteins in a cell?
  - a. Ribosomes
  - b. Smooth endoplasmic reticulum (SER)
  - c. Rough endoplasmic reticulum (RER)
  - d. Golgi apparatus
4. Different motor proteins like kinesin and myosin are similar in that they can
  - a. interact with microtubules.
  - b. use energy from ATP to produce movement.
  - c. interact with actin.
  - d. do both a and b.
5. The protein sorting pathway involves the following organelles/compartments in order:
  - a. SER, RER, transport vesicle, Golgi.
  - b. RER, lysosome, Golgi.
  - c. RER, transport vesicle, Golgi, final destination.
  - d. Golgi, transport vesicle, RER, final destination.
6. Chloroplasts and mitochondria have many common features because both
  - a. are present in plant cells.
  - b. arose by endosymbiosis.
  - c. function to oxidize glucose.
  - d. function to produce glucose.

7. Eukaryotic cells are composed of three types of cytoskeletal filaments. How are these three filaments similar?
  - a. They contribute to the shape of the cell.
  - b. They are all made of the same type of protein.
  - c. They are all the same size and shape.
  - d. They are all equally dynamic and flexible.

## SYNTHESIZE

1. The smooth endoplasmic reticulum is the site of synthesis of the phospholipids that make up all the membranes of a cell—especially the plasma membrane. Use the diagram of an animal cell (see figure 4.6) to trace a pathway that would carry a phospholipid molecule from the SER to the plasma membrane. What endomembrane compartments would the phospholipids travel through? How can a phospholipid molecule move between membrane compartments?
2. Use the information provided in table 4.3 to develop a set of predictions about the properties of mitochondria and chloroplasts if these organelles were once free-living prokaryotic cells. How do your predictions match with the evidence for endosymbiosis?
3. In evolutionary theory, homologous traits are those with a similar structure and function derived from a common ancestor. Analogous traits represent adaptations to a similar environment, but from distantly related organisms. Consider the structure and function of the flagella found on eukaryotic and prokaryotic cells. Are the flagella an example of a homologous or analogous trait? Defend your answer.
4. The protist, *Giardia intestinalis*, is the organism associated with water-borne diarrheal diseases. *Giardia* is an unusual eukaryote because it seems to lack mitochondria. Provide two possible evolutionary scenarios for this in the context of the endosymbiotic theory.

# Membranes

## Chapter Outline

- 5.1 The Structure of Membranes
- 5.2 Phospholipids: The Membrane's Foundation
- 5.3 Proteins: Multifunctional Components
- 5.4 Passive Transport Across Membranes
- 5.5 Active Transport Across Membranes
- 5.6 Bulk Transport by Endocytosis and Exocytosis

## Introduction

A cell's interactions with the environment are critical, a give-and-take that never ceases. Without it, life could not exist. Living cells are encased within a lipid membrane through which few water-soluble substances can pass. The membrane also contains protein passageways that permit specific substances to move into and out of the cell and allow the cell to exchange information with its environment. Eukaryotic cells also contain internal membranes like those of the mitochondrion and endoplasmic reticulum pictured here. We call the delicate skin of lipids with embedded protein molecules that encase the cell a plasma membrane. This chapter examines the structure and function of this remarkable membrane.

## 5.1 The Structure of Membranes

### Learning Outcomes

1. Describe the components of biological membranes.
2. Explain the fluid mosaic model of membrane structure.

The membranes that encase all living cells are two phospholipid sheets that are only 5–10 nanometers thick; more than 10,000 of these sheets piled on one another would just equal the thickness of this sheet of paper. Biologists established the components of membranes—not only lipids, but also proteins and other molecules—through biochemical assays, but the organization of the membrane components remained elusive.

We begin by considering the theories that have been advanced about membrane structure. We then look at the individual components of membranes more closely.

## The fluid mosaic model shows proteins embedded in a fluid lipid bilayer

The lipid layer that forms the foundation of a cell's membranes is a bilayer formed of **phospholipids** (figure 5.1). For many years, biologists thought that the protein components of the cell membrane covered the inner and outer surfaces of the phospholipid bilayer like a coat of paint. An early model portrayed the membrane as a sandwich; a phospholipid bilayer between two layers of globular protein.

In 1972, S. Jonathan Singer and Garth J. Nicolson revised the model in a simple but profound way: They proposed that the globular proteins are *inserted* into the lipid bilayer, with their nonpolar segments in contact with the nonpolar interior of the bilayer and their polar portions protruding out from the membrane surface. In this model, called the *fluid mosaic model*, a mosaic of proteins floats in or on the fluid lipid bilayer like boats on a pond (figure 5.2).

We now recognize two categories of membrane proteins based on their association with the membrane. *Integral membrane proteins* are embedded in the membrane, and *peripheral proteins* are associated with the surface of the membrane.

## Cellular membranes consist of four component groups

A eukaryotic cell contains many membranes. Although they are not all identical, they share the same fundamental architecture. Cell membranes are assembled from four components (table 5.1):

1. **Phospholipid bilayer.** Every cell membrane is composed of phospholipids in a bilayer. The other components of the membrane are embedded within the bilayer, which provides a flexible matrix and, at the same time, imposes a barrier to permeability. Animal cell membranes also contain cholesterol, a steroid with a polar hydroxyl group ( $\text{—OH}$ ). Plant cells have a much lower cholesterol content.
2. **Transmembrane proteins.** A major component of every membrane is a collection of proteins that float in the lipid bilayer. These proteins have a variety of functions, including transport and communication across the membrane. Many integral membrane proteins are not fixed in position. They can move about, just as the phospholipid molecules do. Some membranes are

**Figure 5.1 Different views of phospholipid structure.** Phospholipids are composed of glycerol (*pink*) linked to two fatty acids and a phosphate group. The phosphate group (*yellow*) can have additional molecules attached, such as the positively charged choline (*green*) shown. Phosphatidylcholine is a common component of membranes, it is shown in (a) with its chemical formula, (b) as a space-filling model, and (c) as the icon that is used in most of the figures in this chapter.

**Figure 5.2 The fluid mosaic model of cell membranes.**

Integral proteins protrude through the plasma membrane, with nonpolar regions that tether them to the membrane's hydrophobic interior. Carbohydrate chains are often bound to the extracellular portion of these proteins, forming glycoproteins. Peripheral membrane proteins are associated with the surface of the membrane. Membrane phospholipids can be modified by the addition of carbohydrates to form glycolipids. Inside the cell, actin filaments and intermediate filaments interact with membrane proteins. Outside the cell, many animal cells have an elaborate extracellular matrix composed primarily of glycoproteins.

TABLE 5.1 Components of the Cell Membrane				
Component	Composition	Function	How It Works	Example
Phospholipid bilayer	Phospholipid molecules	Provides permeability barrier, matrix for proteins	Excludes water-soluble molecules from nonpolar interior of bilayer and cell	Bilayer of cell is impermeable to large water-soluble molecules, such as glucose
Transmembrane proteins	Carriers	Actively or passively transport molecules across membrane	Move specific molecules through the membrane in a series of conformational changes	Glycophorin carrier for sugar transport; sodium–potassium pump
	Channels	Passively transport molecules across membrane	Create a selective tunnel that acts as a passage through membrane	Sodium and potassium channels in nerve, heart, and muscle cells
	Receptors	Transmit information into cell	Signal molecules bind to cell-surface portion of the receptor protein. This alters the portion of the receptor protein within the cell, inducing activity	Specific receptors bind peptide hormones and neurotransmitters
Interior protein network	Spectrins	Determine shape of cell	Form supporting scaffold beneath membrane, anchored to both membrane and cytoskeleton	Red blood cell
	Clathrins	Anchor certain proteins to specific sites, especially on the exterior plasma membrane in receptor-mediated endocytosis	Proteins line coated pits and facilitate binding to specific molecules	Localization of low-density lipoprotein receptor within coated pits
Cell-surface markers	Glycoproteins	“Self” recognition	Create a protein/carbohydrate chain shape characteristic of individual	Major histocompatibility complex protein recognized by immune system
	Glycolipid	Tissue recognition	Create a lipid/carbohydrate chain shape characteristic of tissue	A, B, O blood group markers

crowded with proteins, but in others, the proteins are more sparsely distributed.

- Interior protein network.** Membranes are structurally supported by intracellular proteins that reinforce the membrane's shape. For example, a red blood cell has a characteristic biconcave shape because a scaffold made of a protein called spectrin links proteins in the plasma membrane with actin filaments in the cell's cytoskeleton.

Membranes use networks of other proteins to control the lateral movements of some key membrane proteins, anchoring them to specific sites.

- Cell-surface markers.** As you learned in the preceding chapter, membrane sections assemble in the endoplasmic reticulum, transfer to the Golgi apparatus, and then are transported to the plasma membrane. The ER adds chains of sugar molecules to membrane proteins and lipids, converting them into **glycoproteins** and **glycolipids**. Different cell types exhibit different varieties of these glycoproteins and glycolipids on their surfaces, which act as cell identity markers.

Originally, it was believed that because of its fluidity, the plasma membrane was uniform, with lipids and proteins free to diffuse rapidly in the plane of the membrane. However, in the last decade evidence has accumulated suggesting the plasma membrane is not homogeneous and contains microdomains with distinct lipid and protein composition. One type of microdomain, the *lipid raft*, is heavily enriched with cholesterol, which fills space between the phospholipids, packing them more tightly together than the surrounding membrane.

Although the distribution of membrane lipids is symmetrical in the ER where they are synthesized, this distribution is asymmetrical in the plasma membrane, Golgi apparatus, and endosomes. This is accomplished by enzymes that transport lipids across the bilayer from one face to the other.

## Electron microscopy has provided structural evidence

Electron microscopy allows biologists to examine the delicate, filmy structure of a cell membrane. We discussed two types of electron microscopes in chapter 4: the transmission electron microscope (TEM) and the scanning electron microscope (SEM). Both provide illuminating views of membrane structure.

When examining cell membranes with electron microscopy, specimens must be prepared for viewing. In one method of preparing a specimen, the tissue of choice is embedded in a hard epoxy matrix. The epoxy block is then cut with a microtome, a machine with a very sharp blade that makes incredibly thin, transparent “epoxy shavings” less than 1  $\mu\text{m}$  thick that peel away from the block of tissue.

These shavings are placed on a grid, and a beam of electrons is directed through the grid with the TEM. At the high magnification an electron microscope provides, resolution is good enough to reveal the double layers of a membrane. False color can be added to the micrograph to enhance detail.

Freeze-fracturing a specimen is another way to visualize the inside of the membrane (figure 5.3). The tissue is embedded

**Figure 5.3** Viewing a plasma membrane with freeze-fracture microscopy.

in a medium and quick frozen with liquid nitrogen. The frozen tissue is then “tapped” with a knife, causing a crack between the phospholipid layers of membranes. Proteins, carbohydrates, pits, pores, channels, or any other structure affiliated with the membrane will pull apart (whole, usually) and stick with one or the other side of the split membrane.

Next, a very thin coating of platinum is evaporated onto the fractured surface, forming a replica or “cast” of the surface. After the topography of the membrane has been preserved in the cast, the actual tissue is dissolved away, and the cast is examined with electron microscopy, creating a textured and three-dimensional view of the membrane.

### Learning Outcomes Review 5.1

Cellular membranes contain four components: (1) a phospholipid bilayer, (2) transmembrane proteins, (3) an internal protein network providing structural support, and (4) cell-surface markers composed of glycoproteins and glycolipids. The fluid mosaic model of membrane structure includes both the fluid nature of the membrane and the mosaic composition of proteins floating in the phospholipid bilayer. Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) have provided evidence supporting the fluid mosaic model.

- *If the plasma membrane were just a phospholipid bilayer, how would this affect its function?*

## 5.2 Phospholipids: The Membrane’s Foundation

### Learning Outcomes

1. List the different components of phospholipids.
2. Explain how membranes form spontaneously.
3. Describe the factors involved in membrane fluidity.

Like the fat molecules (triglycerides) described in chapter 3, a phospholipid has a backbone derived from the three-carbon polyalcohol *glycerol*. Attached to this backbone are one to three fatty acids, long chains of carbon atoms ending in a carboxyl ( $\text{—COOH}$ ) group. A triglyceride molecule has three such chains, one attached to each carbon in the backbone. Because these chains are nonpolar, they do not form hydrogen bonds with water, and triglycerides are not water-soluble.

A phospholipid, by contrast, has only two fatty acid chains attached to its backbone. The third carbon of the glycerol carries a phosphate group, thus the name *phospholipid*. An additional polar organic molecule is often added to the phosphate group as well.

From this simple molecular framework, a large variety of lipids can be constructed by varying the polar organic group attached to the phosphate and the fatty acid chains attached to the glycerol. Mammalian membranes, for example, contain hundreds of chemically distinct species of lipids.

## Phospholipids spontaneously form bilayers

The phosphate groups are charged, and other molecules attached to them are polar or charged. This creates a huge change in the molecule’s physical properties compared with a triglyceride. The strongly polar phosphate end is hydrophilic, or “water-loving,” while the fatty acid end is strongly nonpolar and hydrophobic, or “water-fearing.” The two nonpolar fatty acids extend in one direction, roughly parallel to each other, and the polar phosphate group points in the other direction. To represent this structure, phospholipids are often diagrammed as a polar head with two dangling nonpolar tails, as in figure 5.1c.

What happens when a collection of phospholipid molecules is placed in water? The polar water molecules repel the long, nonpolar tails of the phospholipids while seeking partners for hydrogen bonding. Because of the polar nature of the water molecules, the nonpolar tails of the phospholipids end up packed closely together, sequestered as far as possible from water. Every phospholipid molecule is oriented with its polar head toward water and its nonpolar tails away. When *two* layers form with the tails facing each other, no tails ever come in contact with water. The resulting structure is the phospholipid bilayer. Phospholipid bilayers form spontaneously, driven by the tendency of water molecules to form the maximum number of hydrogen bonds.

The nonpolar interior of a lipid bilayer impedes the passage of any water-soluble substances through the bilayer, just as a layer of oil impedes the passage of a drop of water. This barrier to water-soluble substances is the key biological property of the lipid bilayer.

## The phospholipid bilayer is fluid

A lipid bilayer is stable because water’s affinity for hydrogen bonding never stops. Just as surface tension holds a soap bubble together, even though it is made of a liquid, so the hydrogen bonding of water holds a membrane together. Although water continually drives phospholipid molecules into the bilayer configuration, it does not have any effect on the mobility of phospholipids relative to their lipid and nonlipid neighbors in the bilayer. Because phospholipids interact relatively weakly with one another, individual phospholipids and unanchored proteins are comparatively free to move about within the membrane. This can be demonstrated vividly by fusing cells and watching their proteins intermix with time (figure 5.4).

## Membrane fluidity can change

The degree of membrane fluidity changes with the composition of the membrane itself. Much like triglycerides can be solid or liquid at room temperature, depending on their fatty acid

## SCIENTIFIC THINKING

**Hypothesis:** *The plasma membrane is fluid, not rigid.*

**Prediction:** *If the membrane is fluid, membrane proteins may diffuse laterally.*

**Test:** *Fuse mouse and human cells, then observe the distribution of membrane proteins over time by labeling specific mouse and human proteins.*

**Result:** *Over time, hybrid cells show increasingly intermixed proteins.*

**Conclusion:** *At least some membrane proteins can diffuse laterally in the membrane.*

**Further Experiments:** *Can you think of any other explanation for these observations? What if newly synthesized proteins were inserted into the membrane during the experiment? How could you use this basic experimental design to rule out this or other possible explanations?*

**Figure 5.4** Test of membrane fluidity.

composition, membrane fluidity can be altered by changing the membrane's fatty acid composition.

Saturated fats tend to make the membrane less fluid because they pack together well. Unsaturated fats make the membrane more fluid—the “kinks” introduced by the double bonds keep them from packing tightly. You saw this effect on fats and oils earlier in chapter 3. Most membranes also contain sterols such as cholesterol, which can either increase or decrease membrane fluidity, depending on the temperature.

Changes in the environment can have drastic effects on the membranes of single-celled organisms such as bacteria. Increasing temperature makes a membrane more fluid, and decreasing temperature makes it less fluid. Bacteria have evolved mechanisms to maintain a constant membrane fluidity despite fluctuating temperatures. Some bacteria contain enzymes called *fatty acid desaturases* that can introduce double bonds into fatty acids in membranes. Genetic studies, involving either the inactivation of these enzymes or the introduction of them into cells that normally lack them, indicate that the action of these enzymes confers cold tolerance. At colder temperatures, the double bonds introduced by fatty acid desaturase make the membrane more fluid, counteracting the environmental effect of reduced temperature.

## Learning Outcomes Review 5.2

Biological membranes consist of a phospholipid bilayer. Each phospholipid has a hydrophilic (phosphate) head and a hydrophobic (lipid) tail. In water, phospholipid molecules spontaneously form a bilayer, with phosphate groups facing out toward the water and lipid tails facing in, where they are sequestered from water. Membrane fluidity varies with composition and conditions: unsaturated fats disturb packing of the lipid tails and make the membrane more fluid, as do higher temperatures.

- **Would a phospholipid bilayer form in a nonpolar solvent?**

## 5.3 Proteins: Multifunctional Components

### Learning Outcomes

1. List the functions of membrane proteins.
2. Explain how proteins can associate with the membrane.
3. Identify a transmembrane domain.

Cell membranes contain a complex assembly of proteins enmeshed in the fluid soup of phospholipid molecules. This very flexible organization permits a broad range of interactions with the environment, some directly involving membrane proteins.

### Proteins and protein complexes perform key functions

Although cells interact with their environment through their plasma membranes in many ways, we will focus on six key classes of membrane protein in this chapter and in chapter 9 (figure 5.5).

1. **Transporters.** Membranes are very selective, allowing only certain solutes to enter or leave the cell, either through channels or carriers composed of proteins.
2. **Enzymes.** Cells carry out many chemical reactions on the interior surface of the plasma membrane, using enzymes attached to the membrane.
3. **Cell-surface receptors.** Membranes are exquisitely sensitive to chemical messages, which are detected by receptor proteins on their surfaces.
4. **Cell-surface identity markers.** Membranes carry cell-surface markers that identify them to other cells. Most cell types carry their own ID tags, specific combinations of cell-surface proteins and protein complexes such as glycoproteins that are characteristic of that cell type.
5. **Cell-to-cell adhesion proteins.** Cells use specific proteins to glue themselves to one another. Some act by forming temporary interactions, and others form a more permanent bond. (See chapter 9.)
6. **Attachments to the cytoskeleton.** Surface proteins that interact with other cells are often anchored to the cytoskeleton by linking proteins.

**Figure 5.5 Functions of plasma membrane proteins.** Membrane proteins act as transporters, enzymes, cell-surface receptors, and cell-surface identity markers, as well as aiding in cell-to-cell adhesion and securing the cytoskeleton.

### Inquiry question

? According to the fluid mosaic model, membranes are held together by hydrophobic interactions. Considering the forces that some cells may experience, why do membranes not break apart every time an animal moves?

## Structural features of membrane proteins relate to function

As we've just detailed, membrane proteins can serve a variety of functions. These diverse functions arise from the diverse structures of these proteins, yet they also have common structural features related to their role as membrane proteins.

### The anchoring of proteins in the bilayer

Some membrane proteins are attached to the surface of the membrane by special molecules that associate strongly with phospholipids. Like a ship tied to a floating dock, these anchored proteins are free to move about on the surface of the membrane tethered to a phospholipid. The anchoring molecules are modified lipids that have (1) nonpolar regions that insert into the internal portion of the lipid bilayer and (2) chemical bonding domains that link directly to proteins.

In contrast, other proteins actually span the lipid bilayer (transmembrane proteins). The part of the protein that extends through the lipid bilayer and that is in contact with the nonpolar interior are  $\alpha$ -helices or  $\beta$ -pleated sheets (see chapter 3) that consist of nonpolar amino acids. Because water avoids nonpolar amino acids, these portions of the protein are held within the interior of the lipid bilayer. The polar ends protrude from both sides of the membrane. Any movement of the protein out of the membrane, in either direction, brings the nonpolar regions of the protein into contact with water, which “shoves” the protein back into the interior. These forces prevent the transmembrane proteins from simply popping out of the membrane and floating away.

### Transmembrane domains

Cell membranes contain a variety of different transmembrane proteins, which differ in the way they traverse the lipid bilayer. The primary difference lies in the number of times that the protein crosses the membrane. Each membrane-spanning region is called a **transmembrane domain**. These domains are composed of hydrophobic amino acids usually arranged into  $\alpha$  helices (figure 5.6).

Proteins need only a single transmembrane domain to be anchored in the membrane, but they often have more than one such domain. An example of a protein with a single transmembrane domain is the linking protein that attaches the spectrin network of the cytoskeleton to the interior of the plasma membrane.

**Figure 5.6 Transmembrane domains.** Integral membrane proteins have at least one hydrophobic transmembrane domain (shown in blue) to anchor them in the membrane. *a.* Receptor protein with seven transmembrane domains. *b.* Protein with single transmembrane domain.

Biologists classify some types of receptors based on the number of transmembrane domains they have, such as G protein-coupled receptors with seven membrane-spanning domains (chapter 9). These receptors respond to external molecules, such as epinephrine, and initiate a cascade of events inside the cell.

Another example is bacteriorhodopsin, one of the key transmembrane proteins that carries out photosynthesis in halophilic (salt-loving) archaea. It contains seven nonpolar

**Figure 5.7 Bacteriorhodopsin.** This transmembrane protein mediates photosynthesis in the archaean *Halobacterium salinarium*. The protein traverses the membrane seven times with hydrophobic helical strands that are within the hydrophobic center of the lipid bilayer. The helical regions form a structure across the bilayer through which protons are pumped by the retinal chromophore (green) using energy from light.

helical segments that traverse the membrane, forming a structure within the membrane through which protons pass during the light-driven pumping of protons (figure 5.7).

### Pores

Some transmembrane proteins have extensive nonpolar regions with secondary configurations of  $\beta$ -pleated sheets instead of  $\alpha$  helices (chapter 3). The  $\beta$  sheets form a characteristic motif, folding back and forth in a cylinder so the sheets arrange themselves like a pipe through the membrane. This forms a polar environment in the interior of the  $\beta$  sheets spanning the membrane. This so-called  $\beta$  barrel, open on both ends, is a common feature of the porin class of proteins that are found within the outer membrane of some bacteria. The openings allow molecules to pass through the membrane (figure 5.8).

### Learning Outcomes Review 5.3

Proteins in the membrane confer the main differences between membranes of different cells. Their functions include transport, enzymatic action, reception of extracellular signals, cell-to-cell interactions, and cell identity markers. Peripheral proteins can be anchored in the membrane by modified lipids. Integral membrane proteins span the membrane and have one or more hydrophobic regions, called transmembrane domains, that anchor them.

- Why are transmembrane domains hydrophobic?

### Inquiry question

? Based only on amino acid sequence, how would you recognize an integral membrane protein?

**Figure 5.8 A pore protein.** The bacterial transmembrane protein porin creates large open tunnels called pores in the outer membrane of a bacterium. Sixteen strands of  $\beta$ -pleated sheets run antiparallel to one another, creating a so-called  $\beta$  barrel in the bacterial outer cell membrane. The tunnel allows water and other materials to pass through the membrane.

## 5.4 Passive Transport Across Membranes

### Learning Outcomes

1. Compare simple diffusion and facilitated diffusion.
2. Differentiate between channel proteins and carrier proteins.
3. Explain the movement of water by osmosis.

Many substances can move in and out of the cell without the cell's having to expend energy. This type of movement is termed **passive transport**. Some ions and molecules can pass through the membrane fairly easily and do so because of a *concentration gradient*—a difference between the concentration on the inside of the membrane and that on the outside. Some substances also move in response to a gradient, but do so through specific channels formed by proteins in the membrane.

### Transport can occur by simple diffusion

Molecules and ions dissolved in water are in constant random motion. This random motion causes a net movement of these substances from regions of high concentration to regions of lower concentration, a process called **diffusion** (figure 5.9).

Net movement driven by diffusion will continue until the concentration is the same in all regions. Consider what happens when you add a drop of colored ink to a bowl of water. Over time the ink becomes dispersed throughout the solution. This is due to diffusion of the ink molecules. In the context of cells, we are usually concerned with differences in concentration of molecules across the plasma membrane. We need to consider the relative concentrations both inside and outside the cell, as well as how readily a molecule can cross the membrane.

**Figure 5.9 Diffusion.** If a drop of colored ink is dropped into a beaker of water (a) its molecules dissolve (b) and diffuse (c). Eventually, diffusion results in an even distribution of ink molecules throughout the water (d).

The major barrier to crossing a biological membrane is the hydrophobic interior that repels polar molecules but not nonpolar molecules. If a concentration difference exists for a nonpolar molecule, it will move across the membrane until the concentration is equal on both sides. At this point, movement in both directions still occurs, but there is no net change in either direction. This includes molecules like  $O_2$  and nonpolar organic molecules such as steroid hormones.

The plasma membrane has limited permeability to small polar molecules and very limited permeability to larger polar molecules and ions. The movement of water, one of the most important polar molecules, is discussed in its own section later on.

### Proteins allow membrane diffusion to be selective

Many important molecules required by cells cannot easily cross the plasma membrane. These molecules can still enter the cell by diffusion through specific channel proteins or carrier proteins embedded in the plasma membrane, provided there is a higher concentration of the molecule outside the cell than inside. We call this process of diffusion mediated by a membrane protein **facilitated diffusion**. **Channel proteins** have a hydrophilic interior that provides an aqueous channel through which polar molecules can pass when the channel is open. **Carrier proteins**, in contrast to channels, bind specifically to the molecule they assist, much like an enzyme binds to its substrate. These channels and carriers are usually selective for one type of molecule, and thus the cell membrane is said to be **selectively permeable**.

#### Facilitated diffusion of ions through channels

You saw in chapter 2 that atoms with an unequal number of protons and electrons have an electric charge and are called ions. Those that carry a positive charge are called *cations* and those that carry a negative charge are called *anions*.

Because of their charge, ions interact well with polar molecules such as water, but are repelled by nonpolar molecules such as the interior of the plasma membrane. Therefore, ions cannot move between the cytoplasm of a cell and the extracellular fluid without the assistance of membrane transport proteins.

**Ion channels** possess a hydrated interior that spans the membrane. Ions can diffuse through the channel in either direction, depending on their relative concentration across the membrane (figure 5.10). Some channel proteins can be opened or closed

in response to a stimulus. These channels are called *gated channels*, and depending on the nature of the channel, the stimulus can be either chemical or electrical.

Three conditions determine the direction of net movement of the ions: (1) their relative concentrations on either side of the membrane, (2) the voltage difference across the membrane and for the gated channels, and

**Figure 5.10 Facilitated diffusion.** Diffusion can be facilitated by membrane proteins. *a.* The movement of ions through a channel is shown. On the left the concentration is higher outside the cell, so the ions move into the cell. On the right the situation is reversed. In both cases, transport continues until the concentration is equal on both sides of the membrane. At this point, ions continue to cross the membrane in both directions, but there is no net movement in either direction. *b.* Carrier proteins bind specifically to the molecules they transport. In this case, the concentration is higher outside the cell, so molecules bind to the carrier on the outside. The carrier's shape changes, allowing the molecule to cross the membrane. This is reversible, so net movement continues until the concentration is equal on both sides of the membrane.

(3) the state of the gate (open or closed). A voltage difference is an electrical potential difference across the membrane called a *membrane potential*. Changes in membrane potential form the basis for transmission of signals in the nervous system and some other tissues. (We discuss this topic in detail in chapter 45.) Each type of channel is specific for a particular ion, such as calcium ( $\text{Ca}^{2+}$ ), sodium ( $\text{Na}^+$ ), potassium ( $\text{K}^+$ ), or chloride ( $\text{Cl}^-$ ), or in some cases, for more than one cation or anion. Ion channels play an essential role in signaling by the nervous system.

### Facilitated diffusion by carrier proteins

Carrier proteins can help transport both ions and other solutes, such as some sugars and amino acids, across the membrane. Transport through a carrier is still a form of diffusion and therefore requires a concentration difference across the membrane.

Carriers must bind to the molecule they transport, so the relationship between concentration and rate of transport differs from that due to simple diffusion. As concentration increases, transport by simple diffusion shows a linear increase in rate of transport. But when a carrier protein is involved, a concentration increase means that more of the carriers are bound to the transported molecule. At high enough concentrations all carriers will be occupied, and the rate of transport will be constant. This means that the carrier exhibits *saturation*.

This situation is somewhat like that of a stadium (the cell) where a crowd must pass through turnstiles to enter. If there are unoccupied turnstiles, you can go right through, but when all are occupied, you must wait. When ticket holders are passing through the gates at maximum speed, the rate at which they enter cannot increase, no matter how many are waiting outside.

### Facilitated diffusion in red blood cells

Several examples of facilitated diffusion can be found in the plasma membrane of vertebrate red blood cells (RBCs). One RBC carrier protein, for example, transports a different molecule in each direction: chloride ion ( $\text{Cl}^-$ ) in one direction and bicarbonate ion ( $\text{HCO}_3^-$ ) in the opposite direction. As you will

learn in chapter 51, this carrier is important in the uptake and release of carbon dioxide.

The glucose transporter is a second vital facilitated diffusion carrier in RBCs. Red blood cells keep their internal concentration of glucose low through a chemical trick: They immediately add a phosphate group to any entering glucose molecule, converting it to a highly charged glucose phosphate that can no longer bind to the glucose transporter, and therefore cannot pass back across the membrane. This maintains a steep concentration gradient for unphosphorylated glucose, favoring its entry into the cell.

The glucose transporter that assists the entry of glucose into the cell does not appear to form a channel in the membrane. Instead, this transmembrane protein appears to bind to a glucose molecule and then to flip its shape, dragging the glucose through the bilayer and releasing it on the inside of the plasma membrane. After it releases the glucose, the transporter reverts to its original shape and is then available to bind the next glucose molecule that comes along outside the cell.

## Osmosis is the movement of water across membranes

The cytoplasm of a cell contains ions and molecules, such as sugars and amino acids, dissolved in water. The mixture of these substances and water is called an *aqueous solution*. Water is termed the **solvent**, and the substances dissolved in the water are **solutes**. Both water and solutes tend to diffuse from regions of high concentration to ones of low concentration; that is, they diffuse down their concentration gradients.

When two regions are separated by a membrane, what happens depends on whether the solutes can pass freely through that membrane. Most solutes, including ions and sugars, are not lipid-soluble and, therefore, are unable to cross the lipid bilayer. The concentration gradient of these solutes can lead to the movement of water.

## Osmosis

Water molecules interact with dissolved solutes by forming hydration shells around the charged solute molecules. When a membrane separates two solutions with different concentrations of solutes, the concentrations of *free* water molecules on the two sides of the membrane also differ. The side with higher solute concentration has tied up more water molecules in hydration shells and thus has fewer free water molecules.

As a consequence of this difference, free water molecules move down their concentration gradient, toward the higher solute concentration. This net diffusion of water across a membrane toward a higher solute concentration is called **osmosis** (figure 5.11).

The concentration of *all* solutes in a solution determines the **osmotic concentration** of the solution. If two solutions have unequal osmotic concentrations, the solution with the higher concentration is **hypertonic** (Greek *hyper*, “more than”), and the solution with the lower concentration is **hypotonic** (Greek *hypo*, “less than”). When two solutions have the same osmotic concentration, the solutions are **isotonic** (Greek *iso*, “equal”). The terms *hyperosmotic*, *hyposmotic*, and *isosmotic* are also used to describe these conditions.

**Figure 5.11 Osmosis.** Concentration differences in charged or polar molecules that cannot cross a semipermeable membrane result in movement of water, which can cross the membrane. Water molecules form hydrogen bonds with charged or polar molecules creating a hydration shell around them in solution. A higher concentration of polar molecules (urea) shown on the left side of the membrane leads to water molecules gathering around each urea molecule. These water molecules are no longer free to diffuse across the membrane. The polar solute has reduced the concentration of free water molecules, creating a gradient. This causes a net movement of water by diffusion from right to left in the U-tube, raising the level on the left and lowering the level on the right.

A cell in any environment can be thought of as a plasma membrane separating two solutions: the cytoplasm and the extracellular fluid. The direction and extent of any diffusion of water across the plasma membrane is determined by comparing the osmotic strength of these solutions. Put another way, water diffuses out of a cell in a hypertonic solution (that is, the cytoplasm of the cell is hypotonic, compared with the extracellular fluid). This loss of water causes the cell to shrink until the osmotic concentrations of the cytoplasm and the extracellular fluid become equal.

## Aquaporins: Water channels

The transport of water across the membrane is complex. Studies on artificial membranes show that water, despite its polarity, can cross the membrane, but this flow is limited. Water flow in living cells is facilitated by **aquaporins**, which are specialized channels for water.

A simple experiment demonstrates this. If an amphibian egg is placed in hypotonic spring water (the solute concentration in the cell is higher than that of the surrounding water), it does not swell. If aquaporin mRNA is then injected into the egg, the channel proteins are expressed and appear in the egg's plasma membrane. Water can now diffuse into the egg, causing it to swell.

More than 11 different kinds of aquaporins have been found in mammals. These fall into two general classes: those that are specific for only water, and those that allow other small hydrophilic molecules, such as glycerol or urea, to cross the membrane as well. This latter class explains how some membranes allow the easy passage of small hydrophilic substances.

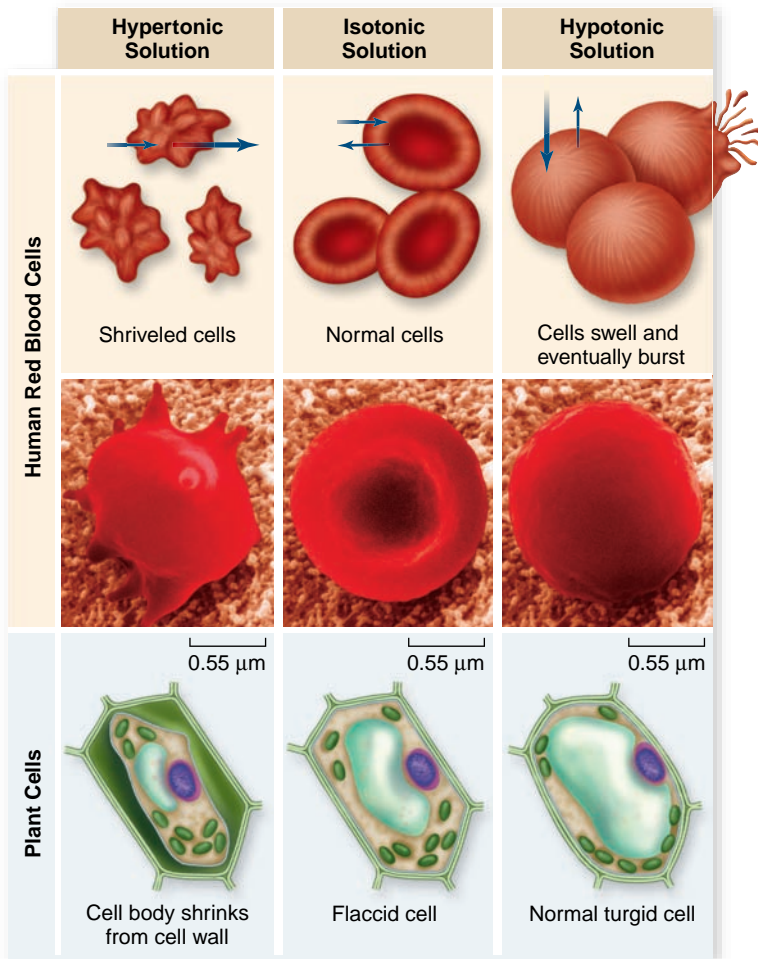

The human genetic disease, hereditary (nephrogenic) diabetes insipidus (NDI), has been shown to be caused by a non-functional aquaporin protein. This disease causes the excretion of large volumes of dilute urine, illustrating the importance of aquaporins to our physiology.

## Osmotic pressure

What happens to a cell in a hypotonic solution? (That is, the cell's cytoplasm is hypertonic relative to the extracellular fluid.) In this situation, water diffuses into the cell from the extracellular fluid, causing the cell to swell. The pressure of the cytoplasm pushing out against the cell membrane, or hydrostatic pressure, increases. The amount of water that enters the cell depends on the difference in solute concentration between the cell and the extracellular fluid. This is measured as **osmotic pressure**, defined as the force needed to stop osmotic flow.

If the membrane is strong enough, the cell reaches an equilibrium, at which the osmotic pressure, which tends to drive water into the cell, is exactly counterbalanced by the hydrostatic pressure, which tends to drive water back out of the cell. However, a plasma membrane by itself cannot withstand large internal pressures, and an isolated cell under such conditions would burst like an overinflated balloon (figure 5.12).

Accordingly, it is important for animal cells, which only have plasma membranes, to maintain osmotic balance. In contrast, the cells of prokaryotes, fungi, plants, and many protists are surrounded by strong cell walls, which can withstand high internal pressures without bursting.

**Figure 5.12** How solutes create osmotic pressure. In a hypertonic solution, water moves out of the cell, causing the cell to shrivel. In an isotonic solution, water diffuses into and out of the cell at the same rate, with no change in cell size. In a hypotonic solution, water moves into the cell. Direction and amount of water movement is shown with blue arrows (*top*). As water enters the cell from a hypotonic solution, pressure is applied to the plasma membrane until the cell ruptures. Water enters the cell due to osmotic pressure from the higher solute concentration in the cell. Osmotic pressure is measured as the force needed to stop osmosis. The strong cell wall of plant cells can withstand the hydrostatic pressure to keep the cell from rupturing. This is not the case with animal cells.

### Maintaining osmotic balance

Organisms have developed many strategies for solving the dilemma posed by being hypertonic to their environment and therefore having a steady influx of water by osmosis.

**Extrusion.** Some single-celled eukaryotes, such as the protist *Paramecium*, use organelles called contractile vacuoles to remove water. Each vacuole collects water from various parts of the cytoplasm and transports it to the central part of the vacuole, near the cell surface. The vacuole possesses a small pore that opens to the outside of the cell. By contracting rhythmically, the vacuole pumps out (extrudes) through this pore the water that is continuously drawn into the cell by osmotic forces.

**Isosmotic Regulation.** Some organisms that live in the ocean adjust their internal concentration of solutes to match that of the surrounding seawater. Because they are isosmotic with respect to their environment, no net flow of water occurs into or out of these cells.

Many terrestrial animals solve the problem in a similar way, by circulating a fluid through their bodies that bathes cells in an isotonic solution. The blood in your body, for example, contains a high concentration of the protein albumin, which elevates the solute concentration of the blood to match that of your cells' cytoplasm.

**Turgor.** Most plant cells are hypertonic to their immediate environment, containing a high concentration of solutes in their central vacuoles. The resulting internal hydrostatic pressure, known as **turgor pressure**, presses the plasma membrane firmly against the interior of the cell wall, making the cell rigid. Most green plants depend on turgor pressure to maintain their shape, and thus they wilt when they lack sufficient water.

### Learning Outcomes Review 5.4

Passive transport involves diffusion, which requires a concentration gradient. Hydrophobic molecules can diffuse directly through the membrane (simple diffusion). Polar molecules and ions can also diffuse through the membrane, but only with the aid of a channel or carrier protein (facilitated diffusion). Channel proteins assist by forming a hydrophilic passageway through the membrane, whereas carrier proteins bind to the molecule they assist. Water passes through the membrane and through aquaporins in response to solute concentration differences inside and outside the cell. This process is called osmosis.

- If you require intravenous (IV) medication in the hospital, what should the concentration of solutes in the IV solution be relative to your blood cells?

## 5.5 Active Transport Across Membranes

### Learning Outcomes

1. Differentiate between active transport and diffusion.
2. Describe the function of the  $\text{Na}^+/\text{K}^+$  pump.
3. Explain the energetics of coupled transport.

Diffusion, facilitated diffusion, and osmosis are passive transport processes that move materials down their concentration gradients, but cells can also actively move substances across a cell membrane *up* their concentration gradients. This process requires the expenditure of energy, typically from ATP, and is therefore called **active transport**.

## Active transport uses energy to move materials against a concentration gradient

Like facilitated diffusion, active transport involves highly selective protein carriers within the membrane that bind to the transported substance, which could be an ion or a simple molecule, such as a sugar, an amino acid, or a nucleotide. These carrier proteins are called **uniporters** if they transport a single type of molecule and **symporters** or **antiporters** if they transport two different molecules together. **Symporters** transport two molecules in the same direction, and **antiporters** transport two molecules in opposite directions. These terms can also be used to describe facilitated diffusion carriers.

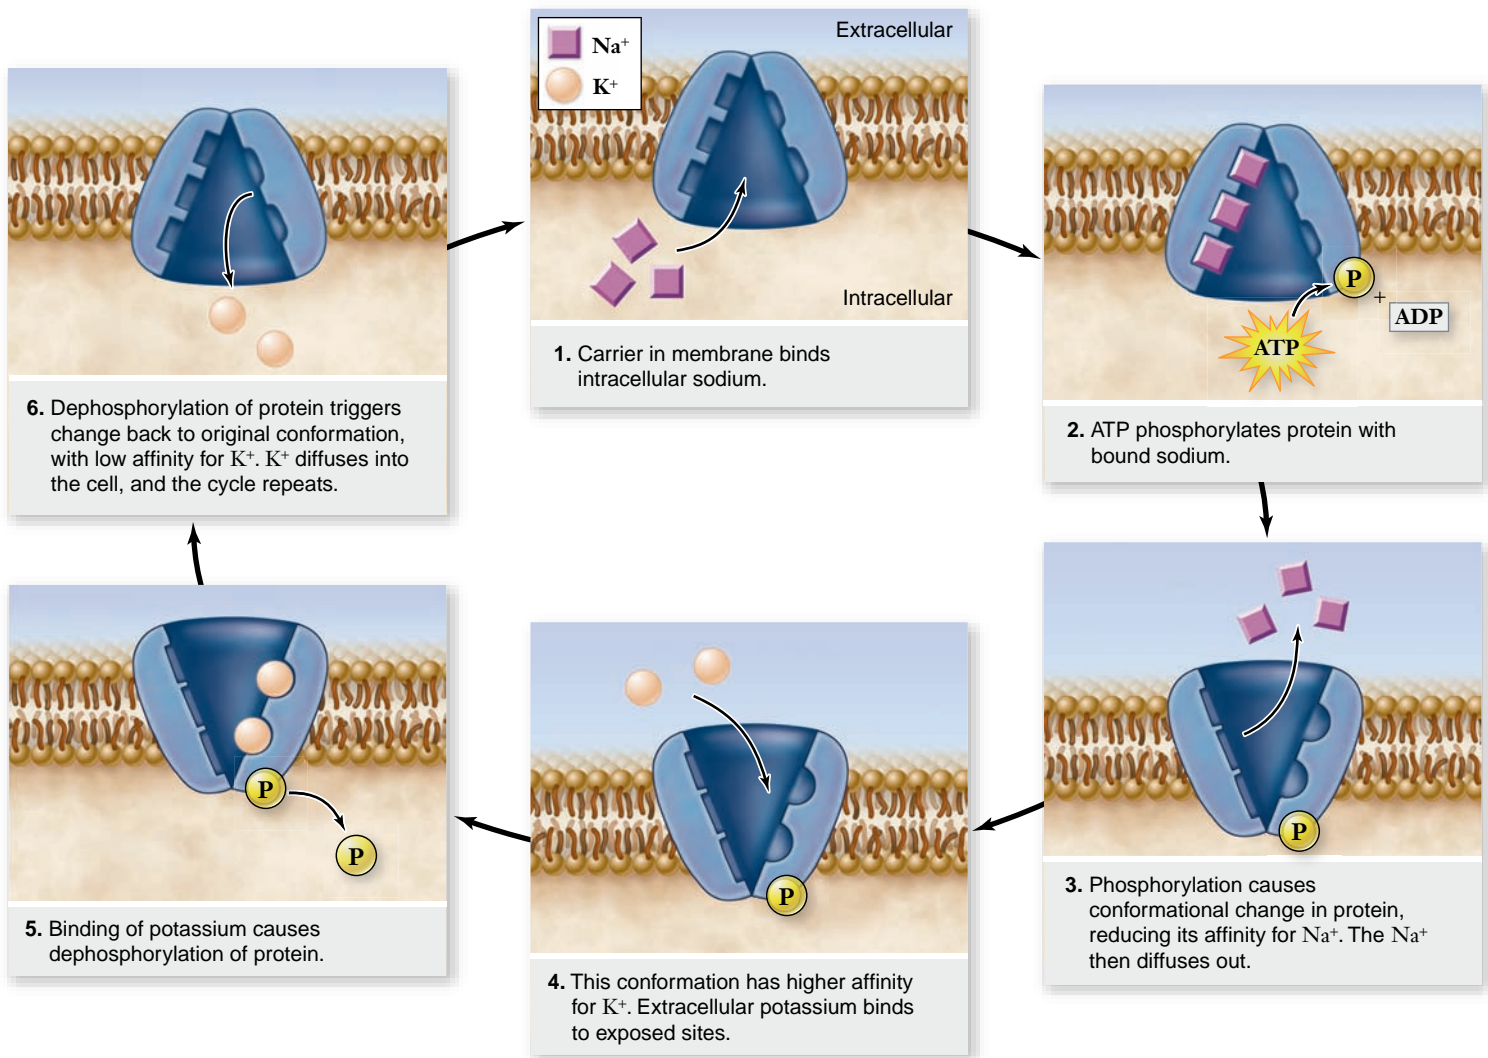

Active transport is one of the most important functions of any cell. It enables a cell to take up additional molecules of a substance that is already present in its cytoplasm in concentrations higher than in the extracellular fluid. Active

transport also enables a cell to move substances out of its cytoplasm and into the extracellular fluid, despite higher external concentrations.

The use of energy from ATP in active transport may be direct or indirect. Let's first consider how ATP is used directly to move ions against their concentration gradients.

## The sodium–potassium pump runs directly on ATP

More than one-third of all of the energy expended by an animal cell that is not actively dividing is used in the active transport of sodium ( $\text{Na}^+$ ) and potassium ( $\text{K}^+$ ) ions. Most animal cells have a low internal concentration of  $\text{Na}^+$ , relative to their surroundings, and a high internal concentration of  $\text{K}^+$ . They maintain these concentration differences by actively pumping  $\text{Na}^+$  out of the cell and  $\text{K}^+$  in.

**Figure 5.13 The sodium–potassium pump.** The protein carrier known as the sodium–potassium pump transports sodium ( $\text{Na}^+$ ) and potassium ( $\text{K}^+$ ) across the plasma membrane. For every three  $\text{Na}^+$  transported out of the cell, two  $\text{K}^+$  are transported into it. The sodium–potassium pump is fueled by ATP hydrolysis. The affinity of the pump for  $\text{Na}^+$  and  $\text{K}^+$  is changed by adding or removing phosphate (P), which changes the conformation of the protein.

The remarkable protein that transports these two ions across the cell membrane is known as the **sodium–potassium pump** (figure 5.13). This carrier protein uses the energy stored in ATP to move these two ions. In this case, the energy is used to change the conformation of the carrier protein, which changes its affinity for either  $\text{Na}^+$  ions or  $\text{K}^+$  ions. This is an excellent illustration of how subtle changes in the structure of a protein affect its function.

The important characteristic of the sodium–potassium pump is that it is an active transport mechanism, transporting  $\text{Na}^+$  and  $\text{K}^+$  from areas of low concentration to areas of high concentration. This transport is the opposite of passive transport by diffusion; it is achieved only by the constant expenditure of metabolic energy. The sodium–potassium pump works through the following series of conformational changes in the transmembrane protein (summarized in figure 5.13):

- Step 1.** Three  $\text{Na}^+$  bind to the cytoplasmic side of the protein, causing the protein to change its conformation.
- Step 2.** In its new conformation, the protein binds a molecule of ATP and cleaves it into adenosine diphosphate (ADP) and phosphate ( $\text{P}_i$ ). ADP is released, but the phosphate group is covalently linked to the protein. The protein is now phosphorylated.
- Step 3.** The phosphorylation of the protein induces a second conformational change in the protein. This change translocates the three  $\text{Na}^+$  across the membrane, so they now face the exterior. In this new conformation, the protein has a low affinity for  $\text{Na}^+$ , and the three bound  $\text{Na}^+$  break away from the protein and diffuse into the extracellular fluid.
- Step 4.** The new conformation has a high affinity for  $\text{K}^+$ , two of which bind to the extracellular side of the protein as soon as it is free of the  $\text{Na}^+$ .
- Step 5.** The binding of the  $\text{K}^+$  causes another conformational change in the protein, this time resulting in the hydrolysis of the bound phosphate group.
- Step 6.** Freed of the phosphate group, the protein reverts to its original shape, exposing the two  $\text{K}^+$  to the cytoplasm. This conformation has a low affinity for  $\text{K}^+$ , so the two bound  $\text{K}^+$  dissociate from the protein and diffuse into the interior of the cell. The original conformation has a high affinity for  $\text{Na}^+$ . When these ions bind, they initiate another cycle.

In every cycle, three  $\text{Na}^+$  leave the cell and two  $\text{K}^+$  enter. The changes in protein conformation that occur during the cycle are rapid, enabling each carrier to transport as many as 300  $\text{Na}^+$  per second. The sodium–potassium pump appears to exist in all animal cells, although cells vary widely in the number of pump proteins they contain.

### Coupled transport uses ATP indirectly

Some molecules are moved against their concentration gradient by using the energy stored in a gradient of a different molecule. In this process, called *coupled transport*, the energy released

as one molecule moves down its concentration gradient is captured and used to move a different molecule against its gradient. As you just saw, the energy stored in ATP molecules can be used to create a gradient of  $\text{Na}^+$  and  $\text{K}^+$  across the membrane. These gradients can then be used to power the transport of other molecules across the membrane.

As one example, let's consider the active transport of glucose across the membrane in animal cells. Glucose is such an important molecule that there are a variety of transporters for it, one of which was discussed earlier under passive transport. In a multicellular organism, intestinal epithelial cells can have a higher concentration of glucose inside the cell than outside, so these cells need to be able to transport glucose against its concentration gradient. This requires energy and a different transporter than the one involved in facilitated diffusion of glucose.

The active glucose transporter uses the  $\text{Na}^+$  gradient produced by the sodium–potassium pump as a source of energy to power the movement of glucose into the cell. In this system, both glucose and  $\text{Na}^+$  bind to the transport protein, which allows  $\text{Na}^+$  to pass into the cell down its concentration gradient, capturing the energy and using it to move glucose into the cell. In this kind of cotransport, both molecules are moving in the same direction across the membrane; therefore the transporter is a symporter (figure 5.14).

**Figure 5.14 Coupled transport.** A membrane protein transports  $\text{Na}^+$  into the cell, down its concentration gradient, at the same time it transports a glucose molecule into the cell. The gradient driving the  $\text{Na}^+$  entry allows sugar molecules to be transported against their concentration gradient. The  $\text{Na}^+$  gradient is maintained by the  $\text{Na}^+/\text{K}^+$  pump. ADP = adenosine diphosphate; ATP = adenosine triphosphate;  $\text{P}_i$  = inorganic phosphate

## 5.6

## Bulk Transport by Endocytosis and Exocytosis

## Learning Outcomes

1. Distinguish between endocytosis and exocytosis.
2. Explain how endocytosis can be specific.

In a related process, called *countertransport*, the inward movement of  $\text{Na}^+$  is coupled with the outward movement of another substance, such as  $\text{Ca}^{2+}$  or  $\text{H}^+$ . As in cotransport, both  $\text{Na}^+$  and the other substance bind to the same transport protein, which in this case is an antiporter, as the substances bind on opposite sides of the membrane and are moved in opposite directions. In countertransport, the cell uses the energy released as  $\text{Na}^+$  moves down its concentration gradient into the cell to eject a substance against its concentration gradient. In both cotransport and countertransport, the potential energy in the concentration gradient of one molecule is used to transport another molecule against its concentration gradient. They differ only in the direction that the second molecule moves relative to the first.

## Learning Outcomes Review 5.5

Active transport requires both a carrier protein and energy, usually in the form of ATP, to move molecules against a concentration gradient. The sodium–potassium pump uses ATP to move  $\text{Na}^+$  in one direction and  $\text{K}^+$  in the other to create and maintain concentration differences of these ions. In coupled transport, a favorable concentration gradient of one molecule is used to move a different molecule against its gradient, such as in the transport of glucose by  $\text{Na}^+$ .

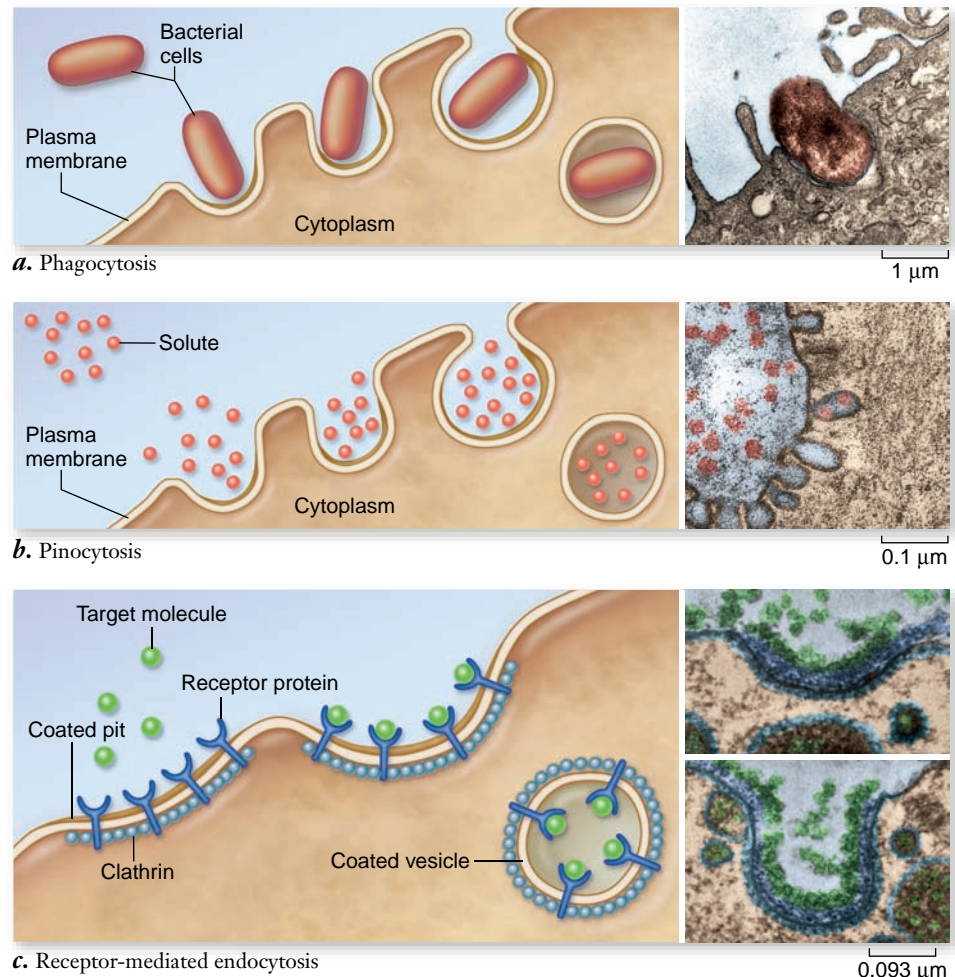

- Can active transport involve a channel protein. Why or why not?

The lipid nature of cell plasma membranes raises a second problem. The substances cells require for growth are mostly large, polar molecules that cannot cross the hydrophobic barrier a lipid bilayer creates. How do these substances get into cells? Two processes are involved in this **bulk transport**: *endocytosis* and *exocytosis*.

## Bulk material enters the cell in vesicles

In **endocytosis**, the plasma membrane envelops food particles and fluids. Cells use three major types of endocytosis: phagocytosis, pinocytosis, and receptor-mediated endocytosis (figure 5.15). Like active transport, these processes also require energy expenditure.

**Figure 5.15 Endocytosis.** Both (a) phagocytosis and (b) pinocytosis are forms of endocytosis. c. In receptor-mediated endocytosis, cells have pits coated with the protein clathrin that initiate endocytosis when target molecules bind to receptor proteins in the plasma membrane. Photo inserts (false color has been added to enhance distinction of structures): (a) A TEM of phagocytosis of a bacterium, *Rickettsia tsutsugamushi*, by a mouse peritoneal mesothelial cell. The bacterium enters the host cell by phagocytosis and replicates in the cytoplasm. (b) A TEM of pinocytosis in a smooth muscle cell. (c) A coated pit appears in the plasma membrane of a developing egg cell, covered with a layer of proteins. When an appropriate collection of molecules gathers in the coated pit, the pit deepens and will eventually seal off to form a vesicle.

## Phagocytosis and pinocytosis

If the material the cell takes in is particulate (made up of discrete particles), such as an organism or some other fragment of organic matter (figure 5.15*a*), the process is called **phagocytosis** (Greek *phagein*, “to eat,” + *cytos*, “cell”). If the material the cell takes in is liquid (figure 5.15*b*), the process is called **pinocytosis** (Greek *pinein*, “to drink”). Pinocytosis is common among animal cells. Mammalian egg cells, for example, “nurse” from surrounding cells; the nearby cells secrete nutrients that the maturing egg cell takes up by pinocytosis.

Virtually all eukaryotic cells constantly carry out these kinds of endocytotic processes, trapping particles and extracellular fluid in vesicles and ingesting them. Endocytosis rates vary from one cell type to another. They can be surprisingly high; some types of white blood cells ingest up to 25% of their cell volume each hour.

## Receptor-mediated endocytosis

Molecules are often transported into eukaryotic cells through **receptor-mediated endocytosis**. These molecules first bind to specific receptors in the plasma membrane—they have a conformation that fits snugly into the receptor. Different cell types contain a characteristic battery of receptor types, each for a different kind of molecule in their membranes.

The portion of the receptor molecule that lies inside the membrane is trapped in an indented pit coated on the cytoplasmic side with the protein *clathrin*. Each pit acts like a molecular mousetrap, closing over to form an internal vesicle when the right molecule enters the pit (figure 5.15*c*). The trigger that releases the trap is the binding of the properly fitted target molecule to the embedded receptor. When binding occurs, the cell reacts by initiating endocytosis; the process is highly specific and very fast. The vesicle is now inside the cell carrying its cargo.

One type of molecule that is taken up by receptor-mediated endocytosis is low-density lipoprotein (LDL). LDL molecules bring cholesterol into the cell where it can be in-

corporated into membranes. Cholesterol plays a key role in determining the stiffness of the body’s membranes. In the human genetic disease familial hypercholesterolemia, the LDL receptors lack tails, so they are never fastened in the clathrin-coated pits and as a result, do not trigger vesicle formation. The cholesterol stays in the bloodstream of affected individuals, accumulating as plaques inside arteries and leading to heart attacks.

It is important to understand that endocytosis in itself does not bring substances directly into the cytoplasm of a cell. The material taken in is still separated from the cytoplasm by the membrane of the vesicle.

## Material can leave the cell by exocytosis

The reverse of endocytosis is **exocytosis**, the discharge of material from vesicles at the cell surface (figure 5.16). In plant cells, exocytosis is an important means of exporting the materials needed to construct the cell wall through the plasma membrane. Among protists, contractile vacuole discharge is considered a form of exocytosis. In animal cells, exocytosis provides a mechanism for secreting many hormones, neurotransmitters, digestive enzymes, and other substances.

The mechanisms for transport across cell membranes are summarized in table 5.2.

### Learning Outcomes Review 5.6

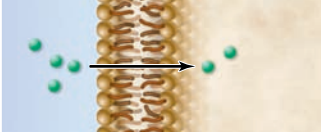

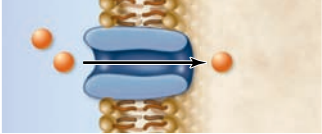

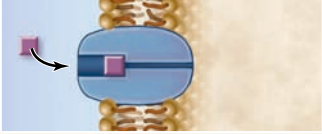

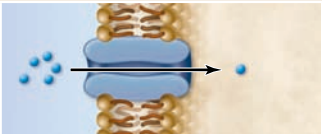

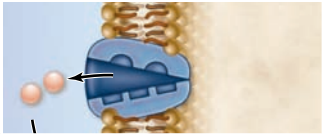

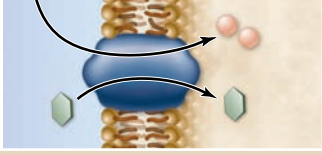

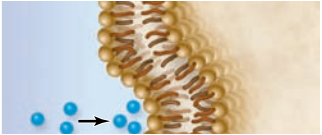

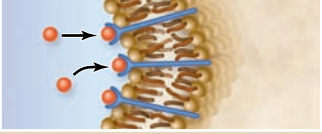

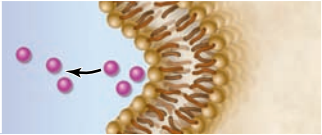

Large molecules and other bulky materials can enter a cell by endocytosis and leave the cell by exocytosis. These processes require energy. Endocytosis may be mediated by specific receptor proteins in the membrane that trigger the formation of vesicles.

- What feature unites transport by receptor-mediated endocytosis, transport by a carrier, and catalysis by an enzyme?

**Figure 5.16 Exocytosis.** *a*. Proteins and other molecules are secreted from cells in small packets called vesicles, whose membranes fuse with the plasma membrane, releasing their contents outside the cell. *b*. A false-colored transmission electron micrograph showing exocytosis.

**TABLE 5.2**
**Mechanisms for Transport Across Cell Membranes**

Process		How It Works	Example
<i>P A S S I V E P R O C E S S E S</i>			
<b>Diffusion</b>			
Direct		Random molecular motion produces net migration of nonpolar molecules toward region of lower concentration	Movement of oxygen into cells
<b>Facilitated Diffusion</b>			
Protein channel		Polar molecules or ions move through a protein channel; net movement is toward region of lower concentration	Movement of ions in or out of cell
Protein carrier		Molecule binds to carrier protein in membrane and is transported across; net movement is toward region of lower concentration	Movement of glucose into cells
<b>Osmosis</b>			
Aquaporins		Diffusion of water across the membrane via osmosis; requires osmotic gradient	Movement of water into cells placed in a hypotonic solution
<i>A C T I V E P R O C E S S E S</i>			
<b>Active Transport</b>			
Protein carrier			
Na <sup>+</sup> /K <sup>+</sup> pump		Carrier uses energy to move a substance across a membrane against its concentration gradient	Na <sup>+</sup> and K <sup>+</sup> against their concentration gradients
Coupled transport		Molecules are transported across a membrane against their concentration gradients by the cotransport of sodium ions or protons down their concentration gradients	Coupled uptake of glucose into cells against its concentration gradient using a Na <sup>+</sup> gradient
<b>Endocytosis</b>			
Membrane vesicle			
Phagocytosis		Particle is engulfed by membrane, which folds around it and forms a vesicle	Ingestion of bacteria by white blood cells
Pinocytosis		Fluid droplets are engulfed by membrane, which forms vesicles around them	"Nursing" of human egg cells
Receptor-mediated endocytosis		Endocytosis triggered by a specific receptor, forming clathrin-coated vesicles	Cholesterol uptake
<b>Exocytosis</b>			
Membrane vesicle			
		Vesicles fuse with plasma membrane and eject contents	Secretion of mucus; release of neurotransmitters

## 5.1 The Structure of Membranes

**The fluid mosaic model shows proteins embedded in a fluid lipid bilayer.**

Membranes are sheets of phospholipid bilayers with associated proteins (figure 5.2). Hydrophobic regions of a membrane are oriented inward and hydrophilic regions oriented outward. In the fluid mosaic model, proteins float on or in the lipid bilayer.

**Cellular membranes consist of four component groups.**

In eukaryotic cells, membranes have four components: a phospholipid bilayer, transmembrane proteins (integral membrane proteins), an interior protein network, and cell-surface markers. The interior protein network is composed of cytoskeletal filaments and peripheral membrane proteins, which are associated with the membrane but are not an integral part. Membranes contain glycoproteins and glycolipids on the surface that act as cell identity markers.

**Electron microscopy has provided structural evidence.**

Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) have confirmed the structure predicted by the fluid mosaic model.

## 5.2 Phospholipids: The Membrane's Foundation

Phospholipids are composed of two fatty acids and a phosphate group linked to a three-carbon glycerol molecule.

**Phospholipids spontaneously form bilayers.**

The phosphate group of a phospholipid is polar and hydrophilic; the fatty acids are nonpolar and hydrophobic, and they orient away from the polar head of the phospholipids. The nonpolar interior of the lipid bilayer impedes the passage of water and water-soluble substances.

**The phospholipid bilayer is fluid.**

Hydrogen bonding of water keeps the membrane in its bilayer configuration; however, phospholipids and unanchored proteins in the membrane are loosely associated and can diffuse laterally.

**Membrane fluidity can change.**

Membrane fluidity depends on the fatty acid composition of the membrane. Unsaturated fats tend to make the membrane more fluid because of the “kinks” of double bonds in the fatty acid tails. Temperature also affects fluidity. Some bacteria have enzymes that alter the fatty acids of the membrane to compensate for temperature changes.

## 5.3 Proteins: Multifunctional Components

**Proteins and protein complexes perform key functions.**

Transporters are integral membrane proteins that carry specific substances through the membrane. Enzymes often occur on the interior surface of the membrane. Cell-surface receptors respond to external chemical messages and change conditions inside the cell; cell identity markers on the surface allow recognition of the body's cells as “self.” Cell-to-cell adhesion proteins glue cells together; surface proteins that interact with other cells anchor to the cytoskeleton.

**Structural features of membrane proteins relate to function.**

Surface proteins are attached to the surface by nonpolar regions that associate with polar regions of phospholipids. Transmembrane proteins may cross the bilayer a number of times, and each membrane-spanning region is called a transmembrane domain. Such a domain is composed of hydrophobic amino acids usually arranged in  $\alpha$ -helices. In certain proteins,  $\beta$ -pleated sheets in the nonpolar region form a pipelike passageway having a polar environment. An example is the porin class of proteins.

## 5.4 Passive Transport Across Membranes

**Transport can occur by simple diffusion.**

Simple diffusion is the passive movement of a substance along a chemical or electrical gradient. Biological membranes pose a barrier to hydrophilic polar molecules, while they allow hydrophobic substances to diffuse freely.

**Proteins allow membrane diffusion to be selective.**

Ions and large hydrophilic molecules cannot cross the phospholipid bilayer. Diffusion can still occur with the help of proteins, thus we call this facilitated diffusion. These proteins can be either channels, or carriers. Channels allow the diffusion of ions based on concentration and charge across the membrane. They are specific for different ions, but form an aqueous pore in the membrane. Carrier proteins bind to the molecules they transport, much like an enzyme. The rate of transport by a carrier is limited by the number of carriers in the membrane.

**Osmosis is the movement of water across membranes.**

The direction of movement due to osmosis depends on the solute concentration on either side of the membrane (figure 5.12). Solutions can be isotonic, hypotonic, or hypertonic. Cells in an isotonic solution are in osmotic balance; cells in a hypotonic solution will gain water; and cells in a hypertonic solution will lose water. Aquaporins are water channels that facilitate the diffusion of water.

## 5.5 Active Transport Across Membranes

**Active transport uses energy to move materials against a concentration gradient.**

Active transport uses specialized protein carriers that couple a source of energy to transport. They are classified based on the number of molecules and direction of transport. Uniporters transport a specific molecule in one direction; symporters transport two molecules in the same direction; and antiporters transport two molecules in opposite directions.

**The sodium–potassium pump runs directly on ATP.**

The sodium–potassium pump moves  $\text{Na}^+$  out of the cell and  $\text{K}^+$  into the cell against their concentration gradients using ATP. In every cycle of the pump, three  $\text{Na}^+$  leave the cell and two  $\text{K}^+$  enter it. This pump appears to be almost universal in animal cells.

**Coupled transport uses ATP indirectly.**

Coupled transport occurs when the energy released by a diffusing molecule is used to transport a different molecule against its concentration gradient in the same direction. Countertransport is similar to coupled transport, but the two molecules move in opposite directions.

## 5.6 Bulk Transport by Endocytosis and Exocytosis

Bulk transport moves large quantities of substances that cannot pass through the cell membrane.

**Bulk material enters the cell in vesicles.**

In endocytosis, the cell membrane surrounds material and pinches off to form a vesicle. In receptor-mediated endocytosis, specific molecules bind to receptors on the cell membrane.

**Material can leave the cell by exocytosis.**

In exocytosis, material in a vesicle is discharged when the vesicle fuses with the membrane.

## Review Questions

### UNDERSTAND

- The fluid mosaic model of the membrane describes the membrane as
  - containing a significant quantity of water in the interior.
  - composed of fluid phospholipids on the outside and protein on the inside.
  - composed of protein on the outside and fluid phospholipids on the inside.
  - made of proteins and lipids that can freely move.
- What chemical property characterizes the interior of the phospholipid bilayer?
  - It is hydrophobic.
  - It is hydrophilic.
  - It is polar.
  - It is saturated.
- The transmembrane domain of an integral membrane protein
  - is composed of hydrophobic amino acids.
  - often forms an  $\alpha$ -helical structure.
  - can cross the membrane multiple times.
  - is all of the above.
- The specific function of a membrane within a cell is determined by the
  - degree of saturation of the fatty acids within the phospholipid bilayer.
  - location of the membrane within the cell.
  - presence of lipid rafts and cholesterol.
  - type and number of membrane proteins.
- The movement of water across a membrane is dependent on
  - the solvent concentration.
  - the solute concentration.
  - the presence of carrier proteins.
  - membrane potential.
- If a cell is in an isotonic environment, then
  - the cell will gain water and burst.
  - no water will move across the membrane.
  - the cell will lose water and shrink.
  - osmosis still occurs, but there is no net gain or loss of cell volume.
- Which of the following is NOT a mechanism for bringing material into a cell?
  - Exocytosis
  - Endocytosis
  - Pinocytosis
  - Phagocytosis

### APPLY

- A bacterial cell that can alter the composition of saturated and unsaturated fatty acids in its membrane lipids is adapted to a cold environment. If this cell is shifted to a warmer environment, it will react by
  - increasing the amount of cholesterol in its membrane.
  - altering the amount of protein present in the membrane.
  - increasing the degree of saturated fatty acids in its membrane.
  - increasing the percentage of unsaturated fatty acids in its membrane.
- What variable(s) influence(s) whether a nonpolar molecule can move across a membrane by passive diffusion?
  - The structure of the phospholipids bilayer
  - The difference in concentration of the molecule across the membrane

- The presence of transport proteins in the membrane
  - All of the above
- Which of the following does NOT contribute to the selective permeability of a biological membrane?
    - Specificity of the carrier proteins in the membrane
    - Selectivity of channel proteins in the membrane
    - Hydrophobic barrier of the phospholipid bilayer
    - Hydrogen bond formation between water and phosphate groups
  - How are *active* transport and *coupled* transport related?
    - They both use ATP to move molecules.
    - Active transport establishes a concentration gradient, but coupled transport doesn't.
    - Coupled transport uses the concentration gradient established by active transport.
    - Active transport moves one molecule, but coupled transport moves two.
  - A cell can use the process of facilitated diffusion to
    - concentrate a molecule such as glucose inside a cell.
    - remove all of a toxic molecule from a cell.
    - move ions or large polar molecules across the membrane regardless of concentration.
    - move ions or large polar molecules from a region of high concentration to a region of low concentration.

### SYNTHESIZE

- Figure 5.4 describes a classic experiment demonstrating the ability of proteins to move within the plane of the cell's plasma membrane. The following table outlines three different experiments using the fusion of labeled mouse and human cells.

Experiment	Conditions	Temperature (°C)	Result
1	Fuse human and mouse cells	37	Intermixed membrane proteins
2	Fuse human and mouse cells in presence of ATP inhibitors	37	Intermixed membrane proteins
3	Fuse human and mouse cells	4	No intermixing of membrane proteins

What conclusions can you reach about the movement of these proteins?

- Each compartment of the endomembrane system of a cell is connected to the plasma membrane. Create a simple diagram of a cell including the RER, Golgi apparatus, vesicle, and the plasma membrane. Starting with the RER, use two different colors to represent the inner and outer halves of the bilayer for each of these membranes. What do you observe?
- The distribution of lipids in the ER membrane is symmetric, that is, it is the same in both leaflets of the membrane. The Golgi apparatus and plasma membrane do not have symmetric distribution of membrane lipids. What kinds of processes could achieve this outcome?

# Chapter 6

## Energy and Metabolism

### Chapter Outline

- 6.1 The Flow of Energy in Living Systems
- 6.2 The Laws of Thermodynamics and Free Energy
- 6.3 ATP: The Energy Currency of Cells
- 6.4 Enzymes: Biological Catalysts
- 6.5 Metabolism: The Chemical Description of Cell Function

### Introduction

*Life can be viewed as a constant flow of energy, channeled by organisms to do the work of living. Each of the significant properties by which we define life—order, growth, reproduction, responsiveness, and internal regulation—requires a constant supply of energy. Both the lion and the giraffe need to eat to provide energy for a wide variety of cellular functions. Deprived of a source of energy, life stops. Therefore, a comprehensive study of life would be impossible without discussing bioenergetics, the analysis of how energy powers the activities of living systems. In this chapter, we focus on energy—what it is and how it changes during chemical reactions.*

## 6.1 The Flow of Energy in Living Systems

### Learning Outcomes

1. Explain what energy is and describe its different forms.
2. Identify the source of energy for the biosphere.
3. Contrast oxidation and reduction reactions.

**Thermodynamics** is the branch of chemistry concerned with energy changes. Cells are governed by the laws of physics and chemistry, so we must understand these laws in order to understand how cells function.

### Energy can take many forms

*Energy* is defined as the capacity to do work. We think of energy as existing in two states: kinetic energy and potential energy (figure 6.1). **Kinetic energy** is the energy of motion. Moving objects perform work by causing other matter to move. **Potential energy** is stored energy. Objects that are not actively moving but have the capacity to do so possess potential energy. A boulder perched on a hilltop has gravitational potential energy. As it begins to roll downhill, some of its potential energy is converted into kinetic energy. Much of the work that living organisms carry out involves transforming potential energy into kinetic energy.

Energy can take many forms: mechanical energy, heat, sound, electric current, light, or radioactivity. Because it can exist in so

many forms, energy can be measured in many ways. Heat is the most convenient way of measuring energy because all other forms of energy can be converted into heat. In fact, the term *thermodynamics* means “heat changes.”

The unit of heat most commonly employed in biology is the kilocalorie (kcal). One kilocalorie is equal to 1000 calories (cal). One calorie is the heat required to raise the temperature of one gram of water one degree Celsius ( $^{\circ}\text{C}$ ). (You are probably more used to seeing the term *Calorie* with a capital C. This is used on food labels and is actually the same as kilocalorie.) Another energy unit, often used in physics, is the *joule*; one joule equals 0.239 cal.

### The sun provides energy for living systems

Energy flows into the biological world from the Sun. It is estimated that the Sun provides the Earth with more than  $13 \times 10^{23}$  calories per year, or 40 million billion calories per second! Plants, algae, and certain kinds of bacteria capture a fraction of this energy through photosynthesis.

In photosynthesis, energy absorbed from sunlight is used to combine small molecules (water and carbon dioxide) into more complex ones (sugars). This process converts carbon from an inorganic to an organic form. In the process, energy from the Sun is stored as potential energy in the covalent bonds between atoms in the sugar molecules.

Breaking the bonds between atoms requires energy. In fact, the strength of a covalent bond is measured by the amount of energy required to break it. For example, it takes 98.8 kcal to break one mole ( $6.023 \times 10^{23}$ ) of the carbon–hydrogen (C—H) bonds found in organic molecules. Fat molecules have many C—H bonds, and breaking those bonds provides lots of energy.

a. Potential energy

b. Kinetic energy

**Figure 6.1 Potential and kinetic energy.** *a.* Objects that have the capacity to move but are not moving have potential energy. The energy required for the girl to climb to the top of the slide is stored as potential energy. *b.* Objects that are in motion have kinetic energy. The stored potential energy is released as kinetic energy as the girl slides down.

## 6.2 The Laws of Thermodynamics and Free Energy

**Figure 6.2 Redox reactions.** Oxidation is the loss of an electron; reduction is the gain of an electron. In this example, the charges of molecules A and B appear as superscripts in each molecule. Molecule A loses energy as it loses an electron, and molecule B gains that energy as it gains an electron.

This is one reason animals store fat. The oxidation of one mole of a 16-carbon fatty acid that is completely saturated with hydrogens yields 2340 kcal.

### Oxidation–reduction reactions transfer electrons while bonds are made or broken

During a chemical reaction, the energy stored in chemical bonds may be used to make new bonds. In some of these reactions, electrons actually pass from one atom or molecule to another. An atom or molecule that loses an electron is said to be oxidized, and the process by which this occurs is called **oxidation**. The name comes from the fact that oxygen is the most common electron acceptor in biological systems. Conversely, an atom or molecule that gains an electron is said to be reduced, and the process is called *reduction*. The reduced form of a molecule has a higher level of energy than the oxidized form (figure 6.2).

Oxidation and reduction always take place together, because every electron that is lost by one atom through oxidation is gained by another atom through reduction. Therefore, chemical reactions of this sort are called **oxidation–reduction**, or **redox**, reactions. Oxidation–reduction reactions play a key role in the flow of energy through biological systems.

In the next two chapters, you will learn the details of how organisms derive energy from the oxidation of organic compounds via respiration, as well as from the energy in sunlight via photosynthesis.

#### Learning Outcomes Review 6.1

Energy is defined as the capacity to do work. The two forms of energy are kinetic energy, or energy of motion, and potential energy, or stored energy. The ultimate source of energy for living systems is the Sun. Organisms derive their energy from oxidation–reduction reactions. In oxidation, a molecule loses an electron; in reduction, a molecule gains an electron.

- **What energy source might ecosystems at the bottom of the ocean use?**

#### Learning Outcomes

1. Explain the laws of thermodynamics.
2. Recognize how free energy can be used to predict the outcome of chemical reactions.
3. Contrast the course of a reaction with and without an enzyme catalyst.

All activities of living organisms—growing, running, thinking, singing, reading these words—involve changes in energy. A set of two universal laws we call the laws of thermodynamics govern all energy changes in the universe, from nuclear reactions to a bird flying through the air.

### The First Law states that energy cannot be created or destroyed

The **First Law of Thermodynamics** concerns the amount of energy in the universe. Energy cannot be created or destroyed; it can only change from one form to another (from potential to kinetic, for example). The total amount of energy in the universe remains constant.

The lion eating a giraffe at the beginning of this chapter is acquiring energy. Rather than creating new energy or capturing the energy in sunlight, the lion is merely transferring some of the potential energy stored in the giraffe's tissues to its own body, just as the giraffe obtained the potential energy stored in the plants it ate while it was alive.

Within any living organism, chemical potential energy stored in some molecules can be shifted to other molecules and stored in different chemical bonds. It can also be converted into other forms, such as kinetic energy, light, or electricity. During each conversion, some of the energy dissipates into the environment as **heat**, which is a measure of the random motion of molecules (and therefore a measure of one form of kinetic energy). Energy continuously flows through the biological world in one direction, with new energy from the Sun constantly entering the system to replace the energy dissipated as heat.

Heat can be harnessed to do work only when there is a heat gradient—that is, a temperature difference between two areas. Cells are too small to maintain significant internal temperature differences, so heat energy is incapable of doing the work of cells. Instead, cells must rely on chemical reactions for energy.

Although the total amount of energy in the universe remains constant, the energy available to do work decreases as more of it is progressively lost as heat.

## The Second Law states that some energy is lost as disorder increases

The **Second Law of Thermodynamics** concerns the transformation of potential energy into heat, or random molecular motion. It states that the disorder in the universe, more formally called **entropy**, is continuously increasing. Put simply, disorder is more likely than order. For example, it is much more likely that a column of bricks will tumble over than that a pile of bricks will arrange themselves spontaneously to form a column.

In general, energy transformations proceed spontaneously to convert matter from a more ordered, less stable form to a less ordered, but more stable form. For this reason, the second law is sometimes called “time’s arrow.” Looking at the photographs in figure 6.3, you could put the pictures into correct sequence using the information that time had elapsed with only natural processes occurring. Although it might be great if our rooms would straighten themselves up, we know from experience how much work it takes to do so.

The Second Law of Thermodynamics can also be stated simply as “entropy increases.” When the universe formed, it held all the potential energy it will ever have. It has become progressively more disordered ever since, with every energy exchange increasing the amount of entropy.

## Chemical reactions can be predicted based on changes in free energy

It takes energy to break the chemical bonds that hold the atoms in a molecule together. Heat energy, because it increases atomic motion, makes it easier for the atoms to pull apart. Both chemical bonding and heat have a significant influence on a molecule. Chemical bonding reduces disorder; heat increases it. The net effect, the amount of energy actually available to break and subsequently form other chemical bonds, is called the *free energy* of that molecule. In a more general sense, **free energy** is defined as the energy available to do work in any system.

For a molecule within a cell, where pressure and volume usually do not change, the free energy is denoted by the symbol  $G$  (for “Gibbs free energy”).  $G$  is equal to the energy contained in a molecule’s chemical bonds (called **enthalpy** and designated  $H$ ) together with the energy term ( $TS$ ) related to the degree of disorder in the system, where  $S$  is the symbol for *entropy* and  $T$  is the absolute temperature expressed in the Kelvin scale ( $K = ^\circ\text{C} + 273$ ):

$$G = H - TS$$

Chemical reactions break some bonds in the reactants and form new ones in the products. Consequently, reactions can produce changes in free energy. When a chemical reaction occurs under conditions of constant temperature, pressure, and volume—as do most biological reactions—the change symbolized by the Greek capital letter delta,  $\Delta$ , in free energy ( $\Delta G$ ) is simply:

$$\Delta G = \Delta H - T\Delta S$$

We can use the change in free energy, or  $\Delta G$ , to predict whether a chemical reaction is spontaneous or not. For some reactions, the  $\Delta G$  is positive, which means that the products of the reaction contain *more* free energy than the reactants; the bond energy ( $H$ ) is higher, or the disorder ( $S$ ) in the system is lower. Such reactions do not proceed spontaneously because they require an input of energy. Any reaction that requires an input of energy is said to be **endergonic** (“inward energy”).

For other reactions, the  $\Delta G$  is negative. In this case, the products of the reaction contain less free energy than the reactants; either the bond energy is lower, or the disorder is higher, or both. Such reactions tend to proceed spontaneously. These reactions release the excess free energy as heat and are thus said to be **exergonic** (“outward energy”). Any chemical reaction tends to proceed spontaneously if the difference in disorder ( $T\Delta S$ ) is *greater* than the difference in bond energies between reactants and products ( $\Delta H$ ).

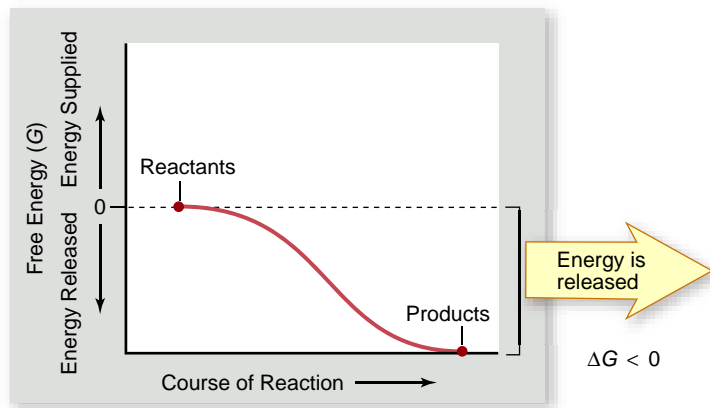

Note that *spontaneous* does not mean the same thing as *instantaneous*. A spontaneous reaction may proceed very slowly. Figure 6.4 sums up endergonic and exergonic reactions.

**Figure 6.3 Entropy in action.** As time elapses, the room shown at right becomes more disorganized. Entropy has increased in this room. It takes energy to restore it to the ordered state shown at left.

a.

b.

**Figure 6.4 Energy in chemical reactions.** *a.* In an endergonic reaction, the products of the reaction contain more energy than the reactants, and the extra energy must be supplied for the reaction to proceed. *b.* In an exergonic reaction, the products contain less energy than the reactants, and the excess energy is released.

Because chemical reactions are reversible, a reaction that is exergonic in the forward direction will be endergonic in the reverse direction. For each reaction, an equilibrium exists at some point between the relative amounts of reactants and products. This equilibrium has a numeric value and is called the *equilibrium constant*. This characteristic of reactions provides us with another way to think about free energy changes: an exergonic reaction has an equilibrium favoring the products, and an endergonic reaction has an equilibrium favoring the reactants.

## Spontaneous chemical reactions require activation energy

If all chemical reactions that release free energy tend to occur spontaneously, why haven't all such reactions already occurred? Consider the gasoline tank of your car: The oxidation of the hydrocarbons in gasoline is an exergonic reaction, but your gas tank does not spontaneously explode. One reason is that most reactions require an input of energy to get started. In the case of your car, this input consists of the electrical sparks in the engine's cylinders, producing a controlled explosion.

## Activation energy

Before new chemical bonds can form, even bonds that contain less energy, existing bonds must first be broken, and that requires energy input. The extra energy needed to destabilize existing chemical bonds and initiate a chemical reaction is called **activation energy** (figure 6.5).

The rate of an exergonic reaction depends on the activation energy required for the reaction to begin. Reactions with larger activation energies tend to proceed more slowly because fewer molecules succeed in getting over the initial energy hurdle. The rate of reactions can be increased in two ways: (1) by increasing the energy of reacting molecules or (2) by lowering activation energy. Chemists often drive important industrial reactions by increasing the energy of the reacting molecules, which is frequently accomplished simply by heating up the reactants. The other strategy is to use a catalyst to lower the activation energy.

## How catalysts work

Activation energies are not constant. Stressing particular chemical bonds can make them easier to break. The process of influencing chemical bonds in a way that lowers the activation energy needed to initiate a reaction is called **catalysis**, and substances that accomplish this are known as *catalysts* (see figure 6.5).

Catalysts cannot violate the basic laws of thermodynamics; they cannot, for example, make an endergonic reaction proceed spontaneously. By reducing the activation energy, a catalyst accelerates both the forward and the reverse reactions by exactly the same amount. Therefore, a catalyst does not alter the proportion of reactant that is ultimately converted into product.

To understand this, imagine a bowling ball resting in a shallow depression on the side of a hill. Only a narrow rim of dirt below the ball prevents it from rolling down the hill. Now imagine digging away that rim of dirt. If you remove enough dirt from below the ball, it will start to roll down the hill—but

**Figure 6.5 Activation energy and catalysis.** Exergonic reactions do not necessarily proceed rapidly because activation energy must be supplied to destabilize existing chemical bonds. Catalysts accelerate particular reactions by lowering the amount of activation energy required to initiate the reaction. Catalysts do not alter the free-energy change produced by the reaction.

removing dirt from below the ball will *never* cause the ball to roll up the hill. Removing the lip of dirt simply allows the ball to move freely; gravity determines the direction it then travels.

Similarly, the direction in which a chemical reaction proceeds is determined solely by the difference in free energy between reactants and products. Like digging away the soil below the bowling ball on the hill, catalysts reduce the energy barrier that is preventing the reaction from proceeding. Only exergonic reactions can proceed spontaneously, and catalysts cannot change that. What catalysts *can* do is make a reaction proceed much faster. In living systems, enzymes act as catalysts.

### Learning Outcomes Review 6.2

The First Law of Thermodynamics states that energy cannot be created or destroyed. The Second Law states that the loss of energy results in greater disorder, or entropy. Free-energy changes ( $\Delta G$ ) can predict whether chemical reactions take place. Reactions with a negative  $\Delta G$  occur spontaneously, and those with a positive  $\Delta G$  do not. Energy needed to initiate a reaction is termed activation energy. Catalysts, such as enzymes in living systems, lower this activation energy to speed up reactions.

- Can an enzyme make an endergonic reaction exergonic?

## 6.3 ATP: The Energy Currency of Cells

### Learning Outcomes

1. Describe the role of ATP in short-term energy storage.
2. Explain what “high-energy” bonds are in ATP.

The chief “currency” all cells use for their energy transactions is the nucleotide *adenosine triphosphate* (ATP). ATP powers almost every energy-requiring process in cells, from making sugars, to supplying activation energy for chemical reactions, to actively transporting substances across membranes, to moving through the environment and growing.

### Cells store and release energy in the bonds of ATP

You saw in chapter 3 that nucleotides serve as the building blocks for nucleic acids, but they play other cellular roles as well. ATP is used as a building block for RNA molecules, and it also has a critical function as a portable source of energy on demand for endergonic cellular processes.

#### The structure of ATP

Like all nucleotides, ATP is composed of three smaller components (figure 6.6). The first component is a five-carbon sugar, ribose, which serves as the framework to which the other two

subunits are attached. The second component is adenine, an organic molecule composed of two carbon–nitrogen rings. Each of the nitrogen atoms in the ring has an unshared pair of electrons and weakly attracts hydrogen ions, making adenine chemically a weak base. The third component of ATP is a chain of three phosphates.

#### How ATP stores energy

The key to how ATP stores energy lies in its triphosphate group. Phosphate groups are highly negatively charged, and thus they strongly repel one another. This electrostatic repulsion makes the covalent bonds joining the phosphates unstable. The molecule is often referred to as a “coiled spring,” with the phosphates straining away from one another.

**Figure 6.6 The ATP molecule.** The model (a) and the structural diagram (b) both show that ATP has a core of AMP. Addition of one phosphate to AMP yields ADP, and addition of a second phosphate yields ATP. These two terminal phosphates are attached by high-energy bonds so that removing either by hydrolysis is an exergonic reaction that releases energy. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate.

The unstable bonds holding the phosphates together in the ATP molecule have a low activation energy and are easily broken by hydrolysis. When they break, they can transfer a considerable amount of energy. In other words, the hydrolysis of ATP has a negative  $\Delta G$ , and the energy it releases can be used to perform work.

In most reactions involving ATP, only the outermost high-energy phosphate bond is hydrolyzed, cleaving off the phosphate group on the end. When this happens, ATP becomes *adenosine diphosphate* (ADP) plus an **inorganic phosphate** ( $P_i$ ), and energy equal to 7.3 kcal/mol is released under standard conditions. The liberated phosphate group usually attaches temporarily to some intermediate molecule. When that molecule is dephosphorylated, the phosphate group is released as  $P_i$ .

Both of the two terminal phosphates can be hydrolyzed to release energy, leaving *adenosine monophosphate* (AMP), but the third phosphate is not attached by a high-energy bond. With only one phosphate group, AMP has no other phosphates to provide the electrostatic repulsion that makes the bonds holding the two terminal phosphate groups high-energy bonds.

## ATP hydrolysis drives endergonic reactions

Cells use ATP to drive endergonic reactions. These reactions do not proceed spontaneously because their products possess more free energy than their reactants. However, if the cleavage of ATP's terminal high-energy bond releases more energy than the other reaction consumes, the two reactions can be coupled so that the energy released by the hydrolysis of ATP can be used to supply the endergonic reaction with the energy it needs. Coupled together, these reactions result in a net release of energy ( $-\Delta G$ ) and are therefore exergonic and proceed spontaneously. Because almost all the endergonic reactions in cells require less energy than is released by the cleavage of ATP, ATP can provide most of the energy a cell needs.

### Inquiry question

**?** When ATP hydrolysis is coupled with an endergonic reaction and supplies more than enough energy, is the overall process endergonic or exergonic? Would the  $\Delta G$  for the overall process be negative or positive?

## ATP cycles continuously

The same feature that makes ATP an effective energy donor—the instability of its phosphate bonds—prevents it from being a good long-term energy-storage molecule. Fats and carbohydrates serve that function better.

The use of ATP can be thought of as a cycle: Cells use exergonic reactions to provide the energy needed to synthesize ATP from ADP +  $P_i$ ; they then use the hydrolysis of ATP to provide energy to drive the endergonic reactions they need (figure 6.7).

Most cells do not maintain large stockpiles of ATP. Instead, they typically have only a few seconds' supply of ATP at any given time, and they continually produce more from ADP and  $P_i$ . It is estimated that even a sedentary individual turns over an amount of ATP in one day roughly equal to his body weight. This statistic makes clear the importance of ATP synthesis. In the next two chapters we will explore in detail the cellular mechanisms for synthesizing ATP.

**Figure 6.7 The ATP cycle.** ATP is synthesized and hydrolyzed in a cyclic fashion. The synthesis of ATP from ADP +  $P_i$  is endergonic and is powered by exergonic cellular reactions. The hydrolysis of ATP to ADP +  $P_i$  is exergonic, and the energy released is used to power endergonic cellular functions such as muscle contraction. ADP, adenosine diphosphate; ATP, adenosine triphosphate;  $P_i$ , inorganic phosphate.

### Learning Outcomes Review 6.3

ATP is a nucleotide with three phosphate groups. Endergonic cellular processes can be driven by coupling to the exergonic hydrolysis of the two terminal phosphates. The bonds holding the terminal phosphate groups together are easily broken, releasing energy like a coiled spring. The cell is constantly building ATP using exergonic reactions and breaking it down to drive endergonic reactions.

- If the molecular weight of ATP is 507.18 g/mol, and the  $\Delta G$  for hydrolysis is  $-7.3$  kcal/mol how much energy is released over the course of the day by a 100-kg man?

## 6.4 Enzymes: Biological Catalysts

### Learning Outcomes

1. Discuss the specificity of enzymes.
2. Explain how enzymes bind to their substrates.
3. List the factors that influence the rate of enzyme-catalyzed reactions.

The chemical reactions within living organisms are regulated by controlling the points at which catalysis takes place. Life itself, therefore, can be seen as regulated by catalysts. The agents that carry out most of the catalysis in living organisms are called enzymes. Most enzymes are proteins, although increasing evidence indicates that some enzymes are actually RNA molecules, as discussed later in this chapter.

## An enzyme alters the activation energy of a reaction

The unique three-dimensional shape of an enzyme enables it to stabilize a temporary association between **substrates**—the molecules that will undergo the reaction. By bringing two substrates together in the correct orientation or by stressing particular chemical bonds of a substrate, an enzyme lowers the

activation energy required for new bonds to form. The reaction thus proceeds much more quickly than it would without the enzyme.

The enzyme itself is not changed or consumed in the reaction, so only a small amount of an enzyme is needed, and it can be used over and over.

As an example of how an enzyme works, let's consider the reaction of carbon dioxide and water to form carbonic acid. This important enzyme-catalyzed reaction occurs in vertebrate red blood cells:

This reaction may proceed in either direction, but because it has a large activation energy, the reaction is very slow in the absence of an enzyme: Perhaps 200 molecules of carbonic acid form in an hour in a cell in the absence of any enzyme. Reactions that proceed this slowly are of little use to a cell. Vertebrate red blood cells overcome this problem by employing an enzyme within their cytoplasm called *carbonic anhydrase* (enzyme names usually end in “-ase”). Under the same conditions, but in the presence of carbonic anhydrase, an estimated 600,000 molecules of carbonic acid form every *second!* Thus, the enzyme increases the reaction rate by more than one million times.

Thousands of different kinds of enzymes are known, each catalyzing one or a few specific chemical reactions. By facilitating particular chemical reactions, the enzymes in a cell determine the course of metabolism—the collection of all chemical reactions—in that cell.

Different types of cells contain different sets of enzymes, and this difference contributes to structural and functional variations among cell types. For example, the chemical reactions taking place within a red blood cell differ from those that occur within a nerve cell, in part because different cell types contain different arrays of enzymes.

## Active sites of enzymes conform to fit the shape of substrates

Most enzymes are globular proteins with one or more pockets or clefts, called **active sites**, on their surface (figure 6.8). Substrates bind to the enzyme at these active sites, forming an **enzyme–substrate complex** (figure 6.10). For catalysis to occur within the complex, a substrate molecule must fit precisely into an active site. When that happens, amino acid side groups of the enzyme end up very close to certain bonds of the substrate. These side groups interact chemically with the substrate, usually stressing or distorting a particular bond and consequently lowering the activation energy needed to break the bond. After the bonds of the substrates are broken, or new bonds are formed, the substrates have been converted to products. These products then dissociate from the enzyme, leaving the enzyme ready to bind its next substrate and begin the cycle again.

Proteins are not rigid. The binding of a substrate induces the enzyme to adjust its shape slightly, leading to a better *induced fit* between enzyme and substrate (see figure 6.9).

**Figure 6.8 Enzyme binding its substrate.** *a.* The active site of the enzyme lysozyme fits the shape of its substrate, a peptidoglycan that makes up bacterial cell walls. *b.* When the substrate, indicated in yellow, slides into the groove of the active site, the protein is induced to alter its shape slightly and bind the substrate more tightly. This alteration of the shape of the enzyme to better fit the substrate is called induced fit.

This interaction may also facilitate the binding of other substrates; in such cases, one substrate “activates” the enzyme to receive other substrates.

## Enzymes occur in many forms

Although many enzymes are suspended in the cytoplasm of cells, not attached to any structure, other enzymes function as

### SCIENTIFIC THINKING

**Hypothesis:** Protein structure is flexible not rigid.

**Prediction:** Antibody–antigen binding can involve a change in protein structure.

**Test:** Determine crystal structure of a fragment of a specific antibody with no antigen bound, and with antigen bound for comparison.

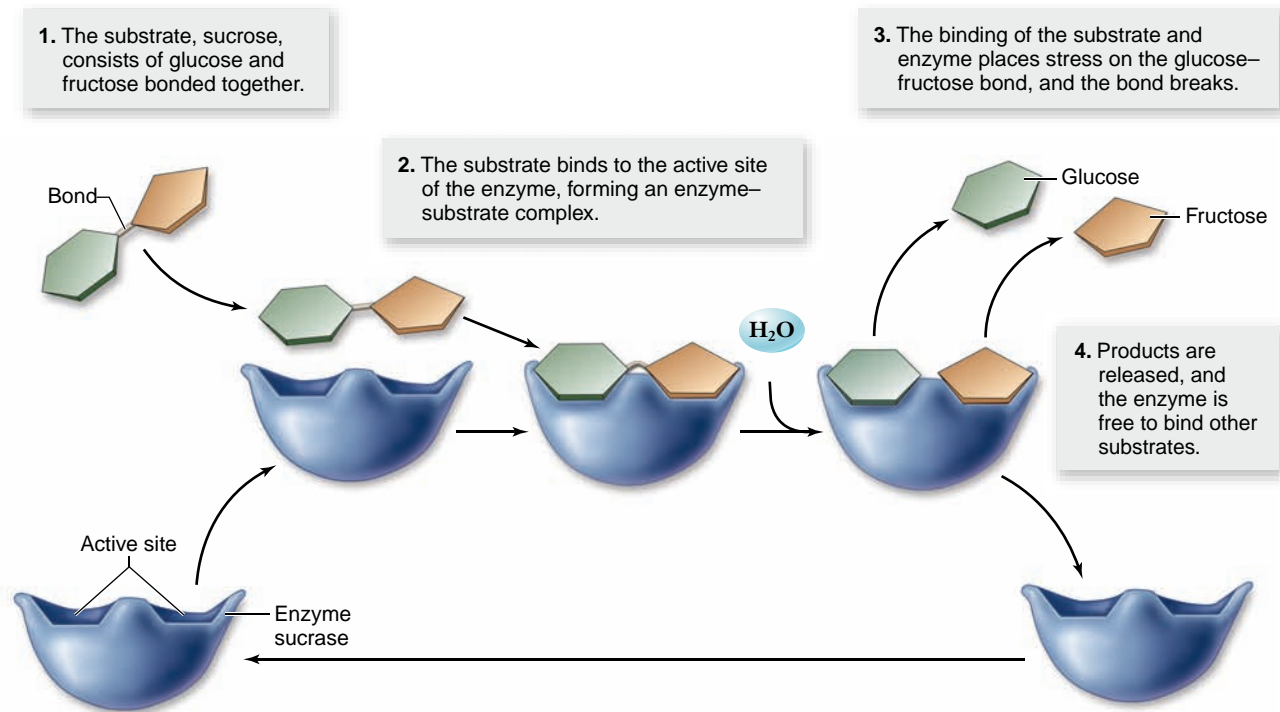

**Result:** After binding, the antibody folds around the antigen forming a pocket.

**Conclusion:** In this case, binding involves an induced-fit kind of change in conformation.

**Further Experiments:** Why is this experiment easier to do with an antibody than with an enzyme? Can this experiment be done with an enzyme?

**Figure 6.9 Induced-fit binding of antibody to antigen.**

**Figure 6.10 The catalytic cycle of an enzyme.** Enzymes increase the speed at which chemical reactions occur, but they are not altered permanently themselves as they do so. In the reaction illustrated here, the enzyme sucrase is splitting the sugar sucrose into two simpler sugars: glucose and fructose.

integral parts of cell membranes and organelles. Enzymes may also form associations called *multienzyme complexes* to carry out reaction sequences. And, as mentioned earlier, evidence exists that some enzymes may consist of RNA rather than being only protein.

### **Multienzyme complexes**

Often several enzymes catalyzing different steps of a sequence of reactions are associated with one another in noncovalently bonded assemblies called **multienzyme complexes**. The bacterial pyruvate dehydrogenase multi-enzyme complex, shown in figure 6.11, contains enzymes that carry out three sequential reactions in oxidative metabolism. Each complex has multiple copies of each of the three enzymes—60 protein subunits in all. The many subunits work together to form a molecular machine that performs multiple functions.

Multienzyme complexes offer the following significant advantages in catalytic efficiency:

1. The rate of any enzyme reaction is limited by how often the enzyme collides with its substrate. If a series of sequential reactions occurs within a multienzyme complex, the product of one reaction can be delivered to the next enzyme without releasing it to diffuse away.
2. Because the reacting substrate doesn't leave the complex while it goes through the series of reactions, unwanted side reactions are prevented.
3. All of the reactions that take place within the multienzyme complex can be controlled as a unit.

**Figure 6.11 A complex enzyme: pyruvate dehydrogenase.** Pyruvate dehydrogenase, which catalyzes the oxidation of pyruvate, is one of the most complex enzymes known. *a.* A model of the enzyme showing the arrangement of the 60 protein subunits. *b.* Many of the protein subunits are clearly visible in the electron micrograph.

In addition to pyruvate dehydrogenase, which controls entry to the Krebs cycle during aerobic respiration (see chapter 7), several other key processes in the cell are catalyzed by multienzyme complexes. One well-studied system is the fatty acid synthetase complex that catalyzes the synthesis of fatty acids from two-carbon precursors. Seven different enzymes make up this multienzyme complex, and the intermediate reaction products remain associated with the complex for the entire series of reactions.

### Nonprotein enzymes

Until a few years ago, most biology textbooks contained statements such as “Proteins called enzymes are the catalysts of biological systems.” We can no longer make that statement without qualification.

Thomas J. Cech and colleagues at the University of Colorado reported in 1981 that certain reactions involving RNA molecules appear to be catalyzed in cells by RNA itself, rather than by enzymes. This initial observation has been corroborated by additional examples of RNA catalysis. Like enzymes, these RNA catalysts, which are loosely called “ribozymes,” greatly accelerate the rate of particular biochemical reactions and show extraordinary substrate specificity.

Research has revealed at least two sorts of ribozymes. Some ribozymes have folded structures and catalyze reactions on themselves, a process called *intramolecular* catalysis. Other ribozymes act on other molecules without being changed themselves, a process called *intermolecular* catalysis.

The most striking example of the role of RNA as enzyme is emerging from recent work on the structure and function of the ribosome. For many years it was thought that RNA was a structural framework for this vital organelle, but it is now clear that ribosomal RNA plays a key role in ribosome function. The ribosome itself is a ribozyme.

The ability of RNA, an informational molecule, to act as a catalyst has stirred great excitement because it seems to answer the question—Which came first, the protein or the nucleic acid? It now seems at least possible that RNA evolved first and may have catalyzed the formation of the first proteins.

### Environmental and other factors affect enzyme function

The rate of an enzyme-catalyzed reaction is affected by the concentrations of both the substrate and the enzyme that works on it. In addition, any chemical or physical factor that alters the enzyme’s three-dimensional shape—such as temperature, pH, and the binding of regulatory molecules—can affect the enzyme’s ability to catalyze the reaction.

#### Temperature

Increasing the temperature of an uncatalyzed reaction increases its rate because the additional heat increases random molecular movement. This motion can add stress to molecular bonds and affect the activation energy of a reaction.

The rate of an enzyme-catalyzed reaction also increases with temperature, but only up to a point called the *optimum*

a.

b.

### Figure 6.12 Enzyme sensitivity to the environment.

The activity of an enzyme is influenced by both (a) temperature and (b) pH. Most human enzymes, such as the protein-degrading enzyme trypsin, work best at temperatures of about 40°C and within a pH range of 6 to 8. The hot springs prokaryote tolerates a higher environmental temperature and a correspondingly higher temperature optimum for enzymes. Pepsin works in the acidic environment of the stomach and has a lower optimum pH.

*temperature* (figure 6.12a). Below this temperature, the hydrogen bonds and hydrophobic interactions that determine the enzyme’s shape are not flexible enough to permit the induced fit that is optimum for catalysis. Above the optimum temperature, these forces are too weak to maintain the enzyme’s shape against the increased random movement of the atoms in the enzyme. At higher temperatures, the enzyme denatures, as described in chapter 3.

Most human enzymes have an optimum temperature between 35°C and 40°C—a range that includes normal body temperature. Prokaryotes that live in hot springs have more stable enzymes (that is, enzymes held together more strongly), so the optimum temperature for those enzymes can be 70°C or higher. In each case the optimal temperature for the enzyme corresponds to the “normal” temperature usually encountered in the body or the environment, depending on the type of organism.

#### pH

Ionic interactions between oppositely charged amino acid residues, such as glutamic acid (–) and lysine (+), also hold enzymes together. These interactions are sensitive to the hydrogen ion concentration of the fluid in which the enzyme is dissolved, because changing that concentration shifts the balance between positively and negatively charged amino acid residues. For this reason, most enzymes have an *optimum pH* that usually ranges from pH 6 to 8.

Enzymes able to function in very acidic environments are proteins that maintain their three-dimensional shape even in

the presence of high hydrogen ion concentrations. The enzyme pepsin, for example, digests proteins in the stomach at pH 2, a very acidic level (figure 6.12b).

### Inhibitors and activators

Enzyme activity is also sensitive to the presence of specific substances that can bind to the enzyme and cause changes in its shape. Through these substances, a cell is able to regulate which of its enzymes are active and which are inactive at a particular time. This ability allows the cell to increase its efficiency and to control changes in its characteristics during development. A substance that binds to an enzyme and *decreases* its activity is called an **inhibitor**. Very often, the end product of a biochemical pathway acts as an inhibitor of an early reaction in the pathway, a process called *feedback inhibition* (discussed later in this chapter).

Enzyme inhibition occurs in two ways: **Competitive inhibitors** compete with the substrate for the same active site, occupying the active site and thus preventing substrates from binding; **noncompetitive inhibitors** bind to the enzyme in a location other than the active site, changing the shape of the enzyme and making it unable to bind to the substrate (figure 6.13).

Many enzymes can exist in either an active or inactive conformation; such enzymes are called *allosteric enzymes*. Most noncompetitive inhibitors bind to a specific portion of the enzyme called an **allosteric site**. These sites serve as chemical on/off switches; the binding of a substance to the site can switch the enzyme between its active and inactive configurations. A substance that binds to an allosteric site and reduces enzyme activity is called an **allosteric inhibitor** (figure 6.13b).

This kind of control is also used to activate enzymes. An **allosteric activator** binds to allosteric sites to keep an enzyme in its active configuration, thereby *increasing* enzyme activity.

### Enzyme cofactors

Enzyme function is often assisted by additional chemical components known as **cofactors**. These can be metal ions

that are often found in the active site participating directly in catalysis. For example, the metallic ion zinc is used by some enzymes, such as protein-digesting carboxypeptidase, to draw electrons away from their position in covalent bonds, making the bonds less stable and easier to break. Other metallic elements, such as molybdenum and manganese, are also used as cofactors. Like zinc, these substances are required in the diet in small amounts.

When the cofactor is a nonprotein organic molecule, it is called a **coenzyme**. Many of the small organic molecules essential in our diets that we call vitamins function as coenzymes. For example the B vitamins B<sub>6</sub> and B<sub>12</sub>, both function as coenzymes for a number of different enzymes. Modified nucleotides are also used as coenzymes.

In numerous oxidation–reduction reactions that are catalyzed by enzymes, the electrons pass in pairs from the active site of the enzyme to a coenzyme that serves as the electron acceptor. The coenzyme then transfers the electrons to a different enzyme, which releases them (and the energy they bear) to the substrates in another reaction. Often, the electrons combine with protons (H<sup>+</sup>) to form hydrogen atoms. In this way, coenzymes shuttle energy in the form of hydrogen atoms from one enzyme to another in a cell. The role of coenzymes and the specifics of their action will be explored in detail in the following two chapters.

### Learning Outcomes Review 6.4

Enzymes are biological catalysts that accelerate chemical reactions inside the cell. Enzymes bind to their substrates based on molecular shape, which allows them to be highly specific. Enzyme activity is affected by conditions such as temperature and pH and the presence of inhibitors or activators. Some enzymes also require an inorganic cofactor or an organic coenzyme.

- Why do proteins and RNA function as enzymes but DNA does not?

a. Competitive inhibition

b. Noncompetitive inhibition

**Figure 6.13** How enzymes can be inhibited. *a.* In competitive inhibition, the inhibitor has a shape similar to the substrate and competes for the active site of the enzyme. *b.* In noncompetitive inhibition, the inhibitor binds to the enzyme at the allosteric site, a place away from the active site, effecting a conformational change in the enzyme, making it unable to bind to its substrate.

## 6.5 Metabolism: The Chemical Description of Cell Function

### Learning Outcomes

1. Explain the kinds of reactions that make up metabolism.
2. Discuss what is meant by a metabolic pathway.
3. Recognize that metabolism is a product of evolution.

Living chemistry, the total of all chemical reactions carried out by an organism, is called **metabolism**. Those chemical reactions that expend energy to build up molecules are called *anabolic* reactions, or **anabolism**. Reactions that harvest energy by breaking down molecules are called *catabolic* reactions, or **catabolism**. This section presents a general overview of metabolic processes that will be described in much greater detail in later chapters.

## Biochemical pathways organize chemical reactions in cells

Organisms contain thousands of different kinds of enzymes that catalyze a bewildering variety of reactions. Many of these reactions in a cell occur in sequences called **biochemical pathways**. In such pathways, the product of one reaction becomes the substrate for the next (figure 6.14). Biochemical pathways are the organizational units of metabolism—the elements an organism controls to achieve coherent metabolic activity.

Many sequential enzyme steps in biochemical pathways take place in specific compartments of the cell; for example, the steps of the Krebs cycle (see chapter 7) occur in the matrix inside mitochondria in eukaryotes. By determining where many of the enzymes that catalyze these steps are located, we can “map out” a model of metabolic processes in the cell.

## Biochemical pathways may have evolved in stepwise fashion

In the earliest cells, the first biochemical processes probably involved energy-rich molecules scavenged from the environment. Most of the molecules necessary for these processes are thought to have existed independently in the “organic soup” of the early oceans.

**Figure 6.14 A biochemical pathway.** The original substrate is acted on by enzyme 1, changing the substrate to a new intermediate, substrate A, recognized as a substrate by enzyme 2. Each enzyme in the pathway acts on the product of the previous stage. These enzymes may be either soluble or arranged in a membrane as shown.

The first catalyzed reactions were probably simple, one-step reactions that brought these molecules together in various combinations. Eventually, the energy-rich molecules became depleted in the external environment, and only organisms that had evolved some means of making those molecules from other substances could survive. Thus, a hypothetical reaction,

where two energy-rich molecules (F and G) react to produce compound H and release energy, became more complex when the supply of F in the environment ran out.

A new reaction was added in which the depleted molecule, F, is made from another molecule, E, which was also present in the environment:

When the supply of E was in turn exhausted, organisms that were able to make E from some other available precursor, D, survived. When D was depleted, those organisms in turn were replaced by ones able to synthesize D from another molecule, C:

This hypothetical biochemical pathway would have evolved slowly through time, with the final reactions in the pathway evolving first and earlier reactions evolving later.

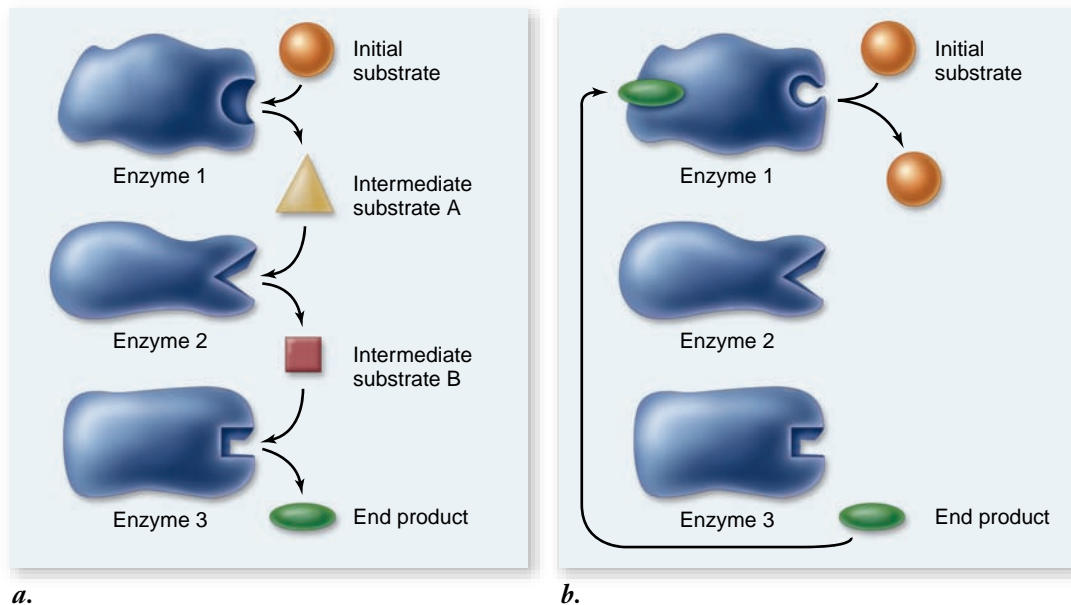

Looking at the pathway now, we would say that the “advanced” organism, starting with compound C, is able to synthesize H by means of a series of steps. This is how the biochemical pathways within organisms are thought to have evolved—not all at once, but one step at a time, backwards.

## Feedback inhibition regulates some biochemical pathways

For a biochemical pathway to operate efficiently, its activity must be coordinated and regulated by the cell. Not only is it unnecessary to synthesize a compound when plenty is already present, but doing so would waste energy and raw materials that could be put to use elsewhere. It is to the cell’s advantage, therefore, to temporarily shut down biochemical pathways when their products are not needed.

The regulation of simple biochemical pathways often depends on an elegant feedback mechanism: The end-product of the pathway binds to an allosteric site on the enzyme that catalyzes the first reaction in the pathway. This mode of regulation is called **feedback inhibition** (figure 6.15).

In the hypothetical pathway we just described, the enzyme catalyzing the reaction  $C \longrightarrow D$  would possess an allosteric site for H, the end-product of the pathway. As the pathway churned out its product and the amount of H in the cell increased, it would become more likely that an H molecule would encounter

**Figure 6.15 Feedback inhibition.** *a.* A biochemical pathway with no feedback inhibition. *b.* A biochemical pathway in which the final end-product becomes the allosteric inhibitor for the first enzyme in the pathway. In other words, the formation of the pathway's final end-product stops the pathway. The pathway could be the synthesis of an amino acid, a nucleotide, or another important cellular molecule.

the allosteric site on the  $C \rightarrow D$  enzyme. Binding to the allosteric site would essentially shut down the reaction  $C \rightarrow D$  and in turn effectively shut down the whole pathway.

In this chapter we have reviewed the basics of energy and its transformations as carried out in living systems. Chemical bonds are the primary location of energy storage and release, and cells have developed elegant methods of making and breaking chemical bonds to create the molecules they need. Enzymes facilitate these reactions by serving as catalysts. In the following chapters you will learn the details of the mechanisms by which organisms harvest, store, and utilize energy.

### Learning Outcomes Review 6.5

Metabolism is the sum of all chemical reactions in a cell. Anabolic reactions use energy to build up molecules. Catabolic reactions release energy by breaking down molecules. In a metabolic pathway, the end-product of one reaction is the substrate for the next reaction. Evolution may have favored organisms that could use precursor molecules to synthesize a nutrient. Over time, more reactions would be linked together as novel enzymes arose by mutation.

- *Is a catabolic pathway likely to be subject to feedback inhibition?*

## Chapter Review

### 6.1 The Flow of Energy in Living Systems

Thermodynamics is the study of energy changes.

#### **Energy can take many forms.**

Energy is the capacity to do work. Potential energy is stored energy, and kinetic energy is the energy of motion. Energy can take many forms: mechanical, heat, sound, electric current, light, or radioactive radiation. Energy is measured in units of heat known as kilocalories.

#### **The Sun provides energy for living systems.**

Photosynthesis stores light energy from the Sun as potential energy in the covalent bonds of sugar molecules. Breaking these bonds in living cells releases energy for use in other reactions.

#### **Oxidation–reduction reactions transfer electrons while bonds are made or broken.**

Oxidation is a reaction involving the loss of electrons. Reduction is the gain of electrons (see figure 6.2). These two reactions take place together and are therefore termed redox reactions.

### 6.2 The Laws of Thermodynamics and Free Energy

#### **The First Law states that energy cannot be created or destroyed.**

Virtually all activities of living organisms require energy. Energy changes form as it moves through organisms and their biochemical systems, but it is not created or destroyed.

#### **The Second Law states that some energy is lost as disorder increases.**

The disorder, or entropy, of the universe is continuously increasing. In an open system like the Earth, which is receiving energy from the Sun, this may not be the case. To increase order however, energy must be expended. In energy conversions, some energy is always lost as heat.

#### **Chemical reactions can be predicted based on changes in free energy.**

Free energy ( $G$ ) is the energy available to do work in any system. Changes in free energy ( $\Delta G$ ) predict the direction of reactions. Reactions with a negative  $\Delta G$  are spontaneous (exergonic) reactions, and reactions with a positive  $\Delta G$  are not spontaneous (endergonic).

Endergonic chemical reactions absorb energy from the surroundings, whereas exergonic reactions release energy to the surroundings.

**Spontaneous chemical reactions require activation energy.**

Activation energy is the energy required to destabilize chemical bonds and initiate chemical reactions (see figure 6.5). Even exergonic reactions require this activation energy. Catalysts speed up chemical reactions by lowering the activation energy.

### 6.3 ATP: The Energy Currency of Cells

Adenosine triphosphate (ATP) is the molecular currency used for cellular energy transactions.

**Cells store and release energy in the bonds of ATP.**

The energy of ATP is stored in the bonds between its terminal phosphate groups. These groups repel each other due to their negative charge and therefore the covalent bonds joining these phosphates are unstable.

**ATP hydrolysis drives endergonic reactions.**

Enzymes hydrolyze the terminal phosphate group of ATP to release energy for reactions. If ATP hydrolysis is coupled to an endergonic reaction with a positive  $\Delta G$  with magnitude less than that for ATP hydrolysis, the two reactions together will be exergonic.

**ATP cycles continuously.**

ATP hydrolysis releases energy to drive endergonic reactions, and it is synthesized with energy from exergonic reactions (see figure 6.7).

### 6.4 Enzymes: Biological Catalysts

**An enzyme alters the activation energy of a reaction.**

Enzymes lower the activation energy needed to initiate a chemical reaction.

**Active sites of enzymes conform to fit the shape of substrates.**

Substrates bind to the active site of an enzyme. Enzymes adjust their shape to the substrate so there is a better fit (see figure 6.8).

**Enzymes occur in many forms.**

Enzymes can be free in the cytosol or exist as components bound to membranes and organelles. Enzymes involved in a biochemical

pathway can form multienzyme complexes. While most enzymes are proteins, some are actually RNA molecules, called ribozymes.

**Environmental and other factors affect enzyme function.**

An enzyme's functionality depends on its ability to maintain its three-dimensional shape, which can be affected by temperature and pH. The activity of enzymes can be affected by inhibitors. Competitive inhibitors compete for the enzyme's active site, which leads to decreased enzyme activity (see figure 6.13). Enzyme activity can be controlled by effectors. Allosteric enzymes have a second site, located away from the active site, that binds effectors to activate or inhibit the enzyme. Noncompetitive inhibitors and activators bind to the allosteric site, changing the structure of the enzyme to inhibit or activate it. Cofactors are nonorganic metals necessary for enzyme function. Coenzymes are nonprotein organic molecules, such as certain vitamins, needed for enzyme function. Often coenzymes serve as electron acceptors.

### 6.5 Metabolism: The Chemical Description of Cell Function

Metabolism is the sum of all biochemical reactions in a cell. Anabolic reactions require energy to build up molecules, and catabolic reactions break down molecules and release energy.

**Biochemical pathways organize chemical reactions in cells.**

Chemical reactions in biochemical pathways use the product of one reaction as the substrate for the next.

**Biochemical pathways may have evolved in stepwise fashion.**

In the primordial "soup" of the early oceans, many reactions were probably single-step reactions combining two molecules. As one of the substrate molecules was depleted, organisms having an enzyme that could synthesize the substrate would have a selective advantage. In this manner, biochemical pathways are thought to have evolved "backward" with new reactions producing limiting substrates for existing reactions.

**Feedback inhibition regulates some biochemical pathways.**

Biosynthetic pathways are often regulated by the end product of the pathway. Feedback inhibition occurs when the end-product of a reaction combines with an enzyme's allosteric site to shut down the enzyme's activity (see figure 6.15).

## Review Questions

#### UNDERSTAND

- A covalent bond between two atoms represents what kind of energy?
  - Kinetic energy
  - Potential energy
  - Mechanical energy
  - Solar energy
- During a redox reaction the molecule that gains an electron has been
  - reduced and now has a higher energy level.
  - oxidized and now has a lower energy level.
  - reduced and now has a lower energy level.
  - oxidized and now has a higher energy level.
- An endergonic reaction has the following properties
  - $+\Delta G$  and the reaction is spontaneous.
  - $+\Delta G$  and the reaction is not spontaneous.
  - $-\Delta G$  and the reaction is spontaneous.
  - $-\Delta G$  and the reaction is not spontaneous.
- A spontaneous reaction is one in which
  - the reactants have a higher free energy than the products.
  - the products have a higher free energy than the reactants.
  - an input of energy is required.
  - entropy is decreased.

5. What is *activation energy*?
    - a. The thermal energy associated with random movements of molecules
    - b. The energy released through breaking chemical bonds
    - c. The difference in free energy between reactants and products
    - d. The energy required to initiate a chemical reaction
  6. Which of the following is NOT a property of a catalyst?
    - a. A catalyst reduces the activation energy of a reaction.
    - b. A catalyst lowers the free energy of the reactants.
    - c. A catalyst does not change as a result of the reaction.
    - d. A catalyst works in both the forward and reverse directions of a reaction.
  7. Where is the energy stored in a molecule of ATP?
    - a. Within the bonds between nitrogen and carbon
    - b. In the carbon-to-carbon bonds found in the ribose
    - c. In the phosphorus-to-oxygen double bond
    - d. In the bonds connecting the two terminal phosphate groups
- c. three-dimensional shape of the enzyme.
  - d. rate of movement of the enzyme.
6. In feedback inhibition, the
    - a. first enzyme in a pathway is inhibited by its own product.
    - b. last enzyme in a pathway is inhibited by its own product.
    - c. first enzyme in a pathway is inhibited by the end-product of the pathway.
    - d. last enzyme in a pathway is inhibited by the end-product of the pathway.

## SYNTHESIZE

1. Examine the graph showing the rate of reaction versus temperature for an enzyme-catalyzed reaction in a human.
  - a. Describe what is happening to the enzyme at around 40°C.
  - b. Explain why the line touches the x-axis at approximately 20°C and 45°C.
  - c. Average body temperature for humans is 37°C. Suggest a reason why the temperature optimum of this enzyme is greater than 37°C.

## APPLY

1. Cells use ATP to drive endergonic reactions because
    - a. ATP is the universal catalyst.
    - b. energy released by ATP hydrolysis makes  $\Delta G$  for coupled reactions more negative.
    - c. energy released by ATP hydrolysis makes  $\Delta G$  for coupled reactions more positive.
    - d. the conversion of ATP to ADP is also endergonic.
  2. Which of the following statements is NOT true about enzymes?
    - a. Enzymes use the three-dimensional shape of their active site to bind reactants.
    - b. Enzymes lower the activation energy for a reaction.
    - c. Enzymes make  $\Delta G$  for a reaction more negative.
    - d. Enzymes can catalyze the forward and reverse directions of a reaction.
  3. What is the function of the *active site* of an enzyme?
    - a. Bind the substrate, forming an enzyme-substrate complex
    - b. Side groups within the active site interact with the substrate
    - c. Bind to regulatory molecules, thereby altering the enzymes conformation
    - d. Both a and b
  4. The discovery of ribozymes meant that
    - a. only proteins have catalytic function.
    - b. only nucleic acids have catalytic function.
    - c. RNAs can act as enzymes.
    - d. RNA has the same function as protein.
  5. Enzymes have similar responses to both changes in temperature and pH. The effect of both is on the
    - a. rate of movement of the substrate molecules.
    - b. strength of the chemical bonds within the substrate.
2. Phosphofructokinase functions to add a phosphate group to a molecule of fructose-6-phosphate. This enzyme functions early in glycolysis, an energy-yielding biochemical pathway discussed in chapter 7. The enzyme has an active site that binds fructose and ATP. An allosteric inhibitory site also binds ATP when cellular levels of ATP are very high.
    - a. Predict the rate of the reaction if the levels of cellular ATP are low.
    - b. Predict the rate of the reaction if levels of cellular ATP are very high.
    - c. Describe what is happening to the enzyme when levels of ATP are very high.

# How Cells Harvest Energy

## Chapter Outline

---

- 7.1 Overview of Respiration
- 7.2 Glycolysis: Splitting Glucose
- 7.3 The Oxidation of Pyruvate to Produce Acetyl-CoA
- 7.4 The Krebs Cycle
- 7.5 The Electron Transport Chain and Chemiosmosis
- 7.6 Energy Yield of Aerobic Respiration
- 7.7 Regulation of Aerobic Respiration
- 7.8 Oxidation Without O<sub>2</sub>
- 7.9 Catabolism of Proteins and Fats
- 7.10 Evolution of Metabolism

## Introduction

Life is driven by energy. All the activities organisms carry out—the swimming of bacteria, the purring of a cat, your thinking about these words—use energy. In this chapter, we discuss the processes all cells use to derive chemical energy from organic molecules and to convert that energy to ATP. Then, in chapter 8, we will examine photosynthesis, which uses light energy to make chemical energy. We consider the conversion of chemical energy to ATP first because all organisms, both the plant, a photosynthesizer, and the caterpillar feeding on the plant, pictured in the photo are capable of harvesting energy from chemical bonds. Energy harvest via respiration is a universal process.

## 7.1 Overview of Respiration

### Learning Outcomes

1. Characterize oxidation–dehydrogenation reactions in biological systems.
2. Understand the role of electron carriers in energy metabolism.
3. Describe the role of ATP in biological systems.

Plants, algae, and some bacteria harvest the energy of sunlight through photosynthesis, converting radiant energy into chemical energy. These organisms, along with a few others that use chemical energy in a similar way, are called **autotrophs** (“self-feeders”). All other organisms live on the organic compounds autotrophs produce, using them as food, and are called **heterotrophs** (“fed by others”). At least 95% of the kinds of organisms on Earth—all animals and fungi, and most protists and prokaryotes—are heterotrophs. Autotrophs also extract energy from organic compounds—they just have the additional capacity to use the energy from sunlight to synthesize these compounds. The process by which energy is harvested is **cellular respiration**—the oxidation of organic compounds to extract energy from chemical bonds.

### Cells oxidize organic compounds to drive metabolism

Most foods contain a variety of carbohydrates, proteins, and fats, all rich in energy-laden chemical bonds. Carbohydrates and fats, as you recall from chapter 3, possess many carbon–hydrogen (C–H) bonds, as well as carbon–oxygen (C–O) bonds.

The job of extracting energy from the complex organic mixture in most foods is tackled in stages. First, enzymes break down the large molecules into smaller ones, a process called

digestion (see chapter 48). Then, other enzymes dismantle these fragments a bit at a time, harvesting energy from C–H and other chemical bonds at each stage.

The reactions that break down these molecules share a common feature: They are oxidations. Energy metabolism is therefore concerned with redox reactions, and to understand the process we must follow the fate of the electrons lost from the food molecules.

These reactions are not the simple transfer of electrons, however; they are also **dehydrogenations**. That is, the electrons lost are accompanied by protons, so that what is really lost is a hydrogen atom, not just an electron.

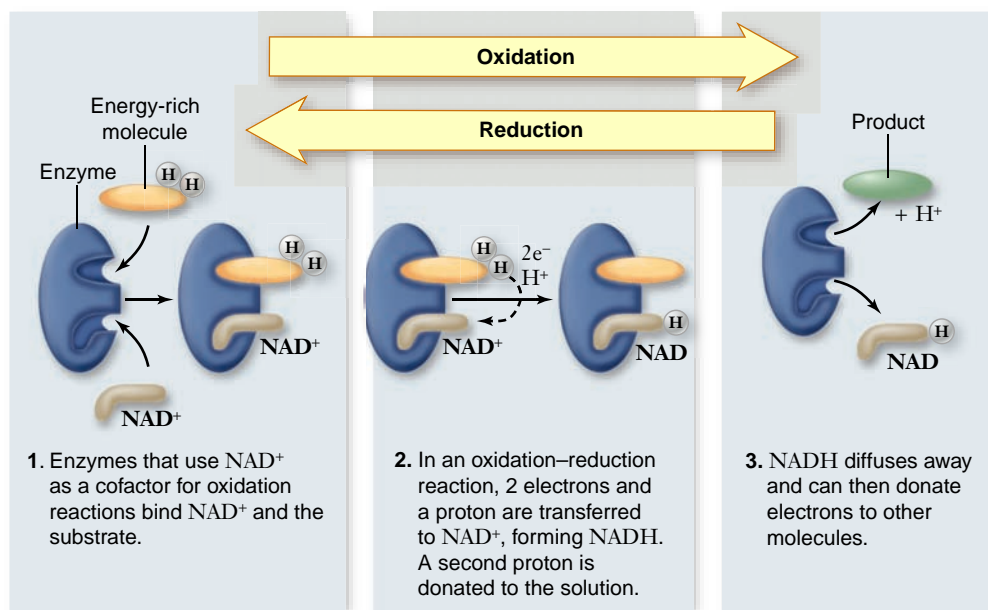

### Cellular respiration is the complete oxidation of glucose

In chapter 6, you learned that an atom that loses electrons is said to be *oxidized*, and an atom accepting electrons is said to be *reduced*. Oxidation reactions are often coupled with reduction reactions in living systems, and these paired reactions are called *redox reactions*. Cells utilize enzyme-facilitated redox reactions to take energy from food sources and convert it to ATP.

### Redox reactions

Oxidation–reduction reactions play a key role in the flow of energy through biological systems because the electrons that pass from one atom to another carry energy with them. The amount of energy an electron possesses depends on its orbital position, or energy level, around the atom’s nucleus. When this electron departs from one atom and moves to another in a redox reaction, the electron’s energy is transferred with it.

Figure 7.1 shows how an enzyme catalyzes a redox reaction involving an energy-rich substrate molecule, with the help of a cofactor, **nicotinamide adenosine dinucleotide (NAD<sup>+</sup>)**. In this reaction, NAD<sup>+</sup> accepts a pair of electrons from the substrate, along with a proton, to form **NADH** (this process is described in more detail shortly). The oxidized product is now released from the enzyme’s active site, as is NADH.

**Figure 7.1** Oxidation–reduction reactions often employ cofactors.

Cells use a chemical cofactor called nicotinamide adenosine dinucleotide (NAD<sup>+</sup>) to carry out many oxidation–reduction reactions. Two electrons and a proton are transferred to NAD<sup>+</sup> with another proton donated to the solution. Molecules that gain electrons are said to be reduced, and ones that lose energetic electrons are said to be oxidized. NAD<sup>+</sup> oxidizes energy-rich molecules by acquiring their electrons (in the figure, this proceeds 1 → 2 → 3) and then reduces other molecules by giving the electrons to them (in the figure, this proceeds 3 → 2 → 1). NADH is the reduced form of NAD<sup>+</sup>.

**Figure 7.3 NAD<sup>+</sup> and NADH.** This dinucleotide serves as an “electron shuttle” during cellular respiration. NAD<sup>+</sup> accepts a pair of electrons and a proton from catabolized macromolecules and is reduced to NADH.

would recover very little of that energy in a useful form. Instead, cells burn their fuel much as a car does, a little at a time.

The electrons in the C—H bonds of glucose are stripped off in stages in the series of enzyme-catalyzed reactions collectively referred to as glycolysis and the Krebs cycle. The electrons are removed by transferring them to NAD<sup>+</sup>, as described earlier, or to other electron carriers.

The energy released by all of these oxidation reactions is also not all released at once (see figure 7.2). The electrons are passed to another set of electron carriers called the **electron transport chain**, which is located in the mitochondrial inner membrane. Movement of electrons through this chain produces potential energy in the form of an electrochemical gradient. We examine this process in more detail later in this chapter.

## ATP plays a central role in metabolism

The previous chapter introduced ATP as the energy currency of the cell. Cells use ATP to power most of those activities that require work—one of the most obvious of which is movement. Tiny fibers within muscle cells pull against one another when muscles contract. Mitochondria can move a meter or more along the narrow nerve cells that extend from your spine to your feet. Chromosomes are pulled apart by microtubules during cell division. All of these movements require the expenditure of energy by ATP hydrolysis. Cells also use ATP to drive endergonic reactions that would otherwise not occur spontaneously (see chapter 6).

How does ATP drive an endergonic reaction? The enzyme that catalyzes a particular reaction has two binding sites on its surface: one for the reactant and another for ATP. The ATP site splits the ATP molecule, liberating over 7 kcal ( $\Delta G = -7.3$  kcal/mol) of chemical energy. This energy pushes the reactant at the second site “uphill,” reaching the activation energy and driving the endergonic reaction. Thus endergonic reactions coupled to ATP hydrolysis become favorable.

The many steps of cellular respiration have as their ultimate goal the production of ATP. ATP synthesis is itself an endergonic reaction, which requires cells to perform exergonic reactions to drive this synthesis.

## Cells make ATP by two fundamentally different mechanisms

The synthesis of ATP can be accomplished by two distinct mechanisms: one that involves chemical coupling with an intermediate bound to phosphate, and another that relies on an electrochemical gradient of protons for the potential energy to phosphorylate ADP.

1. In *substrate-level phosphorylation*, ATP is formed by transferring a phosphate group directly to ADP from a phosphate-bearing intermediate, or substrate (figure 7.4). During **glycolysis**, the initial breakdown of glucose (discussed later), the chemical bonds of glucose are shifted

**Figure 7.4 Substrate-level phosphorylation.** Some molecules, such as phosphoenolpyruvate (PEP), possess a high-energy phosphate (P) bond similar to the bonds in ATP. When PEP’s phosphate group is transferred enzymatically to ADP, the energy in the bond is conserved, and ATP is created.

around in reactions that provide the energy required to form ATP by substrate-level phosphorylation.

- In **oxidative phosphorylation**, ATP is synthesized by the enzyme **ATP synthase**, using energy from a proton ( $H^+$ ) gradient. This gradient is formed by high-energy electrons from the oxidation of glucose passing down an electron transport chain (described later). These electrons, with their energy depleted, are then donated to oxygen, hence the term *oxidative phosphorylation*. ATP synthase uses the energy from the proton gradient to catalyze the reaction:

Eukaryotes and aerobic prokaryotes produce the vast majority of their ATP this way.

In most organisms, these two processes are combined. To harvest energy to make ATP from glucose in the presence of oxygen, the cell carries out a complex series of enzyme-catalyzed reactions that remove energetic electrons via oxidation reactions. These electrons are then used in an electron transport chain that

passes the electrons down a series of carriers while translocating protons into the intermembrane space. The final electron acceptor in aerobic respiration is oxygen, and the resulting proton gradient provides energy for the enzyme ATP synthase to phosphorylate ADP to ATP (figure 7.5). The details of this complex process will be covered in the remainder of this chapter.

### Learning Outcomes Review 7.1

Cells acquire energy from the complete oxidation of glucose. In these redox reactions, protons as well as electrons are transferred, and thus they are dehydrogenation reactions. Electron carriers aid in the gradual, stepwise release of the energy from oxidation, rather than rapid combustion. The result is the synthesis of ATP, a portable source of energy. ATP synthesis can occur by two mechanisms: substrate level phosphorylation and oxidative phosphorylation.

- Why don't cells just link the oxidation of glucose directly to cellular functions that require the energy?

**Figure 7.5** An overview of aerobic respiration.

## 7.2 Glycolysis: Splitting Glucose

### Learning Outcomes

1. Describe the process of glycolysis.
2. Calculate the energy yield from glycolysis.
3. Distinguish between aerobic respiration and fermentation.

Glucose molecules can be dismantled in many ways, but primitive organisms evolved a glucose-catabolizing process that releases enough free energy to drive the synthesis of ATP in enzyme-coupled reactions. Glycolysis occurs in the cytoplasm and converts glucose into two 3-carbon molecules of pyruvate (figure 7.6). For each molecule of glucose that passes through this transformation, the cell nets two ATP molecules.

### Priming changes glucose into an easily cleaved form

The first half of glycolysis consists of five sequential reactions that convert one molecule of glucose into two molecules of the 3-carbon compound *glyceraldehyde 3-phosphate (G3P)*. These reactions require the expenditure of ATP, so they are an endergonic process.

**Step A: Glucose priming** Three reactions “prime” glucose by changing it into a compound that can be cleaved readily into two 3-carbon phosphorylated molecules. Two of these reactions transfer a phosphate from ATP, so this step requires the cell to use two ATP molecules.

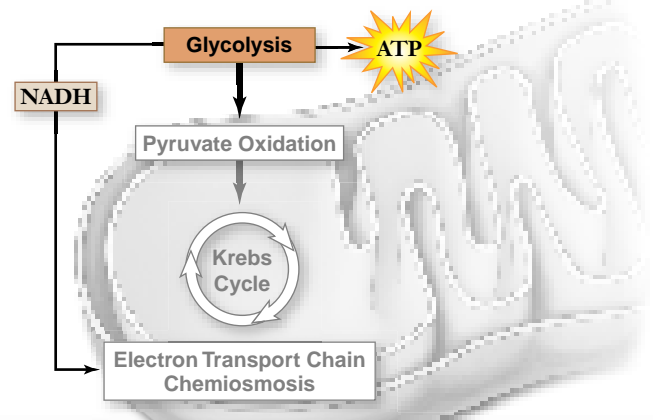

**Step B: Cleavage and rearrangement** In the first of the remaining pair of reactions, the 6-carbon product of step A is split into two 3-carbon molecules. One is G3P, and the other is then converted to G3P by the second reaction (figure 7.7).

### ATP is synthesized by substrate-level phosphorylation

In the second half of glycolysis, five more reactions convert G3P into pyruvate in an energy-yielding process that generates ATP.

**Step C: Oxidation** Two electrons (and one proton) are transferred from G3P to  $\text{NAD}^+$ , forming NADH. A molecule of  $\text{P}_i$  is also added to G3P to produce 1,3-bisphosphoglycerate (BPG). The phosphate incorporated will later be transferred to ADP by substrate-level phosphorylation to allow a net yield of ATP.

**Step D: ATP generation** Four reactions convert BPG into pyruvate. This process generates two ATP molecules per G3P (see figures 7.4 and 7.7) produced in Step B.

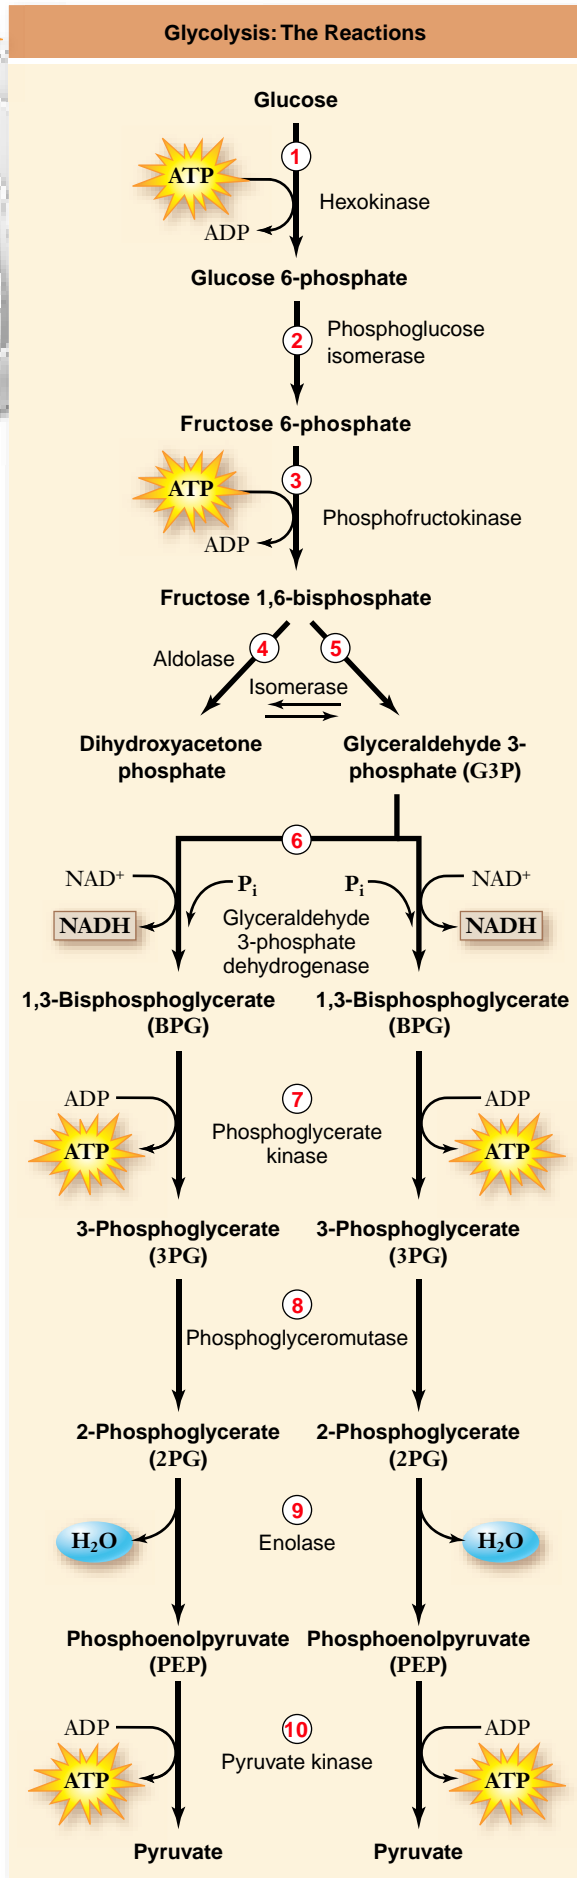

**Figure 7.6** How glycolysis works.

1. Phosphorylation of glucose by ATP.
- 2-3. Rearrangement, followed by a second ATP phosphorylation.
- 4-5. The 6-carbon molecule is split into two 3-carbon molecules—one G3P, another that is converted into G3P in another reaction.
6. Oxidation followed by phosphorylation produces two NADH molecules and two molecules of BPG, each with one high-energy phosphate bond.
7. Removal of high-energy phosphate by two ADP molecules produces two ATP molecules and leaves two 3PG molecules.
- 8-9. Removal of water yields two PEP molecules, each with a high-energy phosphate bond.
10. Removal of high-energy phosphate by two ADP molecules produces two ATP molecules and two pyruvate molecules.

**Figure 7.7**  
**The glycolytic pathway.**

The first five reactions convert a molecule of glucose into two molecules of G3P. The second five reactions convert G3P into pyruvate.

Glucose	<chem>C(C1OC(O)C(O)C1O)O</chem>
Glucose 6-phosphate	<chem>C(C1OC(O)C(O)C1OP(=O)([O-])[O-])O</chem>
Fructose 6-phosphate	<chem>C(C1OC(O)C(O)C1OP(=O)([O-])[O-])O</chem>
Fructose 1,6-bisphosphate	<chem>C(C1OC(O)C(O)C1OP(=O)([O-])[O-])OP(=O)([O-])[O-]</chem>
Dihydroxyacetone Phosphate	<chem>C(C(=O)CO)OP(=O)([O-])[O-]</chem>
Glyceraldehyde 3-phosphate	<chem>C(C(=O)CO)OP(=O)([O-])[O-]</chem>
1,3-Bisphosphoglycerate	<chem>C(C(=O)COP(=O)([O-])[O-])OP(=O)([O-])[O-]</chem>
3-Phosphoglycerate	<chem>C(C(=O)CO)OP(=O)([O-])[O-]</chem>
2-Phosphoglycerate	<chem>C(C(=O)COP(=O)([O-])[O-])O</chem>
Phosphoenolpyruvate	<chem>C(C(=O)COP(=O)([O-])[O-])=C</chem>
Pyruvate	<chem>C(C(=O)C(=O)O)O</chem>

Because each glucose molecule is split into two G3P molecules, the overall reaction sequence has a net yield of two molecules of ATP, as well as two molecules of NADH and two of pyruvate:

$$\begin{array}{r}
 4 \text{ ATP (2 ATP for each of the 2 G3P molecules in step D)} \\
 - 2 \text{ ATP (used in the two reactions in step A)} \\
 \hline
 2 \text{ ATP (net yield for entire process)}
 \end{array}$$

The hydrolysis of one molecule of ATP yields a  $\Delta G$  of  $-7.3$  kcal/mol under standard conditions. Thus cells harvest a maximum of 14.6 kcal of energy per mole of glucose from glycolysis.

### A brief history of glycolysis

Although far from ideal in terms of the amount of energy it releases, glycolysis does generate ATP. For more than a billion years during the anaerobic first stages of life on Earth, glycolysis was the primary way heterotrophic organisms generated ATP from organic molecules.

Like many biochemical pathways, glycolysis is believed to have evolved backward, with the last steps in the process being the most ancient. Thus, the second half of glycolysis, the ATP-yielding breakdown of G3P, may have been the original process. The synthesis of G3P from glucose would have appeared later, perhaps when alternative sources of G3P were depleted.

Why does glycolysis take place in modern organisms, since its energy yield in the absence of oxygen is comparatively little? The answer is that evolution is an incremental process: Change occurs by improving on past successes. In catabolic metabolism, glycolysis satisfied the one essential evolutionary criterion—it was an improvement. Cells that could not carry out glycolysis were at a competitive disadvantage, and only cells capable of glycolysis survived. Later improvements in catabolic metabolism built on this success. Metabolism evolved as one layer of reactions added to another. Nearly every present-day organism carries out glycolysis, as a metabolic memory of its evolutionary past.

The last section of this chapter discusses the evolution of metabolism in more detail.

## NADH must be recycled to continue respiration

Inspect for a moment the net reaction of the glycolytic sequence:

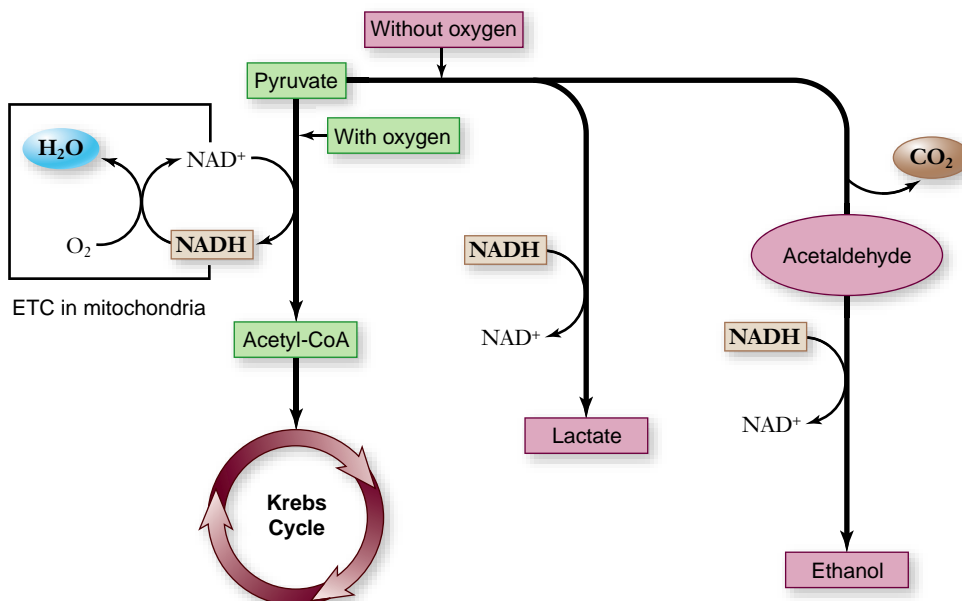

You can see that three changes occur in glycolysis: (1) Glucose is converted into two molecules of pyruvate; (2) two molecules of ADP are converted into ATP via substrate-level phosphorylation; and (3) two molecules of  $\text{NAD}^+$  are reduced to NADH. This leaves the cell with two problems: extracting the energy that remains in the two pyruvate molecules, and regenerating  $\text{NAD}^+$  to be able to continue glycolysis.

### Recycling NADH

As long as food molecules that can be converted into glucose are available, a cell can continually churn out ATP to drive its activities. In doing so, however, it accumulates NADH and depletes the pool of  $\text{NAD}^+$  molecules. A cell does not contain a large amount of  $\text{NAD}^+$ , and for glycolysis to continue, NADH must be recycled into  $\text{NAD}^+$ . Some molecule other than  $\text{NAD}^+$  must ultimately accept the electrons taken from G3P and be reduced. Two processes can carry out this key task (figure 7.8):

1. **Aerobic respiration.** Oxygen is an excellent electron acceptor. Through a series of electron transfers, electrons taken from G3P can be donated to oxygen, forming water. This process occurs in the mitochondria of eukaryotic cells in the presence of oxygen. Because air is rich in oxygen, this process is also referred to as *aerobic metabolism*. A significant amount of ATP is also produced.
2. **Fermentation.** When oxygen is unavailable, an organic molecule, such as acetaldehyde in wine fermentation, can accept electrons instead. This reaction plays an important role in the metabolism of most organisms, even those capable of aerobic respiration.

**Figure 7.8** The fate of pyruvate and NADH produced by glycolysis.

In the presence of oxygen, NADH is oxidized by the electron transport chain (ETC) in mitochondria using oxygen as the final electron acceptor. This regenerates  $\text{NAD}^+$ , allowing glycolysis to continue. The pyruvate produced by glycolysis is oxidized to acetyl-CoA, which enters the Krebs cycle. In the absence of oxygen, pyruvate is instead reduced, oxidizing NADH and regenerating  $\text{NAD}^+$  thus allowing glycolysis to continue. Direct reduction of pyruvate, as in muscle cells, produces lactate. In yeast, carbon dioxide is first removed from pyruvate, producing acetaldehyde, which is then reduced to ethanol.

## The fate of pyruvate

The fate of the pyruvate that is produced by glycolysis depends on which of these two processes takes place. The aerobic respiration path starts with the oxidation of pyruvate to produce acetyl coenzyme A (acetyl-CoA), which is then further oxidized in a series of reactions called the Krebs cycle. The fermentation path, by contrast, uses the reduction of all or part of pyruvate to oxidize NADH back to NAD<sup>+</sup>. We examine aerobic respiration next; fermentation is described in detail in a later section.

### Learning Outcomes Review 7.2

Glycolysis splits the 6-carbon molecule glucose into two 3-carbon molecules of pyruvate. This process uses two ATP molecules in “priming” reactions and eventually produces four molecules of ATP per glucose for a net yield of two ATP. The oxidation reactions of glycolysis require NAD<sup>+</sup> and produce NADH. When oxygen is abundant, NAD<sup>+</sup> is regenerated in the electron transport chain using O<sub>2</sub> as an acceptor. When oxygen is absent, NAD<sup>+</sup> is regenerated in a fermentation reaction using an organic molecule as an electron receptor.

- Does glycolysis taking place in the cytoplasm argue for or against the endosymbiotic origin of mitochondria?

## 7.3 The Oxidation of Pyruvate to Produce Acetyl-CoA

### Learning Outcome

1. Explain how the oxidation of pyruvate joins glycolysis with the Krebs cycle.

In the presence of oxygen, the oxidation of glucose that begins in glycolysis continues where glycolysis leaves off—with pyruvate. In eukaryotic organisms, the extraction of additional energy from pyruvate takes place exclusively inside mitochondria. In prokaryotes similar reactions take place in the cytoplasm and at the plasma membrane.

The cell harvests pyruvate’s considerable energy in two steps. First, pyruvate is oxidized to produce a two-carbon compound and CO<sub>2</sub>, with the electrons transferred to NAD<sup>+</sup> to produce NADH. Next, the two-carbon compound is oxidized to CO<sub>2</sub> by the reactions of the Krebs cycle.

Pyruvate is oxidized in a “decarboxylation” reaction that cleaves off one of pyruvate’s three carbons. This carbon departs as CO<sub>2</sub> (figure 7.9). The remaining 2-carbon compound, called an acetyl group, is then attached to coenzyme A; this entire molecule is called *acetyl-CoA*. A pair of electrons and one associated proton is transferred to the electron carrier NAD<sup>+</sup>, reducing it to NADH, with a second proton donated to the solution.

The reaction involves three intermediate stages, and it is catalyzed within mitochondria by a *multienzyme complex*. As chapter 6 noted, a multienzyme complex organizes a series of enzymatic steps so that the chemical intermediates do not diffuse away or undergo other reactions. Within the complex, component polypeptides pass

### Pyruvate Oxidation: The Reaction

Pyruvate

Acetyl Coenzyme A

**Figure 7.9 The oxidation of pyruvate.** This complex reaction uses NAD<sup>+</sup> to accept electrons, reducing it to NADH. The product, acetyl coenzyme A (acetyl-CoA), feeds the acetyl unit into the Krebs cycle, and the CoA is recycled for another oxidation of pyruvate. NADH provides energetic electrons for the electron transport chain.

the substrates from one enzyme to the next without releasing them. *Pyruvate dehydrogenase*, the complex of enzymes that removes CO<sub>2</sub> from pyruvate, is one of the largest enzymes known; it contains 60 subunits! The reaction can be summarized as:

The molecule of NADH produced is used later to produce ATP. The acetyl group is fed into the Krebs cycle, with the CoA being recycled for another oxidation of pyruvate. The Krebs cycle then completes the oxidation of the original carbons from glucose.

### Learning Outcome Review 7.3

Pyruvate is oxidized in the mitochondria to produce acetyl-CoA and CO<sub>2</sub>. Acetyl-CoA is the molecule that links glycolysis and the reactions of the Krebs cycle.

- What are the advantages and disadvantages of a multienzyme complex?

## 7.4 The Krebs Cycle

### Learning Outcomes

1. Describe the three segments and nine reactions of the Krebs cycle.
2. Explain the fate of the electrons produced by the Krebs cycle.

In this third stage, the acetyl group from pyruvate is oxidized in a series of nine reactions called the *Krebs cycle*. These reactions occur in the matrix of mitochondria.

In this cycle, the 2-carbon acetyl group of acetyl-CoA combines with a 4-carbon molecule called oxaloacetate. The resulting 6-carbon molecule, citrate, then goes through a several-step sequence of electron-yielding oxidation reactions, during which two CO<sub>2</sub> molecules split off, restoring oxaloacetate. The regenerated oxaloacetate is used to bind to another acetyl group for the next round of the cycle.

In each turn of the cycle, a new acetyl group is added and two carbons are lost as two CO<sub>2</sub> molecules, and more electrons are transferred to electron carriers. These electrons are then

used by the electron transport chain to drive *proton pumps* that generate ATP.

### The Krebs cycle has three segments:

#### An overview

The nine reactions of the Krebs cycle can be grouped into three overall segments. These are described in the following sections and summarized in figure 7.10.

**Segment A: Acetyl-CoA plus oxaloacetate** This reaction produces the 6-carbon citrate molecule.

**Segment B: Citrate rearrangement and decarboxylation** Five more steps, which have been simplified in figure 7.10, reduce citrate to a 5-carbon intermediate and then to 4-carbon succinate. During these reactions, two NADH and one ATP are produced.

**Segment C: Regeneration of oxaloacetate** Succinate undergoes three additional reactions, also simplified in the figure, to become oxaloacetate. During these reactions, one NADH is produced; in addition, a molecule of flavin adenine dinucleotide (FAD), another cofactor, becomes reduced to FADH<sub>2</sub>.

The specifics of each reaction are described next.

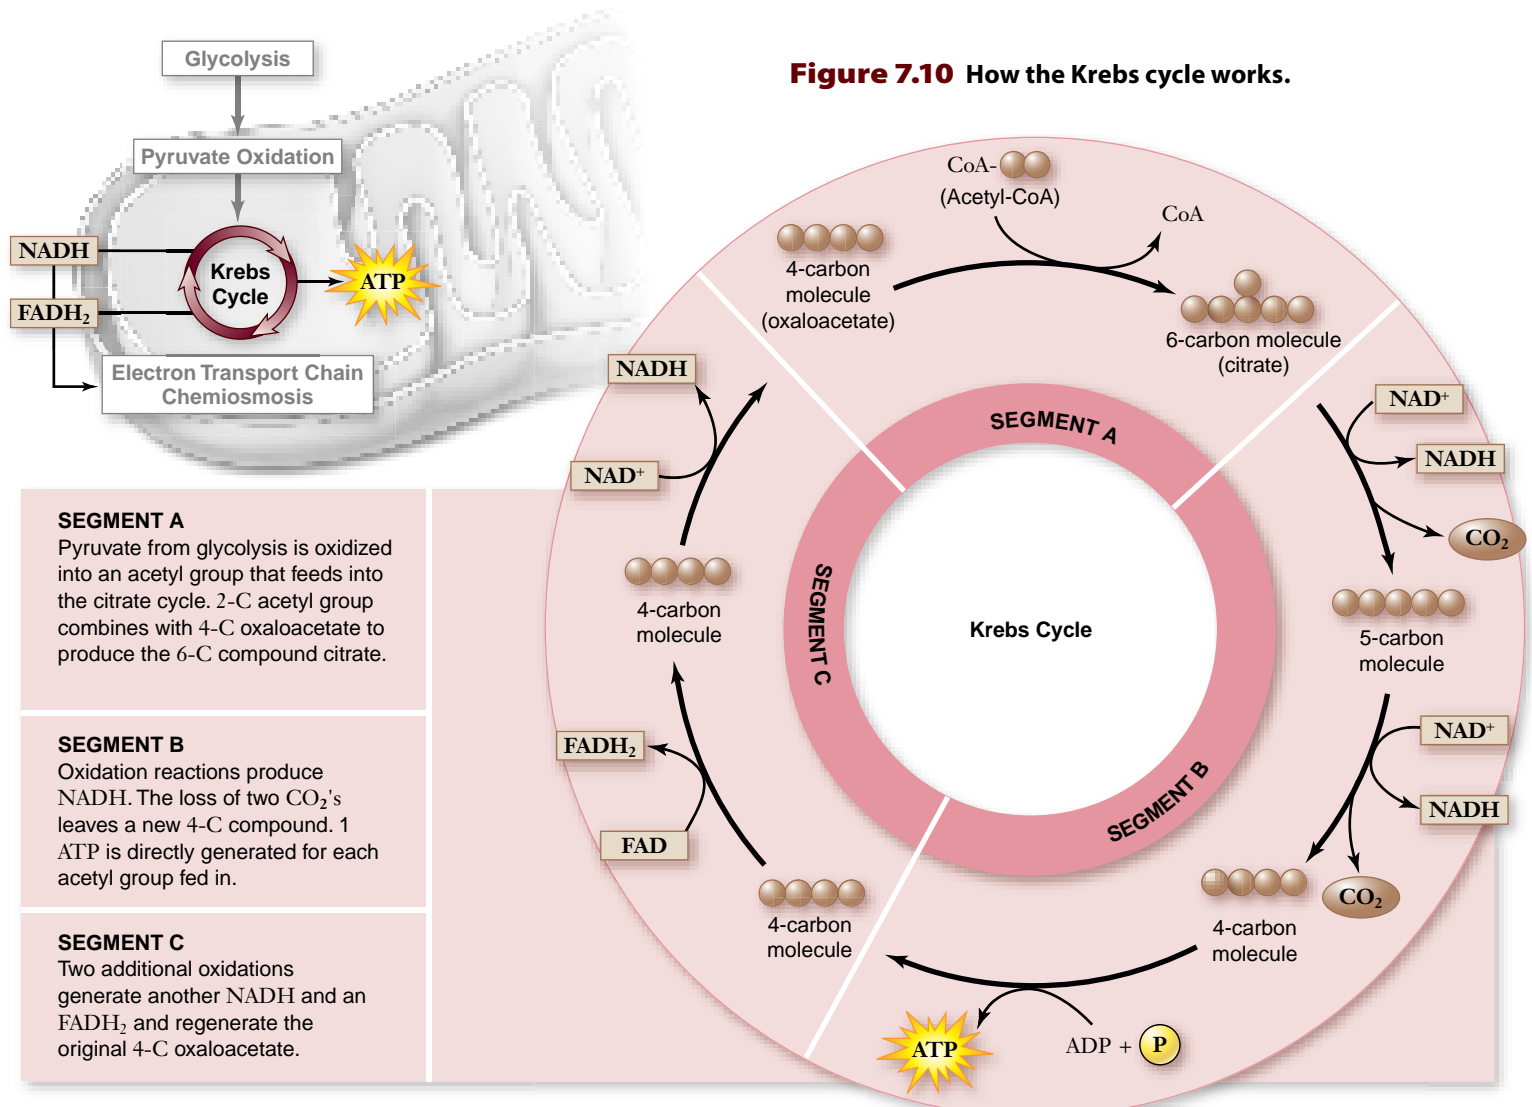

Figure 7.10 How the Krebs cycle works.

## The Krebs cycle extracts electrons and synthesizes one ATP

Figure 7.11 summarizes the sequence of the Krebs cycle reactions. A 2-carbon group from acetyl-CoA enters the cycle at the beginning, and two CO<sub>2</sub> molecules, one ATP, and four pairs of electrons are produced.

**Reaction 1: Condensation** Citrate is formed from acetyl-CoA and oxaloacetate. This condensation reaction is irreversible, committing the 2-carbon acetyl group to the Krebs cycle. The reaction is inhibited when the cell's ATP concentration is high and stimulated when it is low. The result is that when the cell possesses ample amounts of ATP, the Krebs cycle shuts down, and acetyl-CoA is channeled into fat synthesis.

**Reactions 2 and 3: Isomerization** Before the oxidation reactions can begin, the hydroxyl (—OH) group of citrate must be repositioned. This rearrangement is done in two steps: First, a water molecule is removed from one carbon; then water is added to a different carbon. As a result, an —H group and an —OH group change positions. The product is an isomer of citrate called *isocitrate*. This rearrangement facilitates the subsequent reactions.

**Reaction 4: The First Oxidation** In the first energy-yielding step of the cycle, isocitrate undergoes an oxidative decarboxylation reaction. First, isocitrate is oxidized, yielding a pair of electrons that reduce a molecule of NAD<sup>+</sup> to NADH. Then the oxidized intermediate is decarboxylated; the central carboxyl group splits off to form CO<sub>2</sub>, yielding a 5-carbon molecule called *α-ketoglutarate*.

**Reaction 5: The Second Oxidation** Next, *α-ketoglutarate* is decarboxylated by a multienzyme complex similar to pyruvate dehydrogenase. The succinyl group left after the removal of CO<sub>2</sub> joins to coenzyme A, forming *succinyl-CoA*. In the process, two electrons are extracted, and they reduce another molecule of NAD<sup>+</sup> to NADH.

**Reaction 6: Substrate-Level Phosphorylation** The linkage between the 4-carbon succinyl group and CoA is a high-energy bond. In a coupled reaction similar to those that take place in glycolysis, this bond is cleaved, and the energy released drives the phosphorylation of guanosine diphosphate (GDP), forming guanosine triphosphate (GTP). GTP can transfer a phosphate to ADP converting it into ATP. The 4-carbon molecule that remains is called *succinate*.

**Reaction 7: The Third Oxidation** Next, succinate is oxidized to *fumarate* by an enzyme located in the inner mitochondrial membrane. The free-energy change in this reaction is not large enough to reduce NAD<sup>+</sup>. Instead, FAD is the electron acceptor. Unlike NAD<sup>+</sup>, FAD is not free to diffuse within the mitochondrion; it is tightly associated with its enzyme in the inner mitochondrial membrane. Its reduced form, FADH<sub>2</sub>, can only contribute electrons to the electron transport chain in the membrane.

**Reactions 8 and 9: Regeneration of Oxaloacetate** In the final two reactions of the cycle, a water molecule is added to fumarate, forming *malate*. Malate is then oxidized, yielding a 4-carbon molecule of *oxaloacetate* and two electrons that reduce a

molecule of NAD<sup>+</sup> to NADH. Oxaloacetate, the molecule that began the cycle, is now free to combine with another 2-carbon acetyl group from acetyl-CoA and begin the cycle again.

## Glucose becomes CO<sub>2</sub> and potential energy

In the process of aerobic respiration, glucose is entirely consumed. The 6-carbon glucose molecule is cleaved into a pair of 3-carbon pyruvate molecules during glycolysis. One of the carbons of each pyruvate is then lost as CO<sub>2</sub> in the conversion of pyruvate to acetyl-CoA. The two other carbons from acetyl-CoA are lost as CO<sub>2</sub> during the oxidations of the Krebs cycle.

All that is left to mark the passing of a glucose molecule into six CO<sub>2</sub> molecules is its energy, some of which is preserved in four ATP molecules and in the reduced state of 12 electron carriers. Ten of these carriers are NADH molecules; the other two are FADH<sub>2</sub>.

## Following the electrons in the reactions reveals the direction of transfer

As you examine the changes in electrical charge in the reactions that oxidize glucose, a good strategy for keeping the transfers clear is always to *follow the electrons*. For example, in glycolysis, an enzyme extracts two hydrogens—that is, two electrons and two protons—from glucose and transfers both electrons and one of the protons to NAD<sup>+</sup>. The other proton is released as a hydrogen ion, H<sup>+</sup>, into the surrounding solution. This transfer converts NAD<sup>+</sup> into NADH; that is, two negative electrons (2e<sup>-</sup>) and one positive proton (H<sup>+</sup>) are added to one positively charged NAD<sup>+</sup> to form NADH, which is electrically neutral.

As mentioned earlier, energy captured by NADH is not harvested all at once. The two electrons carried by NADH are passed along the electron transport chain, which consists of a series of electron carriers, mostly proteins, embedded within the inner membranes of mitochondria.

NADH delivers electrons to the beginning of the electron transport chain, and oxygen captures them at the end. The oxygen then joins with hydrogen ions to form water. At each step in the chain, the electrons move to a slightly more electronegative carrier, and their positions shift slightly. Thus, the electrons move *down* an energy gradient.

The entire process of electron transfer releases a total of 53 kcal/mol (222 kJ/mol) under standard conditions. The transfer of electrons along this chain allows the energy to be extracted gradually. Next, we will discuss how this energy is put to work to drive the production of ATP.

### Learning Outcomes Review 7.4

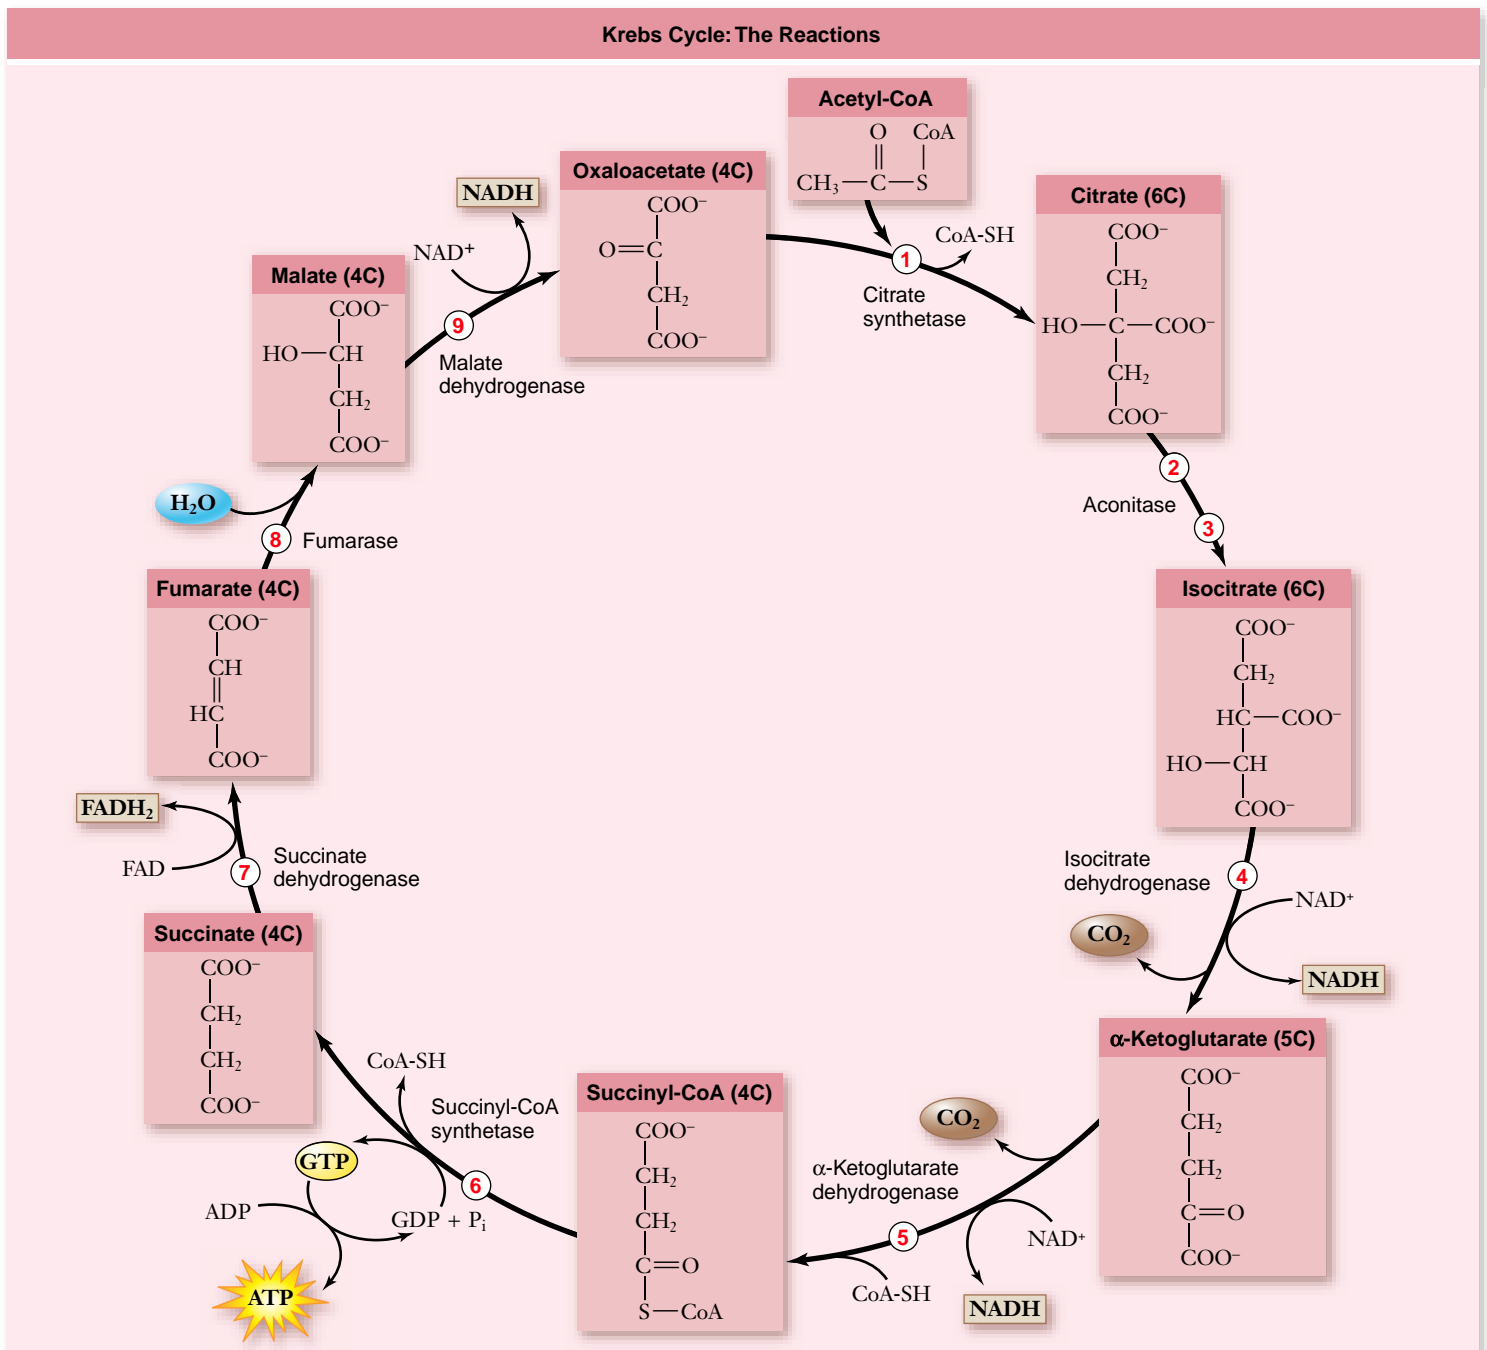

The Krebs cycle completes the oxidation of glucose begun with glycolysis. In the first segment, acetyl-CoA is added to oxaloacetate to produce citrate. In the next segment, five reactions produce succinate, two NADH from NAD<sup>+</sup>, and one ATP. Finally, succinate undergoes three more reactions to regenerate oxaloacetate, producing one more NADH and one FADH<sub>2</sub> from FAD.

- **What happens to the electrons removed from glucose at this point?**

1. Reaction 1: Condensation
- 2-3. Reactions 2 and 3: Isomerization
4. Reaction 4: The first oxidation
5. Reaction 5: The second oxidation
6. Reaction 6: Substrate-level phosphorylation
7. Reaction 7: The third oxidation
- 8-9. Reactions 8 and 9: Regeneration of oxaloacetate and the fourth oxidation

**Figure 7.11 The Krebs cycle.** This series of reactions takes place within the matrix of the mitochondrion. For the complete breakdown of a molecule of glucose, the two molecules of acetyl-CoA produced by glycolysis and pyruvate oxidation each have to make a trip around the Krebs cycle. Follow the different carbons through the cycle, and notice the changes that occur in the carbon skeletons of the molecules and where oxidation reactions take place as they proceed through the cycle.

## 7.5 The Electron Transport Chain and Chemiosmosis

### Learning Outcomes

1. Describe the structure and function of the electron transport chain.
2. Understand how the proton gradient connects electron transport with ATP synthesis.

The NADH and FADH<sub>2</sub> molecules formed during aerobic respiration each contain a pair of electrons that were gained when NAD<sup>+</sup> and FAD were reduced. The NADH molecules carry their electrons to the inner mitochondrial membrane, where they transfer the electrons to a series of membrane-associated proteins collectively called the *electron transport chain*.

### The electron transport chain produces a proton gradient

The first of the proteins to receive the electrons is a complex, membrane-embedded enzyme called **NADH dehydrogenase**. A carrier called *ubiquinone* then passes the electrons to a protein-cytochrome complex called the *bc<sub>1</sub> complex*. Each complex in the

chain operates as a proton pump, driving a proton out across the membrane into the intermembrane space (figure 7.12*a*).

The electrons are then carried by another carrier, *cytochrome c*, to the cytochrome oxidase complex. This complex uses four electrons to reduce a molecule of oxygen. Each oxygen then combines with two protons to form water:

In contrast to NADH, which contributes its electrons to NADH dehydrogenase, FADH<sub>2</sub>, which is located in the inner mitochondrial membrane, feeds its electrons to ubiquinone, which is also in the membrane. Electrons from FADH<sub>2</sub> thus “skip” the first step in the electron transport chain.

The plentiful availability of a strong electron acceptor, oxygen, is what makes oxidative respiration possible. As you’ll see in chapter 8, the electron transport chain used in aerobic respiration is similar to, and may well have evolved from, the chain employed in photosynthesis.

### The gradient forms as electrons move through electron carriers

Respiration takes place within the mitochondria present in virtually all eukaryotic cells. The internal compartment, or matrix, of a mitochondrion contains the enzymes that carry out the reactions of the Krebs cycle. As mentioned earlier, protons (H<sup>+</sup>) are produced when electrons are transferred to NAD<sup>+</sup>. As the electrons harvested

### Figure 7.12 The electron transport chain and chemiosmosis.

**a.** High-energy electrons harvested from catabolized molecules are transported by mobile electron carriers (ubiquinone, marked Q, and cytochrome c, marked C) between three complexes of membrane proteins. These three complexes use portions of the electrons’ energy to pump protons out of the matrix and into the intermembrane space. The electrons are finally used to reduce oxygen, forming water. **b.** This creates a concentration gradient of protons across the inner membrane. This electrochemical gradient is a form of potential energy that can be used by ATP synthase. This enzyme couples the reentry of protons to the phosphorylation of ADP to form ATP.

**a.** The electron transport chain

**b.** Chemiosmosis

by oxidative respiration are passed along the electron transport chain, the energy they release transports protons out of the matrix and into the outer compartment called the intermembrane space.

Three transmembrane complexes of the electron transport chain in the inner mitochondrial membrane actually accomplish the proton transport (see figure 7.12a). The flow of highly energetic electrons induces a change in the shape of pump proteins, which causes them to transport protons across the membrane. The electrons contributed by NADH activate all three of these proton pumps, whereas those contributed by FADH<sub>2</sub> activate only two because of where they enter the chain. In this way a proton gradient is formed between the intermembrane space and the matrix.

## Chemiosmosis utilizes the electrochemical gradient to produce ATP

Because the mitochondrial matrix is negative compared with the intermembrane space, positively charged protons are at-

tracted to the matrix. The higher outer concentration of protons also tends to drive protons back in by diffusion, but because membranes are relatively impermeable to ions, this process occurs only very slowly. Most of the protons that re-enter the matrix instead pass through ATP synthase, an enzyme that uses the energy of the gradient to catalyze the synthesis of ATP from ADP and P<sub>i</sub>. Because the chemical formation of ATP is driven by a diffusion force similar to osmosis, this process is referred to as *chemiosmosis* (figure 7.12b). The newly formed ATP is transported by facilitated diffusion to the many places in the cell where enzymes require energy to drive endergonic reactions. This chemiosmotic mechanism for the coupling of electron transport and ATP synthesis was controversial when it was proposed. Over the years, experimental evidence accumulated to support this hypothesis (figure 7.13).

The energy released by the reactions of cellular respiration ultimately drives the proton pumps that produce the

### SCIENTIFIC THINKING

**Hypothesis:** ATP synthase enzyme uses a proton gradient to provide energy for phosphorylation reaction.

**Prediction:** The source of the proton gradient should not matter. A proton gradient formed by the light-driven pump bacteriorhodopsin should power phosphorylation in the light but not in the dark.

**Test:** Artificial vesicles are made with bacteriorhodopsin and ATP synthase, and ATP synthase alone. These are illuminated with light and assessed for ATP production.

**Result:** The vesicle with both bacteriorhodopsin and ATP synthase can form ATP in the light but not in the dark. The vesicle with ATP synthase alone cannot form ATP in the light.

**Conclusion:** ATP synthase is able to utilize a proton gradient for energy to form ATP.

**Further Experiments:** What other controls would be appropriate for this type of experiment? Why is this experiment a better test of the chemiosmotic hypothesis than the acid bath experiment in Jangendorf/chapter 8 (see figure 8.16)?

**Figure 7.13** Evidence for the chemiosmotic synthesis of ATP by ATP synthase.

**Figure 7.14 Aerobic respiration in the mitochondria.** The entire process of aerobic respiration is shown in cellular context. Glycolysis occurs in the cytoplasm with the pyruvate and NADH produced entering the mitochondria. Here, pyruvate is oxidized and fed into the Krebs cycle to complete the oxidation process. All the energetic electrons harvested by oxidations in the overall process are transferred by NADH and  $\text{FADH}_2$  to the electron transport chain. The electron transport chain uses the energy released during electron transport to pump protons across the inner membrane. This creates an electrochemical gradient that contains potential energy. The enzyme ATP synthase uses this gradient to phosphorylate ADP to form ATP.

proton gradient. The proton gradient provides the energy required for the synthesis of ATP. Figure 7.14 summarizes the overall process.

### ATP synthase is a molecular rotary motor

ATP synthase uses a fascinating molecular mechanism to perform ATP synthesis (figure 7.15). Structurally, the enzyme has a membrane-bound portion and a narrow stalk that connects the membrane portion to a knoblike catalytic portion. This complex can be dissociated into two subportions: the  $F_0$  membrane-bound complex, and the  $F_1$  complex composed of the stalk and a knob, or head domain.

The  $F_1$  complex has enzymatic activity. The  $F_0$  complex contains a channel through which protons move across the membrane down their concentration gradient. As they do so, their movement causes part of the  $F_0$  complex and the stalk to rotate relative to the knob. The mechanical energy of this rotation is used to change the conformation of the catalytic domain in the  $F_1$  complex.

Thus, the synthesis of ATP is achieved by a tiny rotary motor, the rotation of which is driven directly by a gradient of protons. The flow of protons is like that of water in a hydroelectric power plant. Like the flow of water driven by gravity causes a turbine to rotate and generate electrical current, the proton gradient produces the energy that drives the rotation of the ATP synthase generator.

**Figure 7.15 The ATP rotary engine.** Protons move across the membrane down their concentration gradient. The energy released causes the rotor and stalk structures to rotate. This mechanical energy alters the conformation of the ATP synthase enzyme to catalyze the formation of ATP.

## Learning Outcomes Review 7.5

The electron transport chain receives electrons from NADH and FADH<sub>2</sub> and passes them down the chain to oxygen. The protein complexes of the electron transport chain, in the inner membrane of mitochondria, use the energy from electron transfer to pump protons across the membrane, creating an electrochemical gradient. The enzyme ATP synthase uses this gradient to drive the endergonic reaction of phosphorylating ADP to ATP.

- How would poking a small hole in the outer membrane affect ATP synthesis?

## 7.6 Energy Yield of Aerobic Respiration

### Learning Outcome

1. Calculate the number of ATP molecules produced by aerobic respiration.

How much metabolic energy in the form of ATP does a cell gain from aerobic breakdown of glucose? Knowing the steps involved in the process, we can calculate the theoretical yield of ATP and compare it with the actual yield.

### The theoretical yield for eukaryotes is 36 molecules of ATP per glucose molecule

The chemiosmotic model suggests that one ATP molecule is generated for each proton pump activated by the electron transport chain. Because the electrons from NADH activate

three pumps and those from FADH<sub>2</sub> activate two, we would expect each molecule of NADH and FADH<sub>2</sub> to generate three and two ATP molecules, respectively.

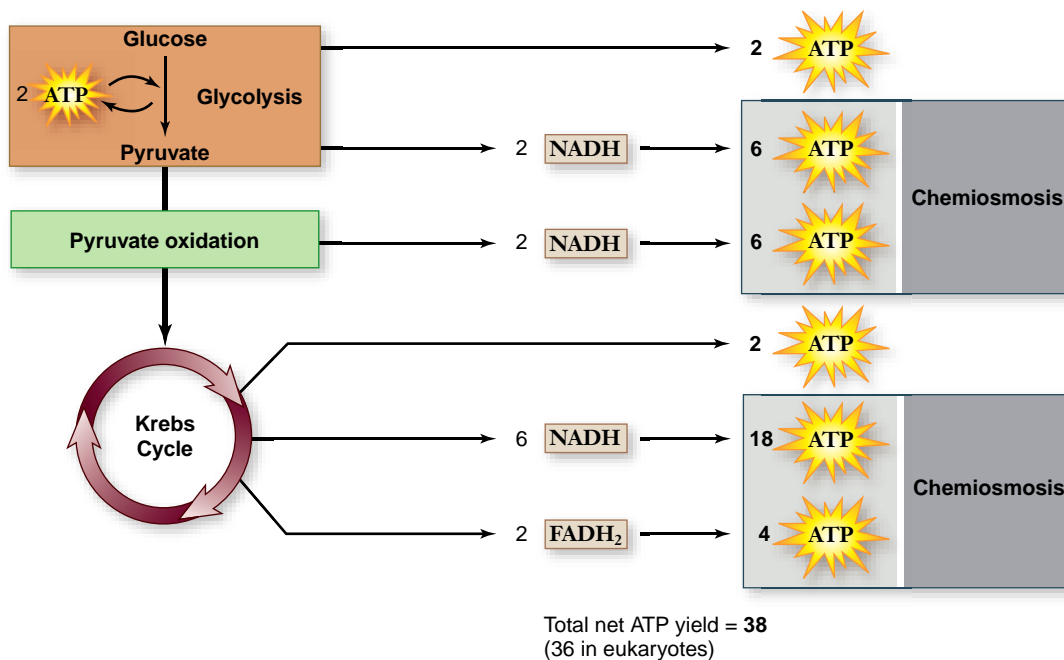

In doing this accounting, remember that everything downstream of glycolysis must be multiplied by 2 because two pyruvates are produced per molecule of glucose. A total of 10 NADH molecules is generated by respiration: 2 from glycolysis, 2 from the oxidation of pyruvate (1 × 2), and another 6 from the Krebs cycle (3 × 2). Also, two FADH<sub>2</sub> are produced (1 × 2). Finally, two ATP are generated directly by glycolysis and another two ATP from the Krebs cycle (1 × 2). This gives a total of 10 × 3 = 30 ATP from NADH, plus 2 × 2 = 4 ATP from FADH<sub>2</sub>, plus 4 ATP, for a total of 38 ATP (figure 7.16).

This number is accurate for bacteria, but it does not hold for eukaryotes because the NADH produced in the cytoplasm by glycolysis needs to be transported into the mitochondria by active transport, which costs one ATP per NADH transported. This reduces the predicted yield for eukaryotes to 36 ATP.

### The actual yield for eukaryotes is 30 molecules of ATP per glucose molecule

The amount of ATP actually produced in a eukaryotic cell during aerobic respiration is somewhat lower than 36, for two reasons. First, the inner mitochondrial membrane is somewhat “leaky” to protons, allowing some of them to reenter the matrix without passing through ATP synthase. Second, mitochondria often use the proton gradient generated by chemiosmosis for purposes other than ATP synthesis (such as transporting pyruvate into the matrix).

Consequently, the actual measured values of ATP generated by NADH and FADH<sub>2</sub> are closer to 2.5 for each NADH, and 1.5 for each FADH<sub>2</sub>. With these corrections, the overall harvest of ATP from a molecule of glucose in a eukaryotic cell is calculated as: 4 ATP from substrate-level

**Figure 7.16 Theoretical ATP yield.** The theoretical yield of ATP harvested from glucose by aerobic respiration totals 38 molecules. In eukaryotes this is reduced to 36 because it takes 1 ATP to transport each molecule of NADH that is generated by glycolysis in the cytoplasm into the mitochondria.

phosphorylation + 25 ATP from NADH ( $2.5 \times 10$ ) + 3 ATP from  $\text{FADH}_2$  ( $1.5 \times 2$ ) - 2 ATP for transport of glycolytic NADH = 30 molecules of ATP.

We mentioned earlier that the catabolism of glucose by aerobic respiration, in contrast to that by glycolysis alone, has a large energy yield. Aerobic respiration in a eukaryotic cell harvests about  $(7.3 \times 30)/686 = 32\%$  of the energy available in glucose. (By comparison, a typical car converts only about 25% of the energy in gasoline into useful energy.)

The higher yield of aerobic respiration was one of the key factors that fostered the evolution of heterotrophs. As this mechanism for producing ATP evolved, nonphotosynthetic organisms could more successfully base their metabolism on the exclusive use of molecules derived from other organisms. As long as some organisms captured energy by photosynthesis, others could exist solely by feeding on them.

### Learning Outcome Review 7.6

Passage of electrons down the electron transport chain produces roughly three ATP per NADH (two ATP per  $\text{FADH}_2$ ). This process plus the ATP generated by substrate-level phosphorylation could yield a maximum of 38 ATP for the complete oxidation of glucose. But NADH generated in the cytoplasm yields only two ATP/NADH because transporting the NADH into the mitochondria uses ATP. Therefore the theoretical total is 36 ATP per glucose in eukaryotes.

- Why is the expected yield not necessarily the same as the actual yield in a cell?

## 7.7 Regulation of Aerobic Respiration

### Learning Outcome

1. Understand the control points for cellular respiration.

When cells possess plentiful amounts of ATP, the key reactions of glycolysis, the Krebs cycle, and fatty acid breakdown are inhibited, slowing ATP production. The regulation of these biochemical pathways by the level of ATP is an example of feedback inhibition. Conversely, when ATP levels in the cell are low, ADP levels are high, and ADP activates enzymes in the pathways of carbohydrate catabolism to stimulate the production of more ATP.

Control of glucose catabolism occurs at two key points in the catabolic pathway, namely at a point in glycolysis and at the beginning of the Krebs cycle (figure 7.17). The control point in glycolysis is the enzyme phosphofructokinase, which catalyzes the conversion of fructose phosphate to fructose bisphosphate. This is the first reaction of glycolysis that is not readily reversible, committing the substrate to the glycolytic sequence. ATP itself is an allosteric inhibitor (see chapter 6) of phosphofructokinase, as is the Krebs cycle intermediate citrate. High levels of both ATP and citrate inhibit phosphofructokinase. Thus, under conditions when

**Figure 7.17 Control of glucose catabolism.** The relative levels of ADP and ATP and key intermediates NADH and citrate control the catabolic pathway at two key points: the committing reactions of glycolysis and the Krebs cycle.

ATP is in excess, or when the Krebs cycle is producing citrate faster than it is being consumed, glycolysis is slowed.

The main control point in the oxidation of pyruvate occurs at the committing step in the Krebs cycle with the enzyme pyruvate dehydrogenase, which converts pyruvate to acetyl-CoA. This enzyme is inhibited by high levels of NADH, a key product of the Krebs cycle.

Another control point in the Krebs cycle is the enzyme citrate synthetase, which catalyzes the first reaction, the conversion of oxaloacetate and acetyl-CoA into citrate. High levels of ATP inhibit citrate synthetase (as well as phosphofructokinase, pyruvate dehydrogenase, and two other Krebs cycle enzymes), slowing down the entire catabolic pathway.

### Learning Outcome Review 7.7

Respiration is controlled by levels of ATP in the cell and levels of key intermediates in the process. The control point for glycolysis is the enzyme phosphofructokinase, which is inhibited by ATP or citrate (or both). The main control point in oxidation of pyruvate is the enzyme pyruvate dehydrogenase, inhibited by NADH.

- How does feedback inhibition ensure economic production of ATP?

## 7.8 Oxidation Without O<sub>2</sub>

### Learning Outcomes

1. Compare anaerobic and aerobic respiration.
2. Distinguish the role of fermentation in anaerobic metabolism.

In the presence of oxygen, cells can use oxygen to produce a large amount of ATP. But even when no oxygen is present to accept electrons, some organisms can still respire *anaerobically*, using inorganic molecules as final electron acceptors for an electron transport chain.

For example, many prokaryotes use sulfur, nitrate, carbon dioxide, or even inorganic metals as the final electron acceptor in place of oxygen (figure 7.18). The free energy released by using these other molecules as final electron acceptors is not as great as that using oxygen because they have a lower affinity for electrons. The amount of ATP produced is less, but the process is still respiration and not fermentation.

### Methanogens use carbon dioxide

Among the heterotrophs that practice anaerobic respiration are Archaea such as thermophiles and methanogens. Methanogens use carbon dioxide (CO<sub>2</sub>) as the electron acceptor, reducing CO<sub>2</sub> to CH<sub>4</sub> (methane). The hydrogens are de-

rived from organic molecules produced by other organisms. Methanogens are found in diverse environments, including soil and the digestive systems of ruminants like cows.

### Sulfur bacteria use sulfate

Evidence of a second anaerobic respiratory process among primitive bacteria is seen in a group of rocks about 2.7 BYA, known as the Woman River iron formation. Organic material in these rocks is enriched for the light isotope of sulfur, <sup>32</sup>S, relative to the heavier isotope, <sup>34</sup>S. No known geochemical process produces such enrichment, but biological sulfur reduction does, in a process still carried out today by certain prokaryotes.

In this sulfate respiration, the prokaryotes derive energy from the reduction of inorganic sulfates (SO<sub>4</sub>) to hydrogen sulfide (H<sub>2</sub>S). The hydrogen atoms are obtained from organic molecules other organisms produce. These prokaryotes thus are similar to methanogens, but they use SO<sub>4</sub> as the oxidizing (that is, electron-accepting) agent in place of CO<sub>2</sub>.

The early sulfate reducers set the stage for the evolution of photosynthesis, creating an environment rich in H<sub>2</sub>S. As discussed in chapter 8, the first form of photosynthesis obtained hydrogens from H<sub>2</sub>S using the energy of sunlight.

### Fermentation uses organic compounds as electron acceptors

In the absence of oxygen, cells that cannot utilize an alternative electron acceptor for respiration must rely exclusively on

**a.** 0.625 μm

**b.**

**Figure 7.18 Sulfur-respiring prokaryote.** *a.* The micrograph shows the archaeal species *Thermoproteus tenax*. This organism can use elemental sulfur as a final electron acceptor for anaerobic respiration. *b.* *Thermoproteus* is often found in sulfur-containing hot springs such as the Norris Geyser Basin in Yellowstone National Park shown here.

glycolysis to produce ATP. Under these conditions, the electrons generated by glycolysis are donated to organic molecules in a process called *fermentation*. This process recycles  $\text{NAD}^+$ , the electron acceptor that allows glycolysis to proceed.

Bacteria carry out more than a dozen kinds of fermentation reactions, often using pyruvate or a derivative of pyruvate to accept the electrons from NADH. Organic molecules other than pyruvate and its derivatives can be used as well; the important point is that the process regenerates  $\text{NAD}^+$ :

Often the reduced organic compound is an organic acid—such as acetic acid, butyric acid, propionic acid, or lactic acid—or an alcohol.

### Ethanol fermentation

Eukaryotic cells are capable of only a few types of fermentation. In one type, which occurs in yeast, the molecule that accepts electrons from NADH is derived from pyruvate, the end-product of glycolysis.

Yeast enzymes remove a terminal  $\text{CO}_2$  group from pyruvate through decarboxylation, producing a 2-carbon molecule called acetaldehyde. The  $\text{CO}_2$  released causes bread made with yeast to rise. The acetaldehyde accepts a pair of electrons from NADH, producing  $\text{NAD}^+$  and ethanol (ethyl alcohol) (figure 7.19).

This particular type of fermentation is of great interest to humans, because it is the source of the ethanol in wine and beer. Ethanol is a by-product of fermentation that is actually toxic to yeast; as it approaches a concentration of about 12%, it begins to kill the yeast. That explains why naturally fermented wine contains only about 12% ethanol.

### Lactic acid fermentation

Most animal cells regenerate  $\text{NAD}^+$  without decarboxylation. Muscle cells, for example, use the enzyme lactate dehydrogenase to transfer electrons from NADH back to the pyruvate that is produced by glycolysis. This reaction converts pyruvate into lactic acid and regenerates  $\text{NAD}^+$  from NADH (see figure 7.19). It therefore closes the metabolic circle, allowing glycolysis to continue as long as glucose is available.

Circulating blood removes excess lactate, the ionized form of lactic acid, from muscles, but when removal cannot keep pace with production, the accumulating lactic acid interferes with muscle function and contributes to muscle fatigue.

#### Learning Outcomes Review 7.8

Nitrate, sulfur, and  $\text{CO}_2$  are all used as terminal electron acceptors in anaerobic respiration of different organisms. Organic molecules can also accept electrons in fermentation reactions that regenerate  $\text{NAD}^+$ . Fermentation reactions produce a variety of compounds, including ethanol in yeast and lactic acid in humans.

- In what kinds of ecosystems would you expect to find anaerobic respiration?

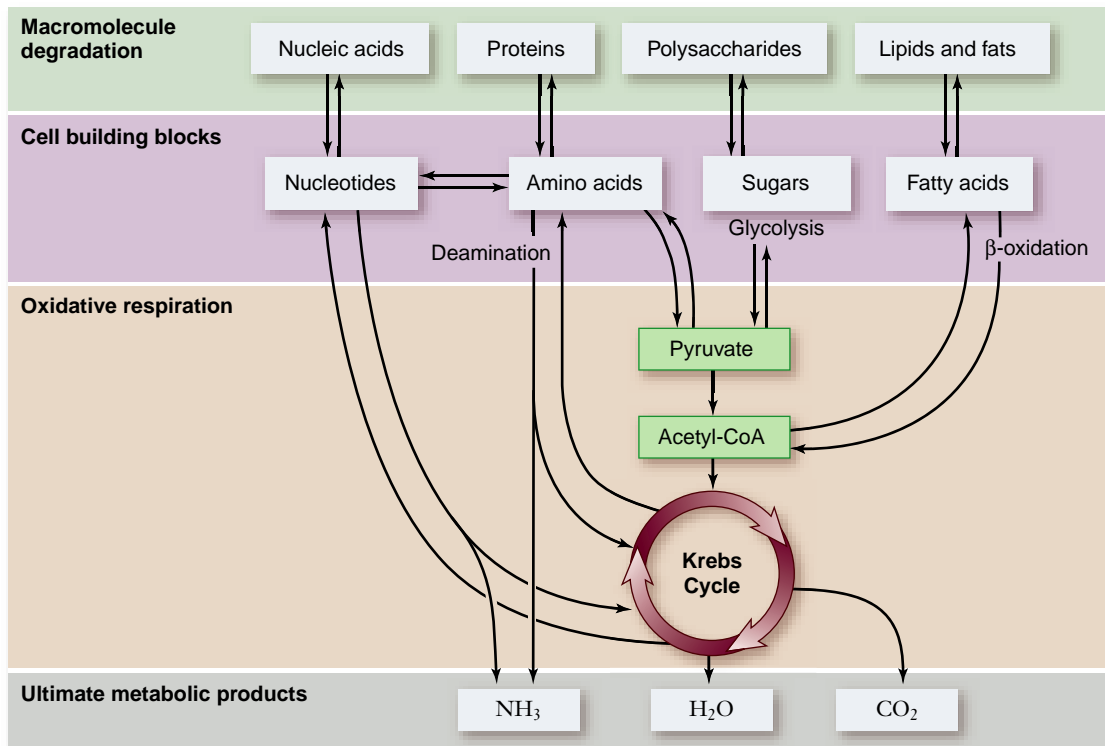

**Figure 7.19 Fermentation.** Yeasts carry out the conversion of pyruvate to ethanol. Muscle cells convert pyruvate into lactate, which is less toxic than ethanol. In each case, the reduction of a metabolite of glucose has oxidized NADH back to  $\text{NAD}^+$  to allow glycolysis to continue under anaerobic conditions.

## 7.9 Catabolism of Proteins and Fats

### Learning Outcomes

1. Identify the points at which proteins and fats enter energy metabolism.
2. Describe the linkages between catabolic and anabolic pathways.

Thus far we have focused on the aerobic respiration of glucose, which organisms obtain from the digestion of carbohydrates or from photosynthesis. Organic molecules other than glucose,

**Figure 7.20** How cells extract chemical energy.

All eukaryotes and many prokaryotes extract energy from organic molecules by oxidizing them. The first stage of this process, breaking down macromolecules into their constituent parts, yields little energy. The second stage, oxidative or aerobic respiration, extracts energy, primarily in the form of high-energy electrons, and produces water and carbon dioxide. Key intermediates in these energy pathways are also used for biosynthetic pathways, shown by reverse arrows.

particularly proteins and fats, are also important sources of energy (figure 7.20).

### Catabolism of proteins removes amino groups

Proteins are first broken down into their individual amino acids. The nitrogen-containing side group (the amino group) is then removed from each amino acid in a process called **deamination**. A series of reactions converts the carbon chain that remains into a molecule that enters glycolysis or the Krebs cycle. For example, alanine is converted into pyruvate, glutamate into  $\alpha$ -ketoglutarate (figure 7.21), and aspartate into oxaloacetate. The reactions of glycolysis and the Krebs cycle then extract the high-energy electrons from these molecules and put them to work making ATP.

**Figure 7.21** Deamination. After proteins are broken down into their amino acid constituents, the amino groups are removed from the amino acids to form molecules that participate in glycolysis and the Krebs cycle. For example, the amino acid glutamate becomes  $\alpha$ -ketoglutarate, a Krebs cycle intermediate, when it loses its amino group.

### Catabolism of fatty acids produces acetyl groups

Fats are broken down into fatty acids plus glycerol. Long-chain fatty acids typically have an even number of carbons, and the many C—H bonds provide a rich harvest of energy. Fatty acids are oxidized in the matrix of the mitochondrion. Enzymes remove the 2-carbon acetyl groups from the end of each fatty acid until the entire fatty acid is converted into acetyl groups (figure 7.22). Each acetyl group is combined with coenzyme A to form acetyl-CoA. This process is known as  **$\beta$  oxidation**. This process is oxygen-dependent, which explains why aerobic exercise burns fat, but anaerobic exercise does not.

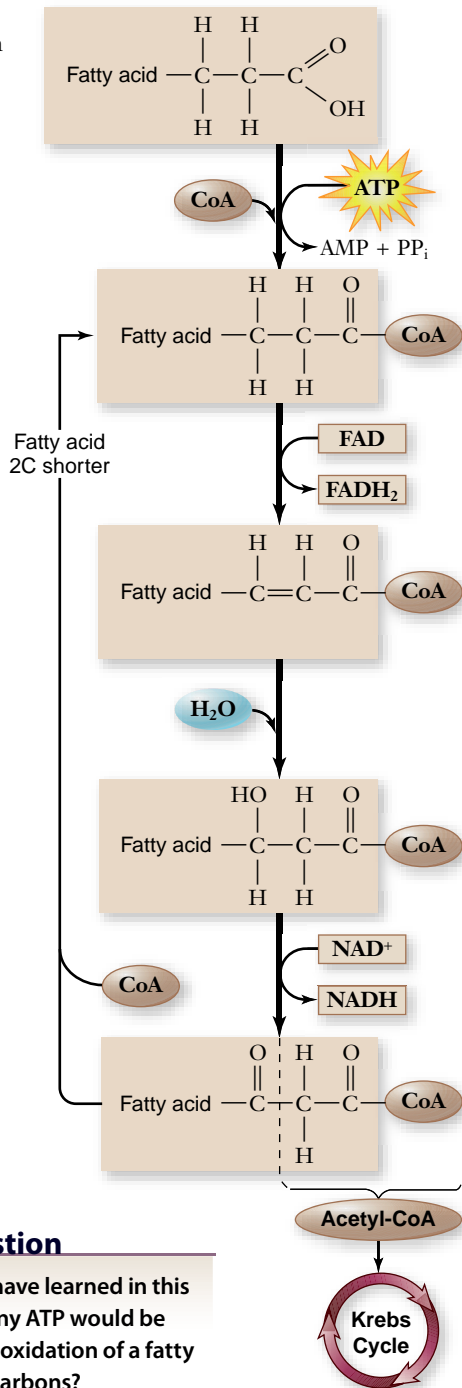

How much ATP does the catabolism of fatty acids produce? Let's compare a hypothetical 6-carbon fatty acid with the 6-carbon glucose molecule, which we've said yields about 30 molecules of ATP in a eukaryotic cell. Two rounds of  $\beta$  oxidation would convert the fatty acid into three molecules of acetyl-CoA. Each round requires one molecule of ATP to prime the process, but it also produces one molecule of NADH and one of  $FADH_2$ . These molecules together yield four molecules of ATP (assuming 2.5 ATPs per NADH, and 1.5 ATPs per  $FADH_2$ ).

The oxidation of each acetyl-CoA in the Krebs cycle ultimately produces an additional 10 molecules of ATP. Overall, then, the ATP yield of a 6-carbon fatty acid is approximately: 8 (from two rounds of  $\beta$  oxidation) – 2 (for priming those two rounds) + 30 (from oxidizing the three acetyl-CoAs) = 36 molecules of ATP. Therefore, the respiration of a 6-carbon fatty acid yields 20% more ATP than the respiration of glucose.

Moreover, a fatty acid of that size would weigh less than two thirds as much as glucose, so a gram of fatty acid contains more than twice as many kilocalories as a gram of glucose. You can see from this fact why fat is a storage molecule for excess

### Figure 7.22

**$\beta$  oxidation.** Through a series of reactions known as  $\beta$  oxidation, the last two carbons in a fatty acid combine with coenzyme A to form acetyl-CoA, which enters the Krebs cycle. The fatty acid, now two carbons shorter, enters the pathway again and keeps reentering until all its carbons have been used to form acetyl-CoA molecules. Each round of  $\beta$  oxidation uses one molecule of ATP and generates one molecule each of  $\text{FADH}_2$  and  $\text{NADH}$ .

#### Inquiry question

? Given what you have learned in this chapter, how many ATP would be produced by the oxidation of a fatty acid that has 16 carbons?

energy in many types of animals. If excess energy were stored instead as carbohydrate, as it is in plants, animal bodies would have to be much bulkier.

### A small number of key intermediates connect metabolic pathways

Oxidation pathways of food molecules are interrelated in that a small number of key intermediates, such as pyruvate and acetyl-CoA, link the breakdown from different starting points. These key intermediates allow the interconversion of different types of molecules, such as sugars and amino acids (see figure 7.20).

Cells can make glucose, amino acids, and fats, as well as getting them from external sources. They use reactions similar to those that break down these substances. In many cases, the reverse pathways even share enzymes if the free-energy changes are small. For example, gluconeogenesis, the process of making new glucose, uses all but three enzymes of the glycolytic pathway. Thus, much of glycolysis runs forward or backward, depending on the concentrations of the intermediates—with only three key steps having different enzymes for forward and reverse directions.

### Acetyl-CoA has many roles

Many different metabolic processes generate acetyl-CoA. Not only does the oxidation of pyruvate produce it, but the metabolic breakdown of proteins, fats, and other lipids also generates acetyl-CoA. Indeed, almost all molecules catabolized for energy are converted into acetyl-CoA.

Acetyl-CoA has a role in anabolic metabolism as well. Units of two carbons derived from acetyl-CoA are used to build up the hydrocarbon chains in fatty acids. Acetyl-CoA produced from a variety of sources can therefore be channeled into fatty acid synthesis or into ATP production, depending on the organism's energy requirements. Which of these two options is taken depends on the level of ATP in the cell.

When ATP levels are high, the oxidative pathway is inhibited, and acetyl-CoA is channeled into fatty acid synthesis. This explains why many animals (humans included) develop fat reserves when they consume more food than their activities require. Alternatively, when ATP levels are low, the oxidative pathway is stimulated, and acetyl-CoA flows into energy-producing oxidative metabolism.

#### Learning Outcomes Review 7.9

Proteins can be broken into their constituent amino acids, which are then deaminated and can enter metabolism at glycolysis or different steps of the Krebs cycle. Fats can be broken into units of acetyl-CoA by  $\beta$  oxidation and then fed into the Krebs cycle. Many metabolic processes can be used reversibly, to either build up (anabolism) or break down (catabolism) the major biological macromolecules. Key intermediates, such as pyruvate and acetyl-CoA, connect these processes.

- Can fats be oxidized in the absence of  $\text{O}_2$ ?

## 7.10 Evolution of Metabolism

### Learning Outcome

1. Describe one possible hypothesis for the evolution of metabolism.

We talk about cellular respiration as a continuous series of stages, but it is important to note that these stages evolved over time, and metabolism has changed a great deal in that time.

Both anabolic processes and catabolic processes evolved in concert with each other. We do not know the details of this biochemical evolution, or the order of appearance of these processes. Therefore the following timeline is based on the available geochemical evidence and represents a hypothesis rather than a strict timeline.

## The earliest life forms degraded carbon-based molecules present in the environment

The most primitive forms of life are thought to have obtained chemical energy by degrading, or breaking down, organic molecules that were abiotically produced, that is, carbon-containing molecules formed by inorganic processes on the early Earth.

The first major event in the evolution of metabolism was the origin of the ability to harness chemical bond energy. At an early stage, organisms began to store this energy in the bonds of ATP.

## The evolution of glycolysis also occurred early

The second major event in the evolution of metabolism was glycolysis, the initial breakdown of glucose. As proteins evolved diverse catalytic functions, it became possible to capture a larger fraction of the chemical bond energy in organic molecules by breaking chemical bonds in a series of steps.

Glycolysis undoubtedly evolved early in the history of life on Earth, because this biochemical pathway has been retained by all living organisms. It is a chemical process that does not appear to have changed for more than 2 billion years.

## Anoxygenic photosynthesis allowed the capture of light energy

The third major event in the evolution of metabolism was anoxygenic photosynthesis. Early in the history of life, a different way of generating ATP evolved in some organisms. Instead of obtaining energy for ATP synthesis by reshuffling chemical bonds, as in glycolysis, these organisms developed the ability to use light to pump protons out of their cells and to use the resulting proton gradient to power the production of ATP through chemiosmosis.

Photosynthesis evolved in the absence of oxygen and works well without it. Dissolved  $\text{H}_2\text{S}$ , present in the oceans of the early Earth beneath an atmosphere free of oxygen gas, served as a ready source of hydrogen atoms for building organic molecules. Free sulfur was produced as a by-product of this reaction.

## Oxygen-forming photosynthesis used a different source of hydrogen

The substitution of  $\text{H}_2\text{O}$  for  $\text{H}_2\text{S}$  in photosynthesis was the fourth major event in the history of metabolism. Oxygen-forming photosynthesis employs  $\text{H}_2\text{O}$  rather than  $\text{H}_2\text{S}$  as a source of hydrogen atoms and their associated electrons. Because it garners its electrons from reduced oxygen rather than from reduced sulfur, it generates oxygen gas rather than free sulfur.

More than 2 BYA, small cells capable of carrying out this oxygen-forming photosynthesis, such as cyanobacteria,

became the dominant forms of life on Earth. Oxygen gas began to accumulate in the atmosphere. This was the beginning of a great transition that changed conditions on Earth permanently. Our atmosphere is now 20.9% oxygen, every molecule of which is derived from an oxygen-forming photosynthetic reaction.

## Nitrogen fixation provided new organic nitrogen

Nitrogen is available from dead organic matter, and from chemical reactions that generated the original organic molecules. For life to expand, a new source of nitrogen was needed. Nitrogen fixation was the fifth major step in the evolution of metabolism. Proteins and nucleic acids cannot be synthesized from the products of photosynthesis because both of these biologically critical molecules contain nitrogen. Obtaining nitrogen atoms from  $\text{N}_2$  gas, a process called *nitrogen fixation*, requires breaking an  $\text{N}\equiv\text{N}$  triple bond.

This important reaction evolved in the hydrogen-rich atmosphere of the early Earth, where no oxygen was present. Oxygen acts as a poison to nitrogen fixation, which today occurs only in oxygen-free environments or in oxygen-free compartments within certain prokaryotes.

## Aerobic respiration utilized oxygen

Respiration is the sixth and final event in the history of metabolism. Aerobic respiration employs the same kind of proton pumps as photosynthesis and is thought to have evolved as a modification of the basic photosynthetic machinery.

Biologists think that the ability to carry out photosynthesis without  $\text{H}_2\text{S}$  first evolved among purple nonsulfur bacteria, which obtain their hydrogens from organic compounds instead. It was perhaps inevitable that among the descendants of these respiring photosynthetic bacteria, some would eventually do without photosynthesis entirely, subsisting only on the energy and electrons derived from the breakdown of organic molecules. The mitochondria within all eukaryotic cells are thought to be descendants of these bacteria.

The complex process of aerobic metabolism developed over geological time, as natural selection favored organisms with more efficient methods of obtaining energy from organic molecules. The process of photosynthesis, as you have seen in this concluding section, has also developed over time, and the rise of photosynthesis changed life on Earth forever. The next chapter explores photosynthesis in detail.

### Learning Outcome Review 7.10

Major milestones in the evolution of metabolism include the evolution of pathways to extract energy from organic compounds, the pathways of photosynthesis, and those of nitrogen fixation. Photosynthesis began as an anoxygenic process that later evolved to produce free oxygen, thus allowing the evolution of aerobic metabolism.

- **What evidence can you cite for this hypothesis of the evolution of metabolism?**

## 7.1 Overview of Respiration

**Cells oxidize organic compounds to drive metabolism.**

**Cellular respiration is the complete oxidation of glucose.**

Aerobic respiration uses oxygen as the final electron acceptor for redox reactions. Anaerobic respiration utilizes inorganic molecules as acceptors, and fermentation uses organic molecules.

**Electron carriers play a critical role in energy metabolism.**

Electron carriers can be reversibly oxidized and reduced. For example,  $\text{NAD}^+$  is reduced to NADH by acquiring two electrons; NADH supplies these electrons to other molecules to reduce them.

**Metabolism harvests energy in stages.**

Mitochondria of eukaryotic cells move electrons in steps via the electron transport chain to capture energy efficiently.

**ATP plays a central role in metabolism.**

The ultimate goal of cellular respiration is synthesis of ATP, which is used to power most of the cell's activities.

**Cells make ATP by two fundamentally different mechanisms.**

Substrate-level phosphorylation transfers a phosphate directly to ADP (see figure 7.4). Oxidative phosphorylation generates ATP via the enzyme ATP synthase, powered by a proton gradient.

## 7.2 Glycolysis: Splitting Glucose (see figure 7.6)

Glycolysis converts glucose into two 3-carbon molecules of pyruvate. Each molecule of glucose yields two net ATP molecules.

**Priming changes glucose into an easily cleaved form.**

Priming reactions add two phosphates to glucose; this is cleaved into two 3-carbon molecules of glyceraldehyde 3-phosphate (G3P).

**ATP is synthesized by substrate-level phosphorylation.**

Oxidation of G3P transfers electrons to  $\text{NAD}^+$ , yielding NADH. After four more reactions, the final product is two molecules of pyruvate. Glycolysis produces 2 net ATP, 2 NADH, and 2 pyruvate.

**NADH must be recycled into  $\text{NAD}^+$  to continue respiration.**

In the presence of oxygen, NADH passes electrons to the electron transport chain. In the absence of oxygen, NADH passes the electrons to an organic molecule such as acetaldehyde (fermentation).

## 7.3 The Oxidation of Pyruvate to Produce Acetyl-CoA

Pyruvate is oxidized to yield 1  $\text{CO}_2$ , 1 NADH, and 1 acetyl-CoA. Acetyl-CoA enters the Krebs cycle as 2-carbon acetyl units.

## 7.4 The Krebs Cycle

**The Krebs cycle extracts electrons and synthesizes one ATP.**

The first reaction is an irreversible condensation that produces citrate; it is inhibited when ATP is plentiful. The second and third reactions rearrange citrate to isocitrate. The fourth and fifth reactions are oxidations; in each reaction, one  $\text{NAD}^+$  is reduced to NADH. The sixth reaction is a substrate-level phosphorylation producing GTP, and from that ATP. The seventh reaction is another oxidation that reduces FAD to  $\text{FADH}_2$ . Reactions eight and nine regenerate oxaloacetate, including one final oxidation that reduces  $\text{NAD}^+$  to NADH.

**Glucose becomes  $\text{CO}_2$  and potential energy.**

As a glucose molecule is broken down to  $\text{CO}_2$ , some of its energy is preserved in 4 ATPs, 10 NADH, and 2  $\text{FADH}_2$ .

**Following the electrons in the reactions reveals the direction of transfer.**

## 7.5 The Electron Transport Chain and Chemiosmosis (see figure 7.12)

**The electron transport chain produces a proton gradient.**

In the inner mitochondrial membrane, NADH is oxidized to  $\text{NAD}^+$  by NADH dehydrogenase. Electrons move through ubiquinone and the  $b_c_1$  complex to cytochrome oxidase, where they join with  $\text{H}^+$  and  $\text{O}_2$  to form  $\text{H}_2\text{O}$ . This results in three protons being pumped into the intermembrane space. For  $\text{FADH}_2$ , electrons are passed directly to ubiquinone. Thus only two protons are pumped into the intermembrane space.

**The gradient forms as electrons move through electron carriers**

**Chemiosmosis utilizes the electrochemical gradient to produce ATP**

**ATP synthase is a molecular rotary motor.**

Protons diffuse back into the mitochondrial matrix via the ATP synthase channel. The enzyme uses this energy to synthesize ATP (see figure 7.15).

## 7.6 Energy Yield of Aerobic Respiration

**The theoretical yield for eukaryotes is 36 molecules of ATP per glucose molecule.**

**The actual yield for eukaryotes is 30 molecules of ATP per glucose molecule (see figure 7.16).**

## 7.7 Regulation of Aerobic Respiration

Glucose catabolism is controlled by the concentration of ATP molecules and intermediates in the Krebs cycle (see figure 7.17).

## 7.8 Oxidation Without $\text{O}_2$ (see figure 7.8)

In the absence of oxygen other final electron acceptors can be used for respiration.

**Methanogens use carbon dioxide.**

**Sulfur bacteria use sulfate.**

**Fermentation uses organic compounds as electron acceptors.**

Fermentation is the regeneration of  $\text{NAD}^+$  by oxidation of NADH and reduction of an organic molecule. In yeast, pyruvate is decarboxylated, then reduced to ethanol. In animals, pyruvate is reduced directly to lactate.

## 7.9 Catabolism of Proteins and Fats

**Catabolism of proteins removes amino groups (see figure 7.20).**

**Catabolism of fatty acids produces acetyl groups.**

Fatty acids are converted to acetyl groups by successive rounds of  $\beta$ -oxidation (see figure 7.22). These acetyl groups feed into the Krebs cycle to be oxidized and generate NADH for electron transport.

**A small number of key intermediates connect metabolic pathways.**

*Acetyl-CoA has many roles.*

With high ATP, acetyl-CoA is converted into fatty acids.

## 7.10 Evolution of Metabolism

Major milestones are recognized in the evolution of metabolism; the order of events is hypothetical.

*The earliest life forms degraded carbon-based molecules present in the environment.*

*The evolution of glycolysis also occurred early.*

*Anoxygenic photosynthesis allowed the capture of light energy.*

*Oxygen-forming photosynthesis used a different source of hydrogen.*

*Nitrogen fixation provided new organic nitrogen.*

*Aerobic respiration utilized oxygen.*

## Review Questions

### UNDERSTAND

1. An *autotroph* is an organism that
  - a. extracts energy from organic sources.
  - b. converts energy from sunlight into chemical energy.
  - c. relies on the energy produced by other organisms as an energy source.
  - d. does both a and b.
2. Which of the following processes is (are) required for the complete oxidation of glucose?
  - a. The Krebs cycle
  - b. Glycolysis
  - c. Pyruvate oxidation
  - d. All of the above
3. Which of the following is NOT a product of glycolysis?
  - a. ATP
  - b. Pyruvate
  - c. CO<sub>2</sub>
  - d. NADH
4. Glycolysis produces ATP by
  - a. phosphorylating organic molecules in the priming reactions.
  - b. the production of glyceraldehyde 3-phosphate.
  - c. substrate-level phosphorylation.
  - d. the reduction of NAD<sup>+</sup> to NADH.
5. What is the role of NAD<sup>+</sup> in the process of cellular respiration?
  - a. It functions as an electron carrier.
  - b. It functions as an enzyme.
  - c. It is the final electron acceptor for anaerobic respiration.
  - d. It is a nucleotide source for the synthesis of ATP.
6. The reactions of the Krebs cycle occur in the
  - a. inner membrane of the mitochondria.
  - b. intermembrane space of the mitochondria.
  - c. the cytoplasm.
  - d. matrix of the mitochondria.
7. The electrons carried by NADH and FADH<sub>2</sub> can be
  - a. pumped into the intermembrane space.
  - b. transferred to the ATP synthase.
  - c. moved between proteins in the inner membrane of the mitochondrion.
  - d. transported into the matrix of the mitochondrion.

### APPLY

1. Which of the following is NOT a true statement regarding cellular respiration?
  - a. Enzymes catalyze reactions that transfer electrons.
  - b. Electrons have a higher potential energy at the end of the process.
  - c. Carbon dioxide gas is a by-product.
  - d. The process involves multiple redox reactions.
2. The direct source of energy for the ATP produced by ATP synthase comes from
  - a. the electron transport chain.
  - b. the proton gradient.
  - c. substrate-level phosphorylation.
  - d. the oxidation reactions occurring during respiration.
3. Can cellular respiration occur in the absence of O<sub>2</sub>?
  - a. No, O<sub>2</sub> is necessary as the final electron acceptor.
  - b. No, anaerobic organisms only need glycolysis and fermentation.
  - c. Yes, because oxygen can be generated by splitting H<sub>2</sub>O.
  - d. Yes, but it requires an alternative to O<sub>2</sub> as a final electron acceptor.
4. Why is fermentation an important metabolic function in cells?
  - a. It generates glucose for the cell in the absence of O<sub>2</sub>.
  - b. It oxidizes NADH to NAD<sup>+</sup>.
  - c. It oxidizes pyruvate.
  - d. It produces ATP.
5. Which of the following statements is NOT true about the oxidation of pyruvate?
  - a. Pyruvate oxidation occurs in the cytoplasm.
  - b. Pyruvate oxidation only occurs if oxygen is present.
  - c. Pyruvate is converted into acetyl-CoA.
  - d. Pyruvate oxidation results in the production of NADH.
6. A chemical agent that makes holes in the inner membrane of the mitochondria would
  - a. stop the movement of electrons down the electron transport chain.
  - b. stop ATP synthesis.
  - c. stop the Krebs cycle.
  - d. all of the above.

7. Yeast cells that have mutations in genes that encode enzymes in glycolysis can still grow on glycerol. They are able to utilize glycerol because it
  - a. enters glycolysis after the step affected by the mutation.
  - b. can feed into the Krebs cycle and generate ATP via electron transport and chemiosmosis.
  - c. can be utilized by fermentation.
  - d. can donate electrons directly to the electron transport chain.

2. Human babies and hibernating or cold-adapted animals are able to maintain body temperature (a process called *thermogenesis*) due to the presence of brown fat. Brown fat is characterized by a high concentration of mitochondria. These brown fat mitochondria have a special protein located within their inner membranes. *Thermogenin* is a protein that functions as a passive proton transporter. Propose a likely explanation for the role of brown fat in thermogenesis based on your knowledge of metabolism, transport, and the structure and function of mitochondria.
3. Recent data indicate a link between colder temperatures and weight loss. If adults retain brown fat, how could this be explained?

## SYNTHESIZE

1. Use the following table to outline the relationship between the molecules and the metabolic reactions.

Molecules	Glycolysis	Cellular Respiration
Glucose		
Pyruvate		
Oxygen		
ATP		
CO <sub>2</sub>

# Chapter 8

## Photosynthesis

### Chapter Outline

- 8.1 Overview of Photosynthesis
- 8.2 The Discovery of Photosynthetic Processes
- 8.3 Pigments
- 8.4 Photosystem Organization
- 8.5 The Light-Dependent Reactions
- 8.6 Carbon Fixation: The Calvin Cycle
- 8.7 Photorespiration

### Introduction

*The rich diversity of life that covers our Earth would be impossible without photosynthesis. Almost every oxygen atom in the air we breathe was once part of a water molecule, liberated by photosynthesis. All the energy released by the burning of coal, firewood, gasoline, and natural gas, and by our bodies' burning of all the food we eat—directly or indirectly—has been captured from sunlight by photosynthesis. It is vitally important, then, that we understand photosynthesis. Research may enable us to improve crop yields and land use, important goals in an increasingly crowded world. In chapter 7, we described how cells extract chemical energy from food molecules and use that energy to power their activities. In this chapter, we examine photosynthesis, the process by which organisms such as the aptly named sunflowers in the picture capture energy from sunlight and use it to build food molecules that are rich in chemical energy.*

### 8.1 Overview of Photosynthesis

#### Learning Outcomes

1. Explain the reaction for photosynthesis.
2. Describe the structure of the chloroplast.

Life is powered by sunshine. The energy used by most living cells comes ultimately from the Sun and is captured by plants, algae, and bacteria through the process of photosynthesis.

The diversity of life is only possible because our planet is awash in energy streaming Earthward from the Sun. Each day, the radiant energy that reaches Earth equals the power from about 1 million Hiroshima-sized atomic bombs. Photosynthesis captures about 1% of this huge supply of energy (an amount equal to 10,000 Hiroshima bombs) and uses it to provide the energy that drives all life.

## Photosynthesis combines CO<sub>2</sub> and H<sub>2</sub>O, producing glucose and O<sub>2</sub>

Photosynthesis occurs in a wide variety of organisms, and it comes in different forms. These include a form of photosynthesis that does not produce oxygen (anoxygenic) and a form that does (oxygenic). Anoxygenic photosynthesis is found in four different bacterial groups: purple bacteria, green sulfur bacteria, green nonsulfur bacteria, and heliobacteria. Oxygenic photosynthesis is found in cyanobacteria, seven groups of algae, and essentially all land plants. These two types of photosynthesis share similarities in the types of pigments they use to trap light energy, but they differ in the arrangement and action of these pigments.

In the case of plants, photosynthesis takes place primarily in the leaves. Figure 8.1 illustrates the levels of organization in a plant leaf. As you learned in chapter 4, the cells of plant leaves contain organelles called chloroplasts, which carry out the photosynthetic process. No other structure in a plant cell is able to carry out photosynthesis (figure 8.2). Photosynthesis takes place in three stages:

1. capturing energy from sunlight;
2. using the energy to make ATP and to reduce the compound NADP<sup>+</sup>, an electron carrier, to NADPH; and
3. using the ATP and NADPH to power the synthesis of organic molecules from CO<sub>2</sub> in the air.

The first two stages require light and are commonly called the **light-dependent reactions**.

The third stage, the formation of organic molecules from CO<sub>2</sub>, is called **carbon fixation**. This process takes place via a cyclic series of reactions. As long as ATP and NADPH are available, the carbon fixation reactions can occur either in the presence or in the absence of light, and so these reactions are also called the **light-independent reactions**.

The following simple equation summarizes the overall process of photosynthesis:

You may notice that this equation is the reverse of the reaction for respiration. In respiration, glucose is oxidized to CO<sub>2</sub> using O<sub>2</sub> as an electron acceptor. In photosynthesis, CO<sub>2</sub> is reduced to glucose using electrons gained from the oxidation of water. The oxidation of H<sub>2</sub>O and the reduction of CO<sub>2</sub> requires energy that is provided by light. Although this statement is an oversimplification, it provides a useful “global perspective.”

### In plants, photosynthesis takes place in chloroplasts

In the preceding chapter, you saw that a mitochondrion’s complex structure of internal and external membranes contribute to its function. The same is true for the structure of the chloroplast.

**Figure 8.1 Journey into a leaf.** A plant leaf possesses a thick layer of cells (the mesophyll) rich in chloroplasts. The inner membrane of the chloroplast is organized into flattened structures called thylakoid disks, which are stacked into columns called grana. The rest of the interior is filled with a semifluid substance called stroma.

The internal membrane of chloroplasts, called the *thylakoid membrane*, is a continuous phospholipid bilayer organized into flattened sacs that are found stacked on one another in columns called *grana* (singular, *granum*). The thylakoid membrane contains **chlorophyll** and other photosynthetic pigments for capturing light energy along with the machinery to make ATP. Connections between grana are termed *stroma lamella*.

Surrounding the thylakoid membrane system is a semiliquid substance called **stroma**. The stroma houses the enzymes needed to assemble organic molecules from CO<sub>2</sub> using energy from ATP coupled with reduction via NADPH. In the thylakoid membrane, photosynthetic pigments are clustered together to form **photo-systems**, which show distinct organization within the thylakoid.

**Figure 8.2 Overview of photosynthesis.** In the light-dependent reactions, photosystems in the thylakoid absorb photons of light and use this energy to generate ATP and NADPH. Electrons lost from the photosystems are replaced by the oxidation of water, producing O<sub>2</sub> as a by-product. The ATP and NADPH produced by the light reactions is used during carbon fixation via the Calvin cycle in the stroma.

Each pigment molecule within the photosystem is capable of capturing photons, which are packets of energy. When light of a proper wavelength strikes a pigment molecule in the photosystem, the resulting excitation passes from one pigment molecule to another.

The excited electron is not transferred physically—rather, its *energy* passes from one molecule to another. The passage is similar to the transfer of kinetic energy along a row of upright dominoes. If you push the first one over, it falls against the next, and that one against the next, and so on, until all of the dominoes have fallen down.

Eventually, the energy arrives at a key chlorophyll molecule in contact with a membrane-bound protein that can accept an electron. The energy is transferred as an excited electron to that protein, which passes it on to a series of other membrane proteins that put the energy to work making ATP and NADPH.

These compounds are then used to build organic molecules. The photosystem thus acts as a large antenna, gathering the light energy harvested by many individual pigment molecules.

### Learning Outcomes Review 8.1

Photosynthesis consists of light-dependent reactions that require sunlight, and others that convert CO<sub>2</sub> into organic molecules. The overall reaction is essentially the reverse of respiration and produces O<sub>2</sub> as a by-product. The chloroplast's inner membrane, the thylakoid, is the site in which photosynthetic pigments are clustered, allowing passage of energy from one molecule to the next. The thylakoid membrane is organized into flattened sacs stacked in columns called grana.

- How is the structure of the chloroplast similar to the mitochondria?

## 8.2 The Discovery of Photosynthetic Processes

### Learning Outcomes

1. Describe experiments that support our understanding of photosynthesis.
2. Explain the difference between the light-dependent and light-independent reactions.

The story of how we learned about photosynthesis begins over 300 years ago, and it continues to this day. It starts with curiosity about how plants manage to grow, often increasing their organic mass considerably.

### Plants do not increase mass from soil and water alone

From the time of the Greeks, plants were thought to obtain their food from the soil, literally sucking it up with their roots. A Belgian doctor, Jan Baptista van Helmont (1580–1644) thought of a simple way to test this idea.

He planted a small willow tree in a pot of soil, after first weighing the tree and the soil. The tree grew in the pot for several years, during which time van Helmont added only water. At the end of five years, the tree was much larger, its weight having increased by 74.4 kg. However, the soil in the pot weighed only 57 g less than it had five years earlier. With this experiment, van Helmont demonstrated that the substance of the plant was not produced only from the soil. He incorrectly concluded, however, that the water he had been adding mainly accounted for the plant's increased biomass.

A hundred years passed before the story became clearer. The key clue was provided by the English scientist Joseph Priestly (1733–1804). On the 17th of August, 1771, Priestly put

a living sprig of mint into air in which a wax candle had burnt out. On the 27th of the same month, Priestly found that another candle could be burned in this same air. Somehow, the vegetation seemed to have restored the air. Priestly found that while a mouse could not breathe candle-exhausted air, air “restored” by vegetation was not “at all inconvenient to a mouse.” The key clue was that *living vegetation adds something to the air*.

How does vegetation “restore” air? Twenty-five years later, the Dutch physician Jan Ingenhousz (1730–1799) solved the puzzle. He demonstrated that air was restored only in the presence of sunlight and only by a plant’s green leaves, not by its roots. He proposed that the green parts of the plant carry out a process that uses sunlight to split carbon dioxide into carbon and oxygen. He suggested that the oxygen was released as O<sub>2</sub> gas into the air, while the carbon atom combined with water to form carbohydrates. Other research refined his conclusions, and by the end of the nineteenth century, the overall reaction for photosynthesis could be written as:

It turns out, however, that there’s more to it than that. When researchers began to examine the process in more detail in the twentieth century, the role of light proved to be unexpectedly complex.

## Photosynthesis includes both light-dependent and light-independent reactions

At the beginning of the twentieth century, the English plant physiologist F. F. Blackman (1866–1947) came to the startling conclusion that photosynthesis is in fact a multistage process, only one portion of which uses light directly.

Blackman measured the effects of different light intensities, CO<sub>2</sub> concentrations, and temperatures on photosynthesis. As long as light intensity was relatively low, he found photosynthesis could be accelerated by increasing the amount of light, but not by increasing the temperature or CO<sub>2</sub> concentration (figure 8.3). At high light intensities, however, an increase in temperature or CO<sub>2</sub> concentration greatly accelerated photosynthesis.

Blackman concluded that photosynthesis consists of an initial set of what he called “light” reactions, that are largely independent of temperature but depend on light, and a second set of “dark” reactions (more properly called light-independent reactions), that seemed to be independent of light but limited by CO<sub>2</sub>.

Do not be confused by Blackman’s labels—the so-called “dark” reactions occur in the light (in fact, they require the products of the light-dependent reactions); his use of the word *dark* simply indicates that light is not *directly* involved in those reactions.

Blackman found that increased temperature increased the rate of the light-independent reactions, but only up to about 35°C. Higher temperatures caused the rate to fall off rapidly. Because many plant enzymes begin to be denatured at 35°C, Blackman concluded that enzymes must carry out the light-independent reactions.

## O<sub>2</sub> comes from water, not from CO<sub>2</sub>

In the 1930s, C. B. van Niel (1897–1985) working at the Hopkins Marine Station at Stanford, discovered that purple sulfur bacteria

do not release oxygen during photosynthesis; instead, they convert hydrogen sulfide (H<sub>2</sub>S) into globules of pure elemental sulfur that accumulate inside them. The process van Niel observed was:

The striking parallel between this equation and Ingenhousz’s equation led van Niel to propose that the generalized process of photosynthesis can be shown as:

In this equation, the substance H<sub>2</sub>A serves as an electron donor. In photosynthesis performed by green plants, H<sub>2</sub>A is water, whereas in purple sulfur bacteria, H<sub>2</sub>A is hydrogen sulfide. The product, A, comes from the splitting of H<sub>2</sub>A. Therefore, the O<sub>2</sub> produced during green plant photosynthesis results from splitting water, not carbon dioxide.

When isotopes came into common use in the early 1950s, van Niel’s revolutionary proposal was tested. Investigators examined photosynthesis in green plants supplied with water containing heavy oxygen (<sup>18</sup>O); they found that the <sup>18</sup>O label ended up in oxygen gas rather than in carbohydrate, just as van Niel had predicted:

**Figure 8.3** Discovery of the light-independent reactions. Blackman measured photosynthesis rates under differing light intensities, CO<sub>2</sub> concentrations, and temperatures. As this graph shows, light is the limiting factor at low light intensities, but temperature and CO<sub>2</sub> concentration are the limiting factors at higher light intensities. This implies the existence of reactions using CO<sub>2</sub> that involve enzymes.

### Inquiry question

Blackman found that increasing light intensity above 2000 foot-candles did not lead to any further increase in the rate of photosynthesis. Can you suggest a hypothesis that would explain this?

## 8.3 Pigments

In algae and green plants, the carbohydrate typically produced by photosynthesis is glucose. The complete balanced equation for photosynthesis in these organisms thus becomes:

### ATP and NADPH from light-dependent reactions reduce CO<sub>2</sub> to make sugars

In his pioneering work on the light-dependent reactions, van Niel proposed that the H<sup>+</sup> ions and electrons generated by the splitting of water were used to convert CO<sub>2</sub> into organic matter in a process he called *carbon fixation*. In the 1950s, Robin Hill (1899–1991) demonstrated that van Niel was right, light energy could be harvested and used in a reduction reaction. Chloroplasts isolated from leaf cells were able to reduce a dye and release oxygen in response to light. Later experiments showed that the electrons released from water were transferred to NADP<sup>+</sup> and that illuminated chloroplasts deprived of CO<sub>2</sub> accumulate ATP. If CO<sub>2</sub> is introduced, neither ATP nor NADPH accumulate, and the CO<sub>2</sub> is assimilated into organic molecules.

These experiments are important for three reasons: First, they firmly demonstrate that photosynthesis in plants occurs within chloroplasts. Second, they show that the light-dependent reactions use light energy to reduce NADP<sup>+</sup> and to manufacture ATP. Third, they confirm that the ATP and NADPH from this early stage of photosynthesis are then used in the subsequent reactions to reduce carbon dioxide, forming simple sugars.

#### Learning Outcomes Review 8.2

Early experiments indicated that plants “restore” air to usable form, that is, produce oxygen—but only in the presence of sunlight. Further experiments showed that there are both light-dependent and independent reactions. The light-dependent reactions produce O<sub>2</sub> from H<sub>2</sub>O, and generate ATP and NADPH. The light-independent reactions synthesize organic compounds through carbon fixation.

- *Where does the carbon in your body come from?*

#### Learning Outcomes

1. Explain how pigments are important to photosynthesis.
2. Relate the absorption spectrum of a pigment to its color.

For plants to make use of the energy of sunlight, some biochemical structure must be present in chloroplasts and the thylakoids that can absorb this energy. Molecules that absorb light energy in the visible range are termed **pigments**. We are most familiar with them as dyes that impart a certain color to clothing or other materials. The color that we see is the color that is not absorbed—that is, it is reflected. To understand how plants use pigments to capture light energy, we must first review current knowledge about the nature of light.

### Light is a form of energy

The wave nature of light produces an electromagnetic spectrum that differentiates light based on its wavelength (figure 8.4). We are most familiar with the visible range of this spectrum because we can actually see it, but visible light is only a small part of the entire spectrum. Visible light can be divided into its separate colors by the use of a prism, which separates light based on wavelength.

A particle of light, termed a **photon**, acts like a discrete bundle of energy. We use the wave concept of light to understand different colors of light and the particle nature of light to understand the energy transfers that occur during photosynthesis. Thus, we will refer both to wavelengths of light and to photons of light throughout the chapter.

#### The energy in photons

The energy content of a photon is inversely proportional to the wavelength of the light: Short-wavelength light contains photons of higher energy than long-wavelength light (see figure 8.4). X-rays, which contain a great deal of energy, have very short wavelengths—much shorter than those of visible light.

**Figure 8.4** The electromagnetic spectrum. Light is a form of electromagnetic energy conveniently thought of as a wave. The shorter the wavelength of light, the greater its energy. Visible light represents only a small part of the electromagnetic spectrum between 400 and 740 nm.

A beam of light is able to remove electrons from certain molecules, creating an electrical current. This phenomenon is called the **photoelectric effect**, and it occurs when photons transfer energy to electrons. The strength of the photoelectric effect depends on the wavelength of light; that is, short wavelengths are much more effective than long ones in producing the photoelectric effect because they have more energy.

In photosynthesis, chloroplasts are acting as photoelectric devices: They absorb sunlight and transfer the excited electrons to a carrier. As we unravel the details of this process, it will become clear how this process traps energy and uses it to synthesize organic compounds.

## Each pigment has a characteristic absorption spectrum

When a photon strikes a molecule with the amount of energy needed to excite an electron, then the molecule will absorb the photon raising the electron to a higher energy level. Whether the photon's energy is absorbed depends on how much energy it carries (defined by its wavelength), and also on the chemical nature of the molecule it hits.

As described in chapter 2, electrons occupy discrete energy levels in their orbits around atomic nuclei. To boost an electron into a different energy level requires just the right amount of energy, just as reaching the next rung on a ladder requires you to raise your foot just the right distance. A specific atom, therefore, can absorb only certain photons of light—namely, those that correspond to the atom's available energy levels. As a result, each molecule has a characteristic **absorption spectrum**, the range and efficiency of photons it is capable of absorbing.

As mentioned earlier, pigments are good absorbers of light in the visible range. Organisms have evolved a variety of different pigments, but only two general types are used in green plant photosynthesis: chlorophylls and carotenoids. In some organisms, other molecules also absorb light energy.

### Chlorophyll absorption spectra

Chlorophylls absorb photons within narrow energy ranges. Two kinds of chlorophyll in plants, chlorophyll *a* and chlorophyll *b*, preferentially absorb violet-blue and red light (figure 8.5). Neither of these pigments absorbs photons with wavelengths between about 500 and 600 nm; light of these wavelengths is reflected. When these reflected photons are subsequently absorbed by the retinal pigment in our eyes, we perceive them as green.

**Chlorophyll *a*** is the main photosynthetic pigment in plants and cyanobacteria and the only pigment that can act directly to convert light energy to chemical energy. **Chlorophyll *b***, acting as an **accessory pigment**, or secondary light-absorbing pigment, complements and adds to the light absorption of chlorophyll *a*.

Chlorophyll *b* has an absorption spectrum shifted toward the green wavelengths. Therefore, chlorophyll *b* can absorb photons that chlorophyll *a* cannot, greatly increasing the proportion of the photons in sunlight that plants can harvest. In addition, a variety of different accessory pigments are found in plants, bacteria, and algae.

**Figure 8.5** Absorption spectra for chlorophyll and carotenoids. The peaks represent wavelengths of light of sunlight absorbed by the two common forms of photosynthetic pigment, chlorophylls *a* and *b*, and the carotenoids. Chlorophylls absorb predominantly violet-blue and red light in two narrow bands of the spectrum and reflect green light in the middle of the spectrum. Carotenoids absorb mostly blue and green light and reflect orange and yellow light.

### Structure of chlorophylls

Chlorophylls absorb photons by means of an excitation process analogous to the photoelectric effect. These pigments contain a complex ring structure, called a *porphyrin ring*, with alternating single and double bonds. At the center of the ring is a magnesium atom (figure 8.6).

**Figure 8.6** Chlorophyll.

Chlorophyll molecules consist of a porphyrin head and a hydrocarbon tail that anchors the pigment molecule to hydrophobic regions of proteins embedded within the thylakoid membrane. The only difference between the two chlorophyll molecules is the substitution of a —CHO (aldehyde) group in chlorophyll *b* for a —CH<sub>3</sub> (methyl) group in chlorophyll *a*.

## SCIENTIFIC THINKING

**Hypothesis:** All wavelengths of light are equally effective in promoting photosynthesis.

**Prediction:** Illuminating plant cells with light broken into different wavelengths by a prism will produce the same amount of O<sub>2</sub> for all wavelengths.

**Test:** A filament of algae immobilized on a slide is illuminated by light that has passed through a prism. Motile bacteria that require O<sub>2</sub> for growth are added to the slide.

**Result:** The bacteria move to regions of high O<sub>2</sub>, or regions of most active photosynthesis. This is in the purple/blue and red regions of the spectrum.

**Conclusion:** All wavelengths are not equally effective at promoting photosynthesis. The most effective constitute the action spectrum for photosynthesis.

**Further Experiments:** How does the action spectrum relate to the various absorption spectra in figure 8.5?

### Figure 8.7 Determination of an action spectrum for photosynthesis.

Photons excite electrons in the porphyrin ring, which are then channeled away through the alternating carbon single- and double-bond system. Different small side groups attached to the outside of the ring alter the absorption properties of the molecule in the different kinds of chlorophyll (see figure 8.6). The precise absorption spectrum is also influenced by the local microenvironment created by the association of chlorophyll with different proteins.

The **action spectrum** of photosynthesis—that is, the relative effectiveness of different wavelengths of light in promoting photosynthesis—corresponds to the absorption spectrum for chlorophylls. This is demonstrated in the experiment in figure 8.7. All plants, algae, and cyanobacteria use chlorophyll *a* as their primary pigments.

It is reasonable to ask why these photosynthetic organisms do not use a pigment like retinal (the pigment in our eyes), which has a broad absorption spectrum that covers the range of 500 to 600 nm. The most likely hypothesis involves *photo-efficiency*. Although retinal absorbs a broad range of wavelengths, it does so with relatively low efficiency. Chlorophyll, in contrast, absorbs in only two narrow bands, but does so with high efficiency. Therefore, plants and most other photosynthetic organisms achieve far higher overall energy capture rates with chlorophyll than with other pigments.

### Carotenoids and other accessory pigments

**Carotenoids** consist of carbon rings linked to chains with alternating single and double bonds. They can absorb photons

with a wide range of energies, although they are not always highly efficient in transferring this energy. Carotenoids assist in photosynthesis by capturing energy from light composed of wavelengths that are not efficiently absorbed by chlorophylls (figure 8.5; see also figure 8.8).

Carotenoids also perform a valuable role in scavenging free radicals. The oxidation–reduction reactions that occur in the chloroplast can generate destructive free radicals. Carotenoids can act as general-purpose antioxidants to lessen damage. Thus carotenoids have a protective role in addition to their role as light-absorbing molecules. This protective role is not surprising, because unlike the chlorophylls, carotenoids are found in many different kinds of organisms, including members of all three domains of life.

A typical carotenoid is  $\beta$ -carotene, which contains two carbon rings connected by a chain of 18 carbon atoms with alternating single and double bonds. Splitting a molecule of  $\beta$ -carotene into equal halves produces two molecules of vitamin A. Oxidation of vitamin A produces retinal, the

### Figure 8.8 Fall colors are produced by carotenoids and other accessory pigments.

During the spring and summer, chlorophyll in leaves masks the presence of carotenoids and other accessory pigments. When cool fall temperatures cause leaves to cease manufacturing chlorophyll, the chlorophyll is no longer present to reflect green light, and the leaves reflect the orange and yellow light that carotenoids and other pigments do not absorb.

pigment used in vertebrate vision. This connection explains why eating carrots, which are rich in  $\beta$ -carotene, may enhance vision.

**Phycobiloproteins** are accessory pigments found in cyanobacteria and some algae. These pigments are composed of proteins attached to a tetrapyrrole group. These pyrrole rings contain a system of alternating double bonds similar to those found in other pigments and molecules that transfer electrons. Phycobiloproteins can be organized into complexes called phycobilisomes to form another light-harvesting complex that can absorb green light, which is typically reflected by chlorophyll. These complexes are probably ecologically important to cyanobacteria, helping them to exist in low-light situations in oceans. In this habitat, green light remains because red and blue light has been absorbed by green algae closer to the surface.

### Learning Outcomes Review 8.3

A pigment is a molecule that can absorb light energy; its absorption spectrum shows the wavelengths at which it absorbs energy most efficiently. A pigment's color results from the wavelengths it does not absorb, which we then see. The main photosynthetic pigment is chlorophyll, which exists in several forms with slightly different absorption spectra. Many photosynthetic organisms have accessory pigments with absorption spectra different from chlorophyll; these increase light capture.

- What is the difference between an action spectrum and an absorption spectrum?

## 8.4 Photosystem Organization

### Learning Outcomes

1. Describe the nature of photosystems.
2. Understand what happens in the reaction center.

One way to study the role that pigments play in photosynthesis is to measure the correlation between the output of photosynthesis and the intensity of illumination—that is, how much photosynthesis is produced by how much light. Experiments on plants show that the output of photosynthesis increases linearly at low light intensities, but finally becomes saturated (no further increase) at high-intensity light. Saturation occurs because all of the light-absorbing capacity of the plant is in use.

### Production of one O<sub>2</sub> molecule requires many chlorophyll molecules

Given the saturation observed with increasing light intensity, the next question is how many chlorophyll molecules have actually absorbed a photon. The question can be phrased this way: “Does saturation occur when all chlorophyll molecules have absorbed photons?” Finding an answer required being able to measure both photosynthetic output (on the basis of O<sub>2</sub> production) and the number of chlorophyll molecules present.

**Figure 8.9 Saturation of photosynthesis.** When photosynthetic saturation is achieved, further increases in intensity cause no increase in output. This saturation occurs far below the level expected for the number of individual chlorophyll molecules present. This led to the idea of organized photosystems, each containing many chlorophyll molecules. These photosystems saturate at a lower O<sub>2</sub> yield than that expected for the number of individual chlorophyll molecules.

### Inquiry question

? Under what experimental conditions would you expect the saturation levels for a given number of chlorophyll molecules to be higher?

Using the unicellular algae *Chlorella*, investigators could obtain these values. Illuminating a *Chlorella* culture with pulses of light with increasing intensity should increase the yield of O<sub>2</sub> per pulse until the system becomes saturated. Then O<sub>2</sub> production can be compared with the number of chlorophyll molecules present in the culture.

The observed level of O<sub>2</sub> per chlorophyll molecule at saturation, however, turned out to be only one molecule of O<sub>2</sub> per 2500 chlorophyll molecules (figure 8.9). This result was very different from what was expected, and it led to the idea that light is absorbed not by independent pigment molecules, but rather by clusters of chlorophyll and accessory pigment molecules (photosystems). Light is absorbed by any one of hundreds of pigment molecules in a photosystem, and each pigment molecule transfers its excitation energy to a single molecule with a lower energy level than the others.

### A generalized photosystem contains an antenna complex and a reaction center

In chloroplasts and all but one class of photosynthetic prokaryotes, light is captured by photosystems. Each photosystem is a network of chlorophyll *a* molecules, accessory pigments, and associated proteins held within a protein matrix on the surface of the photosynthetic membrane. Like a magnifying glass focusing light on a precise point, a photosystem channels the excitation energy gathered by any one of its pigment molecules to a specific molecule, the reaction center chlorophyll. This molecule then passes the energy out of the photosystem as excited electrons that are put to work driving the synthesis of ATP and organic molecules.

A photosystem thus consists of two closely linked components: (1) an *antenna complex* of hundreds of pigment molecules that gather photons and feed the captured light energy to the

reaction center; and (2) a *reaction center* consisting of one or more chlorophyll *a* molecules in a matrix of protein, that passes excited electrons out of the photosystem.

### The antenna complex

The **antenna complex** is also called a light-harvesting complex, which accurately describes its role. This light-harvesting complex captures photons from sunlight (figure 8.10) and channels them to the reaction center chlorophylls.

In chloroplasts, light-harvesting complexes consist of a web of chlorophyll molecules linked together and held tightly in the thylakoid membrane by a matrix of proteins. Varying amounts of carotenoid accessory pigments may also be present. The protein matrix holds individual pigment molecules in orientations that are optimal for energy transfer.

The excitation energy resulting from the absorption of a photon passes from one pigment molecule to an adjacent molecule on its way to the reaction center. After the transfer, the excited electron in each molecule returns to the low-energy level it had before the photon was absorbed. Consequently, it is energy, not the excited electrons themselves, that passes from one pigment molecule to the next. The antenna complex funnels the energy from many electrons to the reaction center.

### The reaction center

The **reaction center** is a transmembrane protein–pigment complex. The reaction center of purple photosynthetic bacteria is simpler than the one in chloroplasts but better understood. A pair of bacteriochlorophyll *a* molecules acts as a trap for photon energy, passing an excited electron to an acceptor precisely positioned as its neighbor. Note that here in the reaction center, the excited electron itself is transferred, and not just the energy, as was the case in the pigment–pigment transfers of the antenna complex. This difference allows the energy

**Figure 8.10 How the antenna complex works.** When light of the proper wavelength strikes any pigment molecule within a photosystem, the light is absorbed by that pigment molecule. The excitation energy is then transferred from one molecule to another within the cluster of pigment molecules until it encounters the reaction center chlorophyll *a*. When excitation energy reaches the reaction center chlorophyll, electron transfer is initiated.

**Figure 8.11 Converting light to chemical energy.** When a chlorophyll in the reaction center absorbs a photon of light, an electron is excited to a higher energy level. This light-energized electron can be transferred to the primary electron acceptor, reducing it. The oxidized chlorophyll then fills its electron “hole” by oxidizing a donor molecule. The source of this donor varies with the photosystem as discussed in the text.

absorbed from photons to move away from the chlorophylls, and it is the key conversion of light into chemical energy.

Figure 8.11 shows the transfer of excited electrons from the reaction center to the primary electron acceptor. By energizing an electron of the reaction center chlorophyll, light creates a strong electron donor where none existed before. The chlorophyll transfers the energized electron to the primary acceptor (a molecule of quinone), reducing the quinone and converting it to a strong electron donor. A nearby weak electron donor then passes a low-energy electron to the chlorophyll, restoring it to its original condition. The quinone transfers its electrons to another acceptor, and the process is repeated.

In plant chloroplasts, water serves as this weak electron donor. When water is oxidized in this way, oxygen is released along with two protons ( $H^+$ ).

### Learning Outcomes Review 8.4

Chlorophylls and accessory pigments are organized into photosystems found in the thylakoid membrane. The photosystem can be subdivided into an antenna complex, which is involved in light harvesting, and a reaction center, where the photochemical reactions occur. In the reaction center, an excited electron is passed to an acceptor; this transfers energy away from the chlorophylls and is key to the conversion of light into chemical energy.

#### ■ Why were photosystems an unexpected finding?

## 8.5 The Light-Dependent Reactions

### Learning Outcomes

1. Compare the function of the two photosystems in green plants.
2. Explain how the light reactions generate ATP and NADPH.

As you have seen, the light-dependent reactions of photosynthesis occur in membranes. In photosynthetic bacteria, the plasma membrane itself is the photosynthetic membrane. In many bacteria, the plasma membrane folds in on itself repeatedly to produce an increased surface area. In plants and algae, photosynthesis is carried out by chloroplasts, which are thought to be the evolutionary descendants of photosynthetic bacteria.

The internal thylakoid membrane is highly organized and contains the structures involved in the light-dependent reactions. For this reason, the reactions are also referred to as the thylakoid reactions. The thylakoid reactions take place in four stages:

1. **Primary photoevent.** A photon of light is captured by a pigment. This primary photoevent excites an electron within the pigment.
2. **Charge separation.** This excitation energy is transferred to the reaction center, which transfers an energetic electron to an acceptor molecule, initiating electron transport.
3. **Electron transport.** The excited electrons are shuttled along a series of electron carrier molecules embedded within the photosynthetic membrane. Several of them react by transporting protons across the membrane, generating a proton gradient. Eventually the electrons are used to reduce a final acceptor, NADPH.
4. **Chemiosmosis.** The protons that accumulate on one side of the membrane now flow back across the membrane through ATP synthase where chemiosmotic synthesis of ATP takes place, just as it does in aerobic respiration (see chapter 7).

These four processes make up the two stages of the light-dependent reactions mentioned at the beginning of this chapter. Steps 1 through 3 represent the stage of capturing energy from light; step 4 is the stage of producing ATP (and, as you'll see, NADPH). In the rest of this section we discuss the evolution of photosystems and the details of photosystem function in the light-dependent reactions.

### Some bacteria use a single photosystem

Photosynthetic pigment arrays are thought to have evolved more than 2 BYA in bacteria similar to the purple and green bacteria alive today. In these bacteria, a single photosystem is used that generates ATP via electron transport. This process then returns the electrons to the reaction center. For this reason, it is called

**Figure 8.12** The path of an electron in purple nonsulfur bacteria. When a light-energized electron is ejected from the photosystem reaction center (P<sub>870</sub>) it returns to the photosystem via a cyclic path that produces ATP but not NADPH.

cyclic photophosphorylation. These systems do not evolve oxygen and are thus referred to as anoxygenic photosynthesis.

In the purple nonsulfur bacteria, peak absorption occurs at a wavelength of 870 nm (near infrared, not visible to the human eye), and thus the reaction center pigment is called P<sub>870</sub>. Absorption of a photon by chlorophyll P<sub>870</sub> does not raise an electron to a high enough level to be passed to NADP, thus they must generate reducing power in a different way.

When the P<sub>870</sub> reaction center absorbs a photon, the excited electron is passed to an electron transport chain that passes the electrons back to the reaction center, generating a proton gradient for ATP synthesis (figure 8.12). The proteins in the purple bacterial photosystem appear to be homologous to the proteins in the modern photosystem II.

In the green sulfur bacteria, peak absorption occurs at a wavelength of 840 nm (near infrared, not visible to the human eye), and thus the reaction center pigment is called P<sub>840</sub>. Excited electrons from this photosystem can be passed to NADPH, or returned to the chlorophyll by an electron transport chain similar to the purple bacteria. To replace electrons passed to NADPH, hydrogen sulfide is used as an electron donor. The proteins in the green sulfur bacterial photosystem appear to be homologous to the proteins in the modern photosystem I.

Neither of these systems generate sufficient oxidizing power to oxidize H<sub>2</sub>O. They are thus anoxygenic and take place under anaerobic conditions. The linked photosystems of cyanobacteria and plant chloroplasts generate the oxidizing power necessary to oxidize H<sub>2</sub>O, allowing it to serve as a source of both electrons and protons.

### Chloroplasts have two connected photosystems

In contrast to the sulfur bacteria, plants have two linked photosystems. This overcomes the limitations of cyclic photophosphorylation by providing an alternative source of electrons

from the oxidation of water. The oxidation of water also generates  $O_2$ , thus oxygenic photosynthesis. The noncyclic transfer of electrons also produces NADPH, which can be used in the biosynthesis of carbohydrates.

One photosystem, called **photosystem I**, has an absorption peak of 700 nm, so its reaction center pigment is called  $P_{700}$ . This photosystem functions in a way analogous to the photosystem found in the sulfur bacteria discussed earlier. The other photosystem, called **photosystem II**, has an absorption peak of 680 nm, so its reaction center pigment is called  $P_{680}$ . This photosystem can generate an oxidation potential high enough to oxidize water. Working together, the two photosystems carry out a noncyclic transfer of electrons that is used to generate both ATP and NADPH.

The photosystems were named I and II in the order of their discovery, and not in the order in which they operate in the light-dependent reactions. In plants and algae, the two photosystems are specialized for different roles in the overall process of oxygenic photosynthesis. Photosystem I transfers electrons ultimately to  $NADP^+$ , producing NADPH. The electrons lost from photosystem I are replaced by electrons from photosystem II. Photosystem II with its high oxidation potential can oxidize water to replace the electrons transferred to photosystem I. Thus there is an overall flow of electrons from water to NADPH.

These two photosystems are connected by a complex of electron carriers called the **cytochrome/ $b_6$ - $f$  complex** (explained shortly). This complex can use the energy from the passage of electrons to move protons across the thylakoid membrane to generate the proton gradient used by an ATP synthase enzyme.

## The two photosystems work together in noncyclic photophosphorylation

Evidence for the action of two photosystems came from experiments that measured the rate of photosynthesis using two light beams of different wavelengths: one red and the other far-red. Using both beams produced a rate greater than the sum of the rates using individual beams of these wavelengths (figure 8.13). This surprising result, called the *enhancement effect*, can be explained by a mechanism involving two photosystems acting in series (that is, one after the other), one photosystem absorbs preferentially in the red, the other in the far-red.

Plants use photosystems II and I in series, first one and then the other, to produce both ATP and NADPH. This two-stage process is called **noncyclic photophosphorylation** because the path of the electrons is not a circle—the electrons ejected from the photosystems do not return to them, but rather end up in NADPH. The photosystems are replenished with electrons obtained by splitting water.

The scheme shown in figure 8.14, called a *Z diagram*, illustrates the two electron-energizing steps, one catalyzed by each photosystem. The horizontal axis shows the progress of the light reactions and the relative positions of the complexes, and the vertical axis shows relative energy levels of electrons. The electrons originate from water, which holds onto its electrons very tightly (redox potential = +820 mV), and end up in NADPH, which holds its electrons much more loosely (redox potential = -320 mV).

Photosystem II acts first. High-energy electrons generated by photosystem II are used to synthesize ATP and are then

**Figure 8.13** The enhancement effect. The rate of photosynthesis when red and far-red light are provided together is greater than the sum of the rates when each wavelength is provided individually. This result baffled researchers in the 1950s. Today, it provides key evidence that photosynthesis is carried out by two photochemical systems that act in series. One absorbs maximally in the far red, the other in the red portion of the spectrum.

### Inquiry question

What would you conclude if “both lights on” did not change the relative rate of photosynthesis?

passed to photosystem I to drive the production of NADPH. For every pair of electrons obtained from a molecule of water, one molecule of NADPH and slightly more than one molecule of ATP are produced.

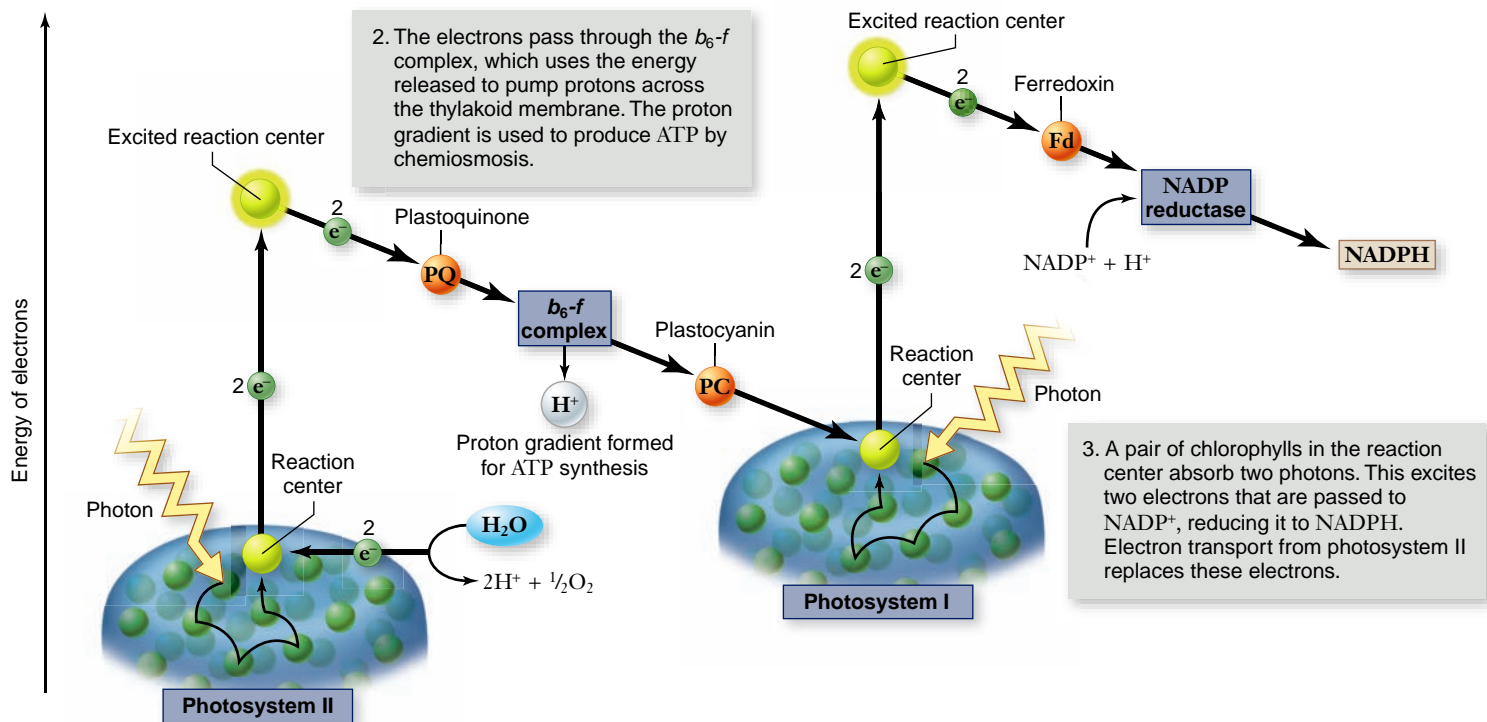

### Photosystem II

The reaction center of photosystem II closely resembles the reaction center of purple bacteria. It consists of a core of 10 transmembrane protein subunits with electron transfer components and two  $P_{680}$  chlorophyll molecules arranged around this core. The light-harvesting antenna complex consists of molecules of chlorophyll *a* and accessory pigments bound to several protein chains. The reaction center of photosystem II differs from the reaction center of the purple bacteria in that it also contains four manganese atoms. These manganese atoms are essential for the oxidation of water.

Although the chemical details of the oxidation of water are not entirely clear, the outline is emerging. Four manganese atoms are bound in a cluster to reaction center proteins. Two water molecules are also bound to this cluster of manganese atoms. When the reaction center of photosystem II absorbs a photon, an electron in a  $P_{680}$  chlorophyll molecule is excited, which transfers this electron to an acceptor. The oxidized  $P_{680}$  then removes an electron from a manganese atom. The oxidized manganese atoms, with the aid of reaction center proteins, remove electrons from oxygen atoms in the two water molecules. This process requires the reaction center to absorb four photons to complete the oxidation of two water molecules, producing one  $O_2$  in the process.

### The role of the $b_6$ - $f$ complex

The primary electron acceptor for the light-energized electrons leaving photosystem II is a quinone molecule. The reduced

**Figure 8.14 Z diagram of photosystems I and II.** Two photosystems work sequentially and have different roles. Photosystem II passes energetic electrons to photosystem I via an electron transport chain. The electrons lost are replaced by oxidizing water. Photosystem I uses energetic electrons to reduce  $\text{NADP}^+$  to NADPH.

quinone that results from accepting a pair of electrons (*plastoquinone*) is a strong electron donor; it passes the excited electron pair to a proton pump called the  $b_6-f$  complex embedded within the thylakoid membrane (figure 8.15). This complex closely resembles the  $bc_1$  complex in the respiratory electron transport chain of mitochondria, discussed in chapter 7.

Arrival of the energetic electron pair causes the  $b_6-f$  complex to pump a proton into the thylakoid space. A small, copper-containing protein called *plastocyanin* then carries the electron pair to photosystem I.

### Photosystem I

The reaction center of photosystem I consists of a core trans-membrane complex consisting of 12 to 14 protein subunits with two bound  $\text{P}_{700}$  chlorophyll molecules. Energy is fed to it by an antenna complex consisting of chlorophyll *a* and accessory pigment molecules.

Photosystem I accepts an electron from plastocyanin into the “hole” created by the exit of a light-energized electron. The absorption of a photon by photosystem I boosts the electron leaving the reaction center to a very high energy level. The electrons are passed to an iron–sulfur protein called *ferredoxin*. Unlike photosystem II and the bacterial photosystem, the plant photosystem I does not rely on quinones as electron acceptors.

### Making NADPH

Photosystem I passes electrons to ferredoxin on the stromal side of the membrane (outside the thylakoid). The reduced ferredoxin carries an electron with very high potential. Two of them, from

two molecules of reduced ferredoxin, are then donated to a molecule of  $\text{NADP}^+$  to form NADPH. The reaction is catalyzed by the membrane-bound enzyme *NADP reductase*.

Because the reaction occurs on the stromal side of the membrane and involves the uptake of a proton in forming NADPH, it contributes further to the proton gradient established during photosynthetic electron transport. The function of the two photosystems is summarized in figure 8.15.

### ATP is generated by chemiosmosis

Protons are pumped from the stroma into the thylakoid compartment by the  $b_6-f$  complex. The splitting of water also produces added protons that contribute to the gradient. The thylakoid membrane is impermeable to protons, so this creates an electrochemical gradient that can be used to synthesize ATP.

### ATP synthase

The chloroplast has ATP synthase enzymes in the thylakoid membrane that form a channel, allowing protons to cross back out into the stroma. These channels protrude like knobs on the external surface of the thylakoid membrane. As protons pass out of the thylakoid through the ATP synthase channel, ADP is phosphorylated to ATP and released into the stroma (see figure 8.15). The stroma contains the enzymes that catalyze the reactions of carbon fixation—the Calvin cycle reactions.

This mechanism is the same as that seen in the mitochondrial ATP synthase, and, in fact, the two enzymes are evolutionarily related. This similarity in generating a proton gradient by

**Figure 8.15** The photosynthetic electron transport system and ATP synthase. The two photosystems are arranged in the thylakoid membrane joined by an electron transport system that includes the  $b_6-f$  complex. These function together to create a proton gradient that is used by ATP synthase to synthesize ATP.

electron transport and ATP by chemiosmosis illustrates the similarities in structure and function in mitochondria and chloroplasts. Evidence for this chemiosmotic mechanism for photo-

phosphorylation was actually discovered earlier (figure 8.16) and formed the background for experiments using the mitochondrial ATP synthase.

### SCIENTIFIC THINKING

**Hypothesis:** Photophosphorylation is coupled to electron transport by a proton gradient.

**Prediction:** If a proton gradient can be formed artificially, then isolated chloroplasts will phosphorylate ADP in the dark.

**Test:** Isolated chloroplasts are incubated in acid medium, then transferred in the dark to a basic medium to create an artificial proton gradient.

**Result:** Isolated chloroplasts can phosphorylate ADP in the dark as assayed by the incorporation of radioactive  $PO_4$  into ATP.

**Conclusion:** The energy from electron transport in the chloroplast is coupled to the phosphorylation of ADP by a proton gradient.

**Further Experiments:** If an agent that makes membranes permeable to protons were included in this experiment, what would be the outcome? Would this argue for or against the hypothesis?

**Figure 8.16** The Jagendorf acid bath experiment.

### The production of additional ATP

The passage of an electron pair from water to NADPH in noncyclic photophosphorylation generates one molecule of NADPH and slightly more than one molecule of ATP. But as you will learn later in this chapter, building organic molecules takes more energy than that—it takes 1.5 ATP molecules per NADPH molecule to fix carbon.

To produce the extra ATP, many plant species are capable of short-circuiting photosystem I, switching photosynthesis into a *cyclic photophosphorylation* mode, so that the light-excited electron leaving photosystem I is used to make ATP instead of NADPH. The energetic electrons are simply passed back to the  $b_6-f$  complex, rather than passing on to NADP<sup>+</sup>. The  $b_6-f$  complex pumps protons into the thylakoid space, adding to the proton gradient that drives the chemiosmotic synthesis of ATP. The relative proportions of cyclic and noncyclic photophosphorylation in these plants determine the relative amounts of ATP and NADPH available for building organic molecules.

### Thylakoid structure reveals components' locations

The four complexes responsible for the light-dependent reactions—namely photosystems I and II, cytochrome  $b_6-f$ , and ATP synthase—are not randomly arranged in the thylakoid. Researchers are beginning to image these complexes with the atomic force microscope, which can resolve nanometer scale structures, and a picture is emerging in which photosystem II is found primarily in the grana, whereas photosystem I and ATP synthase are found primarily in the stroma lamella. Photosystem I and ATP synthase may also be found in the edges of the grana that are not stacked. The cytochrome  $b_6-f$  complex is found in the borders between grana and stroma lamella. One possible model for the arrangement of the complexes is shown in figure 8.17.

The thylakoid itself is no longer thought of only as stacked disks. Some models of the thylakoid, based on electron microscopy and other imaging, depict the grana as folds of the interconnecting stroma lamella. This kind of arrangement is more similar to the folds seen in bacterial photosynthesis, and it would therefore allow for more flexibility in how the various complexes are arranged relative to one another.

#### Learning Outcomes Review 8.5

The chloroplast has two photosystems located in the thylakoid membrane that are connected by an electron transport chain. Photosystem I passes an electron to NADPH. This electron is replaced by one from photosystem II. Photosystem II can oxidize water to replace the electron it has lost. A proton gradient is built up in the thylakoid space, and this gradient is used to generate ATP as protons pass through the ATP synthase enzyme.

- **If the thylakoid membrane were leaky to protons, would ATP still be produced? Would NADPH?**

**Figure 8.17** Model for the arrangement of complexes within the thylakoid.

The arrangement of the two kinds of photosystems and the other complexes involved in photosynthesis is not random. Photosystem II is concentrated within grana, especially in stacked areas. Photosystem I and ATP synthase are concentrated in stroma lamella and the edges of grana. The cytochrome  $b_6-f$  complex is in the margins between grana and stroma lamella. This is one possible model for this arrangement.

## 8.6 Carbon Fixation: The Calvin Cycle

### Learning Outcomes

1. Describe carbon fixation.
2. Explain how the Calvin cycle produces glucose.

Carbohydrates contain many C—H bonds and are highly reduced compared with CO<sub>2</sub>. To build carbohydrates, cells use energy and a source of electrons produced by the light-dependent reactions of the thylakoids:

1. **Energy.** ATP (provided by cyclic and noncyclic photophosphorylation) drives the endergonic reactions.
2. **Reduction potential.** NADPH (provided by photosystem I) provides a source of protons and the energetic electrons needed to bind them to carbon atoms. Much of the light energy captured in photosynthesis ends up invested in the energy-rich C—H bonds of sugars.

### Calvin cycle reactions convert inorganic carbon into organic molecules

Because early research showed temperature dependence, photosynthesis was predicted to involve enzyme-catalyzed reactions. These reactions form a cycle of enzyme-catalyzed steps much like the Krebs cycle of respiration. Unlike the Krebs cycle,

however, carbon fixation is geared toward producing new compounds, so the nature of the cycles is quite different.

The cycle of reactions that allow carbon fixation is called the **Calvin cycle**, after its discoverer, Melvin Calvin (1911–1997). Because the first intermediate of the cycle, phosphoglycerate, contains three carbon atoms, this process is also called **C<sub>3</sub> photosynthesis**.

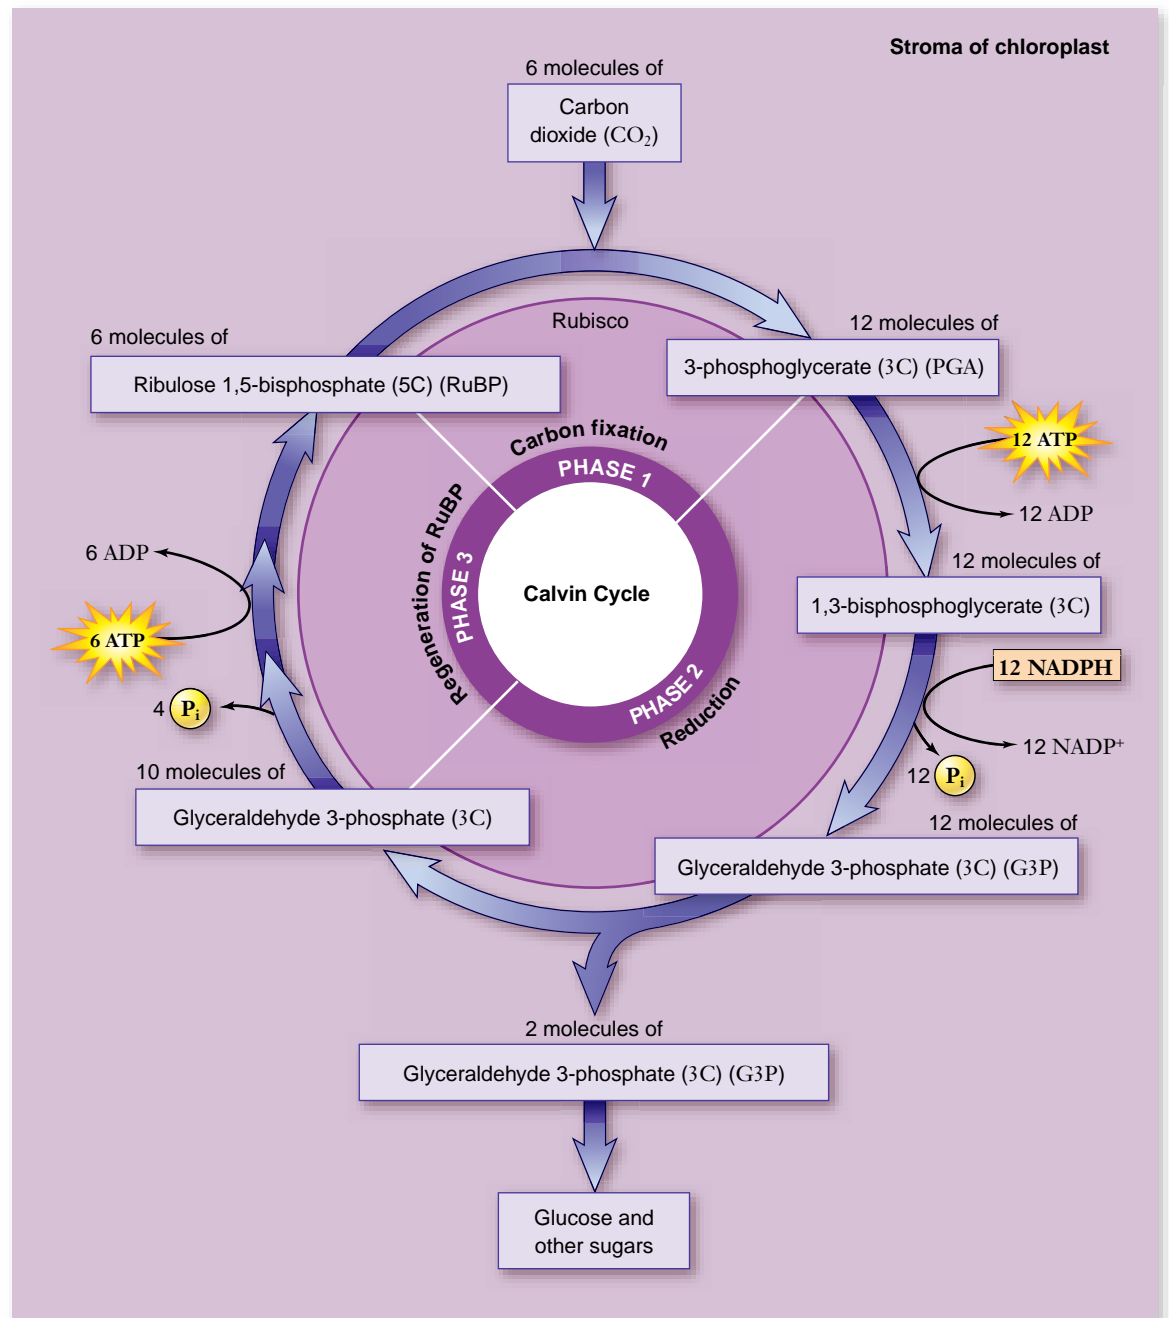

The key step in this process—the event that makes the reduction of CO<sub>2</sub> possible—is the attachment of CO<sub>2</sub> to a highly specialized organic molecule. Photosynthetic cells produce this molecule by reassembling the bonds of two intermediates in glycolysis—fructose 6-phosphate and glyceraldehyde 3-phosphate (G3P)—to form the energy-rich 5-carbon sugar **ribulose 1,5-bisphosphate (RuBP)**.

CO<sub>2</sub> reacts with RuBP to form a transient 6-carbon intermediate that immediately splits into two molecules of the three-

carbon **3-phosphoglycerate (PGA)**. This overall reaction is called the **carbon fixation reaction** because inorganic carbon (CO<sub>2</sub>) has been incorporated into an organic form: the acid PGA. The enzyme that carries out this reaction, **ribulose bisphosphate carboxylase/oxygenase** (usually abbreviated **rubisco**) is a large, 16-subunit enzyme found in the chloroplast stroma.

## Carbon is transferred through cycle intermediates, eventually producing glucose

We will consider how the Calvin cycle can produce one molecule of glucose, although this glucose is not produced directly by the cycle (figure 8.18). In a series of reactions, six molecules of CO<sub>2</sub> are bound to six RuBP by rubisco to produce 12 molecules of

**Figure 8.18 The Calvin cycle.** The Calvin cycle accomplishes carbon fixation: converting inorganic carbon in the form of CO<sub>2</sub> into organic carbon in the form of carbohydrates. The cycle can be broken down into three phases: (1) carbon fixation, (2) reduction, and (3) regeneration of RuBP. For every six CO<sub>2</sub> molecules fixed by the cycle, a molecule of glucose can be synthesized from the products of the reduction reactions, G3P. The cycle uses the ATP and NADPH produced by the light reactions.

PGA (containing  $12 \times 3 = 36$  carbon atoms in all, 6 from  $\text{CO}_2$  and 30 from RuBP). The 36 carbon atoms then undergo a cycle of reactions that regenerates the six molecules of RuBP used in the initial step (containing  $6 \times 5 = 30$  carbon atoms). This leaves two molecules of *glyceraldehyde 3-phosphate* (G3P) (each with three carbon atoms) as the net gain. (You may recall G3P as also being the product of the first half of glycolysis, described in chapter 7.) These two molecules of G3P can then be used to make one molecule of glucose.

The net equation of the Calvin cycle is:

With six full turns of the cycle, six molecules of carbon dioxide enter, two molecules of G3P are produced, and six molecules of RuBP are regenerated. Thus six turns of the cycle produce two G3P that can be used to make a single glucose molecule. The six turns of the cycle also incorporated six  $\text{CO}_2$  molecules, providing enough carbon to synthesize glucose, although the six carbon atoms do not all end up in this molecule of glucose.

### Phases of the cycle

The Calvin cycle can be thought of as divided into three phases: (1) carbon fixation, (2) reduction, and (3) regeneration of RuBP. The carbon fixation reaction generates two molecules of the 3-carbon acid PGA; PGA is then reduced to G3P by reactions that are essentially a reverse of part of glycolysis; finally, the PGA is used to regenerate RuBP. Three turns

around the cycle incorporate enough carbon to produce a new molecule of G3P, and six turns incorporate enough carbon to synthesize one glucose molecule.

We now know that light is required *indirectly* for different segments of the  $\text{CO}_2$  reduction reactions. Five of the Calvin cycle enzymes—including rubisco—are light-activated; that is, they become functional or operate more efficiently in the presence of light. Light also promotes transport of required 3-carbon intermediates across chloroplast membranes. And finally, light promotes the influx of  $\text{Mg}^{2+}$  into the chloroplast stroma, which further activates the enzyme rubisco.

### Output of the Calvin cycle

Glyceraldehyde 3-phosphate is a 3-carbon sugar, a key intermediate in glycolysis. Much of it is transported out of the chloroplast to the cytoplasm of the cell, where the reversal of several reactions in glycolysis allows it to be converted to fructose 6-phosphate and glucose 1-phosphate. These products can then be used to form sucrose, a major transport sugar in plants. (Sucrose, table sugar, is a disaccharide made of fructose and glucose.)

In times of intensive photosynthesis, G3P levels rise in the stroma of the chloroplast. As a consequence, some G3P in the chloroplast is converted to glucose 1-phosphate. This takes place in a set of reactions analogous to those occurring in the cytoplasm, by reversing several reactions similar to those of glycolysis. The glucose 1-phosphate is then combined into an insoluble polymer, forming long chains of starch stored as bulky starch grains in the cytoplasm. These starch grains represent stored glucose for later use.

### Figure 8.19 Chloroplasts and mitochondria: completing an energy cycle.

Water and  $\text{O}_2$  cycle between chloroplasts and mitochondria within a plant cell, as do glucose and  $\text{CO}_2$ . Cells with chloroplasts require an outside source of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  and generate glucose and  $\text{O}_2$ . Cells without chloroplasts, such as animal cells, require an outside source of glucose and  $\text{O}_2$  and generate  $\text{CO}_2$  and  $\text{H}_2\text{O}$ .

## The energy cycle

The energy-capturing metabolisms of the chloroplasts studied in this chapter and the mitochondria studied in chapter 7 are intimately related (figure 8.19). Photosynthesis uses the products of respiration as starting substrates, and respiration uses the products of photosynthesis as starting substrates. The production of glucose from G3P even uses part of the ancient glycolytic pathway, run in reverse. Also, the principal proteins involved in electron transport and ATP production in plants are evolutionarily related to those in mitochondria.

Photosynthesis is but one aspect of plant biology, although it is an important one. In chapters 36 through 42, we examine plants in more detail. We have discussed photosynthesis as a part of cell biology because photosynthesis arose long before plants did, and because most organisms depend directly or indirectly on photosynthesis for the energy that powers their lives.

### Learning Outcomes Review 8.6

Carbon fixation takes place in the stroma of the chloroplast, where inorganic  $\text{CO}_2$  is incorporated into an organic molecule. The key intermediate is the 5-carbon sugar RuBP that combines with  $\text{CO}_2$  in a reaction catalyzed by the enzyme rubisco. The cycle can be broken down into three stages: carbon fixation, reduction, and regeneration of RuBP. ATP and NADPH from the light reactions provide energy and electrons for the reduction reactions, which produce G3P. Glucose is synthesized when two molecules of G3P are combined.

- How does the Calvin cycle compare with glycolysis?

## 8.7 Photorespiration

### Learning Outcomes

1. Explain the action of rubisco in oxidizing RuBP.
2. Compare the function of carbon fixation in the  $\text{C}_3$ ,  $\text{C}_4$ , and CAM pathways.

Evolution does not necessarily result in optimum solutions. Rather, it favors workable solutions that can be derived from fea-

**Figure 8.21 Conditions favoring photorespiration.** In hot, arid environments, stomata close to conserve water, which also prevents  $\text{CO}_2$  from entering and  $\text{O}_2$  from exiting the leaf. The high- $\text{O}_2$ /low- $\text{CO}_2$  conditions favor photorespiration.

**Figure 8.20 Stoma.** A closed stoma in the leaf of a tobacco plant. Each stoma is formed from two guard cells whose shape changes with turgor pressure to open and close. Under dry conditions plants close their stomata to conserve water.

tures that already exist. Photosynthesis is no exception. Rubisco, the enzyme that catalyzes the key carbon-fixing reaction of photosynthesis, provides a decidedly suboptimal solution. This enzyme has a second enzymatic activity that interferes with carbon fixation, namely that of *oxidizing* RuBP. In this process, called **photorespiration**,  $\text{O}_2$  is incorporated into RuBP, which undergoes additional reactions that actually release  $\text{CO}_2$ . Hence, photorespiration releases  $\text{CO}_2$ , essentially undoing carbon fixation.

### Photorespiration reduces the yield of photosynthesis

The carboxylation and oxidation of RuBP are catalyzed at the same active site on rubisco, and  $\text{CO}_2$  and  $\text{O}_2$  compete with each other at this site. Under normal conditions at  $25^\circ\text{C}$ , the rate of the carboxylation reaction is four times that of the oxidation reaction, meaning that 20% of photosynthetically fixed carbon is lost to photorespiration.

This loss rises substantially as temperature increases, because under hot, arid conditions, specialized openings in the leaf called *stomata* (singular, *stoma*) (figure 8.20) close to conserve water. This closing also cuts off the supply of  $\text{CO}_2$  entering the leaf and does not allow  $\text{O}_2$  to exit (figure 8.21). As a result, the low- $\text{CO}_2$  and high- $\text{O}_2$  conditions within the leaf favor photorespiration.

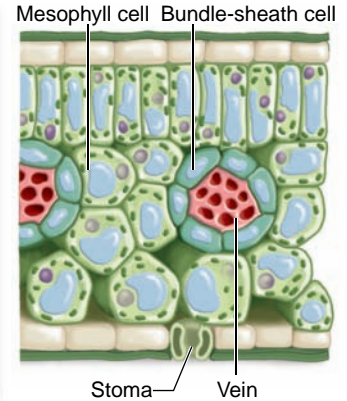

**Figure 8.22**  
**Comparison of C<sub>3</sub> and C<sub>4</sub> pathways of carbon fixation.**

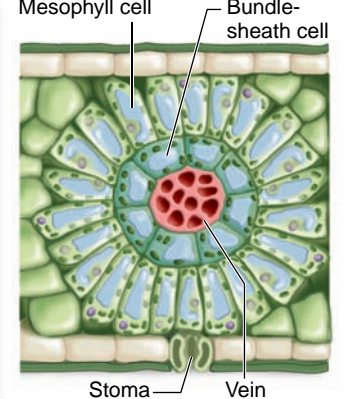

**a.** The C<sub>3</sub> pathway uses the Calvin cycle to fix carbon. All reactions occur in mesophyll cells using CO<sub>2</sub> that diffuses in through stomata. **b.** The C<sub>4</sub> pathway incorporates CO<sub>2</sub> into a 4-carbon molecule of malate in mesophyll cells. This is transported to the bundle sheath cells where it is converted back into CO<sub>2</sub> and pyruvate, creating a high level of CO<sub>2</sub>. This allows efficient carbon fixation by the Calvin cycle.

**a.** C<sub>3</sub> pathway

**b.** C<sub>4</sub> pathway

Plants that fix carbon using only C<sub>3</sub> photosynthesis (the Calvin cycle) are called **C<sub>3</sub> plants** (figure 8.22a). Other plants add CO<sub>2</sub> to phosphoenolpyruvate (PEP) to form a 4-carbon molecule. This reaction is catalyzed by the enzyme PEP *carboxylase*. This enzyme has two advantages over rubisco: it has a much greater affinity for CO<sub>2</sub> than rubisco, and it does not have oxidase activity.

The 4-carbon compound produced by PEP carboxylase undergoes further modification, only to be eventually decarboxylated. The CO<sub>2</sub> released by this decarboxylation is then used by rubisco in the Calvin cycle. This allows CO<sub>2</sub> to be pumped directly to the site of rubisco, which increases the local concentration of CO<sub>2</sub> relative to O<sub>2</sub>, minimizing photorespiration. The 4-carbon compound produced by PEP carboxylase allows CO<sub>2</sub> to be stored in an organic form, to then be released in a different cell, or at a different time to keep the level of CO<sub>2</sub> high relative to O<sub>2</sub>.

The reduction in the yield of carbohydrate as a result of photorespiration is not trivial. C<sub>3</sub> plants lose between 25% and 50% of their photosynthetically fixed carbon in this way. The rate depends largely on temperature. In tropical climates, especially those in which the temperature is often above 28°C, the problem is severe, and it has a major effect on tropical agriculture.

The two main groups of plants that initially capture CO<sub>2</sub> using PEP carboxylase differ in how they maintain high

levels of CO<sub>2</sub> relative to O<sub>2</sub>. In **C<sub>4</sub> plants** (figure 8.22b), the capture of CO<sub>2</sub> occurs in one cell and the decarboxylation occurs in an adjacent cell. This represents a spatial solution to the problem of photorespiration. The second group, **CAM plants**, perform both reactions in the same cell, but capture CO<sub>2</sub> using PEP carboxylase at night, then decarboxylate during the day. CAM stands for **crassulacean acid metabolism**, after the plant family Crassulaceae (the stonecrops, or hens-and-chicks), in which it was first discovered. This mechanism represents a temporal solution to the photorespiration problem.

**C<sub>4</sub> plants have evolved to minimize photorespiration**

The C<sub>4</sub> plants include corn, sugarcane, sorghum, and a number of other grasses. These plants initially fix carbon using PEP carboxylase in mesophyll cells. This reaction produces the organic acid oxaloacetate, which is converted to malate and transported to bundle-sheath cells that surround the leaf veins. Within the bundle-sheath cells, malate is decarboxylated to produce pyruvate and CO<sub>2</sub> (figure 8.23). Because the bundle-sheath cells are impermeable to CO<sub>2</sub>, the local level of CO<sub>2</sub> is high and carbon fixation by rubisco and the Calvin cycle is efficient. The

**Figure 8.23 Carbon fixation in  $C_4$  plants.** This process is called the  $C_4$  pathway because the first molecule formed, oxaloacetate, contains four carbons. The oxaloacetate is converted to malate, which moves into bundle-sheath cells where it is decarboxylated back to  $CO_2$  and pyruvate. This produces a high level of  $CO_2$  in the bundle-sheath cells that can be fixed by the usual  $C_3$  Calvin cycle with little photorespiration. The pyruvate diffuses back into the mesophyll cells, where it is converted back to PEP to be used in another  $C_4$  fixation reaction.

pyruvate produced by decarboxylation is transported back to the mesophyll cells, where it is converted back to PEP, thereby completing the cycle.

The  $C_4$  pathway, although it overcomes the problems of photorespiration, does have a cost. The conversion of pyruvate back to PEP requires breaking two high-energy bonds in ATP. Thus each  $CO_2$  transported into the bundle-sheath cells cost the equivalent of two ATP. To produce a single glucose, this requires 12 additional ATP compared with the Calvin cycle alone. Despite this additional cost,  $C_4$  photosynthesis is advantageous in hot dry climates where photorespiration would remove more than half of the carbon fixed by the usual  $C_3$  pathway alone.

**Figure 8.24 Carbon fixation in CAM plants.** CAM plants also use both  $C_4$  and  $C_3$  pathways to fix carbon and minimize photorespiration. In CAM plants, the two pathways occur in the same cell but are separated in time: The  $C_4$  pathway is utilized to fix carbon at night, then  $CO_2$  is released from these accumulated stores during the day to drive the  $C_3$  pathway. This achieves the same effect of minimizing photorespiration while also minimizing loss of water by opening stomata at night when temperatures are lower.

### The Crassulacean acid pathway splits photosynthesis into night and day

A second strategy to decrease photorespiration in hot regions has been adopted by the CAM plants. These include many succulent (water-storing) plants, such as cacti, pineapples, and some members of about two dozen other plant groups.

In these plants, the stomata open during the night and close during the day (figure 8.24). This pattern of stomatal opening and closing is the reverse of that in most plants. CAM plants initially fix  $CO_2$  using PEP carboxylase to produce oxaloacetate. The oxaloacetate is often converted into other organic acids, depending on the particular CAM plant. These organic compounds accumulate during the night and are stored in the vacuole. Then during the day, when the stomata are closed, the organic acids are decarboxylated to yield high levels of  $CO_2$ . These high levels of  $CO_2$  drive the Calvin cycle and minimize photorespiration.

Like  $C_4$  plants, CAM plants use both  $C_3$  and  $C_4$  pathways. They differ in that they use both of these pathways in the same cell: the  $C_4$  pathway at night and the  $C_3$  pathway during the day. In  $C_4$  plants the two pathways occur in different cells.

#### Learning Outcomes Review 8.7

Rubisco can also oxidize RuBP under conditions of high  $O_2$  and low  $CO_2$ . In plants that use only  $C_3$  metabolism (Calvin cycle), up to 20% of fixed carbon is lost to this photorespiration. Plants adapted to hot, dry environments are capable of storing  $CO_2$  as a 4-carbon molecule and avoiding some of this loss; they are called  $C_4$  plants. In CAM plants,  $CO_2$  is fixed at night into a  $C_4$  organic compound; in the daytime, this compound is used as a source of  $CO_2$ ,  $C_3$  metabolism when stomata are closed to prevent water loss.

#### ■ How do $C_4$ plants and CAM plants differ?

## Chapter Review

### 8.1 Overview of Photosynthesis

Photosynthesis is the conversion of light energy into chemical energy (see figure 8.2).

**Photosynthesis combines  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , producing glucose and  $\text{O}_2$ .**

Photosynthesis has three stages: absorbing light energy, using this energy to synthesize ATP and NADPH, and using the ATP and NADPH to convert  $\text{CO}_2$  to organic molecules. The first two stages consist of light-dependent reactions, and the third stage of light-independent reactions.

**In plants, photosynthesis takes place in chloroplasts.**

Chloroplasts contain internal thylakoid membranes and a fluid matrix called stroma. The photosystems involved in energy capture are found in the thylakoid membranes, and enzymes for assembling organic molecules are in the stroma.

### 8.2 The Discovery of Photosynthetic Processes

**Plants do not increase mass from soil and water alone.**

Early investigations revealed that plants produce  $\text{O}_2$  from carbon dioxide and water in the presence of light.

**Photosynthesis includes both light-dependent and light-independent reactions.**

The light-dependent reactions require light; the light-independent reactions occur in both daylight and darkness. The rate of photosynthesis depends on the amount of light, the  $\text{CO}_2$  concentration, and temperature.

**$\text{O}_2$  comes from water, not from  $\text{CO}_2$ .**

The use of isotopes revealed the individual origins and fates of different molecules in photosynthetic reactions.

**ATP and NADPH from light-dependent reactions reduce  $\text{CO}_2$  to make sugars.**

Carbon fixation requires ATP and NADPH, which are products of the light-dependent reactions. As long as these are available,  $\text{CO}_2$  is reduced by enzymes in the stroma to form simple sugars.

### 8.3 Pigments

**Light is a form of energy.**

Light exists both as a wave and as a particle (photon). Light can remove electrons from some metals by the photoelectric effect, and in photosynthesis, chloroplasts act as photoelectric devices.

**Each pigment has a characteristic absorption spectrum.**

Chlorophyll *a* is the only pigment that can convert light energy into chemical energy. Chlorophyll *b* is an accessory pigment that increases the harvest of photons for photosynthesis.

Carotenoids and other accessory pigments further increase a plant's ability to harvest photons.

### 8.4 Photosystem Organization (see figure 8.10)

**Production of one  $\text{O}_2$  molecule requires many chlorophyll molecules.**

Measurement of  $\text{O}_2$  output led to the idea of photosystems—clusters of pigment molecules that channel energy to a reaction center.

**A generalized photosystem contains an antenna complex and a reaction center.**

A photosystem is a network of chlorophyll *a*, accessory pigments, and proteins embedded in the thylakoid membrane. Pigment molecules of the antenna complex harvest photons and feed light

energy to the reaction center. The reaction center is composed of two chlorophyll *a* molecules in a protein matrix that pass an excited electron to an electron acceptor.

### 8.5 The Light-Dependent Reactions

The light reactions can be broken down into four processes: primary photoevent, charge separation, electron transport, and chemiosmosis.

**Some bacteria use a single photosystem (figure 8.12).**

An excited electron moves along a transport chain and eventually returns to the photosystem. This cyclic process is used to generate a proton gradient. In some bacteria, this can also produce NADPH.

**Chloroplasts have two connected photosystems.**

Photosystem I transfers electrons to  $\text{NADP}^+$ , reducing it to NADPH. Photosystem II replaces electrons lost by photosystem I. Electrons lost from photosystem II are replaced by electrons from oxidation of water, which also produces  $\text{O}_2$ .

**The two photosystems work together in noncyclic photophosphorylation.**

Photosystem II and photosystem I are linked by an electron transport chain; the *b<sub>6</sub>-f* complex in this chain pumps protons into the thylakoid space.

**ATP is generated by chemiosmosis.**

ATP synthase is a channel enzyme; as protons flow through the channel down their gradient, ADP is phosphorylated producing ATP, similar to the mechanism in mitochondria. Plants can make additional ATP by cyclic photophosphorylation.

**Thylakoid structure reveals components' locations.**

Imaging studies suggest that photosystem II is primarily found in the grana, while photosystem I and ATP synthase are found in the stroma lamella.

### 8.6 Carbon Fixation: The Calvin Cycle (see figure 8.18)

**Calvin cycle reactions convert inorganic carbon into organic molecules.**

The Calvin cycle, also known as  $\text{C}_3$  photosynthesis, uses  $\text{CO}_2$ , ATP, and NADPH to build simple sugars.

**Carbon is transferred through cycle intermediates, eventually producing glucose.**

The Calvin cycle occurs in three stages: carbon fixation via the enzyme rubisco's action on RuBP and  $\text{CO}_2$ ; reduction of the resulting 3-carbon PGA to G3P, generating ATP and NADPH; and regeneration of RuBP. Six turns of the cycle fix enough carbon to produce two excess G3Ps used to make one molecule of glucose.

### 8.7 Photorespiration

**Photorespiration reduces the yield of photosynthesis.**

Rubisco can catalyze the oxidation of RuBP, reversing carbon fixation. Dry, hot conditions tend to increase this reaction.

**$\text{C}_4$  plants have evolved to minimize photorespiration.**

$\text{C}_4$  plants fix carbon by adding  $\text{CO}_2$  to a 3-carbon molecule, forming oxaloacetate. Carbon is fixed in one cell by the  $\text{C}_4$  pathway, then  $\text{CO}_2$  is released in another cell for the Calvin cycle (see figure 8.23).

**The Crassulacean acid pathway splits photosynthesis into night and day.**

CAM plants use the  $\text{C}_4$  pathway during the day when stomata are closed, and the Calvin cycle at night in the same cell.

## Review Questions

### UNDERSTAND

- The *light-dependent* reactions of photosynthesis are responsible for the production of
  - glucose.
  - CO<sub>2</sub>.
  - ATP and NADPH.
  - H<sub>2</sub>O.
- Which region of a chloroplast is associated with the capture of light energy?
  - Thylakoid membrane
  - Outer membrane
  - Stroma
  - Both a and c
- The colors of light that are most effective for photosynthesis are
  - red, blue, and violet.
  - green, yellow, and orange.
  - infrared and ultraviolet.
  - All colors of light are equally effective.
- During noncyclic photosynthesis, photosystem I functions to \_\_\_\_\_, and photosystem II functions to \_\_\_\_\_.
  - synthesize ATP; produce O<sub>2</sub>
  - reduce NADP<sup>+</sup>; oxidize H<sub>2</sub>O
  - reduce CO<sub>2</sub>; oxidize NADPH
  - restore an electron to its reaction center; gain an electron from water
- How is a reaction center pigment in a photosystem different from a pigment in the antenna complex?
  - The reaction center pigment is a chlorophyll molecule.
  - The antenna complex pigment can only reflect light.
  - The reaction center pigment loses an electron when it absorbs light energy.
  - The antenna complex pigments are not attached to proteins.
- The ATP and NADPH from the light reactions are used
  - in glycolysis in roots.
  - directly in most biochemical reactions in the cell.
  - during the reactions of the Calvin cycle to produce glucose.
  - to synthesize chlorophyll.
- The carbon fixation reaction converts
  - inorganic carbon into an organic acid.
  - CO<sub>2</sub> into glucose.
  - inactive rubisco into active rubisco.
  - an organic acid into CO<sub>2</sub>.
- C<sub>4</sub> plants initially fix carbon by
  - the same pathway as C<sub>3</sub> plants, but they modify this product.
  - incorporating CO<sub>2</sub> into oxaloacetate, which is converted to malate.
  - incorporating CO<sub>2</sub> into citrate via the Krebs cycle.
  - incorporating CO<sub>2</sub> into glucose via reverse glycolysis.
- In the intermembrane space
- In the antenna complex
- How does the reaction center of photosystem I regain an electron during noncyclic photosynthesis?
  - The electron is recycled directly back to the reaction center pigment.
  - The electron is donated from H<sub>2</sub>O.
  - The electron is donated from photosystem II.
  - The electron is donated from NADPH.
- If the Calvin cycle runs through six turns
  - all of the fixed carbon will end up in the same glucose molecule.
  - 12 carbons will be fixed by the process.
  - enough carbon will be fixed to make one glucose, but they will not all be in the same molecule.
  - one glucose will be converted into six CO<sub>2</sub>.
- Which of the following are similarities between the structure and function of mitochondria and chloroplasts?
  - They both create internal proton gradients by electron transport.
  - They both generate CO<sub>2</sub> by oxidation reactions.
  - They both have an outer membrane and an inner membrane system.
  - Both a and c are correct.
- Carbon fixation by the C<sub>4</sub> pathway produces
  - the same product as is produced by the Calvin cycle.
  - an organic acid, but a 4-carbon one not a 3-carbon.
  - a 3-carbon organic acid that is converted to the 4-carbon malate.
  - RuBP.
- If the thylakoid membrane became leaky to ions, what would you predict to be the result on the light reactions?
  - It would stop ATP production.
  - It would stop NADPH production.
  - It would stop the oxidation of H<sub>2</sub>O.
  - All of the above are correct.
- The overall process of photosynthesis
  - results in the reduction of CO<sub>2</sub> and the oxidation of H<sub>2</sub>O.
  - results in the reduction of H<sub>2</sub>O and the oxidation of CO<sub>2</sub>.
  - consumes O<sub>2</sub> and produces CO<sub>2</sub>.
  - produces O<sub>2</sub> from CO<sub>2</sub>.

### APPLY

- The overall flow of electrons in the light reactions is from
  - antenna pigments to the reaction center.
  - H<sub>2</sub>O to CO<sub>2</sub>.
  - photosystem I to photosystem II.
  - H<sub>2</sub>O to NADPH.
- Where in a chloroplast would you find the highest concentration of protons?
  - In the stroma
  - In the lumen of the thylakoid

### SYNTHESIZE

- Compare and contrast the fixation of carbon in C<sub>3</sub>, C<sub>4</sub>, and CAM plants.
- Diagram the relationship between the reactants and products of photosynthesis and respiration.
- Do plant cells need mitochondria? Explain your answer.

# Cell Communication

## Chapter Outline

- 9.1 Overview of Cell Communication
- 9.2 Receptor Types
- 9.3 Intracellular Receptors
- 9.4 Signal Transduction Through Receptor Kinases
- 9.5 Signal Transduction Through G Protein-Coupled Receptors

## Introduction

Springtime is a time of rebirth and renewal. Trees that have appeared dead produce new leaves and buds, and flowers sprout from the ground. For sufferers of seasonal allergy, this is not quite such a pleasant time. The pollen in the micrograph and other allergens produced stimulate the immune system to produce the molecule histamine and other molecules that form cellular signals. These signals cause inflammation, mucus secretion, vasodilation, and other responses that together cause the runny nose, itching watery eyes, and other symptoms that make up the allergic reaction. We treat allergy symptoms by using drugs called antihistamines that interfere with this cellular signaling. The popular drug loratadine (better known as Claritin), for example, acts by blocking the receptor for histamine, thus preventing its action.

We will begin this chapter with a general overview of signaling, and the kinds of receptors cells use to respond to signals. Then we will look in more detail at how these different types of receptors can elicit a response from cells, and finally, how cells make connections with one another.

## 9.1 Overview of Cell Communication

### Learning Outcomes

1. Explain the different ways that cells communicate.
2. Describe how cells use signal transduction pathways.

Communication between cells is common in nature. Cell signaling occurs in all multicellular organisms, providing an indispensable mechanism for cells to influence one another. Effective signaling requires a signaling molecule, called a **ligand**, and a molecule to which the signal binds, called a **receptor protein**. The interaction of these two components initiates the process of *signal transduction*, which converts the information in the signal into a cellular response (figure 9.1).

The cells of multicellular organisms use a variety of molecules as signals, including but not limited to, peptides, large

**Figure 9.1 Overview of cell signaling.** Cell signaling involves a signal molecule called a ligand, a receptor, and a signal transduction pathway that produces a cellular response. The location of the receptor can either be intracellular, for hydrophobic ligands that can cross the membrane, or in the plasma membrane, for hydrophilic ligands that cannot cross the membrane.

proteins, individual amino acids, nucleotides, and steroids and other lipids. Even dissolved gases such as NO (nitric oxide) are used as signals.

Any cell of a multicellular organism is exposed to a constant stream of signals. At any time, hundreds of different chemical signals may be present in the environment surrounding the cell. Each cell responds only to certain signals, however, and ignores the rest, like a person following the conversation of one or two individuals in a noisy, crowded room.

How does a cell “choose” which signals to respond to? The number and kind of receptor molecules determine this. When a ligand approaches a receptor protein that has a complementary shape, the two can bind, forming a complex. This binding induces a change in the receptor protein’s shape, ultimately producing a response in the cell via a signal transduction pathway. In this way, a given cell re-

sponds to the signaling molecules that fit the particular set of receptor proteins it possesses and ignores those for which it lacks receptors.

### Signaling is defined by the distance from source to receptor

Cells can communicate through any of four basic mechanisms, depending primarily on the distance between the signaling and responding cells (figure 9.2). These mechanisms are (1) direct contact, (2) paracrine signaling, (3) endocrine signaling, and (4) synaptic signaling.

In addition to using these four basic mechanisms, some cells actually send signals to themselves, secreting signals that bind to specific receptors on their own plasma membranes. This process, called *autocrine signaling*, is thought to play an

**Figure 9.2 Four kinds of cell signaling.** Cells communicate in several ways. *a.* Two cells in direct contact with each other may send signals across gap junctions. *b.* In paracrine signaling, secretions from one cell have an effect only on cells in the immediate area. *c.* In endocrine signaling, hormones are released into the organism’s circulatory system, which carries them to the target cells. *d.* Chemical synapse signaling involves transmission of signal molecules, called neurotransmitters, from a neuron over a small synaptic gap to the target cell.

important role in reinforcing developmental changes, and it is an important component of signaling in the immune system (chapter 52).

### **Direct contact**

As you saw in chapter 5, the surface of a eukaryotic cell is richly populated with proteins, carbohydrates, and lipids attached to and extending outward from the plasma membrane. When cells are very close to one another, some of the molecules on the plasma membrane of one cell can be recognized by receptors on the plasma membrane of an adjacent cell. Many of the important interactions between cells in early development occur by means of direct contact between cell surfaces. Cells also signal through gap junctions (figure 9.2a). We'll examine contact-dependent interactions more closely later in this chapter.

### **Paracrine signaling**

Signal molecules released by cells can diffuse through the extracellular fluid to other cells. If those molecules are taken up by neighboring cells, destroyed by extracellular enzymes, or quickly removed from the extracellular fluid in some other way, their influence is restricted to cells in the immediate vicinity of the releasing cell. Signals with such short-lived, local effects are called **paracrine** signals (figure 9.2b).

Like direct contact, paracrine signaling plays an important role in early development, coordinating the activities of clusters of neighboring cells. The immune response in vertebrates also involves paracrine signaling between immune cells (chapter 52).

### **Endocrine signaling**

A released signal molecule that remains in the extracellular fluid may enter the organism's circulatory system and travel widely throughout the body. These longer-lived signal molecules, which may affect cells very distant from the releasing cell, are called **hormones**, and this type of intercellular communication is known as **endocrine signaling** (figure 9.2c). Chapter 46 discusses endocrine signaling in detail. Both animals and plants use this signaling mechanism extensively.

### **Synaptic signaling**

In animals, the cells of the nervous system provide rapid communication with distant cells. Their signal molecules, **neurotransmitters**, do not travel to the distant cells through the circulatory system as hormones do. Rather, the long, fiberlike extensions of nerve cells release neurotransmitters from their tips very close to the target cells (figure 9.2d). The association of a neuron and its target cell is called a **chemical synapse**, and this type of intercellular communication is called **synaptic signaling**. Whereas paracrine signals move through the fluid between cells, neurotransmitters cross the synaptic gap and persist only briefly. We will examine synaptic signaling more fully in chapter 44.

## **Signal transduction pathways lead to cellular responses**

The types of signaling outlined earlier are descriptive and say nothing about how cells respond to signals. The events that occur within the cell on receipt of a signal are called **signal**

**transduction**. These events form discrete pathways that lead to a cellular response to the signal received by receptors. Knowledge of these signal transduction pathways has exploded in recent years and indicates a high degree of complexity that explains how in some cases different cell types can have the same response to different signals, and in other cases different cell types can have a different response to the same signal.

For example, a variety of cell types respond to the hormone glucagon by mobilizing glucose as part of the body's mechanism to control blood glucose (chapter 46). This involves breaking down stored glycogen into glucose and turning on the genes that encode the enzymes necessary to synthesize glucose. In contrast, the hormone epinephrine has diverse effects on different cell types. We have all been startled or frightened by a sudden event. Your heart beats faster, you feel more alert, and you can even feel the hairs on your skin stand up. All of this is due in part to your body releasing the hormone epinephrine (also called adrenaline) into the bloodstream. This leads to the heightened state of alertness and increased heart rate and energy that prepare us to respond to extreme situations.

These differing effects of epinephrine depend on the different cell types with receptors for this hormone. In the liver, cells are stimulated to mobilize glucose while in the heart muscle cells contract more forcefully to increase blood flow. In addition, blood vessels respond by expanding in some areas and contracting in others to redirect blood flow to the liver, heart, and skeletal muscles. These different reactions depend on the fact that each cell type has a receptor for epinephrine, but different sets of proteins that respond to this signal.

## **Phosphorylation is key in control of protein function**

The function of a signal transduction pathway is to change the behavior or nature of a cell. This action may require changing the composition of proteins that make up a cell or altering the activity of cellular proteins. Many proteins are inactive or nonfunctional as they are initially synthesized and require modification after synthesis for activation. In other cases, a protein may require modification for deactivation. A major source of control for protein function is the addition or removal of phosphate groups, called **phosphorylation** or **dephosphorylation**, respectively.

As you learned in preceding chapters, the end result of the metabolic pathways of cellular respiration and photosynthesis was the phosphorylation of ADP to ATP. The ATP synthesized by these processes can donate phosphate groups to proteins. The phosphorylation of proteins alters their function, which allows them to transmit information from an extracellular signal through a signal transduction pathway.

### **Protein kinases**

The class of enzyme that adds phosphate groups from ATP to proteins is called a *protein kinase*. These phosphate groups can be added to the three amino acids that have an OH as part of their R group, namely serine, threonine, and tyrosine. We categorize protein kinases based on which of these three substrates they alter (figure 9.3). Most cytoplasmic protein kinases fall into the serine/threonine kinase class.

**Figure 9.3 Phosphorylation of proteins.** Many proteins are controlled by their phosphorylation state: that is, they are activated by phosphorylation and deactivated by dephosphorylation or the reverse. The enzymes that add phosphate groups are called kinases. These form two classes depending on the amino acid the phosphate is added to, either serine/threonine kinases or tyrosine kinases. The action of kinases is reversed by protein phosphatase enzymes.

### Phosphatases

Part of the reason for the versatility of phosphorylation as a form of protein modification is that it is reversible. Another class of enzymes called **phosphatases** removes phosphate groups, reversing the action of kinases (see figure 9.3). Thus, a protein activated by a kinase can be deactivated by a phosphatase, or the reverse.

#### Learning Outcomes Review 9.1

Cell communication involves chemical signals, or ligands, that bind to cellular receptors. Binding of ligand to receptor initiates signal transduction pathways that lead to a cellular response. Different cells may have the same response to one signal and the same signal can also elicit different responses in different cells. The phosphorylation–dephosphorylation of proteins is a common mechanism of controlling protein function found in signaling pathways.

- How are receptor ligand interactions similar to enzyme substrate interactions?

## 9.2 Receptor Types

### Learning Outcome

1. Contrast the different types of receptors.

The first step in understanding cell signaling is to consider the receptors themselves. Cells must have a specific receptor to be able to respond to a particular signaling molecule. The interaction of a receptor and its ligand is an example of molecular recognition, a process in which one molecule fits specifically based on its com-

plementary shape with another molecule. This interaction causes subtle changes in the structure of the receptor, thereby activating it. This is the beginning of any signal transduction pathway.

### Receptors are defined by location

The nature of these receptor molecules depends on their location and on the kind of ligands they bind. Intracellular receptors bind hydro-phobic ligands, which can easily cross the membrane, inside the cell. In contrast, cell surface or membrane receptors bind hydrophilic ligands, which cannot easily cross the membrane, outside the cell (figure 9.1). Membrane receptors consist of transmembrane proteins that are in contact with both the cytoplasm and the extracellular environment. Table 9.1 summarizes the types of receptors and communication mechanisms discussed in this chapter.

### Membrane receptors include three subclasses

When a receptor is a transmembrane protein, the ligand binds to the receptor outside of the cell and never actually crosses the plasma membrane. In this case, the receptor itself, and not the signaling molecule is responsible for information crossing the membrane. Membrane receptors can be categorized based on their structure and function.

#### Channel-linked receptors

Chemically gated ion channels are receptor proteins that allow the passage of ions (figure 9.4a). The receptor proteins that bind many neurotransmitters have the same basic structure. Each is a membrane protein with multiple transmembrane domains, meaning that the chain of amino acids threads back and forth across the plasma membrane several times. In the center of the protein is a pore that connects the extracellular fluid with the cytoplasm. The pore is big enough for ions to pass through, so the protein functions as an **ion channel**.

**TABLE 9.1**
**Receptors Involved in Cell Signaling**

Receptor Type	Structure	Function	Example
Intracellular Receptors	No extracellular signal-binding site	Receives signals from lipid-soluble or noncharged, nonpolar small molecules	Receptors for NO, steroid hormone, vitamin D, and thyroid hormone
<b>Cell Surface Receptors</b>			
Chemically gated ion channels	Multipass transmembrane protein forming a central pore	Molecular "gates" triggered chemically to open or close	Neurons
Enzymatic receptors	Single-pass transmembrane protein	Binds signal extracellularly; catalyzes response intracellularly	Phosphorylation of protein kinases
G protein-coupled receptors	Seven-pass transmembrane protein with cytoplasmic binding site for G protein	Binding of signal to receptor causes GTP to bind a G protein; G protein, with attached GTP, detaches to deliver the signal inside the cell	Peptide hormones, rod cells in the eyes

The channel is said to be chemically gated because it opens only when a chemical (the neurotransmitter) binds to it. The type of ion that flows across the membrane when a chemically gated ion channel opens depends on the shape and charge structure of the channel. Sodium, potassium, calcium, and chloride ions all have specific ion channels.

The acetylcholine receptor found in muscle cell membranes functions as a Na<sup>+</sup> channel. When the receptor binds to its ligand,

the neurotransmitter acetylcholine, the channel opens allowing Na<sup>+</sup> to flow into the muscle cell. This is a critical step linking the signal from a motor neuron to muscle cell contraction (chapter 44).

**Enzymatic receptors**

Many cell surface receptors either act as enzymes or are directly linked to enzymes (figure 9.4*b*). When a signal molecule binds to the receptor, it activates the enzyme. In almost all

**a.**

**b.**

**c.**

**Figure 9.4 Cell surface receptors.** *a.* Chemically gated ion channels form a pore in the plasma membrane that can be opened or closed by chemical signals. They are usually selective, allowing the passage of only one type of ion. *b.* Enzymatic receptors bind to ligands on the extracellular surface. A catalytic region on their cytoplasmic portion transmits the signal across the membrane by acting as an enzyme in the cytoplasm. *c.* G protein-coupled receptors (GPCR) bind to ligands outside the cell and to G proteins inside the cell. The G protein then activates an enzyme or ion channel, transmitting signals from the cell's surface to its interior.

cases, these enzymes are **protein kinases**, enzymes that add phosphate groups to proteins. We discuss these receptors in detail in a later section of this chapter.

### G Protein-coupled receptors

A third class of cell surface receptors acts indirectly on enzymes or ion channels in the plasma membrane with the aid of an assisting protein, called a **G protein**. The G protein, which is so named because it binds the nucleotide *guanosine triphosphate* (GTP), can be thought of as being inserted between the receptors and the enzyme (effector). That is, the ligand binds to the receptor, activating it, which activates the G protein, which in turn activates the effector protein (figure 9.4c). These receptors are also discussed in detail later on.

### Membrane receptors can generate second messengers

Some enzymatic receptors and most G protein-coupled receptors utilize other substances to relay the message within the cytoplasm. These other substances, small molecules or ions called **second messengers**, alter the behavior of cellular proteins by binding to them and changing their shape. (The original signal molecule is considered the “first messenger.”) Two common second messengers are **cyclic adenosine monophosphate (cyclic-AMP, or cAMP)** and calcium ions. The role of these second messengers will be explored in more detail in a later section.

#### Learning Outcome Review 9.2

Receptors may be internal (intracellular receptors) or external (membrane receptors). Membrane receptors include channel-linked receptors, enzymatic receptors, and G protein-coupled receptors. Signal transduction through membrane receptors often involves the production of a second signaling molecule, or second messenger, inside the cell.

- **Would a hydrophobic molecule be expected to have an internal or membrane receptor?**

## 9.3 Intracellular Receptors

### Learning Outcomes

1. **Identify the chemical nature of ligands for intracellular receptors.**
2. **Describe the action of intracellular receptors.**

Many cell signals are lipid-soluble or very small molecules that can readily pass through the plasma membrane of the target cell and into the cell, where they interact with an *intracellular receptor*. Some of these ligands bind to protein receptors located in the cytoplasm, others pass across the nuclear membrane as well and bind to receptors within the nucleus.

### Steroid hormone receptors affect gene expression

Of all of the receptor types discussed in this chapter, the action of the steroid hormone receptors is the simplest and most direct.

Steroid hormones form a large class of compounds, including cortisol, estrogen, progesterone, and testosterone, that share a common nonpolar structure. Estrogen, progesterone, and testosterone are involved in sexual development and behavior (chapter 53). Other steroid hormones, such as cortisol, also have varied effects depending on the target tissue, ranging from the mobilization of glucose to the inhibition of white blood cells to control inflammation. Their anti-inflammatory action is the basis of their use in medicine.

The nonpolar structure allows these hormones to cross the membrane and bind to intracellular receptors. The location of steroid hormone receptors prior to hormone binding is cytoplasmic, but their primary site of action is in the nucleus. Binding of the hormone to the receptor causes the complex to shift from the cytoplasm to the nucleus (figure 9.5). As the

**Figure 9.5 Intracellular receptors regulate gene transcription.** Hydrophobic signaling molecules can cross the plasma membrane and bind to intracellular receptors. This starts a signal transduction pathway that produces changes in gene expression.

ligand–receptor complex makes it all the way to the nucleus of the cell, these receptors are often called **nuclear receptors**.

### **Steroid receptor action**

The primary function of steroid hormone receptors, as well as receptors for a number of other small, lipid-soluble signal molecules such as vitamin D and thyroid hormone, is to act as regulators of gene expression (see chapter 16).

All of these receptors have similar structures; the genes that code for them appear to be the evolutionary descendants of a single ancestral gene. Because of their structural similarities, they are all part of the *nuclear receptor superfamily*.

Each of these receptors has three functional domains—

1. a hormone-binding domain,
2. a DNA-binding domain, and
3. a domain that can interact with coactivators to affect the level of gene transcription.

In its inactive state, the receptor typically cannot bind to DNA because an inhibitor protein occupies the DNA-binding site. When the signal molecule binds to the hormone-binding site, the conformation of the receptor changes, releasing the inhibitor and exposing the DNA-binding site, allowing the receptor to attach to specific nucleotide sequences on the DNA (see figure 9.5). This binding activates (or, in a few instances, suppresses) particular genes, usually located adjacent to the hormone-binding sequences. In the case of cortisol, which is a glucocorticoid hormone that can increase levels of glucose in cells, a number of different genes involved in the synthesis of glucose have binding sites for the hormone receptor complex.

The lipid-soluble ligands that intracellular receptors recognize tend to persist in the blood far longer than water-soluble signals. Most water-soluble hormones break down within minutes, and neurotransmitters break down within seconds or even milliseconds. In contrast, a steroid hormone such as cortisol or estrogen persists for hours.

### **Specificity and the role of coactivators**

The target cell's response to a lipid-soluble cell signal can vary enormously, depending on the nature of the cell. This characteristic is true even when different target cells have the same intracellular receptor. Given that the receptor proteins bind to specific DNA sequences, which are the same in all cells, this may seem puzzling. It is explained in part by the fact that the receptors act in concert with **coactivators**, and the number and nature of these molecules can differ from cell to cell. Thus, a cell's response depends on not only the receptors but also the coactivators present.

The hormone estrogen has different effects in uterine tissue than in mammary tissue. This differential response is mediated by coactivators and not by the presence or absence of a receptor in the two tissues. In mammary tissue, a critical coactivator is lacking and the hormone–receptor complex instead interacts with another protein that acts to reduce gene expression. In uterine tissue, the coactivator is present, and the expression of genes that encode proteins involved in preparing the uterus for pregnancy are turned on.

## **Other intracellular receptors act as enzymes**

A very interesting example of a receptor acting as an enzyme is found in the receptor for nitric oxide (NO). This small gas molecule diffuses readily out of the cells where it is produced and passes directly into neighboring cells, where it binds to the enzyme guanylyl cyclase. Binding of NO activates this enzyme, enabling it to catalyze the synthesis of *cyclic guanosine monophosphate (cGMP)*, an intracellular messenger molecule that produces cell-specific responses such as the relaxation of smooth muscle cells.

When the brain sends a nerve signal to relax the smooth muscle cells lining the walls of vertebrate blood vessels, acetylcholine released by the nerve cell binds to receptors on epithelial cells. This causes an increase in intracellular  $\text{Ca}^{2+}$  in the epithelial cell that stimulates nitric oxide synthase to produce NO. The NO diffuses into the smooth muscle, where it increases the level of cGMP, leading to relaxation. This relaxation allows the vessel to expand and thereby increases blood flow. This explains the use of nitroglycerin to treat the pain of angina caused by constricted blood vessels to the heart. The nitroglycerin is converted by cells to NO, which then acts to relax the blood vessels.

The drug sildenafil (better known as Viagra) also functions via this signal transduction pathway by binding to and inhibiting the enzyme cGMP phosphodiesterase, which breaks down cGMP. This keeps levels of cGMP high, thereby stimulating production of NO. The reason for Viagra's selective effect is that it binds to a form of cGMP phosphodiesterase found in cells in the penis. This allows relaxation of smooth muscle in erectile tissue, thereby increasing blood flow.

### **Learning Outcomes Review 9.3**

Hydrophobic signaling molecules can cross the membrane and bind to intracellular receptors. The steroid hormone receptors act by directly influencing gene expression. On binding hormone, the hormone–receptor moves into the nucleus to turn on (or sometimes turn off) gene expression. This also requires another protein called a coactivator that functions with the hormone–receptor. Thus, the cell's response to a hormone depends on the presence of a receptor and coactivators as well.

- *Would these types of intracellular receptors be fast acting, or have effects of longer duration?*

## **9.4** *Signal Transduction Through Receptor Kinases*

### **Learning Outcomes**

1. *Compare the function of RTKs to steroid hormone receptors.*
2. *Describe how information crosses the membrane in RTKs.*
3. *Explain the significance of kinase cascades.*

Earlier you read that protein kinases phosphorylate proteins to alter protein function and that the most common kinases act on the amino acids serine, threonine, and tyrosine. The **receptor**

**tyrosine kinases (RTK)** influence the cell cycle, cell migration, cell metabolism, and cell proliferation—virtually all aspects of the cell are affected by signaling through these receptors. Alterations to the function of these receptors and their signaling pathways can lead to cancers in humans and other animals.

Some of the earliest examples of cancer-causing genes, or oncogenes, involve RTK function (discussed in chapter 10). The cancer-causing simian sarcoma virus carries a gene for platelet-derived growth factor. When the virus infects a cell, the cell overproduces and secretes platelet-derived growth factor, causing overgrowth of the surrounding cells. Another virus, avian erythroblastosis virus, carries an altered form of the epidermal growth factor receptor that lacks most of its extracellular domain. When this virus infects a cell the altered receptors produced are stuck in the “on” state. The continuous signaling from this receptor leads to cells that have lost the normal controls over growth.

Receptor tyrosine kinases recognize hydrophilic ligands and form a large class of membrane receptors in animal cells. Plants possess receptors with a similar overall structure and function, but they are serine–threonine kinases. These plant receptors have been named **plant receptor kinases**.

Because these receptors are performing similar functions in plant and animal cells but differ in their substrates, the duplication

and divergence of each kind of receptor kinase probably occurred after the plant–animal divergence. The proliferation of these types of signaling molecules is thought to be coincident with the independent evolution of multicellularity in each group.

In this section, we will concentrate on the RTK family of receptors that has been extensively studied in a variety of animal cells.

## RTKs are activated by autophosphorylation

Receptor tyrosine kinases have a relatively simple structure consisting of a single transmembrane domain that anchors them in the membrane, an extracellular ligand-binding domain, and an intracellular kinase domain. This kinase domain contains the catalytic site of the receptor, which acts as a protein kinase that adds phosphate groups to tyrosines. On ligand binding to a specific receptor, two of these receptor–ligand complexes associate together (often referred to as dimerization) and phosphorylate each other, a process called *autophosphorylation* (figure 9.6).

The autophosphorylation event transmits across the membrane the signal that began with the binding of the ligand to the receptor. The next step, propagation of the signal in the

**Figure 9.6 Activation of a receptor tyrosine kinase (RTK).** These membrane receptors bind hormones or growth factors that are hydrophilic and cannot cross the membrane. The receptor is a transmembrane protein with an extracellular ligand binding domain and an intracellular kinase domain. Signal transduction pathways begin with response proteins binding to phosphotyrosine on receptor, and by receptor phosphorylation of response proteins.

cytoplasm, can take a variety of different forms. These forms include activation of the tyrosine kinase domain to phosphorylate other intracellular targets or interaction of other proteins with the phosphorylated receptor.

The cellular response after activation depends on the possible response proteins in the cell. Two different cells can have the same receptor yet a different response, depending on what response proteins are present in the cytoplasm. For example fibroblast growth factor stimulates cell division in fibroblasts but stimulates nerve cells to differentiate rather than to divide.

## Phosphotyrosine domains mediate protein–protein interactions

One way that the signal from the receptor can be propagated in the cytoplasm is via proteins that bind specifically to phosphorylated tyrosines in the receptor. When the receptor is activated, regions of the protein outside of the catalytic site are phosphorylated. This creates “docking” sites for proteins that bind specifically to phosphotyrosine. The proteins that bind to these phosphorylated tyrosines can initiate intracellular events to convert the signal from the ligand into a response (see figure 9.6).

### The insulin receptor

The use of docking proteins is illustrated by the insulin receptor. The hormone insulin is part of the body’s control system to maintain a constant level of blood glucose. The role of insulin is to lower blood glucose, acting by binding to an RTK. Another protein called the *insulin response protein* binds to the phosphorylated receptor and is itself phosphorylated. The insulin response protein passes the signal on by binding to additional proteins that lead to the activation of the enzyme glycogen synthase, which converts glucose to glycogen (figure 9.7), thereby lowering blood glucose. Other proteins activated by the insulin receptor act to inhibit the synthesis of enzymes involved in making glucose, and to increase the number of glucose transporter proteins in the plasma membrane.

### Adapter proteins

Another class of proteins, **adapter proteins**, can also bind to phosphotyrosines. These proteins themselves do not participate in signal transduction but act as a link between the receptor and proteins that initiate downstream signaling events. For example, the Ras protein discussed later, is activated by adapter proteins binding to a receptor.

## Protein kinase cascades can amplify a signal

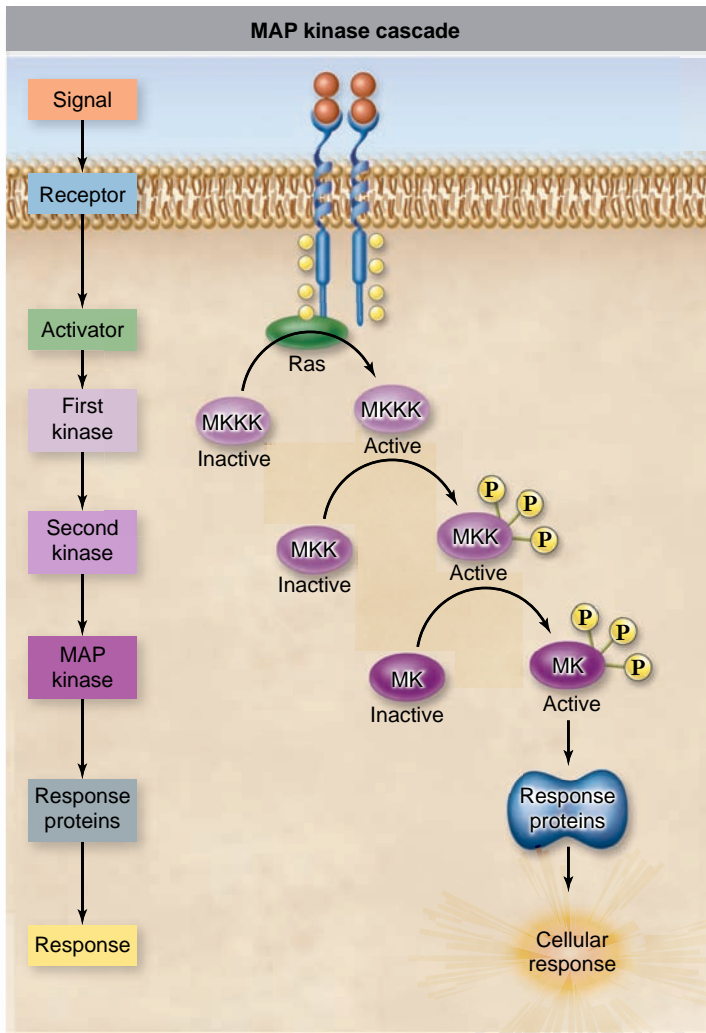

One important class of cytoplasmic kinases are **mitogen-activated protein (MAP) kinases**. A *mitogen* is a chemical that stimulates cell division by activating the normal pathways that control division. The MAP kinases are activated by a signaling module called a *phosphorylation cascade* or a **kinase cascade**. This module is a series of protein kinases that phosphorylate each other in succession. The final step in the cascade is the activation by phosphorylation of MAP kinase itself (figure 9.8).

**Figure 9.7 The insulin receptor.** The insulin receptor is a receptor tyrosine kinase that initiates a variety of cellular responses related to glucose metabolism. One signal transduction pathway that this receptor mediates leads to the activation of the enzyme glycogen synthase. This enzyme converts glucose to glycogen.

One function of a kinase cascade is to amplify the original signal. Because each step in the cascade is an enzyme, it can act on a number of substrate molecules. With each enzyme in the cascade acting on many substrates this produces a large amount of the final product (see figure 9.8). This allows a small number of initial signaling molecules to produce a large response.

The cellular response to this cascade in any particular cell depends on the targets of the MAP kinase, but usually involves phosphorylating transcription factors that then activate gene expression (chapter 16). An example of this kind of signaling

a.

b.

**Figure 9.8 MAP kinase cascade leads to signal amplification.** *a.* Phosphorylation cascade is shown as a flowchart on the left. The corresponding cellular events are shown on the right, beginning with the receptor in the plasma membrane. Each kinase is named starting with the last, the MAP kinase (MK), which is phosphorylated by a MAP kinase kinase (MKK), which is in turn phosphorylated by a MAP kinase kinase kinase (MKKK). The cascade is linked to the receptor protein by an activator protein. *b.* At each step the enzymatic action of the kinase on multiple substrates leads to amplification of the signal.

through growth factor receptors is provided in chapter 10 and illustrates how signal transduction initiated by a growth factor can control the process of cell division through a kinase cascade.

### Scaffold proteins organize kinase cascades

The proteins in a kinase cascade need to act sequentially to be effective. One way the efficiency of this process can be increased is to organize them in the cytoplasm. Proteins called *scaffold proteins* are thought to organize the components of a kinase cascade into a single protein complex, the ultimate in a signaling module. The scaffold protein binds to each individual kinase such that they are spatially organized for optimal function (figure 9.9).

The advantages of this kind of organization are many. A physically arranged sequence is clearly more efficient than one that depends on diffusion to produce the appropriate order of events. This organization also allows the segregation of signaling modules in different cytoplasmic locations.

The disadvantage of this kind of organization is that it reduces the amplification effect of the kinase cascade. Enzymes held in one place are not free to find new substrate molecules, but must rely on substrates being nearby.

The best studied example of a scaffold protein comes from mating behavior in budding yeast. Yeast cells respond to mating pheromones with changes in cell morphology and gene expression, mediated by a protein kinase cascade. A protein called Ste5 was originally identified as a protein required for mating behavior, but no enzymatic activity could be detected for this protein. It has now been shown that this protein interacts with all of the members of the kinase cascade and acts as a scaffold protein that organizes the cascade and insulates it from other signaling pathways.

**Figure 9.9 Kinase cascade can be organized by scaffold proteins.** The scaffold protein binds to each kinase in the cascade, organizing them so each substrate is next to its enzyme. This organization also sequesters the kinases from other signaling pathways in the cytoplasm.

**Figure 9.10 Ras protein links receptor tyrosine kinases to MAP kinase cascade.** Growth factor receptors often are linked to a MAP kinase cascade by the Ras protein. The figure shows the activation of the MAP kinase called extracellular regulated kinase (ERK). Activated ERK phosphorylates a number of response proteins that can act in the cytoplasm and transcription factors that move into the nucleus to turn on the genes needed for cell cycle progression.

## Ras proteins link receptors with kinase cascades

The link between the RTK and the MAP kinase cascade is a small GTP-binding protein (G protein) called **Ras**. The Ras protein is mutated in many human tumors, indicative of its central role in linking growth factor receptors to their cellular response.

The Ras protein is active when bound to GTP and inactive when bound to GDP. When an RTK, such as a growth factor receptor, is activated, it binds to adapter proteins that then act on Ras to stimulate the exchange of GDP for GTP, activating Ras. The Ras protein then activates the first kinase in the MAP kinase cascade (figure 9.10).

One key to signaling through this pathway is that Ras can regulate itself. The Ras protein has intrinsic GTPase activity, hydrolyzing GTP to GDP and  $P_i$ , leaving the GDP bound to Ras, which is now inactivated. The action of the RTK turns on Ras, which can be thought of as a switch that can turn itself off. This is one reason that stimulation of cell division by growth factors is short-lived.

## RTKs are inactivated by internalization

It is important to cells that signaling pathways are only activated transiently. Continued activation could render the cell

unable to respond to other signals or to respond inappropriately to a signal that is no longer relevant. Consequently, inactivation is as important for the control of signaling as activation. Receptor tyrosine kinases can be inactivated by two basic mechanisms—dephosphorylation and internalization. Internalization is by endocytosis, in which the receptor is taken up into the cytoplasm in a vesicle where it can be degraded or recycled.

The enzymes in the kinase cascade are all controlled by dephosphorylation by phosphatase enzymes. This leads to termination of the response at both the level of the receptor and the response proteins.

### Learning Outcomes Review 9.4

Receptor tyrosine kinases (RTK) are membrane receptors that can phosphorylate tyrosine. When activated, they autophosphorylate, creating binding domains for other proteins. These proteins transmit the signal inside the cell. One form of signaling pathway involves the MAP kinase cascade, a series of kinases that each activate the next in the series. This ends with a MAP kinase that activates transcription factors to alter gene expression.

- *Ras protein is mutated in many human cancers. What are possible reasons for this?*

**Figure 9.11** The action of G protein-coupled receptors.

G protein-coupled receptors act through a heterotrimeric G protein that links the receptor to an effector protein. When ligand binds to the receptor, it activates an associated G protein, exchanging GDP for GTP. The active G protein complex dissociates into  $G_{\alpha}$  and  $G_{\beta\gamma}$ . The  $G_{\alpha}$  subunit (bound to GTP) is shown activating an effector protein. The effector protein may act directly on cellular proteins or produce a second messenger to cause a cellular response.  $G_{\alpha}$  can hydrolyze GTP inactivating the system, then reassociate with  $G_{\beta\gamma}$ .

## 9.5 Signal Transduction Through G Protein-Coupled Receptors

### Learning Outcomes

1. Contrast signaling through GPCRs and RTKs.
2. Relate the function of second messengers to signal transduction pathways.

The single largest category of receptor type in animal cells is **G protein-coupled receptors (GPCRs)**, so named because the receptors act by coupling with a G protein. G proteins are proteins that bind guanosine nucleotides, such as Ras discussed previously.

The latest count of genes encoding GPCRs in the human genome is 799 with about half of these encoding odorant receptors involved in the sense of taste and smell. In the mouse, over 1000 different odorant receptors are involved in the sense of smell. The family of GPCRs has been subdivided into 5 groups: Rhodopsin, Secretin, Adhesion, Glutamate, and Frizzled/Taste 2 based on structure and function. The names refer to the first discovered member of each group; for example, Rhodopsin is the GPCR involved in light sensing in mammals. In this section, we will concentrate on the basic mechanism of activation and some of the possible signal transduction pathways.

### G proteins link receptors with effector proteins

The function of the G protein in signaling by GPCRs is to provide a link between a receptor that receives signals and ef-

factor proteins that produce cellular responses. The G protein functions as a switch that is turned on by the receptor. In its “on” state, the G protein activates effector proteins to cause a cellular response.

All G proteins are active when bound to GTP and inactive when bound to GDP. The main difference between the G proteins in GPCRs and the Ras protein described earlier is that these G proteins are composed of three subunits, called  $\alpha$ ,  $\beta$ , and  $\gamma$ . As a result, they are often called *heterotrimeric G proteins*. When a ligand binds to a GPCR and activates its associated G protein, the G protein exchanges GDP for GTP and dissociates into two parts consisting of the  $G_{\alpha}$  subunit bound to GTP, and the  $G_{\beta}$  and  $G_{\gamma}$  subunits together ( $G_{\beta\gamma}$ ). The signal can then be propagated by either the  $G_{\alpha}$  or the  $G_{\beta\gamma}$  components, thereby acting to turn on effector proteins. The hydrolysis of bound GTP to GDP by  $G_{\alpha}$  causes reassociation of the heterotrimer and restores the “off” state of the system (figure 9.11).

The effector proteins are usually enzymes. An effector protein might be a protein kinase that phosphorylates proteins to directly propagate the signal, or it may produce a second messenger to initiate a signal transduction pathway.

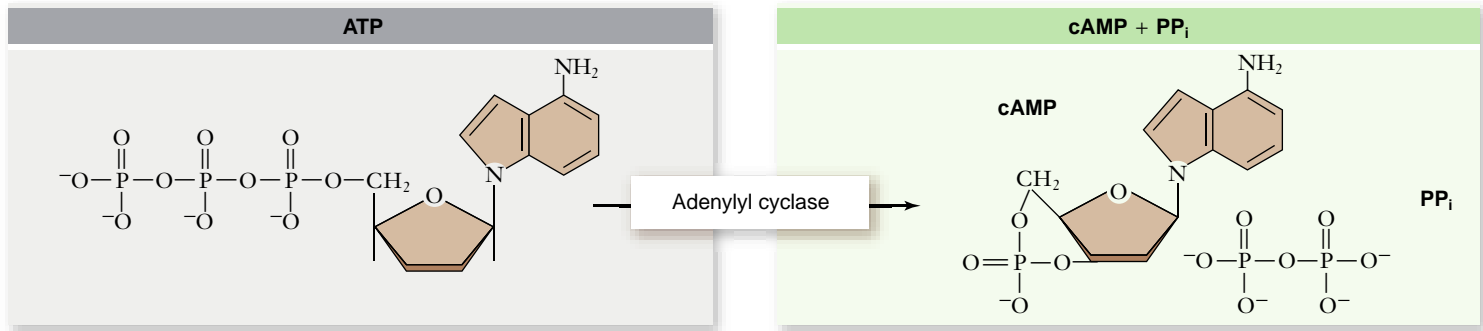

### Effector proteins produce multiple second messengers

Often, the effector proteins activated by G proteins produce a second messenger. Two of the most common effectors are *adenylyl cyclase* and *phospholipase C*, which produce cAMP and  $IP_3$  plus DAG, respectively.

#### Cyclic-AMP

All animal cells studied thus far use cAMP as a second messenger (chapter 46). When a signaling molecule binds to a GPCR that uses the enzyme **adenylyl cyclase** as an effector, a large amount of

a.

### Figure 9.12 Production of second messengers.

Second messengers are signaling molecules produced within the cell. **a.** The nucleotide ATP is converted by the enzyme adenylyl cyclase into cyclic AMP, or cAMP, and pyrophosphate (PP<sub>i</sub>). **b.** The inositol phospholipid PIP<sub>2</sub> is composed of two lipids and a phosphate attached to glycerol. The phosphate is also attached to the sugar inositol. This molecule can be cleaved by the enzyme phospholipase C to produce two different second messengers: DAG, made up of the glycerol with the two lipids, and IP<sub>3</sub>, inositol triphosphate.

b.

cAMP is produced within the cell (figure 9.12a). The cAMP then binds to and activates the enzyme protein kinase A (PKA), which adds phosphates to specific proteins in the cell (figure 9.13).

The effect of this phosphorylation on cell function depends on the identity of the cell and the proteins that are phosphorylated. In muscle cells, for example, PKA activates an enzyme necessary to break down glycogen and inhibits another enzyme necessary to synthesize glycogen. This leads to an increase in glucose available to the muscle. By contrast, in the kidney the action of PKA leads to the production of water channels that can increase the permeability of tubule cells to water.

Disruption of cAMP signaling can have a variety of effects. The symptoms of the disease cholera are due to altered cAMP levels in cells in the gut. The bacterium *Vibrio cholerae* produces a toxin that binds to a GPCR in the epithelium of the gut, causing it to be locked into an “on” state. This causes a large increase in intracellular cAMP that, in these cells, causes Cl<sup>-</sup> ions to be transported out of the cell. Water follows the Cl<sup>-</sup>, leading to diarrhea and dehydration characteristic of the disease.

The molecule cAMP is also an extracellular signal. In the slime mold *Dictyostelium discoideum*, secreted cAMP acts as a signal for aggregation under conditions of starvation.

**Figure 9.13 cAMP signaling pathway.** Extracellular signal binds to a GPCR, activating a G protein. The G protein then activates the effector protein adenylyl cyclase, which catalyzes the conversion of ATP to cAMP. The cAMP then activates protein kinase A (PKA), which phosphorylates target proteins to cause a cellular response.

## SCIENTIFIC THINKING

**Question:** What is the receptor for cAMP?

**Hypothesis:** A previously identified G protein-coupled receptor is the cAMP receptor.

**Prediction:** If the function of the cAMP receptor is removed, then cells will not respond to starvation by aggregating.

**Test:** Use G protein-coupled receptor gene to direct synthesis of antisense RNA complementary to the normal mRNA. This will eliminate gene expression by the cellular copy of the G protein-coupled receptor.

**Result:** Cells transformed with the antisense construct do not aggregate normally.

**Conclusion:** Previously identified G protein-coupled receptor is the cAMP receptor, which controls the aggregation response.

**Further Experiments:** How can this kind of experiment be used to unravel other aspects of this signaling system?

**Figure 9.14** The receptor for cAMP in *D. discoideum* is a GPCR.

Experiments have shown that the receptor for this signal is also a GPCR (figure 9.14).

### Inositol phospholipids

A common second messenger is produced from the molecules called inositol phospholipids. These are inserted into the plasma membrane by their lipid ends and have the *inositol phosphate* portion protruding into the cytoplasm. The most common inositol phospholipid is phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>). This molecule is a substrate of the effector protein phospholipase C, which cleaves PIP<sub>2</sub> to yield **diacylglycerol (DAG)** and **inositol-1,4,5-trisphosphate (IP<sub>3</sub>)** (see figure 9.12b).

**Figure 9.15** Inositol phospholipid and Ca<sup>2+</sup> signaling.

Extracellular signal binds to a GPCR activating a G protein. The G protein activates the effector protein phospholipase C, which converts PIP<sub>2</sub> to DAG and IP<sub>3</sub>. IP<sub>3</sub> is then bound to a channel-linked receptor on the endoplasmic reticular (ER) membrane, causing the ER to release stored Ca<sup>2+</sup> into the cytoplasm. The Ca<sup>2+</sup> then binds to Ca<sup>2+</sup>-binding proteins such as calmodulin and PKC to cause a cellular response.

Both of these compounds then act as second messengers with a variety of cellular effects. DAG, like cAMP, can activate a protein kinase, in this case protein kinase C (PKC).

### Calcium

Calcium ions (Ca<sup>2+</sup>) serve widely as second messengers. Ca<sup>2+</sup> levels inside the cytoplasm are normally very low (less than 10<sup>-7</sup> M), whereas outside the cell and in the endoplasmic reticulum, Ca<sup>2+</sup> levels are quite high (about 10<sup>-3</sup> M). The endoplasmic reticulum has receptor proteins that act as ion channels to release Ca<sup>2+</sup>. One of the most common of these receptors can bind the second messenger IP<sub>3</sub> to release Ca<sup>2+</sup>, linking signaling through inositol phosphates with signaling by Ca<sup>2+</sup> (figure 9.15).

The result of the outflow of Ca<sup>2+</sup> from the endoplasmic reticulum depends on the cell type. For example, in skeletal muscle cells Ca<sup>2+</sup> stimulates muscle contraction but in endocrine cells it stimulates the secretion of hormones.

Ca<sup>2+</sup> initiates some cellular responses by binding to *calmodulin*, a 148-amino-acid cytoplasmic protein that contains four binding sites for Ca<sup>2+</sup> (figure 9.16). When four Ca<sup>2+</sup> ions are bound to calmodulin, the calmodulin/Ca<sup>2+</sup> complex is able to bind to other proteins to activate them. These proteins include

**Figure 9.16 Calmodulin.** *a.* Calmodulin is a protein containing 148 amino acid residues that mediates  $\text{Ca}^{2+}$  function. *b.* When four  $\text{Ca}^{2+}$  are bound to the calmodulin molecule, it undergoes a conformational change that allows it to bind to other cytoplasmic proteins and effect cellular responses.

protein kinases, ion channels, receptor proteins, and cyclic nucleotide phosphodiesterases. These many uses of  $\text{Ca}^{2+}$  make it one of the most versatile second messengers in cells.

### Different receptors can produce the same second messengers

As mentioned previously, the two hormones glucagon and epinephrine can both stimulate liver cells to mobilize glucose. The reason that these different signals have the same effect is that they both act by the same signal transduction pathway to stimulate the breakdown and inhibit the synthesis of glycogen.

The binding of either hormone to its receptor activates a G protein that stimulates adenylyl cyclase. The production of cAMP leads to the activation of PKA, which in turn activates another protein kinase called phosphorylase kinase. Activated phosphorylase kinase then activates glycogen phosphorylase, which cleaves off units of glucose-6-phosphate from the glycogen polymer (figure 9.17). The action of multiple kinases again leads to amplification such that a few signaling molecules result in a large number of glucose molecules being released.

At the same time, PKA also phosphorylates the enzyme glycogen synthase, but in this case it inhibits the enzyme, thus preventing the synthesis of glycogen. In addition, PKA phosphorylates other proteins that activate the expression of genes encoding the enzymes needed to synthesize glucose. This convergence of signal transduction pathways from different receptors leads to the same result—glucose is mobilized.

### Receptor subtypes can lead to different effects in different cells

We also saw earlier how a single signaling molecule, epinephrine, can have different effects in different cells. One way this happens is through the existence of multiple forms of the same

receptor. The receptor for epinephrine actually has nine different subtypes, or isoforms. These are encoded by different genes and are actually different receptor molecules. The sequences of these proteins are very similar, especially in the ligand-binding domain, which allows them to bind epinephrine. They differ mainly in their cytoplasmic domains, which interact with G proteins. This leads to different isoforms activating different G proteins, thereby leading to different signal transduction pathways.

Thus, in the heart, muscle cells have one isoform of the receptor that, when bound to epinephrine, activates a G protein that activates adenylyl cyclase, leading to increased cAMP. This increases the rate and force of contraction. In the intestine, smooth muscle cells have a different isoform of the receptor that, when bound to epinephrine, activates a different G protein that inhibits adenylyl cyclase, which decreases cAMP. This has the result of relaxing the muscle.

### G protein-coupled receptors and receptor tyrosine kinases can activate the same pathways

Different receptor types can affect the same signaling module. For example, RTKs were shown to activate the MAP kinase cascade,

**Figure 9.17 Different receptors can activate the same signaling pathway.** The hormones glucagon and epinephrine both act through GPCRs. Each of these receptors acts via a G protein that activates adenylyl cyclase, producing cAMP. The activation of PKA begins a kinase cascade that leads to the breakdown of glycogen.

but GPCRs can also activate this same cascade. Similarly, the activation of phospholipase C was mentioned previously in the context of GPCR signaling, but it can also be activated by RTKs.

This cross-reactivity may appear to introduce complications into cell function, but in fact it provides the cell with an incredible amount of flexibility. Cells have a large, but limited number of intracellular signaling modules, which can be turned on and off by different kinds of membrane receptors. This leads to signaling networks that interconnect possible cellular effectors with multiple incoming signals.

The Internet represents an example of a network in which many different kinds of computers are connected globally. This network can be broken down into subnetworks that are connected to the overall network. Because of the nature of the connections, when you send an e-mail message across the Internet, it can reach its destination through many different pathways. Likewise, the cell has interconnected networks of signaling pathways in which many different signals, receptors, and response proteins are interconnected. Specific pathways like the MAP kinase cascade, or signal-

ing through second messengers like cAMP and  $\text{Ca}^{2+}$ , represent subnetworks within the global signaling network. A specific signal can activate different pathways in different cells, or different signals can activate the same pathway. We do not yet understand the cell at this level, but the field of systems biology is moving toward such global understanding of cell function.

### Learning Outcomes Review 9.5

Signaling through GPCRs uses a three-part system—a receptor, a G protein, and an effector protein. G proteins are active when bound to GTP and inactive when bound to GDP. A ligand binding to the receptor activates the G protein, which then activates the effector protein. Effector proteins include adenylyl cyclase, which produces the second messenger cAMP. Another effector protein, phospholipase C, cleaves the inositol phosphates and results in the release of  $\text{Ca}^{2+}$  from the ER.

- *There are far more GPCRs than any other receptor type. What is a possible explanation for this?*

## Chapter Review

### 9.1 Overview of Cell Communication (figure 9.1)

Cell communication requires signal molecules, called ligands, binding to specific receptor proteins producing a cellular response.

**Signaling is defined by the distance from source to receptor (figure 9.2).**

Direct contact—molecules on the plasma membrane of one cell contact the receptor molecules on an adjacent cell.

Paracrine signaling—short-lived signal molecules are released into the extracellular fluid and influence neighboring cells.

Endocrine signaling—long-lived hormones enter the circulatory system and are carried to target cells some distance away.

Synaptic signaling—short-lived neurotransmitters are released by neurons into the gap, called a synapse, between nerves and target cells.

**Signal transduction pathways lead to cellular responses.**

Intracellular events initiated by a signaling event are called signal transduction.

**Phosphorylation is key in control of protein function.**

Proteins can be controlled by phosphate added by kinase and removed by phosphatase enzymes.

### 9.2 Receptor Types (figure 9.4)

**Receptors are defined by location.**

Receptors are broadly defined as intracellular or cell-surface receptors (membrane receptors).

Membrane receptors are transmembrane proteins that transfer information across the membrane, but not the signal molecule.

**Membrane receptors include three subclasses.**

Channel-linked receptors are chemically gated ion channels that allow specific ions to pass through a central pore.

Enzymatic receptors are enzymes activated by binding a ligand; these enzymes are usually protein kinases.

G protein-coupled receptors interact with G proteins that control the function of effector proteins: enzymes or ion channels.

**Membrane receptors can generate second messengers.**

Some enzymatic and most G protein-coupled receptors produce second messengers, to relay messages in the cytoplasm.

### 9.3 Intracellular Receptors (figure 9.5)

Many cell signals are lipid-soluble and readily pass through the plasma membrane and bind to receptors in the cytoplasm or nucleus.

**Steroid hormone receptors affect gene expression.**

Steroid hormones bind cytoplasmic receptors then are transported to the nucleus. Thus, they are called nuclear receptors. These can directly affect gene expression, usually activating transcription of the genes they control.

Nuclear receptors have three functional domains: hormone-binding, DNA-binding, and transcription-activating domains.

Ligand binding changes receptor shape, releasing an inhibitor occupying the DNA-binding site.

A cell's response to a lipid-soluble signal depends on the hormone-receptor complex and the other protein coactivators present.

**Other intracellular receptors act as enzymes.**

## 9.4 Signal Transduction Through Receptor Kinases

Receptor kinases in plants and animals recognize hydrophilic ligands and influence the cell cycle, cell migration, cell metabolism, and cell proliferation.

Because they are involved in growth control, alterations of receptor kinases and their signaling pathways can lead to cancer.

### *RTKs are activated by autophosphorylation.*

The activated receptor can also phosphorylate other intracellular proteins.

### *Phosphotyrosine domains mediate protein–protein interactions.*

Adapter proteins can bind to phosphotyrosine and act as links between the receptors and downstream signaling events.

### *Protein kinase cascades can amplify a signal.*

### *Scaffold proteins organize kinase cascades.*

Scaffold proteins and protein kinases form a single complex where the enzymes act sequentially and are optimally functional.

Internalized receptors are degraded or recycled.

### *Ras proteins link receptors with kinase cascades.*

### *RTKs are inactivated by internalization.*

## 9.5 Signal Transduction Through G Protein-Coupled Receptors (figure 9.11)

G protein-coupled receptors function through activation of G proteins.

### *G proteins link receptors with effector proteins.*

G proteins are active bound to GTP and inactive bound to GDP. Receptors promote exchange of GDP for GTP.

The activated G protein dissociates into two parts,  $G_\alpha$  and  $G_{\beta\gamma}$ , each of which can act on effector proteins.

$G_\alpha$  also hydrolyzes GTP to GDP to inactivate the G protein.

### *Effector proteins produce multiple second messengers.*

Two common effector proteins are adenylyl cyclase and phospholipase C, which produce second messengers known as cAMP, and DAG and  $IP_3$ , respectively.

$Ca^{2+}$  is also a second messenger.  $Ca^{2+}$  release is triggered by  $IP_3$  binding to channel-linked receptors in the ER.

$Ca^{2+}$  can bind to a cytoplasmic protein calmodulin, which in turn activates other proteins, producing a variety of responses.

### *Different receptors can produce the same second messengers.*

Different GPCR receptors can converge to activate the same effector enzyme and thus produce the same second messenger.

### *Receptor subtypes can lead to different effects in different cells.*

Epinephrine causes increased contraction in heart muscle but relaxation in smooth muscle.

### *G protein-coupled receptors and receptor tyrosine kinases can activate the same pathways.*

Both RTKs and GPCRs can activate MAP kinase cascades.

## Review Questions

### UNDERSTAND

- Paracrine signaling is characterized by ligands that are
  - produced by the cell itself.
  - secreted by neighboring cells.
  - present on the plasma membrane of neighboring cells.
  - secreted by distant cells.
- Signal transduction pathways
  - are necessary for signals to cross the membrane.
  - include the intracellular events stimulated by an extracellular signal.
  - include the extracellular events stimulated by an intracellular signal.
  - are only found in cases where the signal can cross the membrane.
- The function of a \_\_\_\_\_ is to add phosphates to proteins, whereas a \_\_\_\_\_ functions to remove the phosphates.
  - tyrosine; serine
  - protein phosphatase; protein dephosphatase
  - protein kinase; protein phosphatase
  - receptor; ligand
- Which of the following receptor types is not a membrane receptor?
  - Channel-linked receptor
  - Enzymatic receptor
  - G protein-coupled receptor
  - Steroid hormone receptors
- How does the function of an intracellular receptor differ from that of a membrane receptor?
  - The intracellular receptor binds a ligand.
  - The intracellular receptor binds DNA.
  - The intracellular receptor activates a kinase.
  - The intracellular receptor functions as a second messenger.
- Signaling through receptor tyrosine kinases often
  - leads to the production of the second messenger cAMP.
  - leads to the production of the second messenger  $IP_3$ .
  - stimulates gene expression directly.
  - leads to the activation of a cascade of kinase enzymes.

7. What is the function of Ras during tyrosine kinase cell signaling?
  - a. It activates the opening of channel-linked receptors.
  - b. It is an enzyme that synthesizes second messengers.
  - c. It links the receptor protein to the MAP kinase pathway.
  - d. It phosphorylates other enzymes as part of a pathway.
8. Which of the following best describes the immediate effect of ligand binding to a G protein-coupled receptor?
  - a. The G protein trimer releases a GDP and binds a GTP.
  - b. The G protein trimer dissociates from the receptor.
  - c. The G protein trimer interacts with an effector protein.
  - d. The  $\alpha$  subunit of the G protein becomes phosphorylated.
- c. may be different target proteins in different cells' signal transduction pathways.
- d. all of the above.
6. The receptors for steroid hormones and peptide hormones are fundamentally different because
  - a. of the great difference in size of the molecule.
  - b. peptides are one of the four major polymers and steroids are simple ringed structures.
  - c. peptides are hydrophilic and steroids are hydrophobic.
  - d. peptides are hydrophobic and steroids are hydrophilic.

## APPLY

1. The action of steroid hormone receptors
  - a. stimulates a cascade of phosphorylation reactions.
  - b. leads to a direct affect on gene expression.
  - c. stimulates a second messenger that activates gene expression.
  - d. activates a G protein that stimulates gene expression.
2. The ion  $\text{Ca}^{++}$  can act as a second messenger because it is
  - a. produced by the enzyme calcium synthase.
  - b. normally at a high level in the cytoplasm.
  - c. normally at a low level in the cytoplasm.
  - d. stored in the cytoplasm.
3. The response to signaling through G protein-coupled receptors can vary in different cells because
  - a. all receptors act through the same G protein.
  - b. different isoforms of a receptor bind the same ligand but activate different effectors.
  - c. the amount of receptor in the membrane differs in different cell types.
  - d. different receptors can activate the same effector.
4. Signaling through G proteins is self-limiting because G proteins
  - a. are degraded, shutting the pathway off.
  - b. only bind to GDP and not GTP.
  - c. are internalized, shutting the pathway off.
  - d. hydrolyze GTP to GDP inactivating themselves.
5. The same signal can have different effects in different cells because there
  - a. are different receptor subtypes that initiate different signal transduction pathways.
  - b. may be different coactivators in different cells.

## SYNTHESIZE

1. Describe the common features found in all examples of cellular signaling discussed in this chapter. Provide examples to illustrate your answer.
2. The sheet of cells that form the gut epithelium folds into peaks called villi and valleys called crypts. The cells within the crypt region secrete a protein, Netrin-1, that becomes concentrated within the crypts. Netrin-1 is the ligand for a receptor protein that is found on the surface of all gut epithelial cells. Netrin-1 binding triggers a signal pathway that promotes cell growth. Gut epithelial cells undergo apoptosis (cell death) in the absence of Netrin-1 ligand binding.
  - a. How would you characterize the type of signaling (autocrine, paracrine, endocrine) found in this system?
  - b. Predict where the greatest amount of cell growth and cell death would occur in the epithelium.
  - c. The loss of the Netrin-1 receptor is associated with some types of colon cancer. Suggest an explanation for the link between this signaling pathway and tumor formation.

## How Cells Divide

### Chapter Outline

- 10.1 Bacterial Cell Division
- 10.2 Eukaryotic Chromosomes
- 10.3 Overview of the Eukaryotic Cell Cycle
- 10.4 Interphase: Preparation for Mitosis
- 10.5 M Phase: Chromosome Segregation and the Division of Cytoplasmic Contents
- 10.6 Control of the Cell Cycle

### Introduction

All species of organisms—bacteria, alligators, the weeds in a lawn—grow and reproduce. From the smallest creature to the largest, all species produce offspring like themselves and pass on the hereditary information that makes them what they are. In this chapter, we examine how cells, like the white blood cell shown in the figure, divide and reproduce. Cell division is necessary for the growth of organisms, for wound healing, and to replace cells that are lost regularly, such as those in your skin and in the lining of your gut. The mechanism of cell reproduction and its biological consequences have changed significantly during the evolution of life on Earth. The process is complex in eukaryotes, involving both the replication of chromosomes and their separation into daughter cells. Much of what we are learning about the causes of cancer relates to how cells control this process, and in particular their tendency to divide, a mechanism that in broad outline remains the same in all eukaryotes.

## 10.1 Bacterial Cell Division

### Learning Outcome

1. Describe the process of binary fission.

Bacteria divide as a way of reproducing themselves. Although bacteria exchange DNA, they do not have a sexual cycle like eukaryotes. Thus all growth in a bacterial population is due to division to produce new cells. The reproduction of bacteria is clonal—that is, each cell produced by cell division is an identical copy of the original cell.

### Binary fission is a simple form of cell division

Cell division in both bacterial and eukaryotic cells produces two new cells with the same genetic information as the original. Despite the differences in these cell types, the essentials of the process are the same: duplication and segregation of genetic information into daughter cells, and division of cellular contents. We begin by looking at the simpler process, **binary fission**, which occurs in bacteria.

Most bacteria have a genome made up of a single, circular DNA molecule. In spite of its apparent simplicity, the DNA molecule of the bacterium *Escherichia coli* is actually on the order of 500 times longer than the cell itself! Thus, this “simple” structure is actually packaged very tightly to fit into the cell. Although not found in a nucleus, the DNA is located in a region called the *nucleoid* that is distinct from the cytoplasm around it.

The compaction and organization of the nucleoid involves a class of proteins called structural maintenance of chromosome, or SMC, proteins. These are ancient proteins that have evolved to perform a number of roles related to DNA compression and cohesion. In eukaryotes the cohesin and condensin proteins discussed later in the chapter are SMC proteins.

During binary fission, the chromosome is replicated, and the two products are partitioned to each end of the cell prior to the actual division of the cell. One key feature of bacterial cell division is that replication and partitioning of the chromosome occur as a concerted process. In contrast, DNA replication in eukaryotic cells occurs early in division, and chromosome separation occurs much later.

### Proteins control chromosome separation and septum formation

Binary fission begins with the replication of the bacterial DNA at a specific site—the origin of replication (see chapter 14)—and proceeds both directions around the circular DNA to a specific site of termination (figure 10.1). The cell grows by elongation, and division occurs roughly at midcell. For many years, it was thought that newly replicated *E. coli* DNA molecules were passively segregated by attachment to and growth of the membrane as the cell elongated. Experiments that follow the movement of the origin of replication show that it is at

Figure 10.1 Binary fission.

**Figure 10.2 The FtsZ protein.** In these dividing *E. coli* bacteria, the FtsZ protein is labeled with fluorescent dye to show its location during binary fission. The protein assembles into a ring at approximately the midpoint of the cell, where it facilitates septation and cell division. Bacteria carrying mutations in the *FtsZ* gene are unable to divide.

midcell prior to replication, then the newly replicated origins move toward opposite ends of the cell. This movement is faster than the rate of elongation, showing that growth alone is not enough. The origins appear to be captured at the one quarter and three quarter positions relative to the length of the cell, which will be midcell of the two daughter cells.

Although the actual mechanism of chromosome segregation is unclear, the order of events is not. During replication, first the origin, then the rest of the newly replicated chromosomes are moved to opposite ends of the cell as two new nucleoids are assembled. The final event of replication is decatenation (untangling) of the final replication products. After replication and segregation, the midcell region is cleared of daughter

nucleoids, and division occurs. The force behind chromosome segregation has been attributed to DNA replication itself, transcription, and the polymerization of actin-like molecules. At this point, no single model appears to explain the process, and it may involve more than one.

The cell's other components are partitioned by the growth of new membrane and production of the **septum** (see figure 10.1). This process, termed **septation**, usually occurs at the midpoint of the cell. It begins with the formation of a ring composed of many copies of the protein FtsZ (figure 10.2). Next, accumulation of a number of other proteins occurs, including ones embedded in the membrane. This structure contracts inward radially until the cell pinches off into two new cells. The midcell location of the FtsZ ring is caused by an oscillation between the two poles of an inhibitor of FtsZ formation.

The FtsZ protein is found in most prokaryotes, including archaea. It can form filaments and rings, and recent three-dimensional crystals show a high degree of similarity to eukaryotic tubulin. However, its role in bacterial division is quite different from the role of tubulin in mitosis in eukaryotes.

The evolution of eukaryotic cells included much more complex genomes composed of multiple linear chromosomes housed in a membrane-bounded nucleus. These complex genomes may be possible due to the evolution of mechanisms that delay chromosome separation after replication. Although it is unclear how this ability to keep chromosomes together evolved, it does seem more closely related to binary fission than we once thought (figure 10.3).

**Figure 10.3 A comparison of protein assemblies during cell division among different organisms.** The prokaryotic protein FtsZ has a structure that is similar to that of the eukaryotic protein tubulin. Tubulin is the protein component of microtubules, which are fibers used to separate chromosomes in eukaryotic cell division.

### Learning Outcome Review 10.1

Most bacteria divide by binary fission, a form of cell division in which DNA replication and segregation occur simultaneously. This process involves active partitioning of the single bacterial chromosome and positioning of the site of septation.

- Would binary fission work as well if bacteria had many chromosomes?

## 10.2 Eukaryotic Chromosomes

### Learning Outcomes

1. Describe the structure of eukaryotic chromosomes.
2. Distinguish between homologues and sister chromatids.

TABLE 10.1		Chromosome Number in Selected Eukaryotes
Group	Total Number of Chromosomes	
<i>F U N G I</i>		
<i>Neurospora</i> (haploid)	7	
<i>Saccharomyces</i> (a yeast)	16	
<i>I N S E C T S</i>		
Mosquito	6	
<i>Drosophila</i>	8	
Honeybee	diploid females 32, haploid males 16	
Silkworm	56	
<i>P L A N T S</i>		
<i>Haplopappus gracilis</i>	2	
Garden pea	14	
Corn	20	
Bread wheat	42	
Sugarcane	80	
Horsetail	216	
Adder's tongue fern	1262	
<i>V E R T E B R A T E S</i>		
Opossum	22	
Frog	26	
Mouse	40	
Human	46	
Chimpanzee	48	
Horse	64	
Chicken	78	
Dog	78	

Chromosomes were first observed by the German embryologist Walther Flemming (1843–1905) in 1879, while he was examining the rapidly dividing cells of salamander larvae. When Flemming looked at the cells through what would now be a rather primitive light microscope, he saw minute threads within their nuclei that appeared to be dividing lengthwise. Flemming called their division **mitosis**, based on the Greek word *mitos*, meaning “thread.”

### Chromosome number varies among species

Since their initial discovery, chromosomes have been found in the cells of all eukaryotes examined. Their number may vary enormously from one species to another. A few kinds of organisms have only a single pair of chromosomes, whereas some ferns have more than 500 pairs (table 10.1). Most eukaryotes have between 10 and 50 chromosomes in their body cells.

Human cells each have 46 chromosomes, consisting of 23 nearly identical pairs (figure 10.4). Each of these 46 chromosomes contains hundreds or thousands of genes that play important roles in determining how a person's body develops and functions. Human embryos missing even one chromosome, a condition called *monosomy*, do not survive in most cases. Having an extra copy of any one chromosome, a condition called *trisomy*, is usually fatal except where the smallest chromosomes are involved. (You'll learn more about human chromosome abnormalities in chapter 13.)

### Eukaryotic chromosomes exhibit complex structure

Researchers have learned a great deal about chromosome structure and composition in the more than 125 years since their

**Figure 10.4 Human chromosomes.** This scanning electron micrograph shows human chromosomes as they appear immediately before nuclear division. Each DNA molecule has already replicated, forming identical copies held together at a visible constriction called the centromere. False color has been added to the chromosomes.

discovery. But despite intense research, the exact structure of eukaryotic chromosomes during the cell cycle remains unclear. The structures described in this chapter represent the currently accepted model.

### Composition of chromatin

Chromosomes are composed of *chromatin*, a complex of DNA and protein; most chromosomes are about 40% DNA and 60% protein. A significant amount of RNA is also associated with chromosomes because chromosomes are the sites of RNA synthesis.

The DNA of a single chromosome is one very long, double-stranded fiber that extends unbroken through the chromosome's entire length. A typical human chromosome contains about 140 million ( $1.4 \times 10^8$ ) nucleotides in its DNA. If we think of each nucleotide as a "word," then the amount of information an average chromosome contains would fill about 280 printed books of 1000 pages each, with 500 "words" per page.

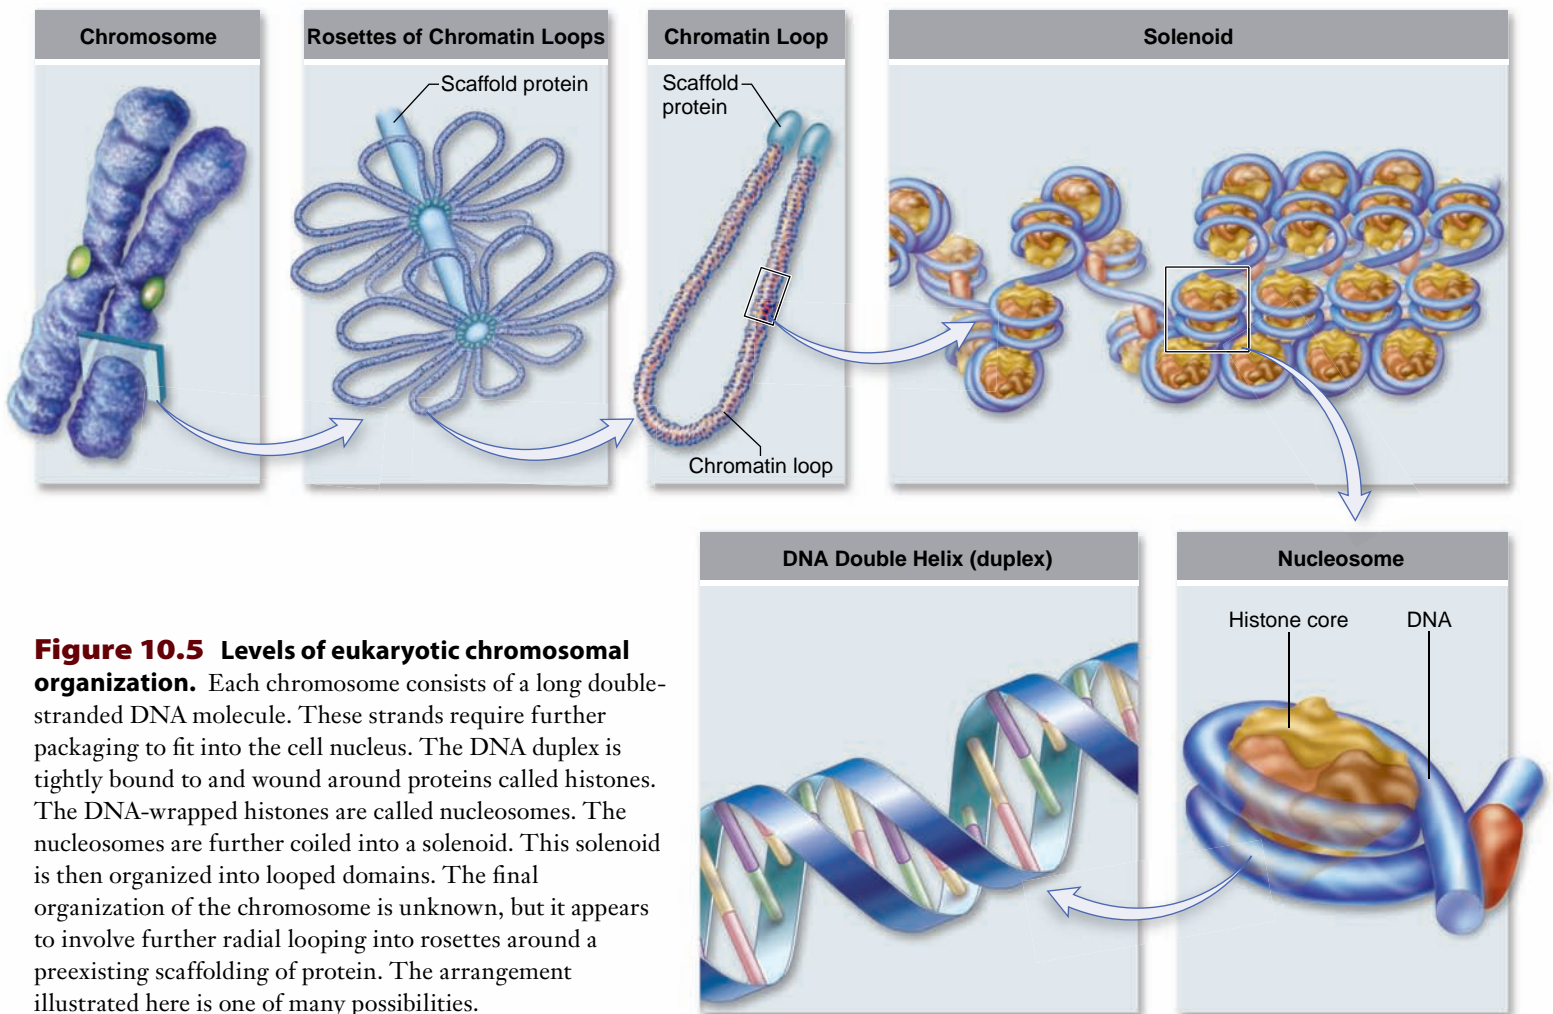

If we could lay out the strand of DNA from a single chromosome in a straight line, it would be about 5 cm (2 in.) long. Fitting such a strand into a cell nucleus is like cramming a string the length of a football field into a baseball—and that's only 1 of 46 chromosomes! In the cell, however, the DNA is coiled, allowing it to fit into a much smaller space than would otherwise be possible.

The organization of chromatin in the nondividing nucleus is not well understood, but geneticists have recognized for years that some domains of chromatin, called **heterochromatin**, are not expressed, and other domains of chromatin, called **euchromatin**, are expressed. This genetically measurable state is also related to the physical state of chromatin, although researchers are just beginning to see the details.

### Chromosome structure

If we gently disrupt a eukaryotic nucleus and examine the DNA with an electron microscope, we find that it resembles a string of beads (figure 10.5). Every 200 nucleotides (nt), the DNA duplex (double strand) is coiled around a core of eight **histone proteins**. Unlike most proteins, which have an overall negative charge, histones are positively charged because of an abundance of the basic amino acids arginine and lysine. Thus, they are strongly attracted to the negatively charged phosphate groups of the DNA, and the histone cores act as "magnetic forms" that promote and guide the coiling of the DNA. The complex of DNA and histone proteins is termed a **nucleosome**.

Further coiling occurs when the string of nucleosomes is wrapped into higher order coils called *solenoids*. The precise path of this higher order folding of chromatin is still a subject of some debate, but it leads to a fiber with a diameter of 30 nm and thus is often called the 30-nm fiber. This 30-nm fiber is the usual state of interphase (nondividing) chromatin.

**Figure 10.5 Levels of eukaryotic chromosomal organization.** Each chromosome consists of a long double-stranded DNA molecule. These strands require further packaging to fit into the cell nucleus. The DNA duplex is tightly bound to and wound around proteins called histones. The DNA-wrapped histones are called nucleosomes. The nucleosomes are further coiled into a solenoid. This solenoid is then organized into looped domains. The final organization of the chromosome is unknown, but it appears to involve further radial looping into rosettes around a preexisting scaffolding of protein. The arrangement illustrated here is one of many possibilities.

During mitosis the chromatin in the solenoid is arranged around a scaffold of protein assembled at this time to achieve maximum compaction of the chromosomes. This process prepares the chromosomes for the events of mitosis described later. The exact nature of this compaction is unknown, but one long-standing model involves radial looping of the solenoid about the protein scaffold, aided by a complex of proteins called **condensin**.

### Chromosome karyotypes

Chromosomes vary in size, staining properties, the location of the centromere (a constriction found on all chromosomes, described shortly), the relative length of the two arms on either side of the centromere, and the positions of constricted regions along the arms. The particular array of chromosomes an individual organism possesses is called its **karyotype**. The karyotype in figure 10.6 shows the set of chromosomes from a normal human cell.

When defining the number of different chromosomes in a species, geneticists count the **haploid** ( $n$ ) number of chromosomes. This refers to one complete set of chromosomes necessary to define an organism. For humans and many other species, the total number of chromosomes in a cell is called the **diploid** ( $2n$ ) number, which is twice the haploid number. For humans, the haploid number is 23 and the diploid number is 46. Diploid

**Figure 10.6 A human karyotype.** The individual chromosomes that make up the 23 pairs differ widely in size and in centromere position. In this preparation of a male karyotype, the chromosomes have been specifically stained to indicate differences in their composition and to distinguish them clearly from one another. Notice that members of a chromosome pair are very similar but not identical.

**Figure 10.7 The difference between homologous chromosomes and sister chromatids.** Homologous chromosomes are the maternal and paternal copies of the same chromosome—say, chromosome number 16. Sister chromatids are the two replicas of a single chromosome held together at their centromeres by cohesin proteins after DNA replication. The kinetochore (described later in the chapter) is composed of proteins found at the centromere that attach to microtubules during mitosis.

chromosomes reflect the equal genetic contribution that each parent makes to offspring. We refer to the maternal and paternal chromosomes as being **homologous**, and each one of the pair is termed a **homologue**.

### Chromosome replication

Chromosomes as seen in a karyotype are only present for a brief period during cell division. Prior to replicating, each chromosome is composed of a single DNA molecule that is arranged into the 30-nm fiber described earlier. After replication, each chromosome is composed of two identical DNA molecules held together by a complex of proteins called **cohesins**. As the chromosomes become more condensed and arranged about the protein scaffold, they become visible as two strands that are held together. At this point, we still call this one chromosome, but it is composed of two sister **chromatids** (figure 10.7).

The fact that the products of replication are held together is critical to the division process. One problem that a cell must solve is how to ensure that each new cell receives a complete set of chromosomes. If we were designing a system, we might use some kind of label to identify each chromosome, much like most of us use when we duplicate files on a computer. The cell has no mechanism to label chromosomes; instead, it keeps the products of replication together until the moment of chromosome segregation, ensuring that one copy of each chromosome goes to each daughter cell. This separation of sister chromatids is the key event in the mitotic process described in detail shortly.

## Learning Outcomes Review 10.2

Eukaryotic chromosomes are complex structures that can be compacted for cell division. During interphase, DNA is coiled around proteins into a structure called a nucleosome. The string of nucleosomes is further coiled into a solenoid (30-nm fiber). Diploid cells contain a maternal and paternal copy, or homologue, for each chromosome. After chromosome replication, each homologue consists of two sister chromatids. The chromatids are held together by proteins called cohesins.

- Is chromosome number related to organismal complexity?

## 10.3 Overview of the Eukaryotic Cell Cycle

### Learning Outcome

1. Describe the eukaryotic cell cycle.

Compared with prokaryotes, the increased size and more complex organization of eukaryotic genomes required radical changes in the partitioning of replicated genomes into daughter cells. The **cell cycle** requires the duplication of the genome, its accurate segregation, and the division of cellular contents.

### The cell cycle is divided into five phases

The cell cycle is divided into phases based on the key events of genome duplication and segregation. The cell cycle is usually diagrammed using the metaphor of a clock face (figure 10.8).

- **G<sub>1</sub> (gap phase 1)** is the primary growth phase of the cell. The term *gap phase* refers to its filling the gap between cytokinesis and DNA synthesis. For most cells, this is the longest phase.
- **S (synthesis)** is the phase in which the cell synthesizes a replica of the genome.
- **G<sub>2</sub> (gap phase 2)** is the second growth phase, and preparation for separation of the newly replicated genome. This phase fills the gap between DNA synthesis and the beginning of mitosis. During this phase, mitochondria and other organelles replicate, and microtubules begin to assemble at a spindle.
  - G<sub>1</sub>, S, and G<sub>2</sub> together constitute **interphase**, the portion of the cell cycle between cell divisions.
- **Mitosis** is the phase of the cell cycle in which the spindle apparatus assembles, binds to the chromosomes, and moves the sister chromatids apart. Mitosis is the essential step in the separation of the two daughter genomes. It is traditionally subdivided into five stages: prophase, prometaphase, metaphase, anaphase, and telophase.
- **Cytokinesis** is the phase of the cell cycle when the cytoplasm divides, creating two daughter cells. In animal

cells, the microtubule spindle helps position a contracting ring of actin that constricts like a drawstring to pinch the cell in two. In cells with a cell wall, such as plant cells, a plate forms between the dividing cells.

Mitosis and cytokinesis together are usually referred to collectively as M phase, to distinguish the dividing phase from interphase.

### The duration of the cell cycle varies depending on cell type

The time it takes to complete a cell cycle varies greatly. Cells in animal embryos can complete their cell cycle in under 20 min; the shortest known animal nuclear division cycles occur in fruit fly embryos (8 min). These cells simply divide their nuclei as quickly as they can replicate their DNA, without cell growth. Half of their cycle is taken up by S, half by M, and essentially none by G<sub>1</sub> or G<sub>2</sub>.

Because mature cells require time to grow, most of their cycles are much longer than those of embryonic tissue. Typically, a dividing mammalian cell completes its cell cycle in about 24 hr, but some cells, such as certain cells in the human liver, have cell cycles lasting more than a year. During the cycle, growth occurs throughout the G<sub>1</sub> and G<sub>2</sub> phases, as well as during the S phase. The M phase takes only about an hour, a small fraction of the entire cycle.

Most of the variation in the length of the cell cycle between organisms or cell types occurs in the G<sub>1</sub> phase. Cells often pause in G<sub>1</sub> before DNA replication and enter a resting state called the **G<sub>0</sub> phase**; cells may remain in this phase for

**Figure 10.8 The cell cycle.** The cell cycle is depicted as a circle. The first gap phase, G<sub>1</sub>, involves growth and preparation for DNA synthesis. During S phase, a copy of the genome is synthesized. The second gap phase, G<sub>2</sub>, prepares the cell for mitosis. During mitosis, replicated chromosomes are partitioned. Cytokinesis divides the cell into two cells with identical genomes.

days to years before resuming cell division. At any given time, most of the cells in an animal's body are in  $G_0$  phase. Some, such as muscle and nerve cells, remain there permanently; others, such as liver cells, can resume  $G_1$  phase in response to factors released during injury.

### Learning Outcome Review 10.3

Cell division in eukaryotes is a complex process that involves five phases: a first gap phase ( $G_1$ ); a DNA synthesis phase (S); a second gap phase ( $G_2$ ); mitosis (M), during which chromatids are separated; and cytokinesis in which a cell becomes two separate cells.

- **When during the cycle is a cell irreversibly committed to dividing?**

## 10.4 Interphase: Preparation for Mitosis

### Learning Outcomes

1. Describe the events that take place during interphase.
2. Explain the structure of the centromere after S phase.

The events that occur during interphase—the  $G_1$ , S, and  $G_2$  phases—are very important for the successful completion of mitosis. During  $G_1$ , cells undergo the major portion of their growth. During the S phase, each chromosome replicates to produce two sister chromatids, which remain attached to each other at the centromere. In the  $G_2$  phase, the chromosomes coil even more tightly.

The **centromere** is a point of constriction on the chromosome containing certain repeated DNA sequences that bind specific proteins. These proteins make up a disklike structure called the **kinetochore**. This disk functions as an attachment site for microtubules necessary to separate the chromosomes during cell division (figure 10.9). As seen in figure 10.6, each chromosome's centromere is located at a characteristic site along the length of the chromosome.

After the S phase, the sister chromatids appear to share a common centromere, but at the molecular level the DNA of the centromere has actually already replicated, so there are two complete DNA molecules. Functionally, however, the two chromatids have a single centromere due to their being attached by cohesin proteins at the centromere site (figure 10.10). In metazoan animals, most of the cohesins that hold sister chromatids together after replication appear to be replaced by condensin during the process of chromosome compaction. This leaves the chromosomes still attached tightly at the centromere, but loosely attached elsewhere.

The cell grows throughout interphase. The  $G_1$  and  $G_2$  segments of interphase are periods of active growth, during which proteins are synthesized and cell organelles are pro-

**Figure 10.9 Kinetochores.** Separation of sister chromatids during mitosis depends on microtubules attaching to proteins found in the kinetochore. These kinetochore proteins are assembled on the centromere of chromosomes. The centromeres of the two sister chromatids are held together by cohesin proteins.

duced. The cell's DNA replicates only during the S phase of the cell cycle.

After the chromosomes have replicated in S phase, they remain fully extended and uncoiled, although cohesin proteins are associated with them at this stage. In  $G_2$  phase, they begin

**Figure 10.10 Proteins found at the centromere.** In this image DNA, a cohesin protein and a kinetochore protein have all been labeled with a different colored fluorescent dye. Cohesin (red), which holds centromeres together, lies between the sister chromatids (blue). Each sister chromatid has its own separate kinetochore (green).

the process of condensation, coiling ever more tightly. Special *motor proteins* are involved in the rapid final condensation of the chromosomes that occurs early in mitosis. Also during G<sub>2</sub> phase, the cells begin to assemble the machinery they will later use to move the chromosomes to opposite poles of the cell. In animal cells, a pair of microtubule-organizing centers called *centrioles* replicate, producing one for each pole. All eukaryotic cells undertake an extensive synthesis of **tubulin**, the protein that forms microtubules.

### Learning Outcomes Review 10.4

Interphase includes the G<sub>1</sub>, S, and G<sub>2</sub> phases of the cell cycle. During interphase, the cell grows; replicates chromosomes, organelles, and centrioles; and synthesizes components needed for mitosis, including tubulin. Cohesin proteins hold chromatids together at the centromere of each chromosome.

- How would a mutation that deleted cohesin proteins affect cell division?

## 10.5 M Phase: Chromosome Segregation and the Division of Cytoplasmic Contents

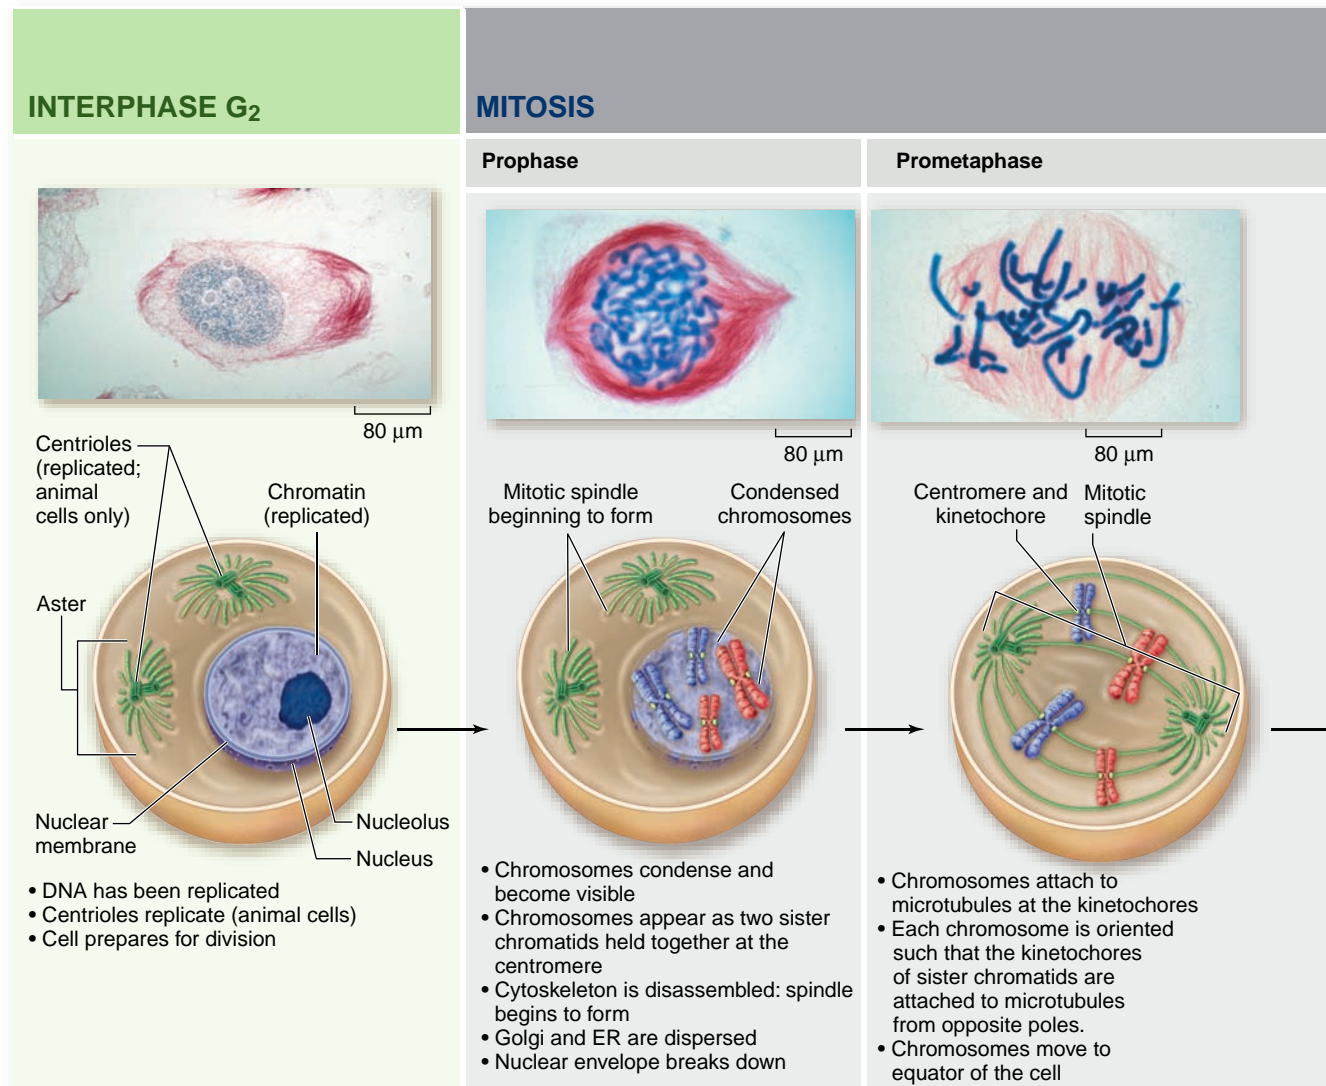

### Learning Outcomes

1. Describe the phases of mitosis.
2. Understand the importance of chromatid cohesion.
3. Compare cytokinesis in plants and animals.

The process of mitosis is one of the most dramatic and beautiful biological processes that can be readily observed. In our attempts to understand this process, we have divided it into discrete phases but it should always be remembered that this is a dynamic, continuous process, not a set of discrete steps. This process is shown both schematically and in micrographs in figure 10.11.

**Figure 10.11 Mitosis and cytokinesis.**

Mitosis is conventionally divided into five stages—prophase, prometaphase, metaphase, anaphase, and telophase—which together act to separate duplicated chromosomes. This is followed by cytokinesis, which divides the cell into two separate cells. Photos depict mitosis and cytokinesis in a plant, the African blood lily (*Haemanthus katherinae*), with chromosomes stained blue and microtubules stained red. Drawings depict mitosis and cytokinesis in animal cells.

## During prophase, the mitotic apparatus forms

When the chromosome condensation initiated in  $G_2$  phase reaches the point at which individual condensed chromosomes first become visible with the light microscope, the first stage of mitosis, **prophase**, has begun. The condensation process continues throughout prophase; consequently, chromosomes that start prophase as minute threads appear quite bulky before its conclusion. Ribosomal RNA synthesis ceases when the portion of the chromosome bearing the rRNA genes is condensed.

### The spindle and centrioles

The assembly of the **spindle** apparatus that will later separate the sister chromatids occurs during prophase. The normal microtubule structure in the cell disassembled in the  $G_2$  phase is replaced by the spindle. In animal cells, the two centriole pairs formed during  $G_2$  phase begin to move apart early in prophase, forming between them an axis of microtubules referred to as spindle fibers. By the time the centrioles reach the opposite poles of the cell, they have established a bridge of microtubules,

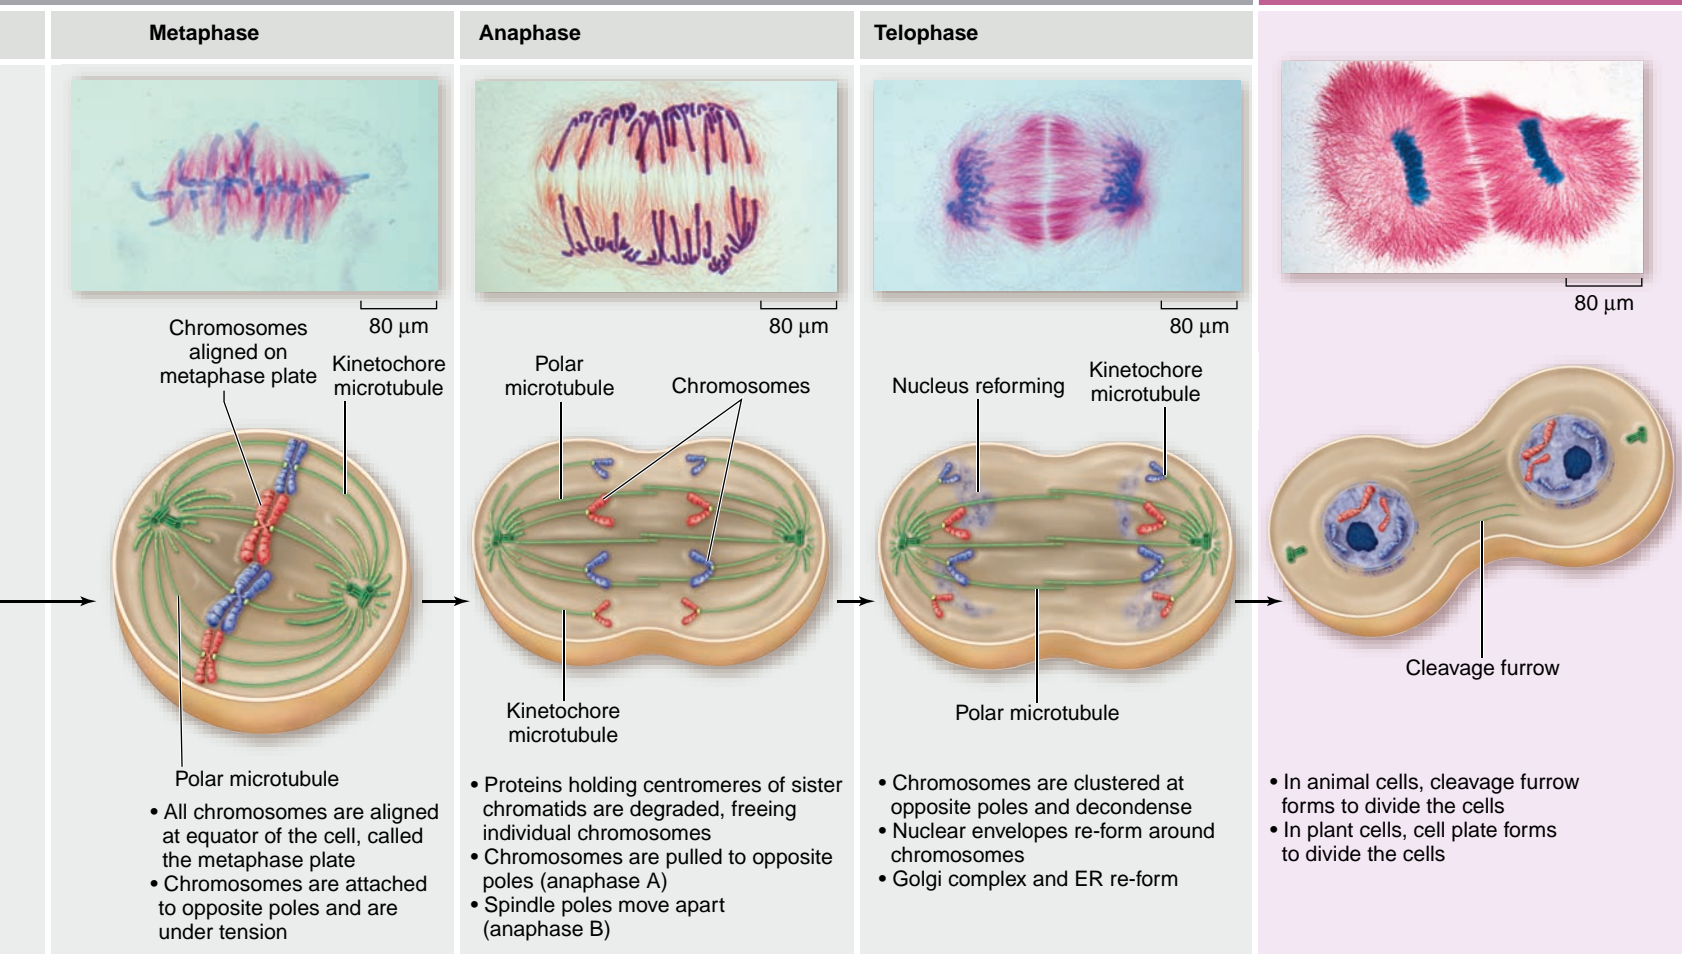

called the spindle apparatus, between them. In plant cells, a similar bridge of microtubular fibers forms between opposite poles of the cell, although centrioles are absent in plant cells.

In animal cell mitosis, the centrioles extend a radial array of microtubules toward the nearby plasma membrane when they reach the poles of the cell. This arrangement of microtubules is called an **aster**. Although the aster's function is not fully understood, it probably braces the centrioles against the membrane and stiffens the point of microtubular attachment during the retraction of the spindle. Plant cells, which have rigid cell walls, do not form asters.

### Breakdown of the nuclear envelope

During the formation of the spindle apparatus, the nuclear envelope breaks down, and the endoplasmic reticulum reabsorbs its components. At this point, the microtubular spindle fibers extend completely across the cell, from one pole to the other. Their orientation determines the plane in which the cell will subsequently divide, through the center of the cell at right angles to the spindle apparatus.

## CYTOKINESIS

## During prometaphase, chromosomes attach to the spindle

The transition from prophase to **prometaphase** occurs following the disassembly of the nuclear envelope. During prometaphase the condensed chromosomes become attached to the spindle by their kinetochores. Each chromosome possesses two kinetochores, one attached to the centromere region of each sister chromatid (see figure 10.9).

### Microtubule attachment

As prometaphase continues, a second group of microtubules grow from the poles of the cell toward the centromeres. These microtubules are captured by the kinetochores on each pair of sister chromatids. This results in the kinetochores of each sister chromatid being connected to opposite poles of the spindle.

This bipolar attachment is critical to the process of mitosis; any mistakes in microtubule positioning can be disastrous. For example, the attachment of the kinetochores of both sister chromatids to the same pole leads to a failure of sister chromatid separation, and they will be pulled to the same pole ending up in the same daughter cell, with the other daughter cell missing that chromosome.

### Movement of chromosomes to the cell center

With each chromosome attached to the spindle by microtubules from opposite poles to the kinetochores of sister chromatids, the chromosomes begin to move to the center of the cell. This movement is jerky, as if a chromosome is being pulled toward both poles at the same time. This process is called *congression*, and it eventually leads to all of the chromosomes being arranged at the equator of the cell with the sister chromatids of each chromosome oriented to opposite poles by their kinetochore microtubules.

The force that moves chromosomes has been of great interest since the process of mitosis was first observed. Two basic mechanisms have been proposed to explain this: (1) assembly and disassembly of microtubules provides the force to move chromosomes, and (2) motor proteins located at the kinetochore and poles of the cell pull on microtubules to provide force. Data have been obtained that support both mechanisms.

In support of the microtubule-shortening proposal, isolated chromosomes can be pulled by microtubule disassembly. The spindle is a very dynamic structure, with microtubules being added to at the kinetochore and shortened at the poles, even during metaphase. In support of the motor protein proposal, multiple motor proteins have been identified as kinetochore proteins, and inhibition of the motor protein dynein slows chromosome separation at anaphase. Like many phenomena that we analyze in living systems, the answer is not a simple either-or choice; both mechanisms are probably at work.

## In metaphase, chromosomes align at the equator

The alignment of the chromosomes in the center of the cell signals the third stage of mitosis, **metaphase**. When viewed with a light microscope, the chromosomes appear to array

**Figure 10.12 Metaphase.** In metaphase, the chromosomes are arrayed at the midpoint of the cell. The imaginary plane through the equator of the cell is called the metaphase plate. As the spindle itself is a three dimensional structure, the chromosomes are arrayed in a rough circle on the metaphase plate.

themselves in a circle along the inner circumference of the cell, just as the equator girdles the Earth (figure 10.12). An imaginary plane perpendicular to the axis of the spindle that passes through this circle is called the *metaphase plate*. The metaphase plate is not an actual structure, but rather an indication of the future axis of cell division.

Positioned by the microtubules attached to the kinetochores of their centromeres, all of the chromosomes line up on the metaphase plate. At this point their centromeres are neatly arrayed in a circle, equidistant from the two poles of the cell, with microtubules extending back toward the opposite poles of the cell. The cell is prepared to properly separate sister chromatids, such that each daughter cell will receive a complete set of chromosomes. Thus metaphase is really a transitional phase in which all the preparations are checked before the action continues.

## At anaphase, the chromatids separate

Of all the stages of mitosis, shown in figure 10.11, **anaphase** is the shortest and the most amazing to watch. It begins when the centromeres split, freeing the two sister chromatids from each other. Up to this point in mitosis, sister chromatids have been held together by cohesin proteins concentrated at the centromere, as mentioned earlier. The key event in anaphase, then, is the simultaneous removal of these proteins from all of the chromosomes. The control and details of this process are discussed later on in the context of control of the entire cell cycle.

Freed from each other, the sister chromatids are pulled rapidly toward the poles to which their kinetochores are attached. In the process, two forms of movement take place simultaneously, each driven by microtubules. These movements are often called anaphase A and anaphase B to distinguish them.

First, during anaphase A, the *kinetochores are pulled toward the poles* as the microtubules that connect them to the poles shorten. This shortening process is not a contraction; the microtubules do not get any thicker. Instead, tubulin subunits are removed from the kinetochore ends of the microtubules. As more subunits are removed, the chromatid-bearing microtubules are progressively disassembled, and the chromatids are pulled ever closer to the poles of the cell.

Second, during anaphase B, the *poles move apart* as microtubular spindle fibers physically anchored to opposite poles slide past each other, away from the center of the cell (figure 10.13). Because another group of microtubules attach the chromosomes to the poles, the chromosomes move apart, too. If a flexible membrane surrounds the cell, it becomes visibly elongated.

When the sister chromatids separate in anaphase, the accurate partitioning of the replicated genome—the essential element of mitosis—is complete.

### During telophase, the nucleus re-forms

In **telophase**, the spindle apparatus disassembles as the microtubules are broken down into tubulin monomers that can be used to construct the cytoskeletons of the daughter cells. A nuclear envelope forms around each set of sister chromatids, which can now be called chromosomes because they are no longer attached at the centromere. The chromosomes soon begin to uncoil into the more extended form that permits gene expression. One of the early group of genes expressed after mitosis is complete are the rRNA genes, resulting in the reappearance of the nucleolus.

**Figure 10.13** Microtubules slide past each other as the chromosomes separate.

In these electron micrographs of dividing diatoms, the overlap of the microtubules lessens markedly during spindle elongation as the cell passes from metaphase to anaphase. During anaphase B the poles move farther apart as the chromosomes move toward the poles.

**Figure 10.14** Cytokinesis in animal cells. *a.* A cleavage furrow forms around a dividing frog egg. *b.* The completion of cytokinesis in an animal cell. The two daughter cells are still joined by a thin band of cytoplasm occupied largely by microtubules.

Telophase can be viewed as a reversal of the process of prophase, bringing the cell back to the state of interphase. Mitosis is complete at the end of telophase. The eukaryotic cell has partitioned its replicated genome into two new nuclei positioned at opposite ends of the cell. Other cytoplasmic organelles, including mitochondria and chloroplasts (if present), were reassorted to areas that will separate and become the daughter cells.

Cell division is still not complete at the end of mitosis, however, because the division of the cell body proper has not yet begun. The phase of the cell cycle when the cell actually divides is called **cytokinesis**. It generally involves the cleavage of the cell into roughly equal halves.

### In animal cells, a belt of actin pinches off the daughter cells

In animal cells and the cells of all other eukaryotes that lack cell walls, cytokinesis is achieved by means of a constricting belt of actin filaments. As these filaments slide past one another, the diameter of the belt decreases, pinching the cell and creating a **cleavage furrow** around the cell's circumference (figure 10.14*a*).

As constriction proceeds, the furrow deepens until it eventually slices all the way into the center of the cell. At this point, the cell is divided in two (figure 10.14*b*).

### In plant cells, a cell plate divides the daughter cells

Plant cell walls are far too rigid to be squeezed in two by actin filaments. Instead, these cells assemble membrane components in their interior, at right angles to the spindle apparatus. This expanding membrane partition, called a **cell plate**, continues to grow outward until it reaches the interior surface of the plasma membrane and fuses with it, effectively dividing the cell in two

## 10.6 Control of the Cell Cycle

### Learning Outcomes

1. Distinguish the role of checkpoints in the control of the cell cycle.
2. Understand the role of the anaphase-promoting complex/cyclosome in mitosis.
3. Describe cancer in terms of cell cycle control.

Our knowledge of how the cell cycle is controlled, although still incomplete, has grown enormously in the past 30 years. Our current view integrates two basic concepts. First, the cell cycle has two irreversible points: the replication of genetic material and the separation of the sister chromatids. Second, the cell cycle can be put on hold at specific points called *checkpoints*. At any of these checkpoints, the process is checked for accuracy and can be halted if there are errors. This leads to extremely high fidelity overall for the entire process. The checkpoint organization also allows the cell cycle to respond to both the internal state of the cell, including nutritional state and integrity of genetic material, and to signals from the environment, which are integrated at major checkpoints.

### Research uncovered cell cycle control factors

The history of investigation into control of the cell cycle is instructive in two ways. First, it allows us to place modern observations into context; second, we can see how biologists using very different approaches often end up at the same place. The following brief history introduces three observations and then shows how they can be integrated into a single mechanism.

#### Discovery of MPF

Research on the activation of frog oocytes led to the discovery of a substance that was first called *maturation-promoting factor (MPF)*. Frog oocytes, which go on to become egg cells, become arrested near the end of their development at the  $G_2$  stage before meiosis I, which is the division leading to the production of gametes (chapter 11). They remain in this arrested state and await hormonal signaling to complete this division process.

Cytoplasm taken from a variety of actively dividing cells could prematurely induce cell division when injected into oocytes (figure 10.16). These experiments indicated the presence of a positive regulator of cell cycle progression in the cytoplasm of dividing cells: MPF. These experiments also fit well with cell fusion experiments done with mitotic and interphase cells that also indicated a cytoplasmic positive regulator that could induce mitosis (figure 10.16).

Further studies highlighted two key aspects of MPF. First, MPF activity varied during the cell cycle: low in early  $G_2$ , rising throughout this phase, and then peaking in mitosis (figure 10.17). Second, the enzymatic activity of MPF involved

### Figure 10.15 Cytokinesis in plant cells.

In this photomicrograph and companion drawing, a cell plate is forming between daughter nuclei. The cell plate forms from the fusion of Golgi-derived vesicles. Once the plate is complete, there will be two cells.

(figure 10.15). Cellulose is then laid down on the new membranes, creating two new cell walls. The space between the daughter cells becomes impregnated with pectins and is called a *middle lamella*.

### In fungi and some protists, daughter nuclei are separated during cytokinesis

In most fungi and some groups of protists, the nuclear membrane does not dissolve, and as a result, all the events of mitosis occur entirely *within* the nucleus. Only after mitosis is complete in these organisms does the nucleus divide into two daughter nuclei; then, during cytokinesis, one nucleus goes to each daughter cell. This separate nuclear division phase of the cell cycle does not occur in plants, animals, or most protists.

After cytokinesis in any eukaryotic cell, the two daughter cells contain all the components of a complete cell. Whereas mitosis ensures that both daughter cells contain a full complement of chromosomes, no similar mechanism ensures that organelles such as mitochondria and chloroplasts are distributed equally between the daughter cells. But as long as at least one of each organelle is present in each cell, the organelles can replicate to reach the number appropriate for that cell.

### Learning Outcomes Review 10.5

Mitosis is divided into phases: prophase, prometaphase, metaphase, anaphase, and telophase. The early phases involve restructuring the cell to create the microtubule spindle that pulls chromosomes to the equator of the cell in metaphase. Chromatids for each chromosome remain attached at the centromere by cohesin proteins. Chromatids are then pulled to opposite poles during anaphase when cohesin proteins are destroyed. The nucleus is re-formed in telophase, and cytokinesis then divides the cell cytoplasm and organelles. In animal cells, actin pinches the cell in two; in plant cells, a cell plate forms in the middle of the dividing cell.

- What would happen to a chromosome that loses cohesin protein between sister chromatids before metaphase?

## SCIENTIFIC THINKING

**Hypothesis:** There are positive regulators of cell division.

**Prediction:** Frog oocytes are arrested in  $G_2$  of meiosis I. They can be induced to mature (undergo meiosis) by progesterone treatment. If maturing oocytes contain a positive regulator of cell division, injection of cytoplasm should induce an immature oocyte to undergo meiosis.

**Test:** Oocytes are induced with progesterone, then cytoplasm from these maturing cells is injected into immature oocytes.

**Result:** Injected oocytes progress from  $G_2$  into meiosis I.

**Conclusion:** The progesterone treatment causes production of a positive regulator of maturation: Maturation Promoting Factor (MPF).

**Prediction:** If mitosis is driven by positive regulators, then cytoplasm from a mitotic cell should cause a  $G_1$  cell to enter mitosis.

**Test:** M phase cells are fused with  $G_1$  phase cells, then the nucleus from the  $G_1$  phase cell is monitored microscopically.

**Conclusion:** Cytoplasm from M phase cells contains a positive regulator that causes a cell to enter mitosis.

**Further Experiments:** How can both of these experiments be rationalized? What would be the next step in characterizing these factors?

**Figure 10.16** Discovery of positive regulator of cell division.

the phosphorylation of proteins. This second point is not surprising given the importance of phosphorylation as a reversible switch on the activity of proteins (see chapter 9). The first observation indicated that MPF itself was not always active, but rather was being regulated with the cell cycle, and the second showed the possible enzymatic activity of MPF.

### Discovery of cyclins

Other researchers examined proteins produced during the early divisions in sea urchin embryos. They identified proteins that were produced in synchrony with the cell cycle, and named them **cyclins** (see figure 10.17). These observations were extended in another marine invertebrate, the surf clam. Two forms of cyclin were found that cycled at slightly different times, reaching peaks at the  $G_1/S$  and  $G_2/M$  boundaries.

**Figure 10.17** Correlation of MPF activity, amount of cyclin protein, and stages of the cell cycle. Cyclin concentration and MPF activity are shown plotted vs. stage of the cell cycle. MPF activity changes in a repeating pattern through the cell cycle. This also correlates with the level of mitotic cyclin in the cell, which shows a similar pattern. The reason for this correlation is that cyclin is actually one component of MPF, the other being a cyclin-dependent kinase (Cdk). Together these act as a positive regulator of cell division.

Despite much effort, no identified enzymatic activity was associated with these proteins. Their hallmark was the timing of their production and not any intrinsic activity.

### Genetic analysis of the cell cycle

Geneticists using two different yeasts, budding yeast and fission yeast, as model systems set out to determine the genes necessary for control of the cell cycle. By isolating mutants that were halted during division, they identified genes that were necessary for cell cycle progression. These studies indicated that in yeast, there were two critical control points: the commitment to DNA synthesis, called START, as it meant committing to divide, and the commitment to mitosis. One particular gene, named *cdc2*, from fission yeast, was shown to be critical for passing both of these boundaries.

### MPF is cyclin plus *cdc2*

All of these findings came together in an elegant fashion with the following observations. First, the protein encoded by the *cdc2* gene was shown to be a protein kinase. Second, the purification and identification of MPF showed that it was composed of both a cyclin component and a kinase component. Last, the kinase itself was the *cdc2* protein!

The *cdc2* protein was the first identified **cyclin-dependent kinase (Cdk)**, that is, a protein kinase enzyme that is only active when complexed with cyclin. This finding led to the renaming of MPF as *mitosis*-promoting factor, as its role was clearly more general than simply promoting the maturation of frog oocytes.

These Cdk enzymes are the key positive drivers of the cell division cycle. They are often called the engine that drives cell division. The control of the cell cycle in higher eukaryotes

is much more complex than the simple single-engine cycle of yeast, but the yeast model remains a useful framework for understanding more complex regulation. The discovery of Cdks and their role in the cell cycle is an excellent example of the progressive nature of science.

## The cell cycle can be halted at three checkpoints

Although we have divided the cell cycle into phases and subdivided mitosis into stages, the cell recognizes three points at which the cycle can be delayed or halted. The cell uses these three checkpoints to both assess its internal state and integrate external signals (figure 10.18):  $G_1/S$ ,  $G_2/M$ , and late metaphase (the spindle checkpoint). Passage through these checkpoints is controlled by the Cdk enzymes described earlier and also in the following section.

### $G_1/S$ checkpoint

The  $G_1/S$  checkpoint is the primary point at which the cell “decides” whether or not to divide. This checkpoint is therefore the primary point at which external signals can influence events of the cycle. It is the phase during which growth factors (discussed later on) affect the cycle and also the phase that links cell division to cell growth and nutrition.

In yeast systems, where the majority of the genetic analysis of the cell cycle has been performed, this checkpoint is called START. In animals, it is called the restriction point (R point). In all systems, once a cell has made this irreversible commitment to replicate its genome, it has committed to divide. Damage to DNA can halt the cycle at this point, as can starvation conditions or lack of growth factors.

**Figure 10.18 Control of the cell cycle.** Cells use a centralized control system to check whether proper conditions have been achieved before passing three key checkpoints in the cell cycle.

### $G_2/M$ checkpoint

The  $G_2/M$  checkpoint has received a large amount of attention because of its complexity and its importance as the stimulus for the events of mitosis. Historically, Cdks active at this checkpoint were first identified as MPFs, a term that has now evolved into **M phase-promoting factor (MPF)**.

Passage through this checkpoint represents the commitment to mitosis. This checkpoint assesses the success of DNA replication and can stall the cycle if DNA has not been accurately replicated. DNA-damaging agents result in arrest at this checkpoint as well as at the  $G_1/S$  checkpoint.

### Spindle checkpoint

The **spindle checkpoint** ensures that all of the chromosomes are attached to the spindle in preparation for anaphase. The second irreversible step in the cycle is the separation of chromosomes during anaphase, and therefore it is critical that they are properly arrayed at the metaphase plate.

## Cyclin-dependent kinases drive the cell cycle

The primary molecular mechanism of cell cycle control is phosphorylation, which you may recall is the addition of a phosphate group to the amino acids serine, threonine, and tyrosine in proteins (chapter 9). The enzymes that accomplish this phosphorylation are the Cdks (figure 10.19).

### The action of Cdks

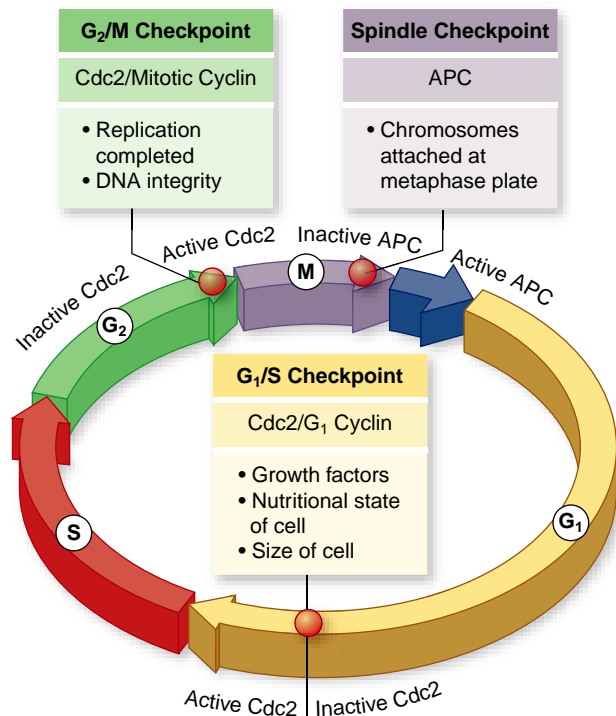

The first important cell cycle kinase was identified in fission yeast and named Cdc2 (now also called Cdk1). In yeast, this Cdk can partner with different cyclins at different points in the cell cycle (figure 10.20).

Even in the simplified cycle of the yeasts, we are left with the important question of what controls the activity of the Cdks during the cycle. For many years, a common view was that cyclins drove the cell cycle—that is, the periodic synthesis and destruction of cyclins acted as a clock. More recently, it has become clear that the Cdc2 kinase is also itself controlled by

**Figure 10.19 Cdk enzyme forms a complex with cyclin.**

Cdk is a protein kinase that activates numerous cell proteins by phosphorylating them. Cyclin is a regulatory protein required to activate Cdk. This complex is also called mitosis-promoting factor (MPF). The activity of Cdk is also controlled by the pattern of phosphorylation: phosphorylation at one site (represented by the red site) inactivates the Cdk, and phosphorylation at another site (represented by the green site) activates the Cdk.

**Figure 10.20 Checkpoints of the yeast cell cycle.** The simplest cell cycle that has been studied in detail is the fission yeast. This is controlled by three main checkpoints and a single Cdk enzyme, called Cdc2. The Cdc2 enzyme partners with different cyclins to control the  $G_1/S$  and  $G_2/M$  checkpoints. The spindle checkpoint is controlled by the anaphase-promoting complex (APC).

phosphorylation: Phosphorylation at one site activates Cdc2, and phosphorylation at another site inactivates it (see figure 10.19). Full activation of the Cdc2 kinase requires complexing with a cyclin and the appropriate pattern of phosphorylation.

As the  $G_1/S$  checkpoint is approached, the triggering signal in yeast appears to be the accumulation of  $G_1$  cyclins. These form a complex with Cdc2 to create the active  $G_1/S$  Cdk, which phosphorylates a number of targets that bring about the increased enzyme activity for DNA replication.

### The action of MPF

MPF and its role at the  $G_2/M$  checkpoint has been extensively analyzed in a number of different experimental systems. The control of MPF is sensitive to agents that disrupt or delay replication and to agents that damage DNA. It was once thought that MPF was controlled solely by the level of the M phase-specific cyclins, but it has now become clear that this is not the case.

Although M phase cyclin is necessary for MPF function, activity is controlled by inhibitory phosphorylation of the kinase component, Cdc2. The critical signal in this process is the removal of the inhibitory phosphates by a protein, phosphatase. This action forms a molecular switch based on positive feedback because the active MPF further activates its own activating phosphatase.

The checkpoint assesses the balance of the kinase that adds inhibitory phosphates with the phosphatase that removes them. Damage to DNA acts through a complex pathway that includes damage sensing and a response to tip the balance toward the inhibitory phosphorylation of MPF. Later on, we describe how some cancers overcome this inhibition.

### The anaphase-promoting complex

The molecular details of the sensing system at the spindle checkpoint are not clear. The presence of all chromosomes at the metaphase plate and the tension on the microtubules between opposite poles are both important. The signal is transmitted through the **anaphase-promoting complex**, also called the *cyclosome* (APC/C).

The function of the APC/C is to trigger anaphase itself. As described earlier, the sister chromatids at metaphase are still held together by the protein complex cohesin. The APC does not act directly on cohesin, but rather acts by marking a protein called *securin* for destruction. The securin protein acts as an inhibitor of another protease called *separase* that appears to be specific for the cohesin complex. Once inhibition is lifted, separase destroys cohesin.

This process has been analyzed in detail in budding yeast, where it has been shown that the separase enzyme specifically degrades a component of cohesin called Scc1. This leads to the release of the sister chromatids and results in their sudden movement toward opposite poles during anaphase.

In vertebrates, most cohesin is removed from the sister chromatids during chromosome condensation, possibly with cohesin being replaced by condensin. At metaphase, the majority of the cohesin that remains on vertebrate chromatids is concentrated at the centromere (figure 10.10). The destruction of this cohesin explains the anaphase movement of chromosomes and the apparent “division” of the centromeres.

The APC/C has a number of roles in mitosis: it activates the protease that removes the cohesins holding sister chromatids together, and it is necessary for the destruction of mitotic cyclins to drive the cell out of mitosis. The APC/C complex marks proteins for destruction by the proteasome, the organelle responsible for the controlled degradation of proteins (chapter 16). The signal to degrade a protein is the addition of a molecule called *ubiquitin*, and the APC/C acts as a ubiquitin ligase. As we learn more about the APC/C and its functions, it is clear that the control of its activity is a key regulator of the cell cycle.

## In multicellular eukaryotes, many Cdks and external signals act on the cell cycle

The major difference between more complex animals and single-celled eukaryotes such as fungi and protists is twofold: First, multiple Cdks control the cycle as opposed to the single Cdk in yeasts; and second, animal cells respond to a greater variety of external signals than do yeasts, which primarily respond to signals necessary for mating.

In higher eukaryotes there are more Cdk enzymes and more cyclins that can partner with these multiple Cdks, but their basic role is the same as in the yeast cycle. A more complex

cell cycle is shown in figure 10.21. These more complex controls allow the integration of more input into control of the cycle. With the evolution of more complex forms of organization (tissues, organs, and organ systems), more complex forms of cell cycle control evolved as well.

A multicellular body's organization cannot be maintained without severely limiting cell proliferation—so that only certain cells divide, and only at appropriate times. The way cells inhibit individual growth of other cells is apparent in mammalian cells growing in tissue culture: A single layer of cells expands over a culture plate until the growing border of cells comes into contact with neighboring cells, and then the cells stop dividing. If a sector of cells is cleared away, neighboring cells rapidly refill that sector and then stop dividing again on cell contact.

How are cells able to sense the density of the cell culture around them? When cells come in contact with one another, receptor proteins in the plasma membrane activate a signal transduction pathway that acts to inhibit Cdk action. This prevents entry into the cell cycle.

### Growth factors and the cell cycle

Growth factors act by triggering intracellular signaling systems. Fibroblasts, for example, possess numerous receptors on their plasma membranes for one of the first growth factors to be identified, **platelet-derived growth factor (PDGF)**. The PDGF recep-

tor is a receptor tyrosine kinase (RTK) that initiates a MAP kinase cascade to stimulate cell division (discussed in chapter 9).

PDGF was discovered when investigators found that fibroblasts would grow and divide in tissue culture only if the growth medium contained blood serum. Serum is the liquid that remains in blood after clotting; blood plasma, the liquid from which cells have been removed without clotting, would not work. The researchers hypothesized that platelets in the blood clots were releasing into the serum one or more factors required for fibroblast growth. Eventually, they isolated such a factor and named it PDGF.

Growth factors such as PDGF can override cellular controls that otherwise inhibit cell division. When a tissue is injured, a blood clot forms, and the release of PDGF triggers neighboring cells to divide, helping to heal the wound. Only a tiny amount of PDGF (approximately  $10^{-10}$  M) is required to stimulate cell division in cells with PDGF receptors.

### Characteristics of growth factors

Over 50 different proteins that function as growth factors have been isolated, and more undoubtedly exist. A specific cell surface receptor recognizes each growth factor, its binding site fitting that growth factor precisely. These growth factor receptors often initiate MAP kinase cascades in which the final kinase enters the nucleus and activates transcription factors by phosphorylation. These transcription factors stimulate the production of  $G_1$  cyclins and the proteins that are necessary for cell cycle progression (figure 10.22).

The cellular selectivity of a particular growth factor depends on which target cells bear its unique receptor. Some growth factors, such as PDGF and epidermal growth factor (EGF), affect a broad range of cell types, but others affect only specific types. For example, nerve growth factor (NGF) promotes the growth of certain classes of neurons, and erythropoietin triggers cell division in red blood cell precursors. Most animal cells need a combination of several different growth factors to overcome the various controls that inhibit cell division.

### The $G_0$ phase

If cells are deprived of appropriate growth factors, they stop at the  $G_1$  checkpoint of the cell cycle. With their growth and division arrested, they remain in this dormant  $G_0$  phase.

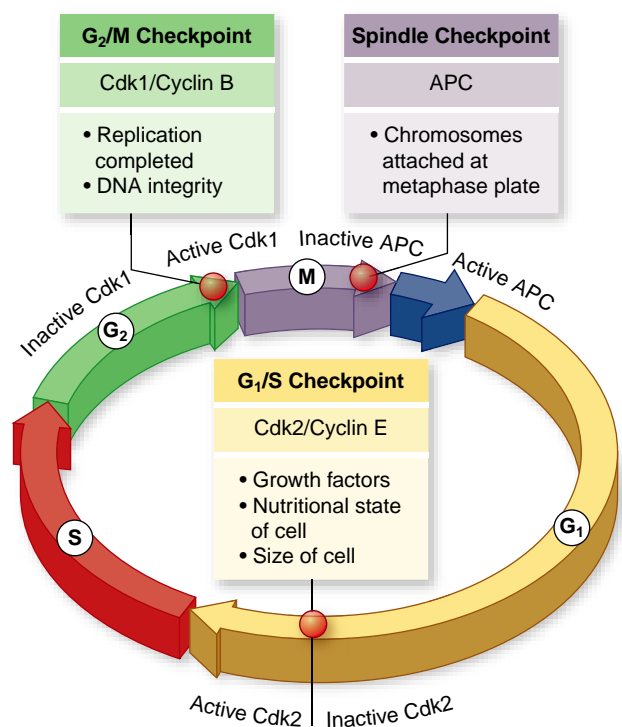

The ability to enter  $G_0$  accounts for the incredible diversity seen in the length of the cell cycle in different tissues. Epithelial cells lining the human gut divide more than twice a day, constantly renewing this lining. By contrast, liver cells divide only once every year or two, spending most of their time in the  $G_0$  phase. Mature neurons and muscle cells usually never leave  $G_0$ .

### Cancer is a failure of cell cycle control

The unrestrained, uncontrolled growth of cells in humans leads to the disease called **cancer**. Cancer is essentially a disease of cell division—a failure of cell division control.

### The p53 gene

Recent work has identified one of the culprits in cancer. Officially dubbed **p53**, this gene plays a key role in the  $G_1$  checkpoint of cell division.

**Figure 10.21** Checkpoints of the mammalian cell cycle.

The more complex mammalian cell cycle is shown. This cycle is still controlled through three main checkpoints. These integrate internal and external signals to control progress through the cycle. These inputs control the state of two different Cdk–cyclin complexes and the anaphase-promoting complex (APC).

**Figure 10.22** The cell proliferation-signaling pathway. Binding of a growth factor sets in motion a MAP kinase intracellular signaling pathway (described in chapter 9), which activates nuclear regulatory proteins that trigger cell division. In this example, when the nuclear retinoblastoma protein (Rb) is phosphorylated, another nuclear protein (the transcription factor E2F) is released and is then able to stimulate the production of cyclin and other proteins necessary for S phase.

The gene's product, the p53 protein, monitors the integrity of DNA, checking that it is undamaged. If the p53 protein detects damaged DNA, it halts cell division and stimulates the activity of special enzymes to repair the damage. Once the DNA has been repaired, p53 allows cell division to continue. In cases where the DNA damage is irreparable, p53 then directs the cell to kill itself.

By halting division in damaged cells, the *p53* gene prevents the development of many mutated cells, and it is therefore considered a **tumor-suppressor gene** although its activities are not limited to cancer prevention. Scientists have found that *p53* is entirely absent or damaged beyond use in the majority of cancerous cells they have examined. It is precisely because *p53* is nonfunctional that cancer cells are able to repeatedly undergo cell division without being halted at the G<sub>1</sub> checkpoint (figure 10.23).

### Proto-oncogenes

The disease we call cancer is actually many different diseases, depending on the tissue affected. The common theme in all cases is the loss of control over the cell cycle. Research has identified numerous so-called **oncogenes**, genes that can, when introduced into a cell, cause it to become a cancer cell. This identification then led to the discovery of **proto-oncogenes**, which are normal cellular genes that become oncogenes when mutated.

The action of proto-oncogenes is often related to signaling by growth factors, and their mutation can lead to loss of growth control in multiple ways. Some proto-oncogenes encode receptors for growth factors, and others encode proteins involved in signal transduction that act after growth factor receptors. If a receptor for a growth factor becomes mutated such that it is permanently "on," the cell is no longer dependent on the presence of the growth factor for cell division. This is analogous

**Figure 10.23** Cell division, cancer, and p53 protein.

Normal p53 protein monitors DNA, destroying cells that have irreparable damage to their DNA. Abnormal p53 protein fails to stop cell division and repair DNA. As damaged cells proliferate, cancer develops.

to a light switch that is stuck on: The light will always be on. PDGF and EGF receptors both fall into the category of proto-oncogenes. Only one copy of a proto-oncogene needs to undergo this mutation for uncontrolled division to take place; thus, this change acts like a dominant mutation.

The number of proto-oncogenes identified has grown to more than 50 over the years. This line of research connects our understanding of cancer with our understanding of the molecular mechanisms governing cell cycle control.

### Tumor-suppressor genes

After the discovery of proto-oncogenes, a second category of genes related to cancer was identified: the tumor-suppressor genes. We mentioned earlier that the *p53* gene acts as a tumor-suppressor gene, and a number of other such genes exist.

Both copies of a tumor-suppressor gene must lose function for the cancerous phenotype to develop, in contrast to the muta-

tions in proto-oncogenes. Put another way, the proto-oncogenes act in a dominant fashion, and tumor suppressors act in a recessive fashion.

The first tumor-suppressor identified was the **retinoblastoma susceptibility gene (*Rb*)**, which predisposes individuals for a rare form of cancer that affects the retina of the eye. Despite the fact that a cell heterozygous for a mutant *Rb* allele is normal, it is inherited as a dominant in families. The reason is that inheriting a single mutant copy of *Rb* means the individual has only one “good” copy left, and during the hundreds of thousands of divisions that occur to produce the retina, any error that damages the remaining good copy leads to a cancerous cell. A single cancerous cell in the retina then leads to the formation of a retinoblastoma tumor.

The role of the Rb protein in the cell cycle is to integrate signals from growth factors. The Rb protein is called a “pocket protein” because it has binding pockets for other proteins. Its role is therefore to bind important regulatory proteins and prevent them from stimulating the production of the necessary cell cycle proteins, such as cyclins or Cdks (see figure 10.21) discussed previously.

The binding of Rb to other proteins is controlled by phosphorylation: When it is dephosphorylated, it can bind a variety of regulatory proteins, but loses this capacity when phosphorylated. The action of growth factors results in the phosphorylation of Rb protein by a Cdk. This then brings us full circle, because the phosphorylation of Rb releases previously bound regulatory proteins, resulting in the production of S phase cyclins that are necessary for the cell to pass the  $G_1/S$  boundary and begin chromosome replication.

Figure 10.24 summarizes the types of genes that can cause cancer when mutated.

**Figure 10.24 Key proteins associated with human cancers.** Mutations in genes encoding key components of the cell division-signaling pathway are responsible for many cancers. Among them are proto-oncogenes encoding growth factor receptors, protein relay switches such as Ras protein, and kinase enzymes such as Src, which act after Ras and growth factor receptors. Mutations that disrupt tumor-suppressor proteins, such as Rb and p53, also foster cancer development.

### Learning Outcomes Review 10.6

Cyclin proteins are produced in synchrony with the cell cycle. These proteins complex with cyclin-dependent kinases to drive the cell cycle. Three checkpoints exist in the cell cycle: the  $G_1/S$  checkpoint, the  $G_2/M$  checkpoint, and the spindle checkpoint. The cell cycle can be halted at these checkpoints if the process is not accurate. The anaphase-promoting complex/cyclosome (APC/C) triggers anaphase by lifting inhibition on a protease that removes cohesin holding chromatids together. The loss of cell cycle control leads to cancer, which can occur by a combination of two basic mechanisms: proto-oncogenes that gain function to become oncogenes, and tumor-suppressor genes that lose function and allow cell proliferation.

- How can you distinguish between a tumor suppressor gene and a proto-oncogene?

## Chapter Review

### 10.1 Bacterial Cell Division

**Binary fission is a simple form of cell division.**

Prokaryotic cell division is clonal, resulting in two identical cells. Bacterial DNA replication and partitioning of the chromosome are concerted processes.

**Proteins control chromosome separation and septum formation.**

DNA replication begins at a specific point, the origin, and proceeds bidirectionally to a specific termination site. Newly replicated chromosomes are segregated to opposite poles at the same time as they are replicated. New cells are separated by septation, which involves insertion of new cell membrane and other cellular materials at the midpoint of the cell. A ring of FtsZ and proteins embedded in the cell membrane expands radially inward, pinching the cell into two new cells.

### 10.2 Eukaryotic Chromosomes

**Chromosome number varies among species.**

The gain or loss of chromosomes is usually lethal.

**Eukaryotic chromosomes exhibit complex structure.**

Chromosomes are composed of chromatin, a complex of DNA, and protein. Heterochromatin is not expressed and euchromatin is expressed. The DNA of a single chromosome is a very long, double-stranded fiber. The DNA is wrapped around a core of eight histones to form a nucleosome, which can be further coiled into a 30-nm fiber in interphase cells. During mitosis, chromosomes are further condensed by arranging coiled 30-nm fibers radially around a protein scaffold.

Newly replicated chromosomes remain attached at a constricted area called a centromere, consisting of repeated DNA sequences. After replication, a chromosome consists of two sister chromatids held together at the centromere by a complex of proteins called cohesins (figure 10.7).

### 10.3 Overview of the Eukaryotic Cell Cycle (figure 10.8)

**The cell cycle is divided into five phases.**

The phases of the cell cycle are gap 1 ( $G_1$ ), synthesis (S), gap 2 ( $G_2$ ), mitosis, and cytokinesis (C).  $G_1$ , S, and  $G_2$  are collectively called interphase, and mitosis and cytokinesis together are called M phase.

**The duration of the cell cycle varies depending on cell type.**

The length of a cell cycle varies with age, cell type, and species. Cells can exit  $G_1$  and enter a nondividing phase called  $G_0$ ; the  $G_0$  phase can be temporary or permanent.

### 10.4 Interphase: Preparation for Mitosis

$G_1$ , S, and  $G_2$ , are the three subphases of interphase.  $G_1$  is the primary growth phase; during S phase, DNA synthesis occurs.  $G_2$  phase occurs after S phase and before mitosis.

The centromere binds proteins assembled into a disklike structure called a kinetochore where microtubules attach during mitosis. The centromeric DNA is replicated, but the two DNA strands are held together by cohesin proteins.

### 10.5 M Phase: Chromosome Segregation and the Division of Cytoplasmic Contents (figure 10.11)

**During prophase, the mitotic apparatus forms.**

In prophase, chromosomes condense, the spindle is formed, and the nuclear envelope disintegrates. In animals cells, centriole pairs

separate and migrate to opposite ends of the cell, establishing the axis of nuclear division.

**During prometaphase, chromosomes attach to the spindle.**

**In metaphase, chromosomes align at the equator.**

Chromatids of each chromosome are connected to opposite poles by kinetochore microtubules. They are held at the equator of the cell by the tension of being pulled toward opposite poles.

**At anaphase, the chromatids separate.**

At this point, cohesin proteins holding sister chromatids together at the centromeres are destroyed, and the chromatids are pulled to opposite poles. This movement is called anaphase A, and the movement of poles farther apart is called anaphase B.

**During telophase, the nucleus re-forms.**

Telophase reverses the events of prophase and prepares the cell for cytokinesis.

**In animals cells, a belt of actin pinches off the daughter cells.**

A contractile ring of actin under the membrane contracts during cytokinesis.

**In plant cells, a cell plate divides the daughter cells.**

Fusion of vesicles produces a new membrane in the middle of the cell to produce the cell plate.

**In fungi and some protists, daughter nuclei are separated during cytokinesis.**

### 10.6 Control of the Cell Cycle (figure 10.18)

**Research uncovered cell cycle control factors.**

Experiments showed that there are positive regulators of mitosis, and that there are proteins produced in synchrony with the cell cycle (cyclins). The positive regulators are cyclin-dependent kinases (Cdks). Cdks are complexes of a kinase and a regulatory molecule called cyclin. They phosphorylate proteins to drive the cell cycle.

**The cell cycle can be halted at three checkpoints.**

Checkpoints are points at which the cell can assess the accuracy of the process and stop if needed. The  $G_1/S$  checkpoint is a commitment to divide; the  $G_2/M$  checkpoint ensures DNA integrity; and the spindle checkpoint ensures that all chromosomes are attached to spindle fibers, with bipolar orientation.

**Cyclin-dependent kinases drive the cell cycle.**

The cycle progresses by the action of Cdks. Yeast have only one CDK enzyme; vertebrates have more than four enzymes. During the  $G_1$  phase,  $G_1$  cyclin combines with Cdc2 kinase to form the Cdk that triggers entry into S phase.

The anaphase-promoting complex/cyclosome (APC/C) activates a protease that removes cohesins holding the centromeres of sister chromatids together; the result is to trigger anaphase, separating the chromatids and drawing them to opposite poles. The APC/C also triggers destruction of mitotic cyclins to exit mitosis.

**In multicellular eukaryotes, many Cdks and external signals act on the cell cycle.**

Growth factors, like platelet-derived growth factor (PDGF), stimulate cell division. This acts through a MAP kinase cascade that results in the production of cyclins and activation of Cdks to stimulate cell division in fibroblasts after tissue injury.

**Cancer is a failure of cell cycle control.**

Mutations in proto-oncogenes have dominant, gain-of-function effects leading to cancer. Mutations in tumor-suppressor genes are recessive; loss of function of both copies leads to cancer.

## Review Questions

### UNDERSTAND

- Binary fission in prokaryotes does not require the
  - replication of DNA.
  - elongation of the cell.
  - separation of daughter cells by septum formation.
  - assembly of the nuclear envelope.
- Chromatin is composed of
  - RNA and protein.
  - DNA and protein.
  - sister chromatids.
  - chromosomes.
- What is a nucleosome?
  - A region in the cell's nucleus that contains euchromatin
  - A region of DNA wound around histone proteins
  - A region of a chromosome made up of multiple loops of chromatin
  - A 30-nm fiber found in chromatin
- What is the role of cohesin proteins in cell division?
  - They organize the DNA of the chromosomes into highly condensed structures.
  - They hold the DNA of the sister chromatids together.
  - They help the cell divide into two daughter cells.
  - They connect microtubules and chromosomes.
- The kinetochore is a structure that functions to
  - connect the centromere to microtubules.
  - connect centrioles to microtubules.
  - aid in chromosome condensation.
  - aid in chromosomes cohesion.
- Separation of the sister chromatids occurs during
  - prophase.
  - prometaphase.
  - anaphase.
  - telophase.
- Why is cytokinesis an important part of cell division?
  - It is responsible for the proper separation of genetic information.
  - It is responsible for the proper separation of the cytoplasmic contents.
  - It triggers the movement of a cell through the cell cycle.
  - It allows cells to halt at checkpoints.

### APPLY

- What steps in the cell cycle represent irreversible commitments?
  - The  $S/G_2$  checkpoint
  - The  $G_1/S$  checkpoint
  - Anaphase
  - Both b and c
- Cyclin-dependent kinases (Cdks) are regulated by
  - the periodic destruction of cyclins.
  - bipolar attachment of chromosomes to the spindle.
  - DNA synthesis.
  - both a and b.
- The bacterial SMC proteins, eukaryotic cohesin proteins, and condensin proteins share a similar structure. Functionally they all
  - interact with microtubules.
  - can act as kinase enzymes.
  - interact with DNA to compact or hold strands together.
  - connect chromosomes to cytoskeletal elements.

- Genetically, proto-oncogenes act in a dominant fashion. This is because
  - there is only one copy of each proto-oncogene in the genome.
  - they act in a gain-of-function fashion to turn on the cell cycle.
  - they act in a loss-of-function fashion to turn off the cell cycle.
  - they require that both genomic copies are altered to affect function.
- The metaphase to anaphase transition involves
  - new force being generated to pull the chromatids apart.
  - an increase in force on sister chromatids to pull them apart.
  - completing DNA replication of centromeres allowing chromosomes to be pulled apart.
  - loss of cohesion between sister chromatids.
- The main difference between bacterial cell division and eukaryotic cell division is that
  - since bacteria only have one chromosome, they can count the number of copies in the cell.
  - eukaryotes mark their chromosomes to identify them and bacteria do not.
  - bacterial DNA replication and chromosome segregation are concerted processes but in eukaryotes they are separated in time.
  - none of the above
- In animal cells, cytokinesis is accomplished by a contractile ring containing actin. The related process in bacteria is
  - chromosome segregation, which also appears to use an actin-like protein.
  - septation via a ring of FtsZ protein, which is an actin-like protein.
  - cytokinesis, which requires formation of a cell plate via vesicular fusion.
  - septation via a ring of FtsZ protein, which is a tubulin-like protein.

### SYNTHESIZE

- Regulation of the cell cycle is very complex and involves multiple proteins. In yeast, a complex of cdc2 and a mitotic cyclin is responsible for moving the cell past the  $G_2/M$  checkpoint. The activity of the cyclin-dependent kinase cdc2 is inhibited when it is phosphorylated by the kinase, Wee-1. What would you predict would be the phenotype of a Wee-1 mutant yeast? What other genes could be altered in a Wee-1 deficient mutant strain that would make the cells act normally?
- Review your knowledge of signaling pathways (chapter 9). Create an outline illustrating how a growth factor (ligand) can lead to the production of a cyclin protein that would trigger S phase.
- Compare and contrast how mutations in cellular proto-oncogenes and in tumor suppressor genes can lead to cancer cells.

# Sexual Reproduction and Meiosis

## Chapter Outline

- 11.1 Sexual Reproduction Requires Meiosis
- 11.2 Features of Meiosis
- 11.3 The Process of Meiosis
- 11.4 Summing Up: Meiosis Versus Mitosis

## Introduction

Most animals and plants reproduce sexually. Gametes of opposite sex unite to form a cell that, dividing repeatedly by mitosis, eventually gives rise to an adult body with some 100 trillion cells. The gametes that form the initial cell are the products of a special form of cell division called meiosis, visible in the photo above, and the subject of this chapter. Meiosis is far more intricate than mitosis, and the details behind it are not as well understood. The basic process, however, is clear. Also clear are the profound consequences of sexual reproduction: It plays a key role in generating the tremendous genetic diversity that is the raw material of evolution.

### 11.1 Sexual Reproduction Requires Meiosis

#### Learning Outcomes

1. Understand the function of meiosis in sexual reproduction.
2. Distinguish between germ-line and somatic cells.

The essence of sexual reproduction is the genetic contribution of two cells. This mode of reproduction imposes difficulties for sexually reproducing organisms that biologists recognized early on. We are only recently making progress on the underlying mechanism for the elaborate behavior of chromosomes during meiosis. To begin, we briefly consider the history of meiosis and its relationship to sexual reproduction.

#### Meiosis reduces the number of chromosomes

Only a few years after Walther Flemming's discovery of chromosomes in 1879, Belgian cytologist Edouard van Beneden was

surprised to find different numbers of chromosomes in different types of cells in the roundworm *Ascaris*. Specifically, he observed that the **gametes** (eggs and sperm) each contained two chromosomes, but all of the nonreproductive cells, or **somatic cells**, of embryos and mature individuals each contained four.

From his observations, van Beneden proposed in 1883 that an egg and a sperm, each containing half the complement of chromosomes found in other cells, fuse to produce a single cell called a **zygote**. The zygote, like all of the cells ultimately derived from it, contains two copies of each chromosome. The fusion of gametes to form a new cell is called **fertilization**, or **syngamy**.

It was clear even to early investigators that gamete formation must involve some mechanism that reduces the number of chromosomes to half the number found in other cells. If it did not, the chromosome number would double with each fertilization, and after only a few generations, the number of chromosomes in each cell would become impossibly large. For example, in just 10 generations, the 46 chromosomes present in human cells would increase to over 47,000 ( $46 \times 2^{10}$ ).

The number of chromosomes does not explode in this way because of a special reduction division, **meiosis**. Meiosis occurs during gamete formation, producing cells with half the normal number of chromosomes. The subsequent fusion of two of these cells ensures a consistent chromosome number from one generation to the next.

## Sexual life cycles have both haploid and diploid stages

Meiosis and fertilization together constitute a cycle of reproduction. Two sets of chromosomes are present in the somatic cells of adult individuals, making them *diploid* cells, but only one set is present in the gametes, which are thus *haploid*. Reproduction that involves this alternation of meiosis and fertilization is called **sexual reproduction**. Its outstanding characteristic is that offspring inherit chromosomes from *two* parents (figure 11.1). You, for example, inherited 23 chromosomes from your mother (maternal homologue), and 23 from your father (paternal homologue).

The life cycles of all sexually reproducing organisms follow a pattern of alternation between diploid and haploid chromosome numbers, but there is some variation in the life cycles. Many types of algae, for example, spend the majority of their life cycle in a haploid state. The zygote undergoing meiosis produces haploid cells that then undergo mitosis. Some plants

**Figure 11.1 Diploid cells carry chromosomes from two parents.** A diploid cell contains two versions of each chromosome, a maternal homologue contributed by the haploid egg of the mother, and a paternal homologue contributed by the haploid sperm of the father.

and some algae alternate between a multicellular haploid phase and a multicellular diploid phase (specific examples can be found in chapters 30 and 31). In most animals, the diploid state dominates; the zygote first undergoes mitosis to produce diploid cells. Then later in the life cycle, some of these diploid cells undergo meiosis to produce haploid gametes (figure 11.2).

## Germ-line cells are set aside early in animal development

In animals, the single diploid zygote undergoes mitosis to give rise to all of the cells in the adult body. The cells that will eventually undergo meiosis to produce gametes are set aside from somatic cells early in the course of development. These cells are referred to as **germ-line cells**.

Both the somatic cells and the gamete-producing germ-line cells are diploid, but whereas somatic cells undergo mitosis to form genetically identical, diploid daughter cells, gamete-producing germ-line cells undergo meiosis to produce haploid gametes (see figure 11.2).

**Figure 11.2 The sexual life cycle in animals.** In animals, the zygote undergoes mitotic divisions and gives rise to all the cells of the adult body. Germ-line cells are set aside early in development and undergo meiosis to form the haploid gametes (eggs or sperm). The rest of the body cells are called somatic cells.

## Learning Outcomes Review 11.1

Sexual reproduction involves the genetic contribution of two cells, each from a different individual. Meiosis produces haploid cells with half the number of chromosomes. Fertilization then unites these haploid cells to restore the diploid state of the next generation. Only germ-line cells are capable of meiosis. All other cells in the body, termed somatic cells, can undergo only mitotic division.

- *Germ-line cells undergo meiosis, but how can the body maintain a constant supply of these cells?*

## 11.2 Features of Meiosis

### Learning Outcomes

1. Describe how homologous chromosomes pair during meiosis.
2. Explain why meiosis I is called the reductive division.

The mechanism of meiotic cell division varies in important details in different organisms. These variations are particularly evident in the chromosomal separation mechanisms:

a.

**Figure 11.3 Unique features of meiosis.** a. Homologous chromosomes pair during prophase I of meiosis. This process, called synapsis, produces homologues connected by a structure called the synaptonemal complex. The paired homologues can physically exchange parts, a process called crossing over. b. The synaptonemal complex of the ascomycete *Neotiella rutilans*, a cup fungus. c. This pairing allows the homologous pairs, and not sister chromatids, to separate as a unit during meiosis I. Because chromosomes are not duplicated again before meiosis II, disjunction of sister chromatids yields the final haploid products.

b.

c.

Those found in protists and fungi are very different from those in plants and animals, which we describe here.

Meiosis in a diploid organism consists of two rounds of division, called **meiosis I** and **meiosis II**, with each round containing prophase, metaphase, anaphase, and telophase stages. Before describing the details of this process, we first examine the features of meiosis that distinguish it from mitosis.

### Homologous chromosomes pair during meiosis

During early prophase I of meiosis, homologous chromosomes find each other and become closely associated, a process called pairing, or **synapsis** (figure 11.3a). Despite a long history of investigation, molecular details remain unclear. Biologists have used electron microscopy, data from genetic crosses, and biochemical analysis to shed light on synapsis. Thus far the results of their investigations have not been integrated into a complete picture.

### The synaptonemal complex

It is clear that homologous chromosomes find their proper partners and become intimately associated during prophase I. This process includes the formation in many species of an elaborate structure called the **synaptonemal complex**, consisting of the homologues paired closely along a lattice of proteins between them (figure 11.3b). The components of the synaptonemal complex include a meiosis-specific form of cohesin, a type of protein that joins sister chromatids during mitosis (described in chapter 10). This form of cohesin helps to join homologues as well as sister chromatids. The result is that all four chromatids of the two homologues are closely associated during this phase of meiosis. This structure is also sometimes called a *tetrad* or *bivalent*.

## 11.3 The Process of Meiosis

### Learning Outcomes

1. Describe the behavior of chromosomes through both meiotic divisions.
2. Explain the importance of monopolar attachment of homologous pairs at metaphase I.
3. Differentiate between the events of anaphase I and anaphase II of meiosis.

### The exchange of genetic material between homologues

While homologues are paired during prophase I, another process unique to meiosis occurs: genetic **recombination**, or **crossing over**. This process literally allows the homologues to exchange chromosomal material. The cytological observation of this phenomenon is called crossing over, and its detection genetically is called recombination—because alleles of genes that were formerly on separate homologues can now be found on the same homologue. (Genetic recombination is covered in detail in chapter 13.)

The sites of crossing over are called **chiasmata** (singular, *chiasma*), and these sites of contact are maintained until anaphase I. The physical connection of homologues due to crossing over and the continued connection of the sister chromatids lock homologues together.

### Homologue association and separation

The association between the homologues persists throughout meiosis I and dictates the behavior of the chromosomes. During metaphase I, the paired homologues move to the metaphase plate and become oriented with homologues of each pair attached to opposite poles of the spindle. By contrast, in mitosis homologues behave independently of one another.

Then, during anaphase I, homologues are pulled to opposite poles for each pair of chromosomes. This again is in contrast to mitosis, in which sister chromatids, not homologues, are pulled to opposite poles.

You can now see why the first division is termed the “reduction division”—it results in daughter cells that contain one homologue from each chromosome pair. The second meiotic division does not further reduce the number of chromosomes; it will merely separate the sister chromatids for each homologue.

### Meiosis features two divisions with one round of DNA replication

The most obvious distinction between meiosis and mitosis is the simple observation that meiosis involves two successive divisions with no replication of genetic material between them. One way to view this is that DNA replication must be suppressed between the two meiotic divisions. Because of the behavior of chromosomes during meiosis I, the resulting cells contain one replicated copy of each chromosome. A division that acts like mitosis, without DNA replication, converts these cells into ones with a single copy of each chromosome (figure 11.3c). This is the last key to understanding meiosis: The second meiotic division is like mitosis with no chromosome duplication.

#### Learning Outcomes Review 11.2

Meiosis is characterized by the pairing of homologous chromosomes during prophase I. In many species, an elaborate structure called the synaptonemal complex forms between homologues. During this pairing, homologues may exchange chromosomal material at sites called chiasmata. In meiosis I, the homologues separate from each other, reducing the chromosome number to the haploid state (thus the reductive division). It is followed by a second division without replication, during which sister chromatids become separated. The result of meiosis I and II is four haploid cells.

- If sister chromatids separated at the first division, would meiosis still work?

To understand meiosis, it is necessary to carefully follow the behavior of chromosomes during each division. The events of meiosis depend on homologues exchanging chromosomal material by crossing over. This allows sister chromatid cohesion around the sites of exchange to hold homologues together. The loss of sister chromatid cohesion is then different on the chromosome arms and at the centromeres: it is lost at anaphase I on the chromosome arms but is retained at the centromeres until anaphase II.

### Prophase I sets the stage for the reductive division

Meiotic cells have an interphase period that is similar to mitosis with  $G_1$ , S, and  $G_2$  phases. After interphase, germ-line cells enter meiosis I. In prophase I, the DNA coils tighter, and individual chromosomes first become visible under the light microscope as a matrix of fine threads. Because the DNA has already replicated before the onset of meiosis, each of these threads actually consists of two sister chromatids joined at their centromeres. In prophase I, homologous chromosomes become closely associated in synapsis, exchange segments by crossing over, and then separate.

#### Synapsis

During interphase in germ-line cells, the ends of the chromatids seem to be attached to the nuclear envelope at specific sites. The sites the homologues attach to are adjacent, so that during prophase I the members of each homologous pair of chromosomes are brought close together. Homologous pairs then align side by side, apparently guided by heterochromatin sequences, in the process of synapsis.

This association joins homologues along their entire length. The sister chromatids of each homologue are also joined by the cohesin complex in a process called *sister chromatid cohesion* (similar to what happens during mitosis). This brings all four chromatids for each set of paired homologues into close association.

**Figure 11.4** The results of crossing over. During crossing over, homologous chromosomes may exchange segments.

**Figure 11.5 Alignment of chromosomes differs between meiosis I and mitosis.** In metaphase I of meiosis I, the chiasmata and connections between sister chromatids hold homologous chromosomes together; paired kinetochores for sister chromatids of each homologue become attached to microtubules from one pole. By the end of meiosis I, connections between sister chromatid arms are broken as microtubules shorten, pulling the homologous chromosomes apart. The sister chromatids remain joined by their centromeres. In mitosis, microtubules from opposite poles attach to the kinetochore of each sister centromere; when the connections between sister centromeres are broken microtubules shorten, pulling the sister chromatids to opposite poles.

### Crossing over

Along with the synaptonemal complex that forms during prophase I (see figure 11.3), another kind of structure appears that correlates in timing with the recombination process. These are called *recombination nodules*, and they are thought to contain the enzymatic machinery necessary to break and rejoin chromatids of homologous chromosomes.

Crossing over involves a complex series of events in which DNA segments are exchanged between nonsister chromatids (figure 11.4). Crossing over between sister chromatids is suppressed during meiosis. Reciprocal crossovers between nonsister chromatids are controlled such that each chromosome arm usually has one or a few crossovers per meiosis, no matter what the size of the chromosome. Human chromosomes typically have two or three.

When crossing over is complete, the synaptonemal complex breaks down, and the homologous chromosomes become less tightly associated but remain attached by chiasmata. At this point, there are four chromatids for each type of chromosome (two homologous chromosomes, each of which consists of two sister chromatids).

The four chromatids do not separate completely because they are held together in two ways: (1) The two sister chromatids of each homologue, recently created by DNA replication, are held together by their common centromeres; and (2) the paired homologues are held together at the points where crossing over occurred by sister chromatid cohesion around the site of exchange. These points are the chiasmata that can be observed microscopically. Like small rings moving down two strands of rope, the chiasmata move to the end of the chromosome arm before metaphase I.

While the elaborate behavior of chromosome pairing is taking place, other events must occur during prophase I. The nuclear envelope must be dispersed, along with the interphase structure of microtubules. The microtubules are formed into a spindle, just as in mitosis.

### During metaphase I, paired homologues align

By metaphase I, the second stage of meiosis I, the chiasmata have moved down the paired chromosomes to the ends. At this point, they are called *terminal chiasmata*. Terminal chiasmata

hold the homologous chromosomes together in metaphase I so that homologues can be aligned at the equator of the cell.

The capture of microtubules by kinetochores occurs such that the kinetochores of sister chromatids act as a single unit. This results in microtubules from opposite poles becoming attached to the kinetochores of *homologues*, and not to those of sister chromatids (figure 11.5).

The ability of sister centromeres to behave as a unit during meiosis I is not understood. It has been suggested, based on electron microscope data, that the centromere–kinetochore complex of sister chromatids is compacted during meiosis I, allowing them to function as a single unit.

The monopolar attachment of centromeres of sister chromatids would be disastrous in mitosis, but it is critical to meiosis I. It produces tension on the homologues, which are joined by chiasmata and sister chromatid cohesion, pulling paired homologues to the equator of the cell. In this way, each joined pair of homologues lines up on the metaphase plate (see figure 11.5).

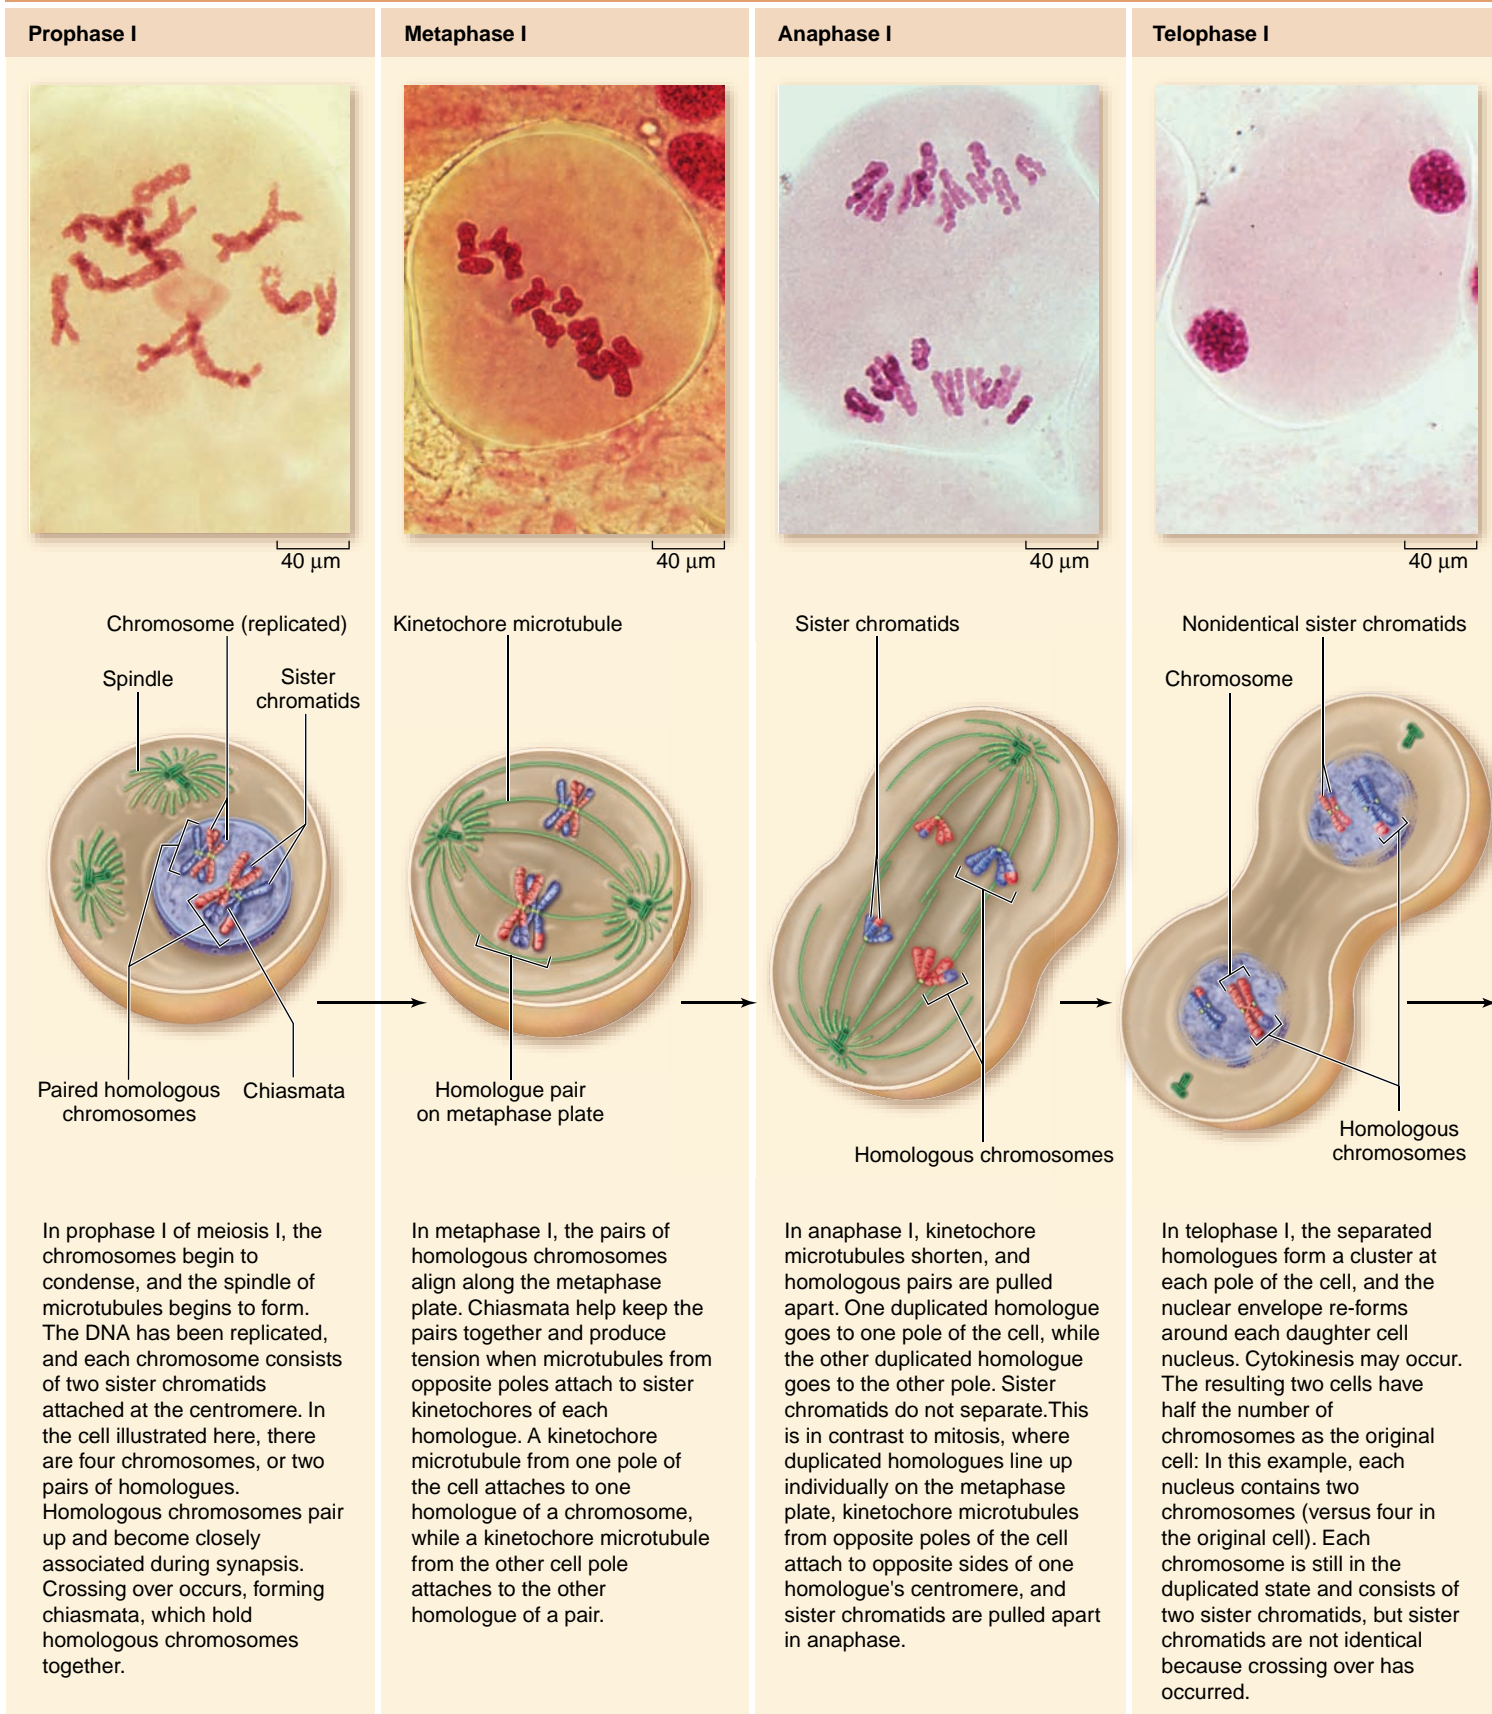

The orientation of each pair on the spindle axis is random; either the maternal or the paternal homologue may be oriented toward a given pole (figure 11.6; see also figure 11.7).

**Figure 11.6 Random orientation of chromosomes on the metaphase plate.** The number of possible chromosome orientations equals 2 raised to the power of the number of chromosome pairs. In this hypothetical cell with three chromosome pairs, eight ( $2^3$ ) possible orientations exist. Each orientation produces gametes with different combinations of parental chromosomes.

## MEIOSIS I

**Figure 11.7 The stages of meiosis.** Meiosis in plant cells (photos) and animal cells (drawings) is shown.

## MEIOSIS II

### Prophase II

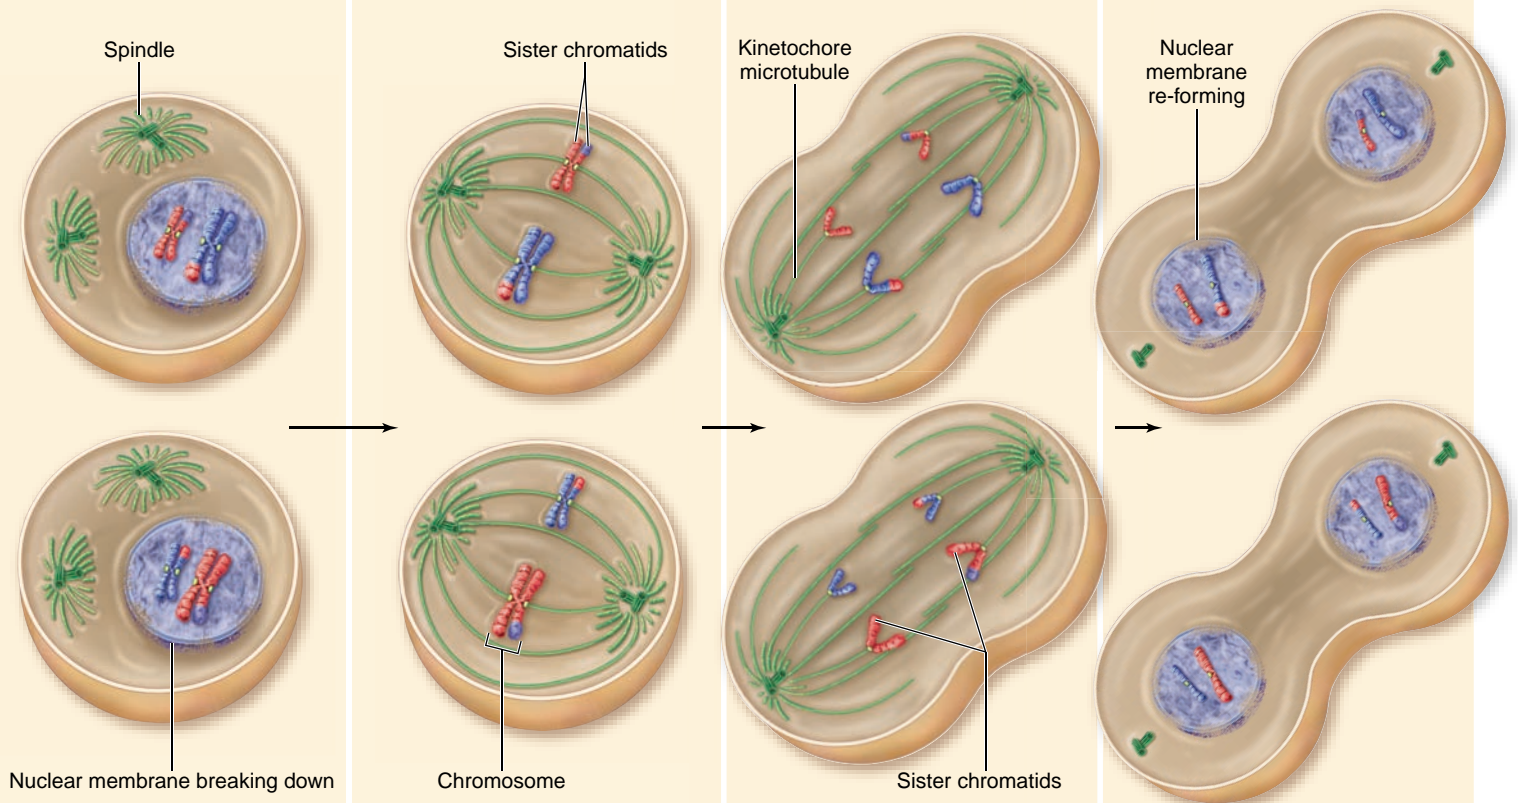

### Metaphase II

### Anaphase II

### Telophase II

Following a typically brief interphase, with no S phase, meiosis II begins. During prophase II, a new spindle apparatus forms in each cell, and the nuclear envelope breaks down. In some species the nuclear envelope does not re-form in telophase I removing the need for nuclear envelope breakdown.

In metaphase II, a completed spindle apparatus is in place in each cell. Chromosomes consisting of sister chromatids joined at the centromere align along the metaphase plate in each cell. Now, kinetochore microtubules from opposite poles attach to kinetochores of sister chromatids.

When microtubules shorten in anaphase II, the centromeres split, and sister chromatids are pulled to opposite poles of the cells.

In telophase II, the nuclear membranes re-form around four different clusters of chromosomes. After cytokinesis, four haploid cells result. No two cells are alike due to the random alignment of homologous pairs at metaphase I and crossing over during prophase I.

## Anaphase I results from the differential loss of sister chromatid cohesion along the arms

In anaphase I, the microtubules of the spindle fibers begin to shorten. As they shorten, they break the chiasmata and pull the centromeres toward the poles, dragging the chromosomes along with them.

Anaphase I comes about by the release of sister chromatid cohesion along the chromosome arms, but not at the centromeres. This release is thought to be the result of the destruction of meiosis-specific cohesin in a process analogous to anaphase in mitosis. The difference is that the destruction is inhibited at the centromeres by a mechanism that is only recently becoming clear.

As a result of this release, the homologues are pulled apart, but not the sister chromatids. Each homologue moves to one pole, taking both sister chromatids with it. When the spindle fibers have fully contracted, each pole has a complete haploid set of chromosomes consisting of one member of each homologous pair.

Because of the random orientation of homologous chromosomes on the metaphase plate, a pole may receive either the maternal or the paternal homologue from each chromosome pair. As a result, the genes on different chromosomes assort independently; that is, meiosis I results in the **independent assortment** of maternal and paternal chromosomes into the gametes (see chapter 12).

## Telophase I completes meiosis I

By the beginning of telophase I, the chromosomes have segregated into two clusters, one at each pole of the cell. Now the nuclear membrane re-forms around each daughter nucleus.

Because each chromosome within a daughter nucleus had replicated before meiosis I began, each now contains two sister chromatids attached by a common centromere. Note that *the sister chromatids are no longer identical* because of the crossing over that occurred in prophase I (see figure 11.7); as you will see, this change has important implications for genetic variability.

Cytokinesis, the division of the cytoplasm and its contents, may or may not occur after telophase I. The second meiotic division, meiosis II, occurs after an interval of variable length.

## Achiasmate segregation of homologues is possible

The preceding description of meiosis I relies on the observation that homologues are held together by chiasmata and by sister chromatid cohesion. This connection produces the critical behavior of chromosomes during metaphase I and anaphase I, when homologues move to the metaphase plate and then move to opposite poles.

Although this connection of homologues is the rule, there are exceptions. In fruit fly (*Drosophila*) males for example, there is no recombination, and yet meiosis proceeds accurately, a process called **achiasmate segregation** (“without chiasmata”).

This seems to involve an alternative mechanism for joining homologues and then allowing their segregation during anaphase I. Telomeres and other heterochromatic sequences have been implicated, but the details remain unclear.

Despite these exceptions, the vast majority of species that have been examined use the formation of chiasmata and sister chromatid cohesion to hold homologues together for segregation during anaphase I.

## Meiosis II is like a mitotic division without DNA replication

Typically, interphase between meiosis I and meiosis II is brief and does not include an S phase: Meiosis II resembles a normal mitotic division. Prophase II, metaphase II, anaphase II, and telophase II follow in quick succession (see figure 11.7).

**Prophase II.** At the two poles of the cell, the clusters of chromosomes enter a brief prophase II, each nuclear envelope breaking down as a new spindle forms.

**Metaphase II.** In metaphase II, spindle fibers from opposite poles bind to kinetochores of each sister chromatid, allowing each chromosome to migrate to the metaphase plate as a result of tension on the chromosomes from polar microtubules pulling on sister centromeres. This process is the same as metaphase during a mitotic division.

**Anaphase II.** The spindle fibers contract, and the cohesin complex joining the centromeres of sister chromatids is destroyed, splitting the centromeres and pulling the sister chromatids to opposite poles. This process is also the same as anaphase during a mitotic division.

**Telophase II.** Finally, the nuclear envelope re-forms around the four sets of daughter chromosomes. Cytokinesis then follows.

The final result of this division is four cells containing haploid sets of chromosomes. The cells that contain these haploid nuclei may develop directly into gametes, as they do in animals. Alternatively, they may themselves divide mitotically, as they do in plants, fungi, and many protists, eventually producing greater numbers of gametes or, as in some plants and insects, adult individuals with varying numbers of chromosome sets.

## Errors in meiosis produce aneuploid gametes

It is critical that the process of meiosis be accurate because any failure produces gametes without the correct number of chromosomes. Failure of chromosomes to move to opposite poles during either meiotic division is called *nondisjunction*, and it produces one gamete that lacks a chromosome and one that has two copies. Gametes with an improper number of chromosomes are called **aneuploid gametes**. In humans, this condition is the most common cause of spontaneous abortion. The implications of aneuploid gametes are explored in more detail in chapter 13.

### Learning Outcomes Review 11.3

Sister chromatid cohesion, combined with crossing over, connects homologous chromosomes during meiosis I. The centromere of each homologue shows monopolar attachment, leading to the alignment of homologous pairs at metaphase I. Loss of cohesion on the arms but not the centromere leads to homologues moving to opposite poles during anaphase I. During anaphase II, cohesin proteins holding sister chromatids together at the centromere are removed, allowing them to move to opposite poles.

- *What would be the result of improper disjunction at anaphase I? At anaphase II?*

## 11.4 Summing Up: Meiosis Versus Mitosis

### Learning Outcomes

1. *Understand the distinct features of meiosis.*
2. *Describe the differences in chromatid cohesion in meiosis and mitosis.*
3. *Explain the importance of the suppression of replication between meiotic divisions.*

The key to meiosis is understanding the differences between meiosis and mitosis. The basic machinery in both processes is the same, but the behavior of chromosomes is distinctly different during the first meiotic division (figure 11.8).

Meiosis is characterized by four distinct features:

1. Homologous pairing and crossing over joins maternal and paternal homologues during meiosis I.
2. Sister chromatids remain connected at the centromere and segregate together during anaphase I.
3. Kinetochores of sister chromatids are attached to the same pole in meiosis I and to opposite poles in mitosis.
4. DNA replication is suppressed between the two meiotic divisions.

Although the underlying molecular mechanisms are unclear, we will consider what we know of each of these features in the following sections.

### Homologous pairing is specific to meiosis

The pairing of homologues during prophase I of meiosis is the first deviation from mitosis and sets the stage for all of the subsequent differences (see figure 11.8). How homologues find each other and become aligned is one of the great mysteries of meiosis. Some cytological evidence implicates telomeres and

other specific sites as being necessary for pairing, but this finding does little to clarify the essential process.

Some light has been shed on the mechanisms with the discovery of meiosis-specific cohesin proteins. In yeast, the protein Rec8 replaces the mitotic Scc1 protein as part of the cohesin complex. You saw in chapter 10 that Scc1 is destroyed during anaphase of mitosis to allow sister chromatids to be pulled to opposite poles. The replacement of this critical cohesin component with a meiosis-specific version seems to be a common feature in systems analyzed to date.

Synaptonemal complex proteins have been identified in diverse species, but these proteins show little sequence conservation. This is despite the similarity of structures observed cytologically. The transverse elements, while showing no sequence conservation, do share the feature of coiled-coil domains that promote protein-protein interactions.

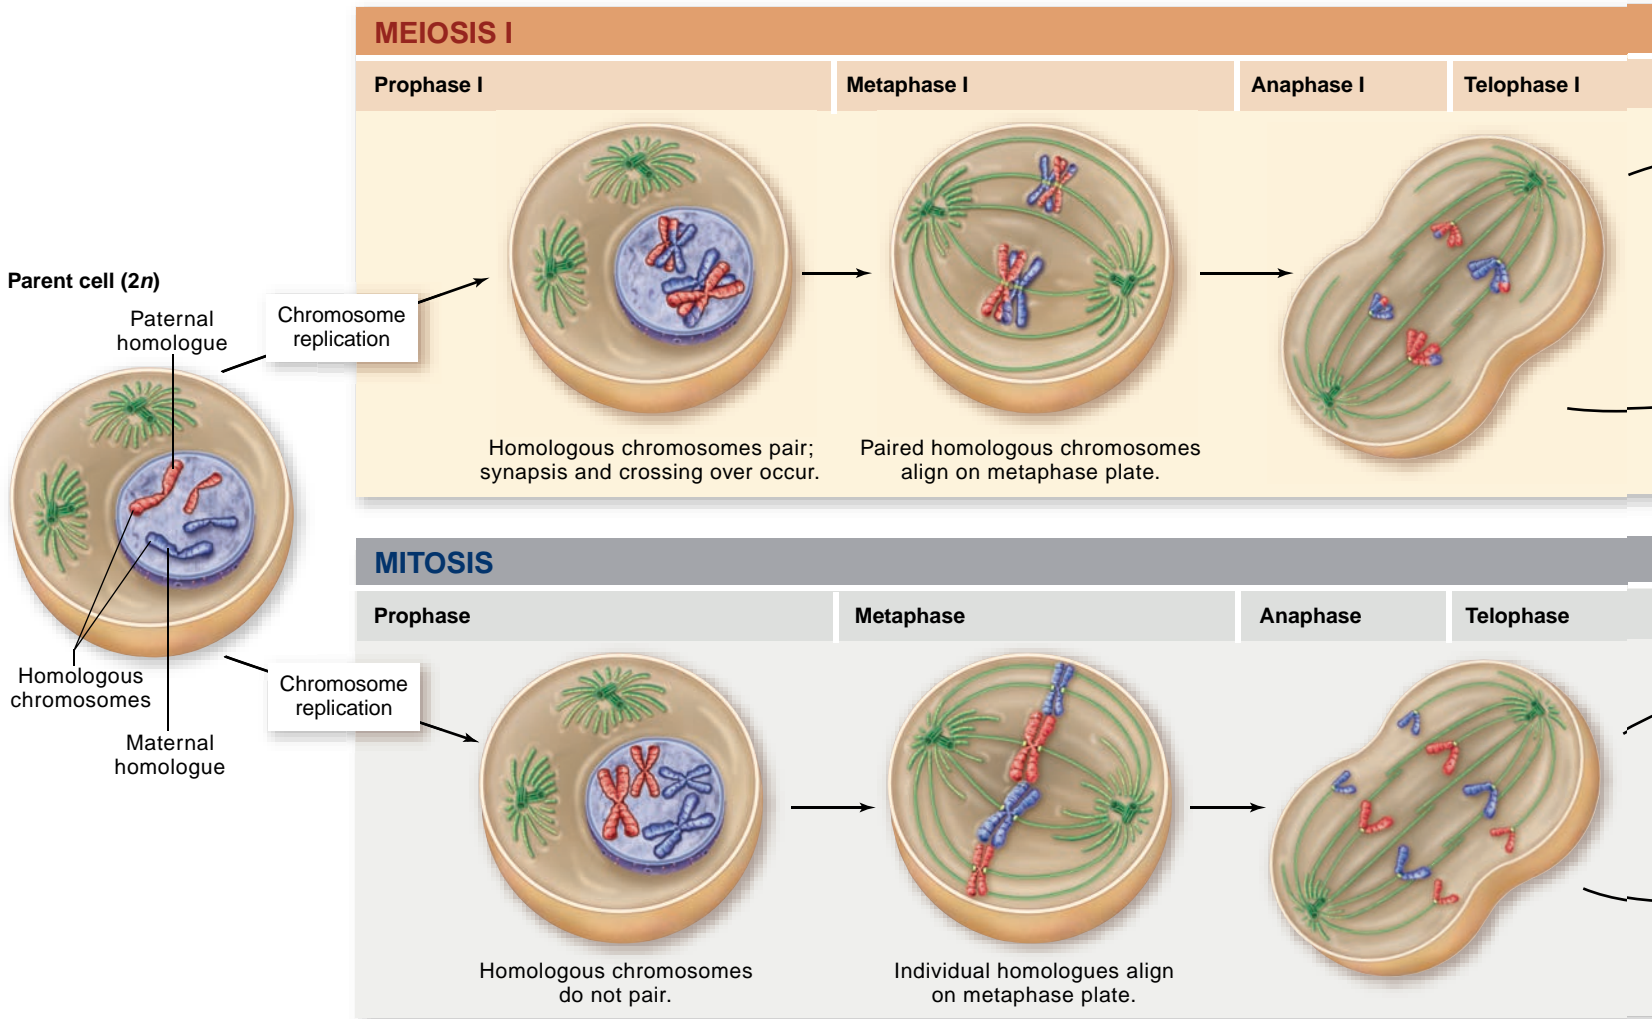

The molecular details of the recombination process that produces crossing over are complex, but many of the proteins involved have been identified. The process is initiated with the introduction of a double-strand break in one homologue. This explains the similarity in the machinery necessary for meiotic recombination and the machinery involved in the repair of double-strand breaks in DNA. Recombination probably first evolved as a repair mechanism and was later co-opted for use in disjoining chromosomes. The importance of recombination for proper disjunction is clear from the observation in many organisms that loss of function for recombination proteins also results in higher levels of nondisjunction.

### Sister chromatid cohesion is maintained through meiosis I but released in meiosis II

Meiosis I is characterized by the segregation of homologues, not sister chromatids, during anaphase. For this separation to occur, the centromeres of sister chromatids must move to the same pole, or cosegregate, during anaphase I. This means that meiosis-specific cohesin proteins must first be removed from the chromosome arms, then later from sister centromeres.

Homologues are joined by chiasmata, and sister chromatid cohesion around the site of exchange then holds homologues together. The destruction of Rec8 protein on the chromosome arms appears to be what allows homologues to be pulled apart at anaphase I.

This leaves the key distinction between meiosis and mitosis being the maintenance of sister chromatid cohesion at the centromere during all of meiosis I, but the loss of cohesion from the chromosome arms during anaphase I (see figure 11.8). Recently, some light was shed on this problem with the identification of conserved proteins, called Shugoshin (a Japanese term meaning “guardian spirit”) required for cohesin protection from separase-mediated cleavage during meiosis I (figure 11.9). Mice have two Shugoshins: Sgo-1 and Sgo-2. Depletion of Sgo-2 results in early sister chromatid separation. This leaves the problem of why Sgo-2 acts only at anaphase I and not anaphase II. It has been suggested that the tension produced by anaphase II causes Sgo-2 to migrate from the centromere to the kinetochore.

### Sister kinetochores are attached to the same pole during meiosis I

The cosegregation of sister centromeres requires that the kinetochores of sister chromatids are attached to the same pole during meiosis I. This attachment is in contrast to both mitosis (see figure 11.8) and meiosis II, in which sister kinetochores must become attached to opposite poles.

The underlying basis of this monopolar attachment of sister kinetochores is unclear, but it seems to be based on structural differences between centromere–kinetochore complexes in meiosis I and in mitosis. Mitotic kinetochores visualized with the electron microscope appear to be recessed, making bipolar attachment more likely. Meiosis I kinetochores protrude more, making monopolar attachment easier.

It is clear that both the maintenance of sister chromatid cohesion at the centromere and monopolar attachment are required for the segregation of homologues that distinguishes meiosis I from mitosis.

### Replication is suppressed between meiotic divisions

After a mitotic division, a new round of DNA replication must occur before the next division. For meiosis to succeed in halving the number of chromosomes, this replication must be suppressed between the two divisions. The detailed mechanism of suppression of replication between meiotic division is unknown. One clue is the observation that the level of one of the cyclins, cyclin B, is reduced between meiotic divisions, but is not lost completely, as it is between mitotic divisions.

During mitosis, the destruction of mitotic cyclin is necessary for a cell to enter another division cycle. The result of this maintenance of cyclin B between meiotic divisions in germ-line cells is the failure to form initiation complexes necessary for DNA replication to proceed. This failure to form initiation complexes appears to be critical to suppressing DNA replication.

**Figure 11.8 A comparison of meiosis and mitosis.** Meiosis involves two nuclear divisions with no DNA replication between them. It thus produces four daughter cells, each with half the original number of chromosomes. Crossing over occurs in prophase I of meiosis. Mitosis involves a single nuclear division after DNA replication. It thus produces two daughter cells, each containing the original number of chromosomes.

### Inquiry question

? If the chromosomes of a mitotic cell behaved the same as chromosomes in meiosis I, would the resulting cells have the proper chromosomal constitution?

## SCIENTIFIC THINKING

**Question:** Why are cohesin proteins at the centromeres of sister chromatids not destroyed at anaphase I of meiosis?

**Hypothesis:** Meiosis-specific cohesin component *Rec8* is protected by another protein at centromeres.

**Prediction:** If *Rec8* and the centromere protecting protein are both expressed in mitotic cells, chromosome separation will be prevented. This is lethal to a dividing cell.

**Test:** Fission yeast strain is designed to produce *Rec8* instead of normal mitotic cohesin. These cells are transformed with a cDNA library that expresses all cellular proteins. Transformed cells are duplicated onto media containing dye for dead cells (allows expression of *Rec8* and cDNA), and media that will result in loss of plasmid cDNA (expresses only *Rec8*). Cells containing cDNA for protecting protein will be dead in presence of *Rec8*.

**Result:** Transformed cells that die on the plates where *Rec8* is coexpressed with cDNA identify the protecting protein. When the cDNA is extracted and analyzed, the encoded protein localizes to the centromeres of meiotic cells.

**Conclusion:** This screen identifies a protein with *Rec8* protecting activity.

**Further Experiments:** If the gene encoding the protecting protein is deleted from cells, what would be the expected phenotype? In mitotic cells? In meiotic cells?

**Figure 11.9 Identification of meiosis-specific cohesin protector.**

## Meiosis produces cells that are not identical

The daughter cells produced by mitosis are identical to the parental cell, at least in terms of their chromosomal constitution. This exact copying is critical to producing new cells for growth, for development, and for wound healing. Meiosis, because of the random orientation of different chromosomes at the first meiotic division and because of crossing over, rarely produces cells that are identical. The gametes from meiosis all carry an entire haploid set of chromosomes, but these chromosomes are a mixture of maternal and paternal homologues; furthermore, the homologues themselves have exchanged material by crossing over. The resulting variation is essential for evolution and is the reason that sexually reproducing populations have much greater variation than asexually reproducing ones.

Meiosis is not only critical for the process of sexual reproduction, but is also the foundation for understanding the basis

of heredity. The different cells produced by meiosis form the basis for understanding the behavior of observable traits in genetic crosses. In the next two chapters we will follow the behavior of traits in genetic crosses and see how this correlates with the behavior of chromosomes in meiosis.

### Learning Outcomes Review 11.4

Meiosis is characterized by homologue pairing and crossing over; by loss of sister chromatid cohesion in the arms, but not at the centromere at the first division; and by the suppression of DNA replication between the two meiotic divisions. Sister chromatid cohesion would be disastrous in mitosis, but in meiosis I it allows the reduction of chromosome number. If replication were not suppressed between meiosis I and meiosis II, gametes would be diploid, and zygotes would be tetraploid.

- *What features of meiosis lead to genetic variation in the products?*

## Chapter Review

### 11.1 Sexual Reproduction Requires Meiosis

(figure 11.2)

**Meiosis reduces the number of chromosomes.**

Eggs and sperm are haploid ( $1n$ ) cells, which contain one set of all chromosomes, and products of meiotic division.

**Sexual life cycles have both haploid and diploid stages.**

During fertilization, or syngamy, the fusion of two haploid gametes results in a diploid ( $2n$ ) zygote, which contains two sets of chromosomes. Meiosis and fertilization constitute a reproductive cycle in sexual organisms as they alternate between diploid and haploid chromosome numbers. Somatic cells divide by mitosis and form the body of an organism.

**Germ-line cells are set aside early in animal development.**

Cells that eventually will form haploid gametes by meiosis are called germ-line cells. These are set aside early in development in animals.

### 11.2 Features of Meiosis

**Homologous chromosomes pair during meiosis.**

The pairing of homologous chromosomes, called synapsis, occurs during early prophase I. Paired homologues are often joined by the synaptonemal complex (see figure 11.3). During synapsis, crossing over occurs between homologous chromosomes, exchanging chromosomal material (see figure 11.4). Because the homologues are paired, they move as a unit to the metaphase plate during metaphase I. During anaphase I, homologues of each pair are pulled to opposite poles, producing two cells that each have one complete set of chromosomes.

**Meiosis features two divisions with one round of DNA replication.**

Meiosis II is like mitosis but without replication of DNA. Sister chromatids are pulled to opposite poles to yield four haploid cells.

### 11.3 The Process of Meiosis (see figures 11.7 and 11.8)

**Prophase I sets the stage for the reductive division.**

Meiotic cells have an interphase period similar to mitosis with  $G_1$ ,  $S$ , and  $G_2$  phases. This is followed by prophase I in which homologous chromosomes align along their entire length. The sister chromatids are held together by cohesin proteins. Homologues exchange chromosomal material by crossing over, which assists in holding the homologues together during meiosis I. The nuclear envelope disperses and the spindle apparatus forms.

**During metaphase I, paired homologues align.**

Spindle fibers attach to the kinetochores of the homologues; the kinetochores of sister chromatids behave as a single unit. Homologues of each pair become attached by kinetochore microtubules to opposite poles, and homologous pairs move to the metaphase plate as a unit. The orientation of each homologous pair on the equator is random; either the maternal or paternal homologue may be oriented toward a given pole.

**Anaphase I results from the differential loss of sister chromatid cohesion along the arms.**

During anaphase I the homologues of each pair are pulled to opposite poles as kinetochore microtubules shorten. Loss of sister chromatid cohesion on the arms but not at the centromeres allows homologues to separate, but sister chromatids to stay together. This is due to the loss of cohesin proteins on the arms but not at the centromere. At the end of anaphase I each pole has a complete set of haploid chromosomes, consisting of one member of each homologous pair. Because of the random orientation of homologous pairs at metaphase I, meiosis I results in the independent assortment of maternal and paternal chromosomes in gametes.

**Telophase I completes meiosis I.**

During telophase I the nuclear envelope re-forms around each daughter nucleus. This phase does not occur in all species. Cytokinesis may or may not occur after telophase I.

**Achiasmata segregation of homologues is possible.**

Although homologues are usually held together by chiasmata, some systems are able to segregate chromosomes without this.

**Meiosis II is like a mitotic division without DNA replication.**

A brief interphase with no DNA replication occurs after meiosis I. During meiosis II, cohesin proteins at the centromeres that hold sister chromatids together are destroyed, allowing each to migrate to opposite poles of the cell. The result of meiosis I and II is four cells, each containing haploid sets of chromosomes that are not identical. Once completed, the haploid cells may produce gametes or divide mitotically to produce even more gametes or haploid adults.

**Errors in meiosis produce aneuploid gametes.**

Errors occur during meiosis because of nondisjunction, the failure of chromosomes to move to opposite poles. It may result in aneuploid gametes: one gamete with no chromosome, and another gamete with two copies of a chromosome.

## 11.4 Summing Up: Meiosis Versus Mitosis

Four distinct features of meiosis I are not found in mitosis: Maternal and paternal homologues pair, and exchange genetic information by crossing over; the kinetochores of sister chromatids function as a unit during meiosis I, allowing sister chromatids to cosegregate during anaphase I; kinetochores of sister chromatids are connected to a single pole in meiosis I and to opposite poles in mitosis; and DNA replication is suppressed between meiosis I and meiosis II.

**Homologous pairing is specific to meiosis.**

How homologues find each other during meiosis is not known. The proteins of the synaptonemal complex do not seem to be conserved in different species, but there are meiosis-specific cohesin proteins. These are involved in the differential destruction of cohesins on the arms versus the centromere during meiosis I. The recombination process that occurs between paired homologues is better known. This process uses proteins involved in DNA repair and starts with a double-stranded break in DNA.

**Sister chromatid cohesion is maintained through meiosis I but released in meiosis II.**

Shugoshin protein protects centromeric cohesin in anaphase I, so that sister chromatids remain connected. Cohesins on the arms are not protected and are thus degraded during anaphase I, allowing homologues to move to opposite poles.

**Sister kinetochores are attached to the same pole during meiosis I.**

Kinetochores of sister chromatids must be attached to the same spindle fibers (monopolar attachment) to segregate together.

**Replication is suppressed between meiotic divisions.**

Suppression of replication may be related to the maintenance of some cyclin proteins that are degraded at the end of mitosis.

**Meiosis produces cells that are not identical.**

Because of the independent assortment of homologues and the process of crossing over, gametes show great variation.

## Review Questions

### UNDERSTAND

- In comparing somatic cells and gametes, somatic cells are
  - diploid with half the number of chromosomes.
  - haploid with half the number of chromosomes.
  - diploid with twice the number of chromosomes.
  - haploid with twice the number of chromosomes.
- What are *homologous* chromosomes?
  - The two halves of a replicated chromosome
  - Two identical chromosomes from one parent
  - Two genetically identical chromosomes, one from each parent
  - Two genetically similar chromosomes, one from each parent
- Chiasmata form
  - between homologous chromosomes.
  - sister chromatids.
  - between replicated copies of the same chromosomes.
  - sex chromosomes but not autosomes.
- Crossing over involves each of the following with the exception of
  - the transfer of DNA between two nonsister chromatids.
  - the transfer of DNA between two sister chromatids.
  - the formation of a synaptonemal complex.
  - the alignment of homologous chromosomes.

- During anaphase I
  - sister chromatids separate and move to the poles.
  - homologous chromosomes move to opposite poles.
  - homologous chromosomes align at the middle of the cell.
  - all the chromosomes align independently at the middle of the cell.
- At metaphase I the kinetochores of sister chromatids are
  - attached to microtubules from the same pole.
  - attached to microtubules from opposite poles.
  - held together with cohesin proteins.
  - not attached to any microtubules.
- What occurs during anaphase of meiosis II?
  - The homologous chromosomes align.
  - Sister chromatids are pulled to opposite poles.
  - Homologous chromosomes are pulled to opposite poles.
  - The haploid chromosomes line up.

### APPLY

- Which of the following does *not* contribute to genetic diversity?
  - Independent assortment
  - Recombination
  - Metaphase of meiosis II
  - Metaphase of meiosis I

2. How does DNA replication differ between mitosis and meiosis?
  - a. DNA replication takes less time in meiosis because the cells are haploid.
  - b. During meiosis, there is only one round of replication for two divisions.
  - c. During mitosis, there is only one round of replication every other division.
  - d. DNA replication is exactly the same in mitosis and meiosis.
3. Which of the following is *not* a distinct feature of meiosis?
  - a. Pairing and exchange of genetic material between homologous chromosomes
  - b. Attachment of sister kinetochores to spindle microtubules
  - c. Movement of sister chromatids to the same pole
  - d. Suppression of DNA replication
4. Which phase of meiosis I is most similar to the comparable phase in mitosis?
  - a. Prophase I
  - b. Metaphase I
  - c. Anaphase I
  - d. Telophase I
5. Structurally, meiotic cohesins have different components than mitotic cohesins. This leads to the following functional difference:
  - a. During metaphase I, the sister kinetochores become attached to the same pole.
  - b. Centromeres remain attached during anaphase I of meiosis.
  - c. Centromeres remain attached through both divisions.
  - d. Centromeric cohesins are destroyed at anaphase I, and cohesins along the arms are destroyed at anaphase II.
6. Mutations that affect DNA repair often also affect the accuracy of meiosis. This is because
  - a. the proteins involved in the repair of double-strand breaks are also involved in crossing over.
  - b. the proteins involved in DNA repair are also involved in sister chromatid cohesion.
  - c. DNA repair only occurs on condensed chromosomes such as those found in meiosis.
  - d. cohesin proteins are also necessary for DNA repair.
- c. Draw a new cell showing how these chromosomes would arrange themselves during metaphase of meiosis I. Do all the maternal homologues have to line up on the same side of the cell?
- d. How would this picture differ if you were diagramming anaphase of meiosis II?
2. Mules are the offspring of the mating of a horse and a donkey. Mules are unable to reproduce. A horse has a total of 64 chromosomes, whereas donkeys have 62 chromosomes. Use your knowledge of meiosis to predict the diploid chromosome number of a mule. Propose a possible explanation for the inability of mules to reproduce.
3. Compare the processes of *independent assortment* and *crossing over*. Which process has the greatest influence on genetic diversity?
4. Aneuploid gametes are cells that contain the wrong number of chromosomes. Aneuploidy occurs as a result of *nondisjunction*, or lack of separation of the chromosomes during either phase of meiosis.
  - a. At what point in meiotic cell division would nondisjunction occur?
  - b. Imagine a cell had a diploid chromosome number of four. Create a diagram to illustrate the effects of nondisjunction of one pair of homologous chromosomes in meiosis I versus meiosis II.

## SYNTHESIZE

1. Diagram the process of meiosis for an imaginary cell with six chromosomes in a diploid cell.
  - a. How many homologous pairs are present in this cell? Create a drawing that distinguishes between homologous pairs.
  - b. Label each homologue to indicate whether it is maternal (M) or paternal (P).

- 12.6** Extensions to Mendel

**Introduction**

*Every living creature is a product of the long evolutionary history of life on Earth. All organisms share this history, but as far as we know, only humans wonder about the processes that led to their origin and investigate the possibilities. We are far from understanding everything about our origins, but we have learned a great deal. Like a partially completed jigsaw puzzle, the boundaries of this elaborate question have fallen into place, and much of the internal structure is becoming apparent. In this chapter, we discuss one piece of the puzzle—the enigma of heredity. Why do individuals, like the children in this picture, differ so much in appearance despite the fact that we are all members of the same species? And, why do members of a single family tend to resemble one another more than they resemble members of other families?*

**12.1** *The Mystery of Heredity***Learning Outcomes**

1. Describe explanations for inheritance prior to Mendel.
2. Explain the advantages of Mendel's experimental system.

As far back as written records go, patterns of resemblance among the members of particular families have been noted and commented on (figure 12.1), but there was no coherent model to explain these patterns. Before the 20th century, two concepts provided the basis for most thinking about heredity. The first was that heredity occurs within species. The second was that traits are transmitted directly from parents to offspring. Taken together, these ideas led to a view of inheritance as resulting from a blending of traits within fixed, unchanging species.

**Figure 12.1 Heredity and family resemblance.** Family resemblances are often strong—a visual manifestation of the mechanism of heredity.

Inheritance itself was viewed as traits being borne through fluid, usually identified as blood, that led to their blending in offspring. This older idea persists today in the use of the term “bloodlines” when referring to the breeding of domestic animals such as horses.

Taken together, however, these two classical assumptions led to a paradox. If no variation enters a species from outside, and if the variation within each species blends in every generation, then all members of a species should soon have the same appearance. It is clear that this does not happen—individuals within most species differ from one another, and they differ in characteristics that are transmitted from generation to generation.

## Early plant biologists produced hybrids and saw puzzling results

The first investigator to achieve and document successful experimental **hybridizations** was Josef Kölreuter, who in 1760 cross-fertilized (or crossed, for short) different strains of tobacco and obtained fertile offspring. The hybrids differed in appearance from both parent strains. When individuals within the hybrid generation were crossed, their offspring were highly variable. Some of these offspring resembled plants of the hybrid generation (their parents), but a few resembled the original strains (their grandparents). The variation observed in second-generation offspring contradicts the theory of direct transmission. This can be seen as the beginning of modern genetics.

Over the next hundred years, other investigators elaborated on Kölreuter’s work. T. A. Knight, an English landholder, in 1823 crossed two varieties of the garden pea, *Pisum sativum* (figure 12.2). One of these varieties had green seeds, and the other had yellow seeds. Both varieties were **true-breeding**, meaning that the offspring produced from self-fertilization remained uniform from

one generation to the next. All of the progeny (offspring) of the cross between the two varieties had yellow seeds. Among the offspring of these hybrids, however, some plants produced yellow seeds and others, less common, produced green seeds.

Other investigators made observations similar to Knight’s, namely that alternative forms of observed traits were being distributed among the offspring. A modern geneticist would say the alternative forms of each trait were **segregating** among the progeny of a mating, meaning that some offspring exhibited one form of a trait (yellow seeds), and other offspring from the same mating exhibited a different form (green seeds). This segregation of alternative forms of a trait provided the clue that led Gregor Mendel to his understanding of the nature of heredity.

Within these deceptively simple results were the makings of a scientific revolution. Nevertheless, another century passed before the process of segregation was fully appreciated.

## Mendel used mathematics to analyze his crosses

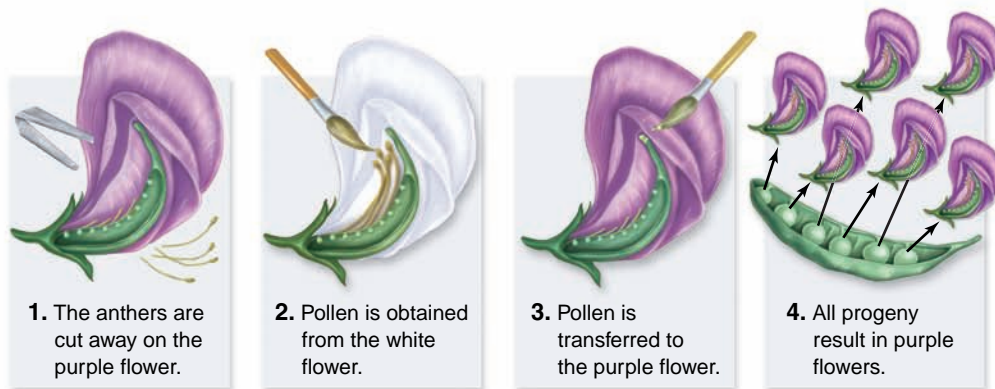

Born in 1822 to peasant parents, Gregor Mendel (figure 12.3) was educated in a monastery and went on to study science and mathematics at the University of Vienna, where he failed his examinations for a teaching certificate. He returned to the monastery and spent the rest of his life there, eventually becoming abbot. In the garden of the monastery, Mendel initiated his own series of experiments on plant hybridization. The results of these experiments would ultimately change our views of heredity irrevocably.

### Practical considerations for use of the garden pea

For his experiments, Mendel chose the garden pea, the same plant Knight and others had studied. The choice was a good one for several reasons. First, many earlier investigators had produced hybrid peas by crossing different varieties, so Mendel knew that he could expect to observe segregation of traits among the offspring.

**Figure 12.2 The garden pea, *Pisum sativum*.** Easy to cultivate and able to produce many distinctive varieties, the garden pea was a popular experimental subject in investigations of heredity as long as a century before Gregor Mendel’s experiments.

**Figure 12.3** How Mendel conducted his experiments. In a pea plant flower, petals enclose both the male anther (containing pollen grains, which give rise to haploid sperm) and the female carpel (containing ovules, which give rise to haploid eggs). This ensures self-fertilization will take place unless the flower is disturbed. Mendel collected pollen from the anthers of a white flower, then placed that pollen onto the stigma of a purple flower with anthers removed. This cross fertilization yields all hybrid seeds that give rise to purple flowers. Using pollen from a white flower to fertilize a purple flower gives the same result.

### Inquiry question

What confounding problems could have been seen if Mendel had chosen another plant with exposed male and female structures?

Second, a large number of pure varieties of peas were available. Mendel initially examined 34 varieties. Then, for further study, he selected lines that differed with respect to seven easily distinguishable traits, such as round versus wrinkled seeds and yellow versus green seeds, the latter a trait that Knight had studied.

Third, pea plants are small and easy to grow, and they have a relatively short generation time. A researcher can therefore conduct experiments involving numerous plants, grow several generations in a single year, and obtain results relatively quickly.

A fourth advantage of studying peas is that both the male and female sexual organs are enclosed within each pea flower (see figure 12.3), and gametes produced by the male and female parts of the same flower can fuse to form viable offspring, a process termed **self-fertilization**. This self-fertilization takes place automatically within an individual flower if it is not disturbed. It is also possible to prevent self-fertilization by removing a flower's male parts before fertilization occurs, then introduce pollen from a different strain, thus performing *cross-pollination* that results in *cross-fertilization* (see figure 12.3).

### Mendel's experimental design

Mendel was careful to focus on only a few specific differences between the plants he was using and to ignore the countless other differences he must have seen. He also had the insight to realize that the differences he selected must be comparable. For example, he recognized that trying to study the inheritance of round seeds versus tall height would be useless.

Mendel usually conducted his experiments in three stages:

1. Mendel allowed plants of a given variety to self-cross for multiple generations to assure himself that the traits he

was studying were indeed true-breeding, that is, transmitted unchanged from generation to generation.

2. Mendel then performed crosses between true-breeding varieties exhibiting alternative forms of traits. He also performed **reciprocal crosses**: using pollen from a white-flowered plant to fertilize a purple-flowered plant, then using pollen from a purple-flowered plant to fertilize a white-flowered plant.
3. Finally, Mendel permitted the hybrid offspring produced by these crosses to self-fertilize for several generations, allowing him to observe the inheritance of alternative forms of a trait. Most important, he counted the numbers of offspring exhibiting each trait in each succeeding generation.

This quantification of results is what distinguished Mendel's research from that of earlier investigators, who only noted differences in a qualitative way. Mendel's mathematical analysis of experimental results led to the inheritance model that we still use today.

### Learning Outcomes Review 12.1

Prior to Mendel, concepts of inheritance did not form a consistent model. The dominant view was of blending inheritance, in which traits of parents were carried by fluid and "blended" in offspring. Plant hybridizers before Mendel, however, had already cast doubt on this model by observing characteristics in hybrids that seemed to change in second-generation offspring. Mendel's experiments with plants involved quantifying types of offspring and mathematically analyzing his observations.

- Which was more important to Mendel's success: his approach, or his choice of experimental material?

## 12.2 Monohybrid Crosses: The Principle of Segregation

### Learning Outcomes

1. Evaluate the outcome of a monohybrid cross.
2. Explain Mendel's principle of segregation.
3. Compare the segregation of alleles with the behavior of homologues in meiosis.

A *monohybrid cross* is a cross that follows only two variations on a single trait, such as white- and purple-colored flowers. This deceptively simple kind of cross can lead to important conclusions about the nature of inheritance.

The seven characteristics, or characters, Mendel studied in his experiments possessed two variants that differed from one another in ways that were easy to recognize and score (figure 12.4). We examine in detail Mendel's crosses with flower color. His experiments with other characters were similar, and they produced similar results.

### The F<sub>1</sub> generation exhibits only one of two traits, without blending

When Mendel crossed white-flowered and purple-flowered plants, the hybrid offspring he obtained did not have flowers of intermediate color, as the hypothesis of blending inheritance would predict. Instead, in every case the flower color of the offspring resembled that of one of their parents. These offspring are customarily referred to as the **first filial generation**, or F<sub>1</sub>. In a cross of white-flowered and purple-flowered plants, the F<sub>1</sub> offspring all had purple flowers, as other scientists had reported before Mendel.

Mendel referred to the form of each trait expressed in the F<sub>1</sub> plants as **dominant**, and to the alternative form that was not expressed in the F<sub>1</sub> plants as **recessive**. For each of the seven pairs of contrasting traits that Mendel examined, one of the pair proved to be dominant and the other recessive.

### The F<sub>2</sub> generation exhibits both traits in a 3:1 ratio

After allowing individual F<sub>1</sub> plants to mature and self-fertilize, Mendel collected and planted the seeds from each plant to see what the offspring in the **second filial generation**, or F<sub>2</sub>, would look like. He found that although most F<sub>2</sub> plants had purple flowers, some exhibited white flowers, the recessive trait. Although hidden in the F<sub>1</sub> generation, the recessive trait had reappeared among some F<sub>2</sub> individuals.

Believing the proportions of the F<sub>2</sub> types would provide some clue about the mechanism of heredity, Mendel counted the numbers of each type among the F<sub>2</sub> progeny. In the cross between the purple-flowered F<sub>1</sub> plants, he obtained a total of 929 F<sub>2</sub> individuals. Of these, 705 (75.9%) had purple flowers, and 224 (24.1%) had white flowers (see figure 12.4).

Dominant	Recessive	F <sub>2</sub> Generation
<b>1. Flower Color</b>		
 Purple	X  White	705 Purple: 224 White  3.15:1
<b>2. Seed Color</b>		
 Yellow	X  Green	6022 Yellow: 2001 Green  3.01:1
<b>3. Seed Texture</b>		
 Round	X  Wrinkled	5474 Round: 1850 Wrinkled  2.96:1
<b>4. Pod Color</b>		
 Green	X  Yellow	428 Green: 152 Yellow  2.82:1
<b>5. Pod Shape</b>		
 Inflated	X  Constricted	882 Inflated: 299 Constricted  2.95:1
<b>6. Flower Position</b>		
 Axial	X  Terminal	651 Axial: 207 Terminal  3.14:1
<b>7. Plant Height</b>		
 Tall	X  Short	787 Tall: 277 Short  2.84:1

**Figure 12.4 Mendel's seven traits.** Mendel studied how differences among varieties of peas were inherited when the varieties were crossed. Similar experiments had been done before, but Mendel was the first to quantify the results and appreciate their significance. Results are shown for seven different monohybrid crosses. The F<sub>1</sub> generation is not shown in the table.

Approximately  $\frac{1}{4}$  of the  $F_2$  individuals, therefore, exhibited the recessive form of the character.

Mendel obtained the same numerical result with the other six characters he examined: Of the  $F_2$  individuals,  $\frac{3}{4}$  exhibited the dominant trait, and  $\frac{1}{4}$  displayed the recessive trait (see figure 12.4). In other words, the dominant-to-recessive ratio among the  $F_2$  plants was always close to 3:1.

### The 3:1 ratio is actually 1:2:1

Mendel went on to examine how the  $F_2$  plants passed traits to subsequent generations. He found that plants exhibiting the recessive trait were always true-breeding. For example, the white-flowered  $F_2$  individuals reliably produced white-flowered offspring when they were allowed to self-fertilize. By contrast, only  $\frac{1}{3}$  of the dominant, purple-flowered  $F_2$  individuals ( $\frac{1}{4}$  of all  $F_2$  offspring) proved true-breeding, but  $\frac{2}{3}$  were not. This last class of plants produced dominant and recessive individuals in the third filial generation ( $F_3$ ) in a 3:1 ratio.

This result suggested that, for the entire sample, the 3:1 ratio that Mendel observed in the  $F_2$  generation was really a disguised 1:2:1 ratio:  $\frac{1}{4}$  true-breeding dominant individuals,  $\frac{1}{2}$  not-true-breeding dominant individuals, and  $\frac{1}{4}$  true-breeding recessive individuals (figure 12.5).

### Mendel's Principle of Segregation explains monohybrid observations

From his experiments, Mendel was able to understand four things about the nature of heredity:

- The plants he crossed did not produce progeny of intermediate appearance, as a hypothesis of blending inheritance would have predicted. Instead, different plants inherited each trait intact, as a discrete characteristic.
- For each pair of alternative forms of a trait, one alternative was not expressed in the  $F_1$  hybrids, although it reappeared in some  $F_2$  individuals. *The trait that “disappeared” must therefore be latent (present but not expressed) in the  $F_1$  individuals.*
- The pairs of alternative traits examined were segregated among the progeny of a particular cross, some individuals exhibiting one trait and some the other.
- These alternative traits were expressed in the  $F_2$  generation in the ratio of  $\frac{3}{4}$  dominant to  $\frac{1}{4}$  recessive. This characteristic 3:1 segregation is referred to as the **Mendelian ratio** for a monohybrid cross.

### Mendel's five-element model

To explain these results, Mendel proposed a simple model that has become one of the most famous in the history of science, containing simple assumptions and making clear predictions. The model has five elements:

1. Parents do not transmit physiological traits directly to their offspring. Rather, they transmit discrete information for the traits, what Mendel called “factors.” We now call these factors *genes*.

**Figure 12.5** The  $F_2$  generation is a disguised 1:2:1 ratio. By allowing the  $F_2$  generation to self-fertilize, Mendel found from the offspring ( $F_3$ ) that the ratio of  $F_2$  plants was 1 true-breeding dominant: 2 not-true-breeding dominant: and 1 true-breeding recessive.

2. Each individual receives one copy of each gene from each parent. We now know that genes are carried on chromosomes, and each adult individual is diploid, with one set of chromosomes from each parent.
3. Not all copies of a gene are identical. The alternative forms of a gene are called **alleles**. When two haploid gametes containing the same allele fuse during fertilization, the resulting offspring is said to be **homozygous**. When the two haploid gametes contain different alleles, the resulting offspring is said to be **heterozygous**.

- The two alleles remain discrete—they neither blend with nor alter each other. Therefore, when the individual matures and produces its own gametes, the alleles segregate randomly into these gametes.
- The presence of a particular allele does not ensure that the trait it encodes will be expressed. In heterozygous individuals, only one allele is expressed (the dominant one), and the other allele is present but unexpressed (the recessive one).

Geneticists now refer to the total set of alleles that an individual contains as the individual's **genotype**. The physical appearance or other observable characteristics of that individual, which result from an allele's expression, is termed the individual's **phenotype**. In other words, the genotype is the blueprint, and the phenotype is the visible outcome in an individual.

This also allows us to present Mendel's ratios in more modern terms. The 3:1 ratio of dominant to recessive is the monohybrid phenotypic ratio. The 1:2:1 ratio of homozygous dominant to heterozygous to homozygous recessive is the monohybrid genotypic ratio. The genotypic ratio "collapses" into the phenotypic ratio due to the action of the dominant allele making the heterozygote appear the same as homozygous dominant.

### The principle of segregation

Mendel's model accounts for the ratios he observed in a neat and satisfying way. His main conclusion—that alternative alleles for a character segregate from each other during gamete formation

and remain distinct—has since been verified in many other organisms. It is commonly referred to as Mendel's first law of heredity, or the **Principle of Segregation**. It can be simply stated as: *The two alleles for a gene segregate during gamete formation and are rejoin at random, one from each parent, during fertilization.*

The physical basis for allele segregation is the behavior of chromosomes during meiosis. As you saw in chapter 11, homologues for each chromosome disjoin during anaphase I of meiosis. The second meiotic division then produces gametes that contain only one homologue for each chromosome.

It is a tribute to Mendel's intellect that his analysis arrived at the correct scheme, even though he had no knowledge of the cellular mechanisms of inheritance; neither chromosomes nor meiosis had yet been described.

### The Punnett square allows symbolic analysis

To test his model, Mendel first expressed it in terms of a simple set of symbols. He then used the symbols to interpret his results.

Consider again Mendel's cross of purple-flowered with white-flowered plants. By convention, we assign the symbol  $P$  (uppercase) to the dominant allele, associated with the production of purple flowers, and the symbol  $p$  (lowercase) to the recessive allele, associated with the production of white flowers.

In this system, the genotype of an individual that is true-breeding for the recessive white-flowered trait would be designated  $pp$ . Similarly, the genotype of a true-breeding purple-flowered

**Figure 12.6** Using a Punnett square to analyze Mendel's cross.

**a.** To make a Punnett square, place the different female gametes along the side of a square and the different male gametes along the top. Each potential zygote is represented as the intersection of a vertical line and a horizontal line. **b.** In Mendel's cross of purple by white flowers, each parent makes only one type of gamete. The  $F_1$  are all purple,  $Pp$ , heterozygotes. These  $F_1$  offspring make two types of gametes that can be combined to produce three kinds of  $F_2$  offspring:  $PP$  homozygous dominant (purple);  $Pp$  heterozygous (also purple); and  $pp$  homozygous recessive (white). The phenotypic ratio is 3 purple:1 white. The genotypic ratio is 1  $PP$ :2  $Pp$ :1  $pp$ .

TABLE 12.1 Some Dominant and Recessive Traits in Humans			
Recessive Traits	Phenotypes	Dominant Traits	Phenotypes
Albinism	Lack of melanin pigmentation	Middigital hair	Presence of hair on middle segment of fingers
Alkaptonuria	Inability to metabolize homogentisic acid	Brachydactyly	Short fingers
Red-green color blindness	Inability to distinguish red or green wavelengths of light	Huntington disease	Degeneration of nervous system, starting in middle age
Cystic fibrosis	Abnormal gland secretion, leading to liver degeneration and lung failure	Phenylthiocarbamide (PTC) sensitivity	Ability to taste PTC as bitter
Duchenne muscular dystrophy	Wasting away of muscles during childhood	Camptodactyly	Inability to straighten the little finger
Hemophilia	Inability of blood to clot properly, some clots form but the process is delayed	Hypercholesterolemia (the most common human Mendelian disorder)	Elevated levels of blood cholesterol and risk of heart attack
Sickle cell anemia	Defective hemoglobin that causes red blood cells to curve and stick together	Polydactyly	Extra fingers and toes

individual would be designated  $PP$ . In contrast, a heterozygote would be designated  $Pp$  (dominant allele first). Using these conventions and denoting a cross between two strains with  $\times$ , we can symbolize Mendel's original purple  $\times$  white cross as  $PP \times pp$ .

Because a white-flowered parent ( $pp$ ) can produce only  $p$  gametes, and a true-breeding purple-flowered parent ( $PP$ , *homozygous dominant*) can produce only  $P$  gametes, the union of these gametes can produce only heterozygous  $Pp$  offspring in the  $F_1$  generation. Because the  $P$  allele is dominant, all of these  $F_1$  individuals are expected to have purple flowers.

When  $F_1$  individuals are allowed to self-fertilize, the  $P$  and  $p$  alleles segregate during gamete formation to produce both  $P$  gametes and  $p$  gametes. Their subsequent union at fertilization to form  $F_2$  individuals is random.

The  $F_2$  possibilities may be visualized in a simple diagram called a **Punnett square**, named after its originator, the English geneticist R. C. Punnett (figure 12.6a). Mendel's model, analyzed in terms of a Punnett square, clearly predicts that the  $F_2$  generation should consist of  $\frac{3}{4}$  purple-flowered plants and  $\frac{1}{4}$  white-flowered plants, a phenotypic ratio of 3:1 (figure 12.6b).

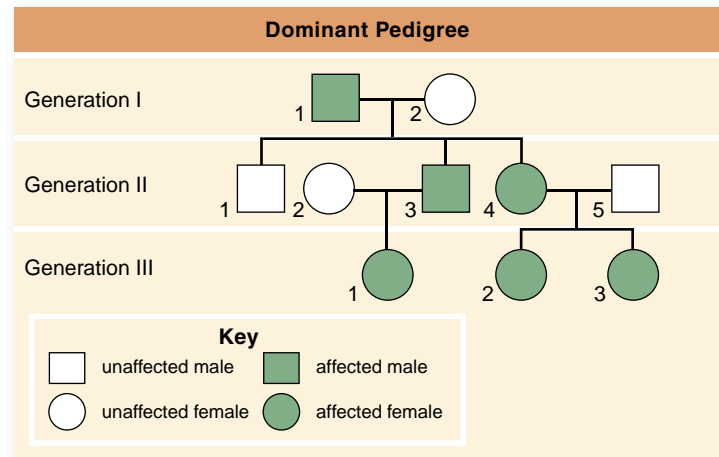

## Some human traits exhibit dominant/recessive inheritance

A number of human traits have been shown to display both dominant and recessive inheritance (table 12.1 provides a sample of these). Researchers cannot perform controlled crosses in humans the way Mendel did with pea plants, instead geneticists study crosses that have already been performed—in other words, family histories. The organized methodology we use is a **pedigree**, a consistent graphical representation of matings and offspring over multiple generations for a particular trait. The information in the pedigree may allow geneticists to deduce a model for the mode of inheritance of the trait. In analyzing these pedigrees, it is important to realize that disease-causing alleles are usually quite rare in the general population.

### A dominant pedigree: Juvenile glaucoma

One of the most extensive pedigrees yet produced traced the inheritance of a form of blindness caused by a dominant allele. The disease allele causes a form of hereditary juvenile glaucoma. The disease causes degeneration of nerve fibers in the optic nerve, leading to blindness.

This pedigree followed inheritance over three centuries, following the origin back to a couple in a small town in northwestern France who died in 1495. A small portion of this pedigree is shown in figure 12.7. The dominant nature of the trait is obvious from the

**Figure 12.7** Dominant pedigree for hereditary juvenile glaucoma. Males are shown as squares and females are shown as circles. Affected individuals are shown shaded. The dominant nature of this trait can be seen in the trait appearing in every generation, a feature of dominant traits.

### Inquiry question

? If one of the affected females in the third generation married an unaffected male, could she produce unaffected offspring? If so, what are the chances of having unaffected offspring?

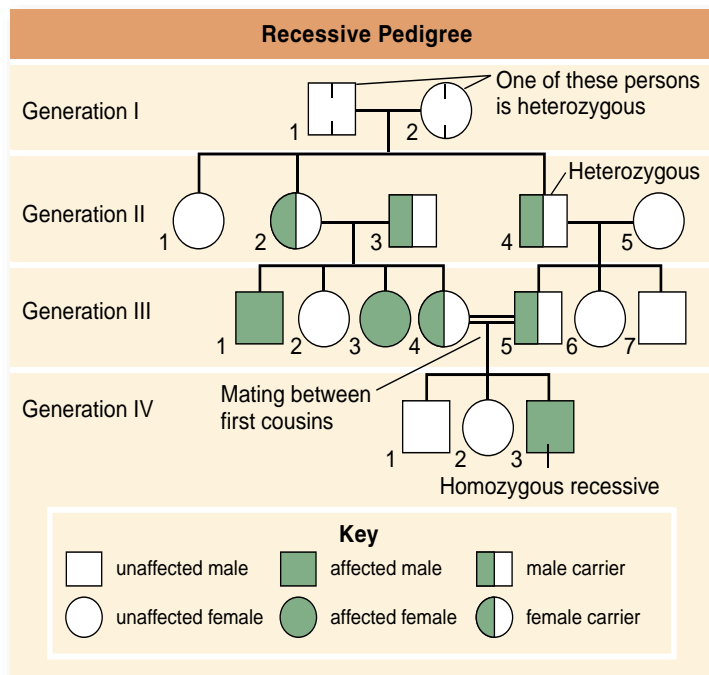

fact that every generation shows the trait. This is extremely unlikely for a recessive trait as it would require large numbers of unrelated individuals to be carrying the disease allele.

### A recessive pedigree: Albinism

An example of inheritance of a recessive human trait is albinism, a condition in which the pigment melanin is not produced. Long thought to be due to a single gene, multiple genes are now known that lead to albinism; the common feature is the loss of pigment from hair, skin, and eyes. The loss of pigment makes albinistic individuals sensitive to the sun. The tanning effect we are all familiar with from exposure to the sun is due to increased numbers of pigment-producing cells, and increased production of pigment. This is lacking in albinistic individuals due to the lack of any pigment to begin with.

The pedigree in figure 12.8 is for a form of albinism due to a nonfunctional allele of the enzyme tyrosinase, which is required for the formation of melanin pigment. The genetic characteristics of this form of albinism are: females and males are affected equally, most affected individuals have unaffected parents, a single affected parent usually does not have affected offspring, and affected offspring are more frequent when parents are related. Each of these features can be seen in figure 12.8, and all of this fits a recessive mode of inheritance.

**Figure 12.8** Recessive pedigree for albinism. One of the two individuals in the first generation must be heterozygous and individuals II-2 and II-4 must be heterozygous. Notice that for each affected individual, neither parent is affected, but both must be heterozygous (carriers). The double line indicates a consanguineous mating (between relatives) that, in this case, produced affected offspring.

### Inquiry question

**?** From a genetic disease standpoint, why is it never advisable for close relatives to mate and have children?

### Learning Outcomes Review 12.2

Mendel's monohybrid crosses refute the idea of blending. One trait disappears in the first generation ( $F_1$ ), then reappears in a predictable ratio in the next ( $F_2$ ). The trait observable in the  $F_1$  is called dominant, and the other recessive. In the  $F_2$ , the ratio of observed dominant offspring to recessive is 3:1, and this represents a ratio of 1 homozygous dominant to 2 heterozygous to 1 homozygous recessive. The Principle of Segregation states that alleles segregate into different gametes, which randomly combine at fertilization. The physical basis for segregation is the separation of homologues during anaphase I of meiosis.

■ What fraction of tall  $F_2$  plants are true-breeding?

## 12.3 Dihybrid Crosses: The Principle of Independent Assortment

### Learning Outcomes

1. Evaluate the outcome of a dihybrid cross.
2. Explain Mendel's Principle of Independent Assortment.
3. Understand the physical basis of independent assortment.

The Principle of Segregation explains the behavior of alternative forms of a single trait in a monohybrid cross. The next step is to extend this to follow the behavior of two different traits in a single cross: a **dihybrid cross**.

With an understanding of the behavior of single traits, Mendel went on to ask if different traits behaved independently in hybrids. He first established a series of true-breeding lines of peas that differed in two of the seven characters he had studied. He then crossed contrasting pairs of the true-breeding lines to create heterozygotes. These heterozygotes are now doubly heterozygous, or dihybrid. Finally, he self-crossed the dihybrid  $F_1$  plants to produce an  $F_2$  generation, and counted all progeny types.

### Traits in a dihybrid cross behave independently

Consider a cross involving different seed shape alleles (round,  $R$ , and wrinkled,  $r$ ) and different seed color alleles (yellow,  $Y$ , and green,  $y$ ). Crossing round yellow ( $RR YY$ ) with wrinkled green ( $rr yy$ ), produces heterozygous  $F_1$  individuals having the same phenotype (namely round and yellow) and the same genotype ( $Rr Yy$ ). Allowing these dihybrid  $F_1$  individuals to self-fertilize produces an  $F_2$  generation.

### The $F_2$ generation exhibits four types of progeny in a 9:3:3:1 ratio

In analyzing these results, we first consider the number of possible phenotypes. We expect to see the two parental phenotypes: round yellow and wrinkled green. If the traits behave independently, then we can also expect one trait from each parent to produce plants with round green seeds and others with wrinkled yellow seeds.

Next consider what types of gametes the  $F_1$  individuals can produce. Again, we expect the two types of gametes found in the parents:  $RY$  and  $ry$ . If the traits behave independently, then we can also expect the gametes  $Ry$  and  $rY$ . Using modern language, two genes each with two alleles can be combined four ways to produce these gametes:  $RY$ ,  $ry$ ,  $Ry$ , and  $rY$ .

### A dihybrid Punnett square

We can then construct a Punnett square with these gametes to generate all possible progeny. This is a  $4 \times 4$  square with 16 possible outcomes. Filling in the Punnett square produces all possible offspring (figure 12.9). From this we can see that there are 9 round yellow, 3 wrinkled yellow, 3 round green, and 1 wrinkled green. This predicts a phenotypic ratio of 9:3:3:1 for traits that behave independently.

## Mendel's Principle of Independent Assortment explains dihybrid results

What did Mendel actually observe? From a total of 556 seeds from self-fertilized dihybrid plants, he observed the following results:

- 315 round yellow (signified  $R\_ Y\_$ , where the underscore indicates the presence of either allele),
- 108 round green ( $R\_ yy$ ),
- 101 wrinkled yellow ( $rr Y\_$ ), and
- 32 wrinkled green ( $rr yy$ ).

These results are very close to a 9:3:3:1 ratio. (The expected 9:3:3:1 ratio from this many offspring would be 313:104:104:35.)

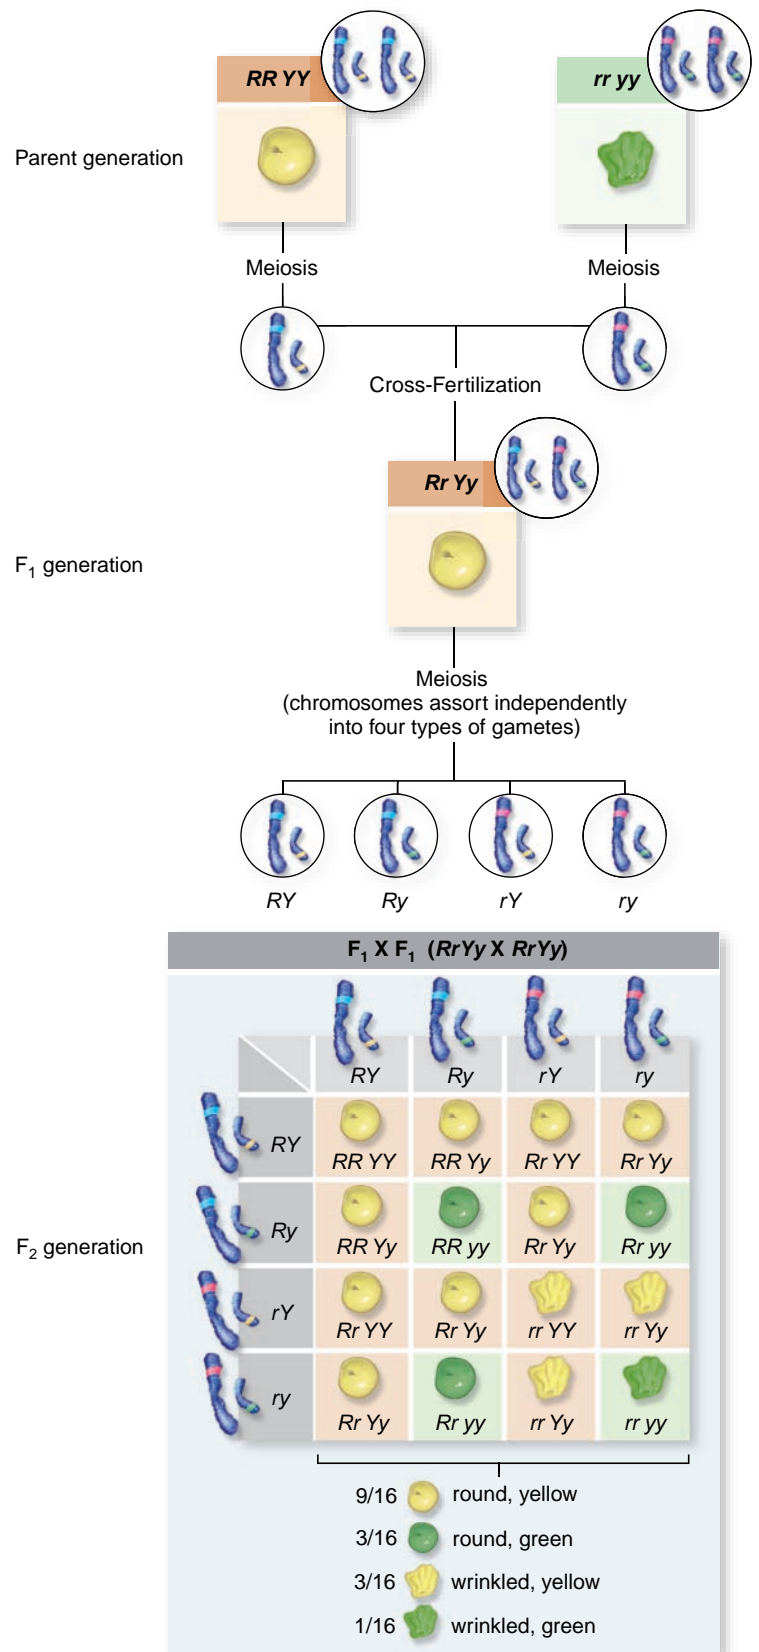

The alleles of two genes appeared to behave independently of each other. Mendel referred to this phenomenon as the traits assorting independently. Note that this *independent assortment* of different genes in no way alters the segregation of individual pairs of alleles for each gene. Round versus wrinkled seeds occur in a ratio of approximately 3:1 (423:133); so do yellow versus green seeds (416:140). Mendel obtained similar results for other pairs of traits.

We call this Mendel's second law of heredity, or the **Principle of Independent Assortment**. This can also be stated simply: *In a dihybrid cross, the alleles of each gene assort independently.* A more precise statement would be: *the segregation of different allele pairs is independent.* This statement more closely ties independent assortment to the behavior of chromosomes during meiosis (see chapter 11). The independent alignment of different homologous chromosome pairs during metaphase I leads to the independent segregation of the different allele pairs.

### Learning Outcomes Review 12.3

Mendel's analysis of dihybrid crosses revealed that the segregation of allele pairs for different traits is independent; this finding is known as Mendel's Principle of Independent Assortment. When individuals that differ in two traits are crossed, and their progeny are intercrossed, the result is four different types that occur in a ratio of 9:3:3:1, Mendel's dihybrid ratio. This occurs because of the independent behavior of different homologous pairs of chromosomes during meiosis I.

- Which is more important in terms of explaining Mendel's laws, meiosis I or meiosis II?

**Figure 12.9 Analyzing a dihybrid cross.** This Punnett square shows the results of Mendel's dihybrid cross between plants with round yellow seeds and plants with wrinkled green seeds. The ratio of the four possible combinations of phenotypes is predicted to be 9:3:3:1, the ratio that Mendel found.

## 12.4 Probability: Predicting the Results of Crosses

### Learning Outcomes

1. Understand the rule of addition and the rule of multiplication.
2. Apply the rules of probability to genetic crosses.

Probability allows us to predict the likelihood of the outcome of random events. Because the behavior of different chromosomes during meiosis is independent, we can use probability to predict the outcome of crosses. The probability of an event that is certain to happen is equal to 1. In contrast, an event that can never happen has a probability of 0. Therefore, probabilities for all other events have fractional values, between 0 and 1. For instance, when you flip a coin, two outcomes are possible; there is only one way to get the event “heads” so the probability of heads is one divided by two, or  $\frac{1}{2}$ . In the case of genetics, consider a pea plant heterozygous for the flower color alleles  $P$  and  $p$ . This individual can produce two types of gametes in equal numbers, again due to the behavior of chromosomes during meiosis. There is one way to get a  $P$  gamete, so the probability of any particular gamete carrying a  $P$  allele is 1 divided by 2 or  $\frac{1}{2}$ , just like the coin toss.

### Two probability rules help predict monohybrid cross results

We can use probability to make predictions about the outcome of genetic crosses using only two simple rules. Before we describe these rules and their uses, we need another definition. We say that two events are *mutually exclusive* if both cannot happen at the same time. The heads and tails of a coin flip are examples of mutually exclusive events. Notice that this is different from two consecutive coin flips where you can get two heads or two tails. In this case, each coin flip represents an *independent event*. It is the distinction between independent and mutually exclusive events that forms the basis for our two rules.

#### The rule of addition

Consider a six-sided die instead of a coin: for any roll of the die, only one outcome is possible, and each of the possible outcomes are mutually exclusive. The probability of any particular number coming up is  $\frac{1}{6}$ . The probability of either of two different numbers is the sum of the individual probabilities, or restated as the **rule of addition**:

For two mutually exclusive events, the probability of either event occurring is the sum of the individual probabilities.

$$\begin{aligned} \text{Probability of rolling either a 2 or a 6} \\ \text{is} = \frac{1}{6} + \frac{1}{6} = \frac{2}{6} = \frac{1}{3} \end{aligned}$$

To apply this to our cross of heterozygous purple  $F_1$ , four mutually exclusive outcomes are possible:  $PP$ ,  $Pp$ ,  $pP$ , and  $pp$ . The

probability of being heterozygous is the same as the probability of being either  $Pp$  or  $pP$ , or  $\frac{1}{4}$  plus  $\frac{1}{4}$ , or  $\frac{1}{2}$ .

$$\text{Probability of } F_2 \text{ heterozygote} = \frac{1}{4}Pp + \frac{1}{4}pP = \frac{1}{2}$$

In the previous example, of 379 total offspring, we would expect about 190 to be heterozygotes. (The actual number is 189.5.)

#### The rule of multiplication

The second rule, and by far the most useful for genetics, deals with the outcome of independent events. This is called the **product rule**, or **rule of multiplication**, and it states that the probability of two independent events both occurring is the *product* of their individual probabilities.

We can apply this to a monohybrid cross in which offspring are formed by gametes from each of two parents. For any particular outcome then, this is due to two independent events: the formation of two different gametes. Consider the purple  $F_1$  parents from earlier. They are all  $Pp$  (heterozygotes), so the probability that a particular  $F_2$  individual will be  $pp$  (homozygous recessive) is the probability of receiving a  $p$  gamete from the male ( $\frac{1}{2}$ ) times the probability of receiving a  $p$  gamete from the female ( $\frac{1}{2}$ ), or  $\frac{1}{4}$ :

$$\begin{aligned} \text{Probability of } pp \text{ homozygote} = \frac{1}{2}p \text{ (male parent)} \times \frac{1}{2}p \\ \text{(female parent)} = \frac{1}{4}pp \end{aligned}$$

This is actually the basis for the Punnett square that we used before. Each cell in the square was the product of the probabilities of the gametes that contribute to the cell. We then use the addition rule to sum the probabilities of the mutually exclusive events that make up each cell.

We can use the result of a probability calculation to predict the number of homozygous recessive offspring in a cross between heterozygotes. For example, out of 379 total offspring, we would expect about 95 to exhibit the homozygous recessive phenotype. (The actual calculated number is 94.75.)

### Dihybrid cross probabilities are based on monohybrid cross probabilities

Probability analysis can be extended to the dihybrid case. For our purple  $F_1$  by  $F_1$  cross, there are four possible outcomes, three of which show the dominant phenotype. Thus the probability of any offspring showing the dominant phenotype is  $\frac{3}{4}$ , and the probability of any offspring showing the recessive phenotype is  $\frac{1}{4}$ . Now we can use this and the product rule to predict the outcome of a dihybrid cross. We will use our example of seed shape and color from earlier, but now examine it using probability.

If the alleles affecting seed shape and seed color segregate independently, then the probability that a particular pair of alleles for seed shape would occur together with a particular pair of alleles for seed color is the product of the individual probabilities for each pair. For example, the probability that an individual with wrinkled green seeds ( $rr yy$ ) would appear in the  $F_2$  generation would be equal to the probability of obtaining wrinkled seeds ( $\frac{1}{4}$ ) times the probability of obtaining green seeds ( $\frac{1}{4}$ ), or  $\frac{1}{16}$ .

$$\text{Probability of } rr yy = \frac{1}{4} rr \times \frac{1}{4} yy = \frac{1}{16} rr yy$$

## 12.5 The Testcross: Revealing Unknown Genotypes

Because of independent assortment, we can think of the dihybrid cross of consisting of two independent monohybrid crosses; since these are independent events, the product rule applies. So, we can calculate the probabilities for each dihybrid phenotype:

$$\text{Probability of round yellow } (R\_ Y\_ ) = \frac{3}{4} R\_ \times \frac{3}{4} Y\_ = \frac{9}{16}$$

$$\text{Probability of round green } (R\_ yy) = \frac{3}{4} R\_ \times \frac{1}{4} yy = \frac{3}{16}$$

$$\text{Probability of wrinkled yellow } (rr Y\_ ) = \frac{1}{4} rr \times \frac{3}{4} Y\_ = \frac{3}{16}$$

$$\text{Probability of wrinkled green } (rr yy) = \frac{1}{4} rr \times \frac{1}{4} yy = \frac{1}{16}$$

The hypothesis that color and shape genes are independently sorted thus predicts that the  $F_2$  generation will display a 9:3:3:1 phenotypic ratio. These ratios can be applied to an observed total offspring to predict the expected number in each phenotypic group. The underlying logic and the results are the same as obtained using the Punnett square.

### Learning Outcomes Review 12.4

The rule of addition states that the probability of either of two events occurring is the sum of their individual probabilities. The rule of multiplication states that the probability of two independent events both occurring is the product of their individual probabilities. These rules can be applied to genetic crosses to determine the probability of particular genotypes and phenotypes. Results can then be compared against these predictions.

- How would you calculate the probability of all dominant phenotype  $F_2$  progeny in a trihybrid cross?

### Learning Outcome

- Interpret data from test crosses to infer genotypes.

To test his model further, Mendel devised a simple and powerful procedure called the **testcross**. In a testcross, an individual with unknown genotype is crossed with the homozygous recessive genotype—that is, the recessive parental variety. The contribution of the homozygous recessive parent can be ignored, because this parent can contribute only recessive alleles.

Consider a purple-flowered pea plant. It is impossible to tell whether such a plant is homozygous or heterozygous simply by looking at it. To learn its genotype, you can perform a testcross to a white-flowered plant. In this cross, the two possible test plant genotypes will give different results (figure 12.10):

*Alternative 1:* Unknown individual is homozygous dominant ( $PP$ )  $PP \times pp$ : All offspring have purple flowers ( $Pp$ ).

*Alternative 2:* Unknown individual is heterozygous ( $Pp$ )  $Pp \times pp$ :  $\frac{1}{2}$  of offspring have white flowers ( $pp$ ), and  $\frac{1}{2}$  have purple flowers ( $Pp$ ).

Put simply, the appearance of the recessive phenotype in the offspring of a testcross indicates that the test individual's genotype is heterozygous.

For each pair of alleles Mendel investigated, he observed phenotypic  $F_2$  ratios of 3:1 (see figure 12.4) and testcross ratios of 1:1, just as his model had predicted. Testcrosses can also be used to determine the genotype of an individual when two genes are involved. Mendel often

**Figure 12.10 A testcross.** To determine whether an individual exhibiting a dominant phenotype, such as purple flowers, is homozygous or heterozygous for the dominant allele, Mendel crossed the individual in question with a plant that he knew to be homozygous recessive—in this case, a plant with white flowers.

Actual Genotype	Results of Testcross	
	Trait A	Trait B
<i>AABB</i>	Trait A breeds true	Trait B breeds true
<i>AaBB</i>	————	Trait B breeds true
<i>AABb</i>	Trait A breeds true	————
<i>AaBb</i>	————	————

performed testcrosses to verify the genotypes of dominant-appearing  $F_2$  individuals.

An  $F_2$  individual exhibiting both dominant traits ( $A\_ B\_$ ) might have any of the following genotypes: *AABB*, *AaBB*, *AABb*, or *AaBb*. By crossing dominant-appearing  $F_2$  individuals with homozygous recessive individuals (that is,  $A\_ B\_ \times aabb$ ), Mendel was able to determine whether either or both of the traits bred true among the progeny, and so to determine the genotype of the  $F_2$  parent (table 12.2).

Testcrossing is a powerful tool that simplifies genetic analysis. We will use this method of analysis in the next chapter, when we explore genetic mapping.

### Learning Outcome Review 12.5

Individuals showing the dominant phenotype can be either homozygous dominant or heterozygous. Unknown genotypes can be revealed using a testcross, which is a cross to a homozygous recessive individual. Heterozygotes produce both dominant and recessive phenotypes in equal numbers as a result of the testcross.

- In a dihybrid testcross of a doubly heterozygous individual, what would be the expected phenotypic ratio?

## 12.6 Extensions to Mendel

### Learning Outcomes

1. Describe how assumptions in Mendel's model result in oversimplification.
2. Discuss a genetic explanation for continuous variation.
3. Explain the genetic basis for observed alterations to Mendel's ratios.

Although Mendel's results did not receive much notice during his lifetime, three different investigators independently rediscovered his pioneering paper in 1900, 16 years after his death. They came across it while searching the literature in prepara-

tion for publishing their own findings, which closely resembled those Mendel had presented more than 30 years earlier.

In the decades following the rediscovery of Mendel's ideas, many investigators set out to test them. However, scientists attempting to confirm Mendel's theory often had trouble obtaining the same simple ratios he had reported.

The reason that Mendel's simple ratios were not obtained had to do with the traits that others examined. A number of assumptions are built into Mendel's model that are oversimplifications. These assumptions include that each trait is specified by a single gene with two alternative alleles; that there are no environmental effects; and that gene products act independently. The idea of dominance also hides a wealth of biochemical complexity. In the following sections, you'll see how Mendel's simple ideas can be extended to provide a more complete view of genetics (table 12.3).

### In polygenic inheritance, more than one gene can affect a single trait

Often, the relationship between genotype and phenotype is more complicated than a single allele producing a single trait. Most phenotypes also do not reflect simple two-state cases like purple or white flowers.

Consider Mendel's crosses between tall and short pea plants. In reality, the "tall" plants actually have normal height, and the "short" plants are dwarfed by an allele at a single gene. But in most species, including humans, height varies over a continuous range, rather than having discrete values. This continuous distribution of a phenotype has a simple genetic explanation: more than one gene is at work. The mode of inheritance operating in this case is often called **polygenic inheritance**.

In reality, few phenotypes result from the action of only one gene. Instead, most characters reflect multiple additive contributions to the phenotype by several genes. When multiple genes act jointly to influence a character, such as height or weight, the character often shows a range of small differences. When these genes segregate independently, a gradation in the degree of difference can be observed when a group consisting of many individuals is examined (figure 12.11). We call this gradation **continuous variation**, and we call such traits **quantitative traits**. The greater the number of genes influencing a character, the more continuous the expected distribution of the versions of that character.

This continuous variation in traits is similar to blending different colors of paint: Combining one part red with seven parts white, for example, produces a much lighter shade of pink than does combining five parts red with three parts white. Different ratios of red to white result in a continuum of shades, ranging from pure red to pure white.

Often, variations can be grouped into categories, such as different height ranges. Plotting the numbers in each height category produces a curve called a *histogram*, such as that shown in figure 12.11. The bell-shaped histogram approximates an idealized *normal distribution*, in which the central tendency is characterized by the mean, and the spread of the curve indicates the amount of variation.

Even simple-appearing traits can have this kind of polygenic basis. For example, human eye colors are often described in

**TABLE 12.3**
**When Mendel's Laws/Results May Not Be Observed**

Genetic Occurrence	Definition	Examples
Polygenic inheritance	More than one gene can affect a single trait.	<ul style="list-style-type: none"> <li>• Four genes are involved in determining eye color.</li> <li>• Human height</li> </ul>
Pleiotropy	A single gene can affect more than one trait.	<ul style="list-style-type: none"> <li>• A pleiotropic allele dominant for yellow fur in mice is recessive for a lethal developmental defect.</li> <li>• Cystic fibrosis</li> <li>• Sickle cell anemia</li> </ul>
Multiple alleles for one gene	Genes may have more than two alleles.	ABO blood types in humans
Dominance is not always complete	<ul style="list-style-type: none"> <li>• In incomplete dominance the heterozygote is intermediate.</li> <li>• In codominance no single allele is dominant, and the heterozygote shows some aspect of both homozygotes.</li> </ul>	<ul style="list-style-type: none"> <li>• Japanese four o'clocks</li> <li>• Human blood groups</li> </ul>
Environmental factors	Genes may be affected by the environment.	Siamese cats
Gene interaction	Products of genes can interact to alter genetic ratios.	<ul style="list-style-type: none"> <li>• The production of a purple pigment in corn</li> <li>• Coat color in mammals</li> </ul>

simple terms with brown dominant to blue, but this is actually incorrect. Extensive analysis indicates that at least four genes are involved in determining eye color. This leads to more complex inheritance patterns than initially reported. For example, blue-eyed parents can have brown-eyed offspring, although it is rare.

**Figure 12.11 Height is a continuously varying trait.** The photo and accompanying graph show variation in height among students of the 1914 class at the Connecticut Agricultural College. Because many genes contribute to height and tend to segregate independently of one another, the cumulative contribution of different combinations of alleles to height forms a *continuous* distribution of possible heights, in which the extremes are much rarer than the intermediate values. Variation can also arise due to environmental factors such as nutrition.

### In pleiotropy, a single gene can affect more than one trait

Not only can more than one gene affect a single trait, but a single gene can affect more than one trait. Considering the complexity of biochemical pathways and the interdependent nature of organ systems in multicellular organisms, this should be no surprise.

An allele that has more than one effect on phenotype is said to be **pleiotropic**. The pioneering French geneticist Lucien Cuenot studied yellow fur in mice, a dominant trait, and found he was unable to obtain a pure-breeding yellow strain by crossing individual yellow mice with each other. Individuals homozygous for the yellow allele died, because the yellow allele was pleiotropic: One effect was yellow coat color, but another was a lethal developmental defect.

A pleiotropic allele may be dominant with respect to one phenotypic consequence (yellow fur) and recessive with respect to another (lethal developmental defect). Pleiotropic effects are difficult to predict, because a gene that affects one trait often performs other, unknown functions.

Pleiotropic effects are characteristic of many inherited disorders in humans, including cystic fibrosis and sickle cell anemia (discussed in chapter 13). In these disorders, multiple symptoms (phenotypes) can be traced back to a single gene defect. Cystic fibrosis patients exhibit clogged blood vessels, overly sticky mucus, salty sweat, liver and pancreas failure, and several other symptoms. It is often difficult to deduce the nature of the primary defect from the range of a gene's pleiotropic effects. As it turns out, all these symptoms of cystic fibrosis are pleiotropic effects of a single defect, a mutation in a gene that encodes a chloride ion transmembrane channel.

### Genes may have more than two alleles

Mendel always looked at genes with two alternative alleles. Although any diploid individual can carry only two alleles for a

gene, there may be more than two alleles in a population. The example of ABO blood types in humans, described later on, involves an allelic series with three alleles.

If you think of a gene as a sequence of nucleotides in a DNA molecule, then the number of possible alleles is huge because even a single nucleotide change could produce a new allele. In reality, the number of alleles possible for any gene is constrained, but usually more than two alleles exist for any gene in an outbreeding population. The dominance relationships of these alleles cannot be predicted, but can be determined by observing the phenotypes for the various heterozygous combinations.

## Dominance is not always complete

Mendel's idea of dominant and recessive traits can seem hard to explain in terms of modern biochemistry. For example, if a recessive trait is caused by the loss of function of an enzyme encoded by the recessive allele, then why should a heterozygote, with only half the activity of this enzyme, have the same appearance as a homozygous dominant individual?

The answer is that enzymes usually act in pathways and not alone. These pathways, as you have seen in earlier chapters, can be highly complex in terms of inputs and outputs, and they can sometimes tolerate large reductions in activity of single enzymes in the pathway without reductions in the level of the end-product. When this is the case, complete dominance will be observed; however, not all genes act in this way.

### Incomplete dominance

In **incomplete dominance**, the heterozygote is intermediate in appearance between the two homozygotes. For example, in a cross between red- and white-flowering Japanese four o'clocks, described in figure 12.12, all the  $F_1$  offspring have pink flowers—indicating that neither red nor white flower color was dominant. Looking only at the  $F_1$ , we might conclude that this is a case of blending inheritance. But when two of the  $F_1$  pink flowers are crossed, they produce red-, pink-, and white-flowered plants in a 1:2:1 ratio. In this case the phenotypic ratio is the same as the genotypic ratio because all three genotypes can be distinguished.

### Codominance

Most genes in a population possess several different alleles, and often no single allele is dominant; instead, each allele has its own effect, and the heterozygote shows some aspect of the phenotype of both homozygotes. The alleles are said to be **codominant**.

Codominance can be distinguished from incomplete dominance by the appearance of the heterozygote. In incomplete dominance, the heterozygote is intermediate between the two homozygotes, whereas in codominance, some aspect of both alleles is seen in the heterozygote. One of the clearest human examples is found in the human blood groups.

The different phenotypes of human blood groups are based on the response of the immune system to proteins on the surface of red blood cells. In homozygotes a single type of protein is found on the surface of cells, and in heterozygotes, two kinds of protein are found, leading to codominance.

### The human ABO blood group system

The gene that determines ABO blood types encodes an enzyme that adds sugar molecules to proteins on the surface of red

## SCIENTIFIC THINKING

**Hypothesis:** The pink  $F_1$  observed in a cross of red and white Japanese four o'clock flowers is due to failure of dominance and is not an example of blending inheritance.

**Prediction:** If pink  $F_1$  are self-crossed, they will yield progeny the same as the Mendelian monohybrid genotypic ratio. This would be 1 red: 2 pink: 1 white.

**Test:** Perform the cross and count progeny.

**Result:** When this cross is performed, the expected outcome is observed.

**Conclusion:** Flower color in Japanese four o'clock plants exhibits incomplete dominance.

**Further Experiments:** How many offspring would you need to count to be confident in the observed ratio?

**Figure 12.12 Incomplete dominance.** In a cross between a red-flowered (genotype  $C^R C^R$ ) Japanese four o'clock and a white-flowered one ( $C^W C^W$ ), neither allele is dominant. The heterozygous progeny have pink flowers and the genotype  $C^R C^W$ . If two of these heterozygotes are crossed, the phenotypes of their progeny occur in a ratio of 1:2:1 (red: pink:white).

blood cells. These sugars act as recognition markers for the immune system (see chapter 52). The gene that encodes the enzyme, designated  $I$ , has three common alleles:  $I^A$ , whose product adds galactosamine;  $I^B$ , whose product adds galactose; and  $i$ , which codes for a protein that does not add a sugar.

The three alleles of the  $I$  gene can be combined to produce six different genotypes. An individual heterozygous for the  $I^A$  and

$I^B$  alleles produces both forms of the enzyme and exhibits both galactose and galactosamine on red blood cells. Because both alleles are expressed simultaneously in heterozygotes, the  $I^A$  and  $I^B$  alleles are codominant. Both  $I^A$  and  $I^B$  are dominant over the  $i$  allele, because both  $I^A$  and  $I^B$  alleles lead to sugar addition, whereas the  $i$  allele does not. The different combinations of the three alleles produce four different phenotypes (figure 12.13):

1. Type A individuals add only galactosamine. They are either  $I^A I^A$  homozygotes or  $I^A i$  heterozygotes (two genotypes).
2. Type B individuals add only galactose. They are either  $I^B I^B$  homozygotes or  $I^B i$  heterozygotes (two genotypes).
3. Type AB individuals add both sugars and are  $I^A I^B$  heterozygotes (one genotype).
4. Type O individuals add neither sugar and are  $ii$  homozygotes (one genotype).

These four different cell-surface phenotypes are called the **ABO blood groups**.

A person's immune system can distinguish among these four phenotypes. If a type A individual receives a transfusion of type B blood, the recipient's immune system recognizes the "foreign" antigen (galactose) and attacks the donated blood cells, causing them to clump, or agglutinate. The same thing would happen if the donated blood is type AB. However, if the donated blood is type O, no immune attack occurs, because there are no galactose antigens.

In general, any individual's immune system can tolerate a transfusion of type O blood, and so type O is termed the "universal donor." Because neither galactose nor galactosamine is foreign to type AB individuals (whose red blood cells have both sugars), those individuals may receive any type of blood, and type AB is termed the "universal recipient." Nevertheless, matching blood is preferable for any transfusion.

### Phenotypes may be affected by the environment

Another assumption, implicit in Mendel's work, is that the environment does not affect the relationship between genotype

Alleles	Blood Type	Sugars Exhibited	Donates and Receives
$I^A I^A$ , $I^A i$ ( $I^A$ dominant to $i$ )	A	Galactosamine	Receives A and O Donates to A and AB
$I^B I^B$ , $I^B i$ ( $I^B$ dominant to $i$ )	B	Galactose	Receives B and O Donates to B and AB
$I^A I^B$ (codominant)	AB	Both galactose and galactosamine	Universal receiver Donates to AB
$ii$ ( $i$ is recessive)	O	None	Receives O Universal donor

**Figure 12.13 ABO blood groups illustrate both codominance and multiple alleles.** There are three alleles of the  $I$  gene:  $I^A$ ,  $I^B$ , and  $i$ .  $I^A$  and  $I^B$  are both dominant to  $i$  (see types A and B), but codominant to each other (see type AB). The genotypes that give rise to each blood type are shown with the associated phenotypes in terms of sugars added to surface proteins and the body's reaction after a blood transfusion.

and phenotype. For example, the soil in the abbey yard where Mendel performed his experiments was probably not uniform, and yet its possible effect on the expression of traits was ignored. But in reality, although the expression of genotype produces phenotype, the environment can affect this relationship.

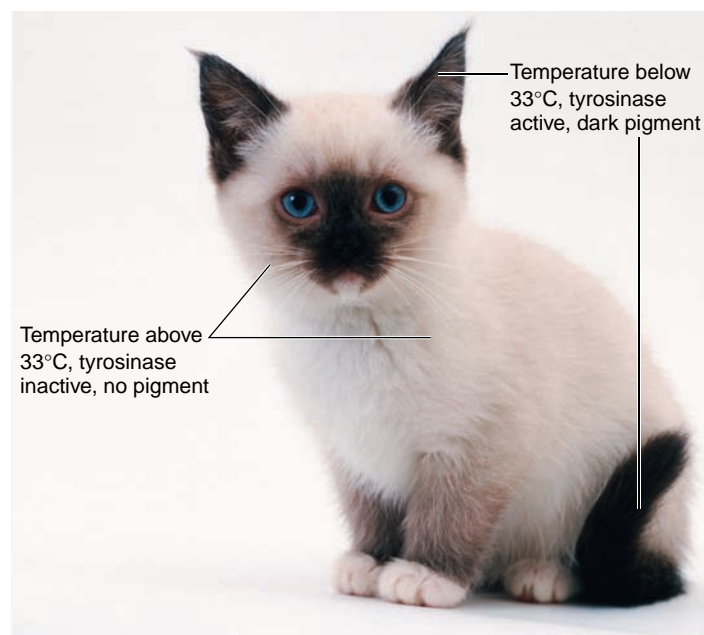

Environmental effects are not limited to the external environment. For example, the alleles of some genes encode heat-sensitive products, that are affected by differences in internal body temperature. The  $ch$  allele in Himalayan rabbits and Siamese cats encodes a heat-sensitive version of the enzyme tyrosinase, which as you may recall is involved in albinism (figure 12.14). The  $Ch$  version of the enzyme is inactivated at temperatures above about 33°C. At the surface of the torso and head of these animals, the temperature is above 33°C and tyrosinase is inactive, producing a whitish coat. At the extremities, such as the tips of the ears and tail, the temperature is usually below 33°C and the enzyme is active, allowing production of melanin that turns the coat in these areas a dark color.

### Inquiry question

? Many studies of identical twins separated at birth have revealed phenotypic differences in their development (height, weight, etc.). If these are identical twins, can you propose an explanation for these differences?

### In epistasis, interactions of genes alter genetic ratios

The last simplistic assumption in Mendel's model is that the products of genes do not interact. But the products of genes may not act independently of one another, and the interconnected behavior of gene products can change the ratio expected by independent assortment, even if the genes are on different chromosomes that do exhibit independent assortment.

**Figure 12.14 Siamese cat.** The pattern of coat color is due to an allele that encodes a temperature-sensitive form of the enzyme tyrosinase.

Given the interconnected nature of metabolism, it should not come as a surprise that many gene products are not independent. Genes that act in the same metabolic pathway, for example, should show some form of dependence at the level of function. In such cases, the ratio Mendel would predict is not readily observed, but it is still there in an altered form.

In the tests of Mendel's ideas that followed the rediscovery of his work, scientists had trouble obtaining Mendel's simple ratios, particularly with dihybrid crosses. Sometimes, it was not possible to identify successfully each of the four phenotypic classes expected, because two or more of the classes looked alike.

An example of this comes from the analysis of particular varieties of corn, *Zea mays*. Some commercial varieties exhibit a purple pigment called anthocyanin in their seed coats, whereas others do not. In 1918, geneticist R. A. Emerson crossed two true-breeding corn varieties, each lacking anthocyanin pigment. Surprisingly, all of the F<sub>1</sub> plants produced purple seeds.

When two of these pigment-producing F<sub>1</sub> plants were crossed to produce an F<sub>2</sub> generation, 56% were pigment producers and 44% were not. This is clearly not what Mendel's ideas would lead us to expect. Emerson correctly deduced that two genes were involved in producing pigment, and that the second cross had thus been a dihybrid cross. According to Mendel's theory, gametes in a dihybrid cross could combine in 16 equally possible ways—so the puzzle was to figure out how these 16 combinations could occur in the two phenotypic groups of progeny. Emerson multiplied the fraction that were pigment producers (0.56) by 16 to obtain 9, and multiplied the fraction that lacked pigment (0.44) by 16 to obtain 7. Emerson therefore had a *modified ratio* of 9:7 instead of the usual 9:3:3:1 ratio (figure 12.15).

This modified ratio is easily rationalized by considering the function of the products encoded by these genes. When gene products act sequentially, as in a biochemical pathway, an allele expressed as a defective enzyme early in the pathway blocks the flow of material through the rest of the pathway. In this case, it is impossible to judge whether the later steps of the pathway are functioning properly. This type of gene interaction, in which one gene can interfere with the expression of another, is the basis of the phenomenon called **epistasis**.

The pigment anthocyanin is the product of a two-step biochemical pathway:

To produce pigment, a plant must possess at least one functional copy of each enzyme's gene. The dominant alleles encode functional enzymes, and the recessive alleles encode nonfunctional enzymes. Of the 16 genotypes predicted by random assortment, 9 contain at least one dominant allele of both genes; they therefore produce purple progeny. The remaining 7 genotypes lack dominant alleles at *either or both* loci (3 + 3 + 1 = 7) and so produce colorless progeny, giving the phenotypic ratio of 9:7 that Emerson observed (see figure 12.15).

You can see that although this ratio is not the expected dihybrid ratio, it is a modification of the expected ratio.

**a.**

**b.**

**Figure 12.15** How epistasis affects grain color.

**a.** Crossing some white varieties of corn yields an all purple F<sub>1</sub>. Self-crossing the F<sub>1</sub> yields 9 purple:7 white. This can be explained by the presence of two genes, each encoding an enzyme necessary for the production of purple pigment. Unless both enzymes are active (genotype is  $A\_B\_$ ), no pigment is expressed. **b.** The biochemical pathway for pigment production with enzymes encoded by *A* and *B* genes.

### Learning Outcomes Review 12.6

Mendel's model assumes that each trait is specified by one gene with only two alleles, no environmental effects alter a trait, and gene products act independently. All of these prove to be oversimplifications. Traits produced by the action of multiple genes (polygenic inheritance) have continuous variation. One gene can affect more than one trait (pleiotropy). Genes may have more than two alleles, and these may not show simple dominance. In incomplete dominance, the heterozygote is intermediate between the two homozygotes, and in codominance the heterozygote shows aspects of both homozygotes, both of which alter the monohybrid ratio. The action of genes is not always independent, which can result in modified dihybrid ratios.

- In the cross in figure 12.15, what proportion of F<sub>2</sub> will be white because they are homozygous recessive for one of the two genes?

## Chapter Review

### 12.1 The Mystery of Heredity

#### *Early plant biologists produced hybrids and saw puzzling results.*

Plant breeders noticed that some forms of a trait can disappear in one generation only to reappear later, that is, they segregate rather than blend.

#### *Mendel used mathematics to analyze his crosses.*

Mendel's experiments involved reciprocal crosses between true-breeding pea varieties followed by one or more generations of self-fertilization. His mathematical analysis of experimental results led to the present model of inheritance.

### 12.2 Monohybrid Crosses: The Principle of Segregation (see figure 12.5)

#### *The F<sub>1</sub> generation exhibits only one of two traits, without blending.*

Mendel called the trait visible in the F<sub>1</sub> the dominant trait; the other he termed recessive.

#### *The F<sub>2</sub> generation exhibits both traits in a 3:1 ratio.*

When F<sub>1</sub> plants are self-fertilized, the F<sub>2</sub> shows a consistent ratio of 3 dominant:1 recessive. We call this 3:1 ratio the Mendelian monohybrid ratio.

#### *The 3:1 ratio is actually 1:2:1.*

Mendel then examined the F<sub>2</sub> and found the recessive F<sub>2</sub> plants always bred true, but only one out of three dominant F<sub>2</sub> bred true. This means the 3:1 ratio is actually 1 true-breeding dominant:2 non-true-breeding dominant:1 recessive.

#### *Mendel's Principle of Segregation explains monohybrid observations.*

Traits are determined by discrete factors we now call genes. These exist in alternative forms we call alleles. Individuals carrying two identical alleles for a gene are said to be homozygous, and individuals carrying different alleles are said to be heterozygous. The genotype is the entire set of alleles of all genes possessed by an individual. The phenotype is the individual's appearance due to these alleles.

The Principle of Segregation states that during gamete formation, the two alleles of a gene separate (segregate). Parental alleles then randomly come together to form the diploid zygote. The physical basis of segregation is the separation of homologues during anaphase of meiosis I.

#### *The Punnett square allows symbolic analysis.*

Punnett squares are formed by placing the gametes from one parent along the top of the square with the gametes from the other parent along the side. Zygotes formed from gamete combinations form the blocks of the square (see figure 12.6).

#### *Some human traits exhibit dominant/recessive inheritance.*

Certain human traits have been found to have a Mendelian basis (see table 12.1). Inheritance patterns in human families can be analyzed and inferred using a pedigree diagram of earlier generations.

### 12.3 Dihybrid Crosses: The Principle of Independent Assortment (see figure 12.9)

#### *Traits in a dihybrid cross behave independently.*

If parents differing in two traits are crossed, the F<sub>1</sub> will be all dominant. Each F<sub>1</sub> parent can produce four different gametes that can be combined to produce 16 possible outcomes in the F<sub>2</sub>. This yields a phenotypic ratio of 9:3:3:1 of the four possible phenotypes.

#### *Mendel's Principle of Independent Assortment explains dihybrid results.*

The Principle of Independent Assortment states that different traits segregate independently of one another. The physical basis of independent assortment is the independent behavior of different pairs of homologous chromosomes during meiosis I.

### 12.4 Probability: Predicting the Results of Crosses

#### *Two probability rules help predict monohybrid cross results.*

The rule of addition states that the probability of two independent events occurring is the sum of their individual probabilities. The rule of multiplication, or product rule, states that the probability of two independent events *both* occurring is the product of their individual probabilities.

#### *Dihybrid cross probabilities are based on monohybrid cross probabilities.*

A dihybrid cross is essentially two independent monohybrid crosses. The product rule applies and can be used to predict the cross's outcome.

### 12.5 The Testcross: Revealing Unknown Genotypes (see figure 12.10)

In a testcross, an unknown genotype is crossed with a homozygous recessive genotype. The F<sub>1</sub> offspring will all be the same if the unknown genotype is homozygous dominant. The F<sub>1</sub> offspring will exhibit a 1:1 dominant:recessive ratio if the unknown genotype is heterozygous.

### 12.6 Extensions to Mendel

#### *In polygenic inheritance, more than one gene can affect a single trait.*

Many traits, such as human height, are due to multiple additive contributions by many genes, resulting in continuous variation.

#### *In pleiotropy, a single gene can affect more than one trait.*

A pleiotropic effect occurs when an allele affects more than one trait. These effects are difficult to predict.

#### *Genes may have more than two alleles.*

There may be more than two alleles of a gene in a population. Given the possible number of DNA sequences, this is not surprising.

#### *Dominance is not always complete.*

In incomplete dominance the heterozygote exhibits an intermediate phenotype; the monohybrid genotypic and phenotypic ratios are the same (see figure 12.12). Codominant alleles each contribute to the phenotype of a heterozygote.

#### *Phenotypes may be affected by the environment.*

Genotype determines phenotype, but the environment will have an effect on this relationship. Environment means both external and internal factors. For example, in Siamese cats, a temperature-sensitive enzyme produces more pigment in the colder peripheral areas of the body.

#### *In epistasis, interactions of genes alter genetic ratios.*

Genes encoding enzymes that act in a single biochemical pathway are not independent. In corn, anthocyanin pigment production requires the action of two enzymes. Doubly heterozygous individuals for these enzymes yield a 9:7 ratio when self-crossed (see figure 12.15).

## Review Questions

### UNDERSTAND

- What property distinguished Mendel's investigation from previous studies?
  - Mendel used true-breeding pea plants.
  - Mendel quantified his results.
  - Mendel examined many different traits.
  - Mendel examined the segregation of traits.
- The  $F_1$  generation of the monohybrid cross purple ( $PP$ )  $\times$  white ( $pp$ ) flower pea plants should
  - all have white flowers.
  - all have a light purple or blended appearance.
  - all have purple flowers.
  - have  $(\frac{3}{4})$  purple flowers, and  $\frac{1}{4}$  white flowers.
- The  $F_1$  plants from the previous question are allowed to self-fertilize. The phenotypic ratio for the  $F_2$  should be
  - all purple.
  - 1 purple:1 white.
  - 3 purple:1 white.
  - 3 white:1 purple.
- Which of the following is *not* a part of Mendel's five-element model?
  - Traits have alternative forms (what we now call alleles).
  - Parents transmit discrete traits to their offspring.
  - If an allele is present it will be expressed.
  - Traits do not blend.
- An organism's \_\_\_\_\_ is/are determined by its \_\_\_\_\_.
  - genotype; phenotype
  - phenotype; genotype
  - alleles; phenotype
  - genes; alleles
- Phenotypes like height in humans, which show a continuous distribution, are usually the result of
  - an alteration of dominance for multiple alleles of a single gene.
  - the presence of multiple alleles for a single gene.
  - the action of one gene on multiple phenotypes.
  - the action of multiple genes on a single phenotype.

### APPLY

- A dihybrid cross between a plant with long smooth leaves and a plant with short hairy leaves produces a long smooth  $F_1$ . If this  $F_1$  is allowed to self-cross to produce an  $F_2$ , what would you predict for the ratio of  $F_2$  phenotypes?
  - 9 long smooth:3 long hairy:3 short hairy:1 short smooth
  - 9 long smooth:3 long hairy:3 short smooth:1 short hairy
  - 9 short hairy:3 long hairy:3 short smooth:1 long smooth
  - 1 long smooth:1 long hairy:1 short smooth:1 short hairy
- Consider a long smooth  $F_2$  plant from the previous question. This plant's genotype
  - must be homozygous for both long alleles and hairy alleles.
  - must be heterozygous at both the leaf length gene, and the leaf hair gene.
  - can only be inferred by another cross.
  - cannot be determined by any means.
- What is the probability of obtaining an individual with the genotype  $bb$  from a cross between two individuals with the genotype  $Bb$ ?
  - $\frac{1}{2}$
  - $\frac{1}{4}$
  - $\frac{1}{8}$
  - 0
- What is the probability of obtaining an individual with the genotype  $CC$  from a cross between two individuals with the genotypes  $CC$  and  $Cc$ ?
  - $\frac{1}{2}$
  - $\frac{1}{4}$
  - $\frac{1}{8}$
  - $\frac{1}{16}$
- You discover a new variety of plant with color varieties of purple and white. When you intercross these, the  $F_1$  is a lighter purple. You consider that this may be an example of blending and self-cross the  $F_1$ . If Mendel is correct, what would you predict for the  $F_2$ ?
  - 1 purple:2 white:1 light purple
  - 1 white:2 purple:1 light purple
  - 1 purple:2 light purple:1 white
  - 1 light purple:2 purple:1 white
- Mendel's model assumes that each trait is determined by a single factor with alternate forms. We now know that this is too simplistic and that
  - a single gene may affect more than one trait.
  - a single trait may be affected by more than one gene.
  - a single gene always affects only one trait, but traits may be affected by more than one gene.
  - a single gene can affect more than one trait, and traits may be affected by more than one gene.

### SYNTHESIZE

- Create a Punnett square for the following crosses and use this to predict phenotypic ratio for dominant and recessive traits. Dominant alleles are indicated by uppercase letters and recessive are indicated by lowercase letters. For parts b and c, predict ratios using probability and the product rule.
  - A monohybrid cross between individuals with the genotype  $Aa$  and  $Aa$
  - A dihybrid cross between two individuals with the genotype  $AaBb$
  - A dihybrid cross between individuals with the genotype  $AaBb$  and  $aabb$
- Explain how the events of meiosis can explain both segregation and independent assortment.
- In mice, there is a yellow strain that when crossed yields 2 yellow:1 black. How could you explain this observation? How could you test this with crosses?
- In mammals, a variety of genes affect coat color. One of these is a gene with mutant alleles that results in the complete loss of pigment, or albinism. Another controls the type of dark pigment with alleles that lead to black or brown colors. The albinistic trait is recessive, and black is dominant to brown. Two black mice are crossed and yield 9 black:4 albino:3 brown. How would you explain these results?

# Chromosomes, Mapping, and the Meiosis–Inheritance Connection

## Chapter Outline

- 13.1 Sex Linkage and the Chromosomal Theory of Inheritance
- 13.2 Sex Chromosomes and Sex Determination
- 13.3 Exceptions to the Chromosomal Theory of Inheritance
- 13.4 Genetic Mapping
- 13.5 Selected Human Genetic Disorders

## Introduction

Mendel's experiments opened the door to understanding inheritance, but many questions remained. In the early part of the 20th century, we did not know the nature of the factors whose behavior Mendel had described. The next step, which involved many researchers in the early part of the century, was uniting information about the behavior of chromosomes, seen in the picture, and the inheritance of traits. The basis for Mendel's principles of segregation and independent assortment lie in events that occur during meiosis.

The behavior of chromosomes during meiosis not only explains Mendel's principles, but leads to new and different approaches to the study of heredity. The ability to construct genetic maps is one of the most powerful tools of classical genetic analysis. The tools of genetic mapping developed in flies and other organisms in combination with information from the Human Genome Project now allow us to determine the location of genes and isolate those that are involved in genetic diseases.

## 13.1 Sex Linkage and the Chromosomal Theory of Inheritance

### Learning Outcomes

1. Describe sex-linked inheritance in fruit flies.
2. Explain the evidence for genes being on chromosomes.

A central role for chromosomes in heredity was first suggested in 1900 by the German geneticist Carl Correns, in one of the papers announcing the rediscovery of Mendel's work. Soon after, observations that similar chromosomes paired with one another during meiosis led directly to the **chromosomal theory of inheritance**, first formulated by the American Walter Sutton in 1902.

### Morgan correlated the inheritance of a trait with sex chromosomes

In 1910, Thomas Hunt Morgan, studying the fruit fly *Drosophila melanogaster*, discovered a mutant male fly with white eyes instead of red (figure 13.1).

Morgan immediately set out to determine whether this new trait would be inherited in a Mendelian fashion. He first crossed the mutant male to a normal red-eyed female to see whether the red-eyed or white-eyed trait was dominant. All of the F<sub>1</sub> progeny had red eyes, so Morgan concluded that red eye color was dominant over white.

#### The F<sub>1</sub> cross

Following the experimental procedure that Mendel had established long ago, Morgan then crossed the red-eyed flies from the F<sub>1</sub> generation with each other. Of the 4252 F<sub>2</sub> progeny Morgan examined, 782 (18%) had white eyes. Although the ratio of red eyes to white eyes in the F<sub>2</sub> progeny was greater than 3:1, the results of the cross nevertheless provided clear evidence that eye color segregates. However, something about the outcome was strange and totally unpredicted by Mendel's theory—*all of the white-eyed F<sub>2</sub> flies were males!* (Figure 13.2)

**Figure 13.1** Red-eyed (wild type) and white-eyed (mutant) *Drosophila*. Mutations are heritable alterations in genetic material. By studying the inheritance pattern of white and red alleles (located on the X chromosome), Morgan first demonstrated that genes are on chromosomes.

**Figure 13.2** The chromosomal basis of sex linkage.

White-eyed male flies are crossed to red-eyed females. The F<sub>1</sub> flies all have red eyes, as expected for a recessive white-eye allele. In the F<sub>2</sub>, all of the white-eyed flies are male because the Y chromosome lacks the white-eye (*white*) gene. Inheritance of the sex chromosomes correlates with eye color, showing the *white* gene is on the X chromosome.

## 13.2 Sex Chromosomes and Sex Determination

### The testcross

Morgan sought an explanation for this result. One possibility was simply that white-eyed female flies don't exist; such individuals might not be viable for some unknown reason. To test this idea, Morgan testcrossed the female  $F_1$  progeny with the original white-eyed male. He obtained white-eyed and red-eyed flies of both sexes in a 1:1:1:1 ratio, just as Mendel's theory had predicted (figure 13.2). Therefore, white-eyed female flies are viable. Given that white-eyed females can exist, Morgan turned to the nature of the chromosomes in males and females for an explanation.

### The gene for eye color lies on the X chromosome

In *Drosophila*, the sex of an individual is determined by the number of copies it has of a particular chromosome, the **X chromosome**. Observations of *Drosophila* chromosomes revealed that female flies have two X chromosomes, but male flies have only one. In males, the single X chromosome pairs in meiosis with a dissimilar partner called the **Y chromosome**. These two chromosomes are termed **sex chromosomes** because of their association with sex.

During meiosis, a female produces only X-bearing gametes, but a male produces both X-bearing and Y-bearing gametes. When fertilization involves an X sperm, the result is an XX zygote, which develops into a female; when fertilization involves a Y sperm, the result is an XY zygote, which develops into a male.

The solution to Morgan's puzzle is that the gene causing the white-eye trait in *Drosophila* resides only on the X chromosome—it is absent from the Y chromosome. (We now know that the Y chromosome in flies carries almost no functional genes.) A trait determined by a gene on the X chromosome is said to be **sex-linked**, or X-linked, because it is associated with the sex of the individual. Knowing the white-eye trait is recessive to the red-eye trait, we can now see that Morgan's result was a natural consequence of the Mendelian segregation of chromosomes (see figure 13.2).

Morgan's experiment was one of the most important in the history of genetics because it presented the first clear evidence that the genes determining Mendelian traits do indeed reside on the chromosomes, as Sutton had proposed. Mendelian traits segregate in genetic crosses because homologues separate during gamete formation.

### Learning Outcomes Review 13.1

Morgan showed that the trait for white eyes in *Drosophila* segregated with the sex of offspring. X and Y chromosomes also segregate with sex, this correlates the behavior of a trait with the behavior of chromosomes. This finding supported the chromosomal theory of inheritance, which states that traits are carried on chromosomes.

- What are the expectations for a cross of white-eyed females to red-eyed males?

### Learning Outcomes

1. Describe the relationship between sex chromosomes and sex determination.
2. Explain dosage compensation in mammals and its genetic consequences.

The structure and number of sex chromosomes vary in different species (table 13.1). In the fruit fly, *Drosophila*, females are XX and males XY, which is also the case for humans and other mammals. However, in birds, the male has two Z chromosomes, and the female has a Z and a W chromosome. Some insects, such as grasshoppers, have no Y chromosome—females are XX and males are characterized as XO (O indicates the absence of a chromosome).

### In humans, the Y chromosome generally determines maleness

In chapter 10, you learned that humans have 46 chromosomes (23 pairs). Twenty-two of these pairs are perfectly matched in both males and females and are called **autosomes**. The remaining pair are the sex chromosomes: XX in females, and XY in males.

TABLE 13.1

Sex Determination in Some Organisms

		Female	Male
Humans, <i>Drosophila</i>		XX	XY
Birds		ZW	ZZ
Grasshoppers		XX	XO
Honeybees		Diploid	Haploid

The Y chromosome in males is highly condensed. Because few genes on the Y chromosome are expressed, recessive alleles on a male's single X chromosome have no *active* counterpart on the Y chromosome.

The "default" setting in human embryonic development is for production of a female. Some of the active genes on the Y chromosome, notably the *SRY* gene, are responsible for the masculinization of genitalia and secondary sex organs, producing features associated with "maleness" in humans. Consequently, any individual with *at least one Y chromosome* is normally a male.

The exceptions to this rule actually provide support for this mechanism of sex determination. For example, movement of part of the Y chromosome to the X chromosome can cause otherwise XX individuals to develop as male. There is also a genetic disorder that causes a failure to respond to the androgen hormones (androgen insensitivity syndrome) that causes XY individuals to develop as female. Lastly, mutations in *SRY* itself can cause XY individuals to develop as females.

This form of sex determination seen in humans is shared among mammals, but is not universal in vertebrates. Among fishes and some species of reptiles, environmental factors can cause changes in the expression of this sex-determining gene, and thus in the sex of the adult individual.

## Some human genetic disorders display sex linkage

From ancient times, people have noted conditions that seem to affect males to a greater degree than females. Red-green color blindness is one well-known condition that is more common in males because the gene affected is carried on the X chromosome.

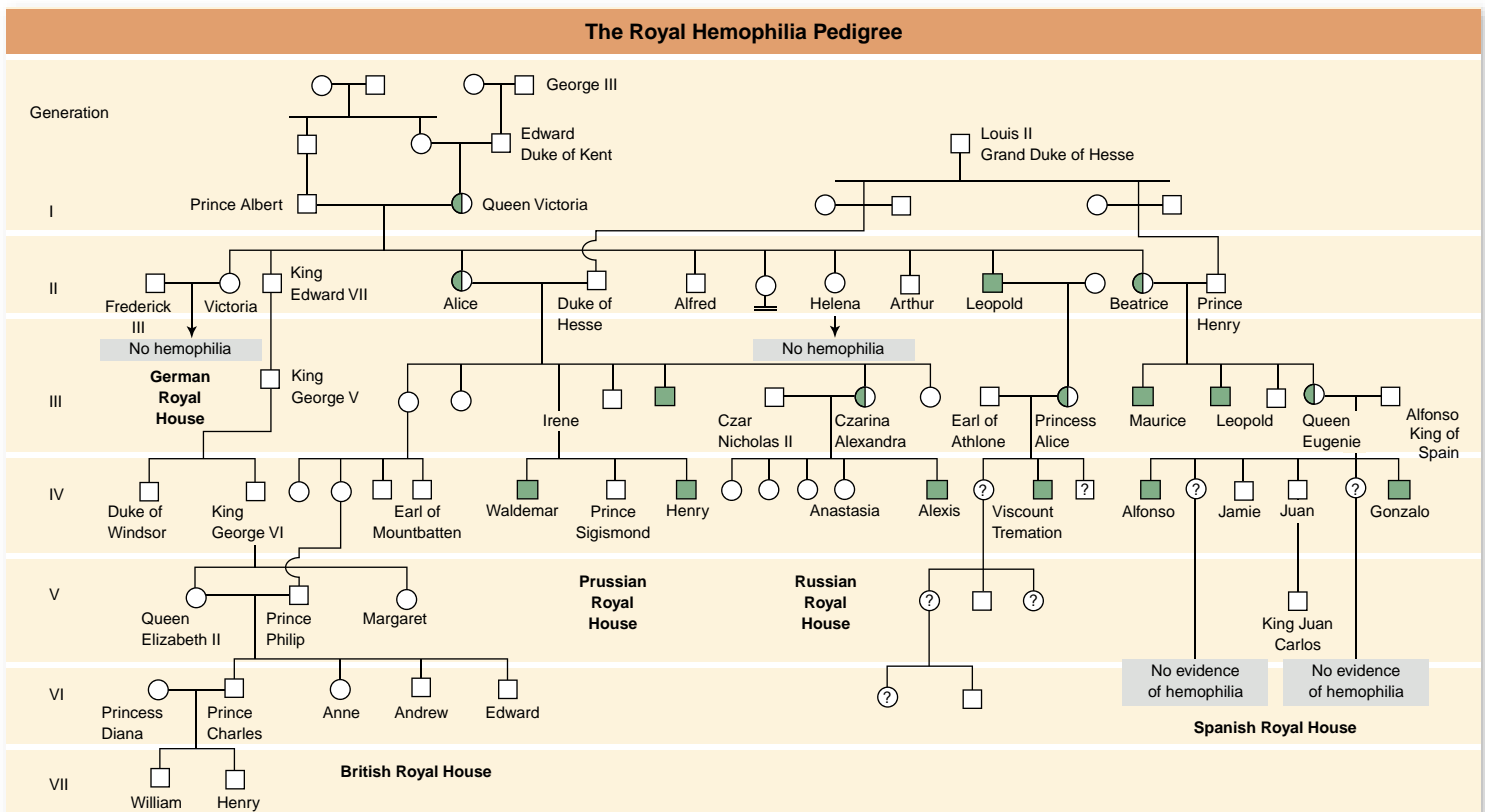

Another example is hemophilia, a disease that affects a single protein in a cascade of proteins involved in the formation of blood clots. Thus, in an untreated hemophiliac, even minor cuts will not stop bleeding. This form of hemophilia is caused by an X-linked recessive allele; women who are heterozygous for the allele are asymptomatic carriers, and men who receive an X chromosome with the recessive allele exhibit the disease.

The allele for hemophilia was introduced into a number of different European royal families by Queen Victoria of England. Because these families kept careful genealogical records, we have an extensive pedigree for this condition. In the five generations after Victoria, ten of her male descendants have had hemophilia as shown in the pedigree in figure 13.3.

The Russian house of Romanov inherited this condition through Alexandra Feodorovna, a granddaughter of Queen

**Figure 13.3 The royal hemophilia pedigree.** Queen Victoria, shown at the bottom center of the photo, was a carrier for hemophilia. Two of Victoria's four daughters, Alice and Beatrice, inherited the hemophilia allele from Victoria. Two of Alice's daughters are standing behind Victoria (wearing feathered boas): Princess Irene of Prussia (*right*) and Alexandra (*left*), who would soon become czarina of Russia. Both Irene and Alexandra were also carriers of hemophilia. From the pedigree, it is clear that Alice introduced hemophilia into the Russian and Prussian royal houses, and Victoria's daughter Beatrice introduced it into the Spanish royal house. Victoria's son Leopold, himself a victim, also transmitted the disorder in a third line of descent. Half-shaded symbols represent carriers with one normal allele and one defective allele; fully shaded symbols represent affected individuals.

Victoria. She married Czar Nicholas II, and their only son, Alexis, was afflicted with the disease. The entire family was executed during the Russian revolution. (Recently, a woman who had long claimed to be Anastasia, a surviving daughter, was shown not to be a Romanov using modern genetic techniques to test her remains.)

Ironically, this condition has not affected the current British royal family, because Victoria's son Edward, who became King Edward VII, did not receive the hemophilia allele. All of the subsequent rulers of England are his descendants.

## Dosage compensation prevents doubling of sex-linked gene products

Although males have only one copy of the X chromosome and females have two, female cells do not produce twice as much of the proteins encoded by genes on the X chromosome. Instead, one of the X chromosomes in females is inactivated early in embryonic development, shortly after the embryo's sex is determined. This inactivation is an example of **dosage compensation**, which ensures an equal level of expression from the sex chromosomes despite a differing number of sex chromosomes in males and females. (In *Drosophila*, by contrast, dosage compensation is achieved by increasing the level of expression on the male X chromosome.)

Which X chromosome is inactivated in females varies randomly from cell to cell. If a woman is heterozygous for a sex-linked trait, some of her cells will express one allele and some the other. The inactivated X chromosome is highly condensed, making it visible as an intensely staining **Barr body**, seen below, attached to the nuclear membrane.

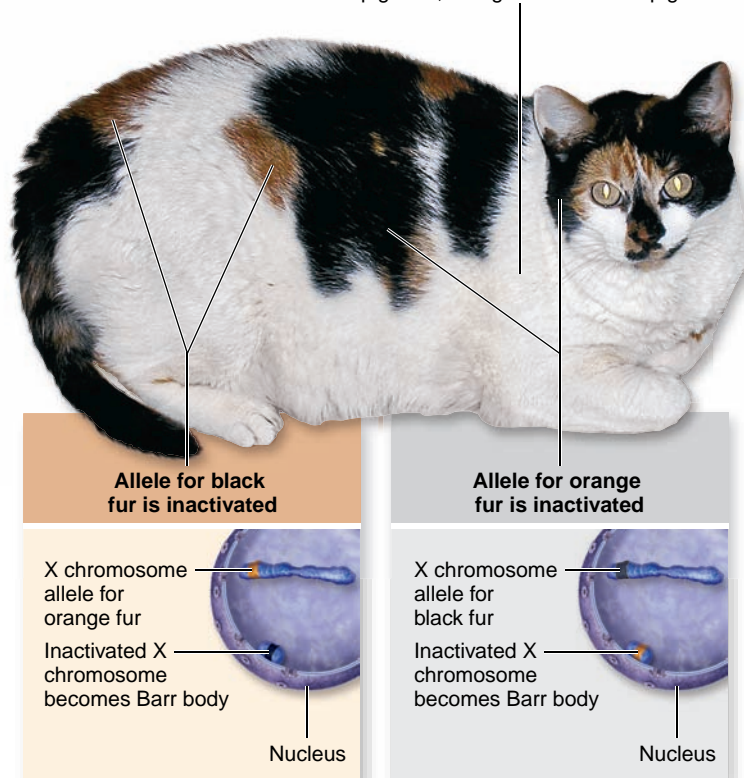

## X chromosome inactivation can lead to genetic mosaics

X chromosome inactivation to produce dosage compensation is not unique to humans but is true of all mammals. Females that are heterozygous for X chromosome alleles are **genetic mosaics**: Their individual cells may express different alleles, depending on which chromosome is inactivated.

One example is the calico cat, a female that has a patchy distribution of dark fur, orange fur, and white fur (figure 13.4). The dark fur and orange fur are due to heterozygosity for a gene on the

Second gene causes patchy distribution of pigment:  
white fur = no pigment, orange or black fur = pigment

**Figure 13.4 A calico cat.** The cat is heterozygous for alleles of a coat color gene that produce either black fur or orange fur. This gene is on the X chromosome, so the different-colored fur is due to inactivation of one X chromosome. The patchy distribution and white color is due to a second gene that is epistatic to the coat color gene and thus masks its effects.

X chromosome that determines pigment color. One allele results in dark fur, and another allele results in orange fur. Which of these colors is observed in any particular patch is due to inactivation of one X chromosome: If the chromosome containing the orange allele is inactivated, then the fur will be dark, and vice versa.

The patchy distribution of color, and the presence of white fur, is due to a second gene that is epistatic to the fur color gene (see chapter 12). That is, the presence of this second gene produces a patchy distribution of pigment, with some areas totally lacking pigment. In the areas that lack pigment, the effect of either fur color allele is masked. Thus, in this one animal we can see an excellent example of both epistasis and X inactivation.

### Learning Outcomes Review 13.2

Sex determination begins with the presence or absence of certain chromosomes termed the sex chromosomes. Additional factors may influence sex determination in different species. In humans, males are XY, and therefore they exhibit recessive traits for alleles on the X chromosome. In mammalian females, one X chromosome in each cell becomes inactivated to balance the levels of gene expression. This random inactivation can lead to genetic mosaics.

- **Would you expect an XXX individual to be viable? If so, would that individual be male or female?**

## 13.3 Exceptions to the Chromosomal Theory of Inheritance

### Learning Outcomes

1. Explain why the presence of DNA in organelles leads to non-Mendelian inheritance.
2. Describe the inheritance pattern of organelle DNA.

Although the chromosomal theory explains most inheritance, there are exceptions. Primarily, these are due to the presence of DNA in organelle genomes, specifically in mitochondria and chloroplasts. Non-Mendelian inheritance via organelles was studied in depth by Ruth Sager, who in the face of universal skepticism constructed the first map of chloroplast genes in *Chlamydomonas*, a unicellular green alga, in the 1960s and 1970s.

Mitochondria and chloroplasts are not partitioned with the nuclear genome by the process of meiosis. Thus any trait that is due to the action of genes in these organelles will not show Mendelian inheritance.

### Mitochondrial genes are inherited from the female parent

Organelles are usually inherited from only one parent, generally the mother. When a zygote is formed, it receives an equal contribution of the nuclear genome from each parent, but it gets all of its mitochondria from the egg cell, which contains a great deal more cytoplasm (and thus organelles). As the zygote divides, these original mitochondria divide as well and are partitioned randomly.

As a result, the mitochondria in every cell of an adult organism can be traced back to the original maternal mitochondria present in the egg. This mode of uniparental (one-parent) inheritance from the mother is called **maternal inheritance**.

In humans, the disease Leber's hereditary optic neuropathy (LHON) shows maternal inheritance. The genetic basis of this disease is a mutant allele for a subunit of NADH dehydrogenase. The mutant allele reduces the efficiency of electron flow in the electron transport chain in mitochondria (see chapter 7), in turn reducing overall ATP production. Some nerve cells in the optic system are particularly sensitive to reduction in ATP production, resulting in neural degeneration.

A mother with this disease will pass it on to all of her progeny, whereas a father with the disease will not pass it on to any of his progeny. Note that this condition differs from sex-linked inheritance because males and females are equally affected.

### Chloroplast genes may also be passed on uniparentally

The inheritance pattern of chloroplasts is also usually maternal, although both paternal and biparental inheritance of chloroplasts may be observed in some species. Carl Correns first hypothesized in 1909 that chloroplasts were responsible for inheritance of variegation

(mixed green and white leaves) in the plant commonly known as the four o'clock (*Mirabilis jalapa*). The offspring exhibited the phenotype of the female parent, regardless of the male's phenotype.

In Sager's work on *Chlamydomonas*, resistance to the antibiotic streptomycin was shown to be transmitted via the chloroplast DNA from only the  $mt^+$  mating type. The  $mt^-$  mating type does not contribute chloroplast DNA to the zygote formed by fusion of  $mt^+$  and  $mt^-$  gametes.

### Learning Outcomes Review 13.3

The genomes of mitochondria and chloroplasts divide independently of the nucleus. These organelles are carried in the cytoplasm of the egg cell, so any traits determined by these genomes are maternally inherited and thus do not follow Mendelian rules. In some species, however, chloroplasts may be passed on paternally or biparentally.

- How can you explain the lack of  $mt^-$  chloroplast DNA in *Chlamydomonas* zygotes from  $mt^-$  by  $mt^+$  crosses?

## 13.4 Genetic Mapping

### Learning Outcomes

1. Recognize that genes on the same chromosome may not assort independently.
2. Explain how recombination frequency is related to genetic distance.
3. Review how data from testcrosses is used to construct genetic maps.

We have seen that Mendelian traits are determined by genes located on chromosomes and that the independent assortment of Mendelian traits reflects the independent assortment of chromosomes in meiosis. This is fine as far as it goes, but it is still incomplete. Of Mendel's seven traits in figure 12.4, six are on different chromosomes and two are on the same chromosome, yet all show independent assortment with one another. The two on the same chromosome should not behave the same as those that are on different chromosomes. In fact, organisms generally have many more genes that assort independently than the number of chromosomes. This means that independent assortment cannot be due only to the random alignment of chromosomes during meiosis.

### Inquiry question

? Mendel did not examine plant height and pod shape in his dihybrid crosses. The genes for these traits are very close together on the same chromosome. How would this have changed Mendel's results?

The solution to this problem is found in an observation that was introduced in chapter 11: the crossing over of homologues during meiosis. In prophase I of meiosis, homologues appear to physically exchange material by crossing over (figure 13.5). In chapter 11, you saw how this was part of the mechanism that allows homologues, and not sister chromatids, to disjoin at anaphase I.

**Figure 13.5** Crossing over exchanges alleles on homologues. When a crossover occurs between two loci, it leads to the production of recombinant chromosomes. If no crossover occurs, then the chromosomes will carry the parental combination of alleles.

### Genetic recombination exchanges alleles on homologues

Consider a dihybrid cross performed using the Mendelian framework. Two true-breeding parents that each differ with respect to two traits are crossed, producing doubly heterozygous  $F_1$  progeny. If the genes for the two traits are on a single chromosome, then during meiosis we would expect alleles for both loci to segregate together and produce only gametes that resemble the two parental types. But if a crossover occurs between the two loci, then each homologue would carry one allele from each parent and produce gametes that combine these parental traits (see figure 13.5). We call gametes with this new combination of alleles *recombinant* gametes as they are formed by recombining the parental alleles.

The first investigator to provide evidence for this was Morgan, who studied three genes on the X chromosome of *Drosophila*. He found an excess of parental types, which he explained as due to the genes all being on the X chromosome and therefore coinherited (inherited together). He went further,

suggesting that the recombinant genotypes were due to crossing over between homologues during meiosis.

Experiments performed independently by Barbara McClintock and Harriet Creighton in maize and by Curt Stern in *Drosophila* provided evidence for this physical exchange of genetic material. The experiment done by Creighton and McClintock is detailed in figure 13.6. In this experiment, they used a chromosome with two alterations visible under a microscope: a knob on one end of the chromosome and an extension of the other end making it longer. In addition to these visible markers, this chromosome also carried a gene that determines kernel color (colored or colorless) and a gene that determines kernel texture (waxy or starchy).

**Figure 13.6** The Creighton and McClintock experiment.

The long chromosome, which also had the knob, carried the dominant colored allele for kernel color (*C*) and the recessive waxy allele for kernel texture (*wx*). Heterozygotes were constructed with this chromosome paired with a visibly normal chromosome carrying the recessive colorless allele for kernel color (*c*) and the dominant starchy allele for kernel texture (*Wx*) (see figure 13.6). These plants appeared colored and starchy because they were heterozygous for both loci, and they were also heterozygous for the two visibly distinct chromosomes.

These plants, heterozygous for both chromosomal and genetic markers, were test crossed to colorless waxy plants with normal appearing chromosomes. The progeny were analyzed for both physical recombination (using a microscope to observe chromosome appearance) and genetic recombination (by examining the phenotype of progeny). The results were striking: All of the progeny that were genetically recombinant (appear colored starchy or colorless waxy) also now had only one of the chromosomal markers. That is, genetic recombination was accompanied by physical exchange of chromosomal material.

## Recombination is the basis for genetic maps

The ability to map the location of genes on chromosomes using data from genetic crosses is one of the most powerful tools of genetics. The insight that allowed this technique, like many great insights, is so simple as to seem obvious in retrospect.

Morgan had already suggested that the frequency with which a particular group of recombinant progeny appeared was a reflection of the relative location of genes on the chromosome. An undergraduate in Morgan's laboratory, Alfred Sturtevant put this observation on a quantitative basis. Sturtevant reasoned that the frequency of recombination observed in crosses could be used as a measure of genetic distance. That is, as physical distance on a chromosome increases, so does the probability of recombination (crossover) occurring between the gene loci. Using this logic, the frequency of recombinant gametes produced is a measure of their distance apart on a chromosome.

### Linkage data

To be able to measure recombination frequency easily, investigators used a testcross instead of intercrossing the  $F_1$  progeny to produce an  $F_2$  generation. In a testcross, as described earlier, the phenotypes of the progeny reflect the gametes produced by the doubly heterozygous  $F_1$  individual. In the case of recombination, progeny that appear parental have not undergone crossover, and progeny that appear recombinant have experienced a crossover between the two loci in question (see figure 13.5).

When genes are close together, the number of recombinant progeny is much lower than the number of parental progeny, and the genes are defined on this basis as being **linked**. The number of recombinant progeny divided by total progeny gives a value defined as the **recombination frequency**. This value is converted to a percentage, and each 1% of recombination is termed a **map unit**. This unit has been named the centimorgan (cM) for T. H. Morgan, although it is also called simply a map unit (m.u.) as well.

### Constructing maps

Constructing genetic maps then becomes a simple process of performing testcrosses with doubly heterozygous individuals

and counting progeny to determine percent recombination. This is best shown with an example using a two-point cross.

*Drosophila* homozygous for two mutations, vestigial wings (*vg*) and black body (*b*), are crossed to flies homozygous for the wild type, or normal alleles, of these genes (*vg<sup>+</sup> b<sup>+</sup>*). The doubly

**Figure 13.7 Two-point cross to map genes.** Flies homozygous for long wings (*vg<sup>+</sup>*) and gray bodies (*b<sup>+</sup>*) are crossed to flies homozygous for vestigial wings (*vg*) and black bodies (*b*). Both vestigial wing and black body are recessive to the normal (wild-type) long wing and grey body. The  $F_1$  progeny are then testcrossed to homozygous vestigial black to produce the progeny for mapping. Data are analyzed in the text.

heterozygous  $F_1$  progeny are then testcrossed to homozygous recessive individuals ( $vg\ b/vg\ b$ ), and progeny are counted (figure 13.7). The data are shown here:

vestigial wings, black body ( $vg\ b$ )	405 (parental)
long wings, gray body ( $vg^+\ b^+$ )	415 (parental)
vestigial wings, gray body ( $vg\ b^+$ )	92 (recombinant)
long wings, black body ( $vg^+\ b$ )	88 (recombinant)
Total Progeny	1000

The numbers of recombinant progeny are added together, and this sum is divided by total progeny to produce the recombination frequency. The recombination frequency is  $92 + 88$  divided by 1000, or 0.18. Converting this number to a percentage yields 18 cM as the map distance between these two loci.

## Multiple crossovers can yield independent assortment results

As the distance separating loci increases, the probability of recombination occurring between them during meiosis also increases. What happens when more than one recombination event occurs?

If homologues undergo two crossovers between loci, then the parental combination is restored. This leads to an underestimate of the true genetic distance because not all events can be noted. As a result, the relationship between true distance on a chromosome and the recombination frequency is not linear. It begins as a straight line, but the slope decreases; the curve levels off at a recombination frequency of 0.5 (figure 13.8).

At long distances, multiple events between loci become frequent. In this case, odd numbers of crossovers (1, 3, 5) produce recombinant gametes, and no crossover or even numbers of crossovers (0, 2, 4) produce parental gametes. At large enough distances, these frequencies are about equal, leading to the number of recombinant gametes being equal to the number of parental gametes, and the loci exhibit independent assortment! This is how Mendel could use two loci on the same chromosome and have them assort independently.

### Inquiry question

? What would Mendel have observed in a dihybrid cross if the two loci were 10 cM apart on the same chromosome? Is this likely to have led him to the idea of independent assortment?

**Figure 13.8** Relationship between true distance and recombination frequency. As distance on a chromosome increases, the recombinants are not all detected due to double crossovers. This leads to a curve that levels off at 0.5.

**Figure 13.9** Use of a three-point cross to order genes.

In a two-point cross, the outside loci appear parental for double crossovers. With the addition of a third locus, the two crossovers can still be detected because the middle locus will be recombinant. This double crossover class should be the least frequent, so whatever locus has recombinant alleles in this class must be in the middle.

## Three-point crosses can be used to put genes in order

Because multiple crossovers reduce the number of observed recombinant progeny, longer map distances are not accurate. As a result, when geneticists try to construct maps from a series of two-point crosses, determining the order of genes is problematic. Using three loci instead of two, or a three-point cross, can help solve the problem.

In a three-point cross, the gene in the middle allows us to see recombination events on either side. For example, a double crossover for the two outside loci is actually a single crossover between the middle locus and each outside locus (figure 13.9).

The probability of two crossovers is equal to the product of the probability of each individual crossover, each of which is relatively low. Therefore, in any three-point cross, the class of offspring with two crossovers is the least frequent class. Analyzing these individuals to see which locus is recombinant identifies the locus that lies in the middle of the three loci in the cross (see figure 13.9).

In practice, geneticists use three-point crosses to determine the order of genes, then use data from the closest two-point crosses to determine distances. Longer distances are generated by simple addition of shorter distances. This avoids using inaccurate measures from two-point crosses between distant loci.

## Genetic maps can be constructed for the human genome

Human genes can be mapped, but the data must be derived from historical pedigrees, such as those of the royal families of Europe mentioned earlier. The principle is the same—genetic distance is still proportional to recombination frequency—but the analysis requires the use of complex statistics and summing data from many families.

### The difficulty of mapping in humans

Looking at nonhuman animals with extensive genetic maps, the majority of genetic markers have been found at loci where alleles

cause morphological changes, such as variant eye color, body color, or wing morphology in flies. In humans, such alleles generally, but not always, correspond to what we consider disease states. As recently as the early 1980s, the number of markers for the human genome numbered in the hundreds. Because the human genome is so large, however, this low number of markers would never provide dense enough coverage to use for mapping.

Another consideration is that the disease-causing alleles are those that we wish to map, but they occur at low frequencies in the population. Any one family would be highly unlikely to carry multiple disease alleles, the segregation of which would allow for mapping.

### Anonymous markers

This situation changed with the development of **anonymous markers**, genetic markers that can be detected using molecular techniques, but that do not cause a detectable phenotype. The nature of these markers has evolved with technology, leading to a standardized set of markers scattered throughout the genome. These markers, which have a relatively high density, can be detected using techniques that are easy to automate. As a result of analysis, geneticists now have several thousand markers to work with, instead of hundreds, and have produced a human genetic map that would have been unthinkable 25 years ago (figure 13.10). (In the following chapters of this unit, you'll learn about some of the molecular techniques that have been developed for use with genomes.)

### Single-nucleotide polymorphisms (SNPs)

The information developed from sequencing the human genome can then be used to identify and map single bases that differ between individuals. Any differences between individuals

in populations are termed *polymorphisms*; polymorphisms affecting a single base of a gene locus are called **single-nucleotide polymorphisms (SNPs)**. Over 2 million such differences have been identified and are being placed on both the genetic map and the human genome sequence. This confluence of techniques will enable the ultimate resolution of genetic analysis.

The recent progress in gene mapping applies to more than just the relatively small number of genes that show simple Mendelian inheritance. The development of a high-resolution genetic map, and the characterization of millions of SNPs, opens up the possibility of being able to characterize complex quantitative traits in humans as well.

On a more practical level, the types of molecular markers described earlier are used in forensic analysis. Although not quite as rapid as some television programs would have you believe, this does allow rapid DNA testing of crime scene samples to help eliminate or confirm crime suspects and for paternity testing.

### Learning Outcomes Review 13.4

Crossing over during meiosis exchanges alleles on homologues. This recombination of alleles can be used to map the location of genes. Genes that are close together are said to be linked, and exhibit an excess of parental versus recombinant types in a testcross. The frequency of recombination in testcrosses is used as a measure of genetic distance. Loci separated by large distances have multiple crossovers between them, which can lead to independent assortment.

- If two genes assort independently, can you tell if they are on a single chromosome and far apart or on two different chromosomes?

**Figure 13.10 The human X chromosome gene map.** Only a partial map for the human X chromosome is presented here, a more detailed map would require a much larger figure. The black bands represent staining patterns that can be seen under the microscope, and the constriction represents the centromere. Analysis of the sequence of the X chromosome indicates 1098 genes on the X chromosome. Many of these may have mutant alleles that can affect disease states. By analyzing inheritance patterns of affected and unaffected individuals, the 59 diseases shown have been traced to specific segments of the X chromosome, indicated by brackets.

## 13.5 Selected Human Genetic Disorders

### Learning Outcomes

1. Explain how mutations can cause disease.
2. Describe the consequences of nondisjunction in humans.
3. Recognize how genomic imprinting can lead to non-Mendelian inheritance.

Diseases that run in families have been known for many years. These can be nonlife-threatening like albinism, or may result in premature death like Huntington's, which were used as examples of recessive and dominant traits in humans previously. A small sample of diseases due to alterations of alleles of a single gene is provided in table 13.2. We will discuss the nature of these genetic changes later in chapter 15. In this section we discuss some of the genetic disorders that have been found in human populations.

### Sickle cell anemia is due to altered hemoglobin

The first human disease shown to be the result of a mutation in a protein was sickle cell anemia. It is caused by a defect in the oxygen carrier molecule, hemoglobin, that leads to impaired oxygen delivery to tissues. The defective hemoglobin molecules stick to one another, leading to stiff, rodlike structures that alter the shape of the red blood cells that carry them. These red blood cells take on a characteristic shape that led to the name “sickle cell” (figure 13.11).

**Figure 13.11 Sickle cell anemia.** In individuals homozygous for the sickle cell trait, many of the red blood cells have sickled or irregular shapes, such as the cell on the far left.

Individuals homozygous for the sickle cell allele exhibit intermittent illness and reduced life span. Individuals heterozygous for the sickle cell allele are indistinguishable from normal individuals in a normal oxygen environment, although their red cells do exhibit reduced ability to carry oxygen.

The sickle cell allele is particularly prevalent in people of African descent. In some regions of Africa, up to 45% of the population is heterozygous for the trait, and 6% are homozygous. This proportion of heterozygotes is higher than would be expected on the basis of chance alone. It turns out that heterozygosity confers a greater resistance to the blood-borne parasite

**TABLE 13.2** Some Important Genetic Disorders

Disorder	Symptom	Defect	Dominant/Recessive	Frequency Among Human Births
Cystic fibrosis	Mucus clogs lungs, liver, and pancreas	Failure of chloride ion transport mechanism	Recessive	1/2500 (Caucasians)
Sickle cell anemia	Blood circulation is poor	Abnormal hemoglobin molecules	Recessive	1/600 (African Americans)
Tay–Sachs disease	Central nervous system deteriorates in infancy	Defective enzyme (hexosaminidase A)	Recessive	1/3500 (Ashkenazi Jews)
Phenylketonuria	Brain fails to develop in infancy, treatable with dietary restriction	Defective enzyme (phenylalanine hydroxylase)	Recessive	1/12,000
Hemophilia	Blood fails to clot	Defective blood-clotting factor VIII	X-linked recessive	1/10,000 (Caucasian males)
Huntington disease	Brain tissue gradually deteriorates in middle age	Production of an inhibitor of brain cell metabolism	Dominant	1/24,000
Muscular dystrophy (Duchenne)	Muscles waste away	Degradation of myelin coating of nerves stimulating muscles	X-linked recessive	1/3700 (males)
Hypercholesterolemia	Excessive cholesterol levels in blood lead to heart disease	Abnormal form of cholesterol cell surface receptor	Dominant	1/500

that causes malaria. In regions of central Africa where malaria is endemic, the sickle cell allele also occurs at a high frequency.

The sickle cell allele is not the end of the story for the  $\beta$ -globin gene; a large number of other alterations of this gene have been observed that lead to anemias. In fact, for hemoglobin, which is composed of two  $\alpha$ -globins and two  $\beta$ -globins, over 700 structural variants have been cataloged. It is estimated that 7% of the human population worldwide are carriers for different inherited hemoglobin disorders.

The Human Gene Mutation Database has cataloged the nature of many disease alleles, including the sickle cell allele. The majority of alleles seem to be simple changes. Almost 60% of the close to 28,000 alleles in the Human Gene Mutation Database are single-base substitutions. Another 23% are due to small insertions or deletions of less than 20 bases. The rest of the alleles are made of more complex alterations. It is clear that simple changes in genes can have profound effects.

## Nondisjunction of chromosomes changes chromosome number

The failure of homologues or sister chromatids to separate properly during meiosis is called **nondisjunction**. This failure leads to the gain or loss of a chromosome, a condition called **aneuploidy**. The frequency of aneuploidy in humans is surprisingly high, being estimated to occur in 5% of conceptions.

### Nondisjunction of autosomes

Humans who have lost even one copy of an autosome are called **monosomics**, and generally do not survive embryonic development. In all but a few cases, humans who have gained an extra autosome (called **trisomics**) also do not survive. Data from clinically recognized spontaneous abortions indicate levels of aneuploidy as high as 35%.

Five of the smallest human autosomes—those numbered 13, 15, 18, 21, and 22—can be present as three copies and still allow the individual to survive, at least for a time. The presence of an extra chromosome 13, 15, or 18 causes severe developmental defects, and infants with such a genetic makeup die within a few months. In contrast, individuals who have an extra copy of chromosome 21 or, more rarely, chromosome 22, usually survive to adulthood. In these people, the maturation of the skeletal system is delayed, so they generally are short and have poor muscle tone. Their mental development is also affected, and children with trisomy 21 are always mentally retarded to some degree.

The developmental defect produced by trisomy 21 (figure 13.12) was first described in 1866 by J. Langdon Down; for this reason, it is called Down syndrome. About 1 in every 750 children exhibits Down syndrome, and the frequency is comparable in all racial groups. Similar conditions also occur in chimpanzees and other related primates.

In humans, the defect occurs when a particular small portion of chromosome 21 is present in three copies instead of two. In 97% of the cases examined, all of chromosome 21 is present in three copies. In the other 3%, a small portion of chromosome 21 containing the critical segment has been added to another chromosome by a process called *translocation* (see chapter 15);

**Figure 13.12 Down syndrome.** As shown in this male karyotype, Down syndrome is associated with trisomy of chromosome 21 (arrow shows third copy of chromosome 21).

it exists along with the normal two copies of chromosome 21. This latter condition is known as *translocation Down syndrome*.

In mothers younger than 20 years of age, the risk of giving birth to a child with Down syndrome is about 1 in 1700; in mothers 20 to 30 years old, the risk is only about 1 in 1400. However, in mothers 30 to 35 years old, the risk rises to 1 in 750, and by age 45, the risk is as high as 1 in 16 (figure 13.13).

**Figure 13.13 Correlation between maternal age and the incidence of Down syndrome.** As women age, the chances they will bear a child with Down syndrome increase. After a woman reaches 35, the frequency of Down syndrome rises rapidly.

### Inquiry question

Over a five-year period between ages 20 and 25, the incidence of Down syndrome increases 0.1 per thousand; over a five-year period between ages 35 and 40, the incidence increases to 8.0 per thousand, 80 times as great. The period of time is the same in both instances. What has changed?

Primary nondisjunctions are far more common in women than in men because all of the eggs a woman will ever produce have developed to the point of prophase in meiosis I by the time she is born. By the time a woman has children, her eggs are as old as she is. Therefore, there is a much greater chance for cell-division problems of various kinds, including those that cause primary nondisjunction, to accumulate over time in female gametes. In contrast, men produce new sperm daily. For this reason, the age of the mother is more critical than that of the father for couples contemplating childbearing.

### Nondisjunction of sex chromosomes

Individuals who gain or lose a sex chromosome do not generally experience the severe developmental abnormalities caused by similar changes in autosomes. Although such individuals have somewhat abnormal features, they often reach maturity and in some cases may be fertile.

**X chromosome nondisjunction.** When X chromosomes fail to separate during meiosis, some of the gametes produced possess both X chromosomes, and so are XX gametes; the other gametes have no sex chromosome and are designated “O” (figure 13.14).

If an XX gamete combines with an X gamete, the resulting XXX zygote develops into a female with one functional X chromosome and two Barr bodies. She may be taller in stature but is otherwise normal in appearance.

If an XX gamete instead combines with a Y gamete, the effects are more serious. The resulting XXY zygote develops into a male who has many female body characteristics and, in some cases but not all, diminished mental capacity. This condition, called *Klinefelter syndrome*, occurs in about 1 out of every 500 male births.

**Figure 13.14** How nondisjunction can produce abnormalities in the number of sex chromosomes.

When nondisjunction occurs in the production of female gametes, the gamete with two X chromosomes (XX) produces Klinefelter males (XXY) and triple-X females (XXX). The gamete with no X chromosome (O) produces Turner females (XO) and nonviable OY males lacking any X chromosome.

### Inquiry question

Can you think of two nondisjunction scenarios that would produce an XXY male?

If an O gamete fuses with a Y gamete, the resulting OY zygote is nonviable and fails to develop further; humans cannot survive when they lack the genes on the X chromosome. But if an O gamete fuses with an X gamete, the XO zygote develops into a sterile female of short stature, with a webbed neck and sex organs that never fully mature during puberty. The mental abilities of an XO individual are in the low-normal range. This condition, called *Turner syndrome*, occurs roughly once in every 5000 female births.

**Y chromosome nondisjunction.** The Y chromosome can also fail to separate in meiosis, leading to the formation of YY gametes. When these gametes combine with X gametes, the XYY zygotes develop into fertile males of normal appearance. The frequency of the XYY genotype (*Jacob syndrome*) is about 1 per 1000 newborn males.

### Genomic imprinting depends on the parental origin of alleles

By the late 20th century, geneticists were confident that they understood the basic mechanisms governing inheritance. It came as quite a surprise when mouse geneticists found an important exception to classical Mendelian genetics that appears to be unique to mammals. In **genomic imprinting**, the phenotype caused by a specific allele is exhibited when the allele comes from one parent, but not from the other.

The basis for genomic imprinting is the expression of a gene depending on passage through maternal or paternal germ lines. Some genes are inactivated in the paternal germ line and therefore are not expressed in the zygote. Other genes are inactivated in the maternal germ line, with the same result. This condition makes the zygote effectively haploid for an imprinted gene. The expression of variant alleles of imprinted genes depends on the parent of origin. Furthermore, imprinted genes seem to be concentrated in particular regions of the genome. These regions include genes that are both maternally and paternally imprinted.

### Prader–Willi and Angelman syndromes

An example of genomic imprinting in humans involves the two diseases Prader–Willi syndrome (PWS) and Angelman syndrome (AS). The effects of PWS include respiratory distress, obesity, short stature, mild mental retardation, and obsessive–compulsive behavior. The effects of AS include developmental delay, severe mental retardation, hyperactivity, aggressive behavior, and inappropriate laughter.

Genetic studies have implicated genes on chromosome 15 for both disorders, but the pattern of inheritance is complementary. The most common cause of both syndromes is a deletion of material on chromosome 15 and, in fact, the same deletion can cause either syndrome. The determining factor is the parental origin of the normal and deleted chromosomes. If the chromosome with the deletion is paternally inherited it causes PWS, if the chromosome with the deletion is maternally inherited it causes AS.

The region of chromosome 15 that is lost is subject to imprinting, with some genes being inactivated in the maternal germ line, and others in the paternal germ line. In PWS, genes

are inactivated in the maternal germ line, such that deletion or other functional loss of paternally derived alleles produces the syndrome. The opposite is true for AS syndrome: Genes are inactivated in the paternal germ line, such that loss of maternally derived alleles leads to the syndrome.

### **Molecular basis of genomic imprinting**

Although genomic imprinting is not well understood, at least one aspect seems clear: The basis for inactivating genes appears to be linked to modifications of the DNA itself. DNA can be modified by the addition of methyl groups, termed *methylation*. This modification is correlated with inactivity of genes. The proteins that are associated with chromosomes can also be modified, leading to effects on gene expression. The control of gene expression is discussed in more detail in the following chapters.

### **Some genetic defects can be detected early in pregnancy**

Although most genetic disorders cannot yet be cured, we are learning a great deal about them, and progress toward successful therapy is being made in many cases. In the absence of a cure, however, the only recourse is to try to avoid producing children with these conditions. The process of identifying parents at risk for having children with genetic defects and of assessing the genetic state of early embryos is called **genetic counseling**.

### **Pedigree analysis**

One way of assessing risks is through pedigree analysis, often employed as an aid in genetic counseling. By analyzing a person's pedigree, it is sometimes possible to estimate the likeli-

hood that the person is a carrier for certain disorders. For example, if a counseling client's family history reveals that a relative has been afflicted with a recessive genetic disorder, such as cystic fibrosis, it is possible that the client is a heterozygous carrier of the recessive allele for that disorder.

When a couple is expecting a child, and pedigree analysis indicates that both of them have a significant chance of being heterozygous carriers of a deleterious recessive allele, the pregnancy is said to be high-risk. In such cases, a significant probability exists that their child will exhibit the clinical disorder.

Another class of high-risk pregnancy is that in which the mothers are older than 35. As discussed earlier, the frequency of Down syndrome increases dramatically in the pregnancies of older women (see figure 13.13).

### **Amniocentesis**

When a pregnancy is diagnosed as high-risk, many women elect to undergo **amniocentesis**, a procedure that permits the prenatal diagnosis of many genetic disorders. In the fourth month of pregnancy, a sterile hypodermic needle is inserted into the expanded uterus of the mother, removing a small sample of the amniotic fluid that bathes the fetus (figure 13.15). Within the fluid are free-floating cells derived from the fetus; once removed, these cells can be grown in cultures in the laboratory.

During amniocentesis, the position of the needle and that of the fetus are usually observed by means of *ultrasound*. The sound waves used in ultrasound are not harmful to mother or fetus, and they permit the person withdrawing the amniotic fluid to do so without damaging the fetus. In addition, ultrasound can be used to examine the fetus for signs of major abnormalities. However, about 1 out of 200 amniocentesis procedures may result in fetal death and miscarriage.

**Figure 13.15**  
**Amniocentesis.** A needle is inserted into the amniotic cavity, and a sample of amniotic fluid, containing some free cells derived from the fetus, is withdrawn into a syringe. The fetal cells are then grown in culture, and their karyotype and many of their metabolic functions are examined.

**Figure 13.16 Chorionic villi sampling.** Cells can be taken from the chorionic villi as early as the eighth to tenth week of pregnancy. Cells are removed by suction with a tube inserted through the cervix. These cells can then be grown in culture and examined for karyotypes and tested biochemically for defects.

### **Chorionic villi sampling**

In recent years, physicians have increasingly turned to a new, less invasive procedure for genetic screening called **chorionic villi sampling**. Using this method, the physician removes cells from the chorion, a membranous part of the placenta that nourishes the fetus (figure 13.16). This procedure can be used earlier in pregnancy (by the eighth week) and yields results much more rapidly than does amniocentesis. Risks from chorionic villi sampling are comparable to those for amniocentesis.

To test for certain genetic disorders, genetic counselors look for three characteristics in the cultures of cells obtained from amniocentesis or chorionic villi sampling. First, analysis of the karyotype can reveal aneuploidy (extra or missing chromosomes) and gross chromosomal alterations. Second, in many cases it is possible to test directly for the proper functioning of enzymes involved in genetic disorders. The lack of normal enzymatic activity signals the presence of the disorder. As examples, the lack of the enzyme responsible for breaking down phenylalanine indicates phenylketonuria (PKU); the absence of the enzyme responsible for the breakdown of gangliosides indicates Tay–Sachs disease; and so forth. Additionally, with information from the Human Genome Project, more disease alleles for genetic disorders are known. If there are a small number of alleles for a specific disease in the population, these can be identified as well.

With the changes in human genetics brought about by the Human Genome Project (see chapter 18), it is possible to

design tests for many more diseases. Difficulties still exist in discerning the number and frequency of disease-causing alleles, but these problems are not insurmountable. At present, tests for at least 13 genes with alleles that lead to clinical syndromes are available. This number is bound to rise and to be expanded to include alleles that do not directly lead to disease states but that predispose a person for a particular disease.

### **Inquiry question**

? Based on what you read in this chapter, what reasons could a mother have to undergo CVS, considering its small but potential risks?

### **Learning Outcomes Review 13.5**

Mutations in DNA that result in altered proteins can cause hereditary diseases. Pedigree studies and genetic testing may clarify the risk of disease. At the chromosome level, nondisjunction during meiosis can result in gametes with too few or too many chromosomes, most of which produce inviable offspring. Imprinting refers to inactivation of alleles depending on which parent the alleles come from; offspring in whom imprinting occurs appear haploid for the affected gene even though they are diploid.

- *During spermatogenesis, is there any difference in outcome between first and second division nondisjunction?*

### 13.1 Sex Linkage and the Chromosomal Theory of Inheritance

**Morgan correlated the inheritance of a trait with sex chromosomes (see figure 13.2).**

Morgan crossed red-eyed and white-eyed flies and found differences in inheritance based on the sex of offspring. All white-eyed offspring were males, but testcrosses showed that white-eyed females were possible, supporting the idea that the white-eye gene was on the X chromosome.

**The gene for eye color lies on the X chromosome.**

The inheritance of eye color in *Drosophila* segregates with the X chromosome, a phenomenon termed sex-linked inheritance.

### 13.2 Sex Chromosomes and Sex Determination

Sex determination in animals is usually associated with a chromosomal difference. In some animals, females have two similar sex chromosomes and males have sex chromosomes that differ. In other species, females have sex chromosomes that differ (see table 13.1).

**In humans the Y chromosome generally determines maleness.**

The Y chromosome is highly condensed and does not have active counterparts to most genes on the X chromosome. The *SRY* gene on the Y chromosome is responsible for the masculinization of genitalia and secondary sex organs. An XY individual can develop into a sterile female due to mutations in the *SRY* gene or the failure of the embryo to respond to androgens.

**Some human genetic disorders display sex linkage (see figure 13.3).**

Human genetic disorders show sex linkage when the relevant gene is on the X chromosome; hemophilia is an example.

**Dosage compensation prevents doubling of sex-linked gene products.**

In fruit flies, males double the gene expression from their single X chromosome. In mammals, one of the X chromosomes in a female is randomly inactivated during development.

**X-chromosome inactivation can lead to genetic mosaics.**

In a mammalian female that is heterozygous for X-chromosome alleles, X inactivation produces a mosaic pattern, as shown in the coat color of calico cats (see figure 13.4).

### 13.3 Exceptions to the Chromosomal Theory of Inheritance

**Mitochondrial genes are inherited from the female parent.**

Mitochondria have their own genomes and divide independently; they are passed to offspring in the cytoplasm of the egg cell.

**Chloroplast genes may also be passed on uniparentally.**

Chloroplasts also reside in the cytoplasm, have their own genomes, and divide independently. They are usually inherited maternally.

### 13.4 Genetic Mapping

Mendel's independent assortment is too simplistic. Genes on the same chromosome may or may not segregate independently.

**Genetic recombination exchanges alleles on homologues.**

Homologous chromosomes may exchange alleles by crossing over (see figure 13.5). This occurs by breakage and rejoining of

chromosomes as shown by crosses in which chromosomes carry both visible and genetic markers (see figure 13.6).

**Recombination is the basis for genetic maps.**

Genes close together on a single chromosome are said to be linked. The further apart two linked genes are, the greater the frequency of recombination. This allows genetic maps to be constructed based on recombination frequency. A map unit is expressed as the percentage of recombinant progeny.

**Multiple crossovers can yield independent assortment results.**

The probability of multiple crossovers increases with distance between two genes and results in an underestimate of recombination frequency. The maximum recombination frequency is 50%, the same value as for independent assortment.

**Three-point crosses can be used to put genes in order (see figure 13.9).**

If three genes are used instead of two, data from multiple crossovers can be used to order genes. Longer map distances fail to reflect the effect of multiple crossovers and thus underestimate true distance. By evaluating intervening genes with less separation, more accurate distances can be obtained.

**Genetic maps can be constructed for the human genome.**

Human genetic mapping was difficult because it required multiple disease-causing alleles segregating in a family. The process has been made easier by the use of anonymous markers, identifiable molecular markers that do not cause a phenotype. Single-nucleotide polymorphisms (SNPs) can be used to detect differences between individuals for identification.

### 13.5 Selected Human Genetic Disorders

**Sickle cell anemia is due to altered hemoglobin.**

The phenotypes in sickle cell anemia can all be traced to alterations in the structure of hemoglobin that affect the shape of red blood cells. Over 700 variants of hemoglobin structure have been characterized, some of which also cause disorders.

**Nondisjunction of chromosomes changes chromosome number.**

Nondisjunction is the failure of homologues or sister chromatids to separate during meiosis. The result is aneuploidy: monosomy or trisomy of a chromosome in the zygote. Most aneuploidies are lethal, but some, such as trisomy 21 in humans (Down syndrome), can result in viable offspring. X-chromosome nondisjunction occurs when X chromosomes fail to separate during meiosis. The resulting gamete carries either XX or O (zero sex chromosomes) (see figure 13.14). Y-chromosome nondisjunction results in YY gametes.

**Genomic imprinting depends on the parental origin of alleles.**

In genomic imprinting, the expression of a gene depends on whether it passes through the maternal or paternal germ line. Imprinted genes appear to be inactivated by methylation. Imprinting produces a haploid phenotype.

**Some genetic defects can be detected early in pregnancy.**

Genetic defects in humans can be determined by pedigree analysis, amniocentesis, or chorionic villi sampling.

## Review Questions

### UNDERSTAND

- Why is the white-eye phenotype always observed in males carrying the white-eye allele?
  - Because the trait is dominant
  - Because the trait is recessive
  - Because the allele is located on the X chromosome and males only have one X
  - Because the allele is located on the Y chromosome and only males have Y chromosomes
- In an organism's genome, *autosomes* are
  - the chromosomes that differ between the sexes.
  - chromosomes that are involved in sex determination.
  - only inherited from the mother (maternal inheritance).
  - all of the chromosomes other than sex chromosomes.
- What cellular process is responsible for genetic recombination?
  - The independent alignment of homologous pairs during meiosis I
  - Separation of the homologues in meiosis I
  - Separation of the chromatids during meiosis II
  - Crossing over between homologues
- The map distance between two genes is determined by the
  - recombination frequency.
  - frequency of parental types.
  - ratio of genes to length of a chromosome.
  - ratio of parental to recombinant progeny.
- How many map units separate two alleles if the recombination frequency is 0.07?
  - 700 cM
  - 70 cM
  - 7 cM
  - 0.7 cM
- How does maternal inheritance of mitochondrial genes differ from sex linkage?
  - Mitochondrial genes do not contribute to the phenotype of an individual.
  - Because mitochondria are inherited from the mother, only females are affected.
  - Since mitochondria are inherited from the mother, females and males are equally affected.
  - Mitochondrial genes must be dominant. Sex-linked traits are typically recessive.
- Which of the following genotypes due to nondisjunction of sex chromosomes is lethal?
  - XXX
  - XXY
  - OY
  - XO
- Down syndrome is the result of trisomy for chromosome 21. Why is this trisomy viable and trisomy for most other chromosomes is not?
  - Chromosome 21 is a large chromosome and excess genetic material is less harmful.
  - Chromosome 21 behaves differently in meiosis I than the other chromosomes.
  - Chromosome 21 is a small chromosome with few genes so this does less to disrupt the genome.
  - Chromosome 21 is less prone to nondisjunction than other chromosomes.
- Genes that are on the same chromosome can show independent assortment
  - when they are far enough apart for two crossovers to occur.
  - when they are far enough apart that odd numbers of crossovers is about equal to even.
  - only if recombination is low for that chromosome.
  - only if the genes show genomic imprinting.
- We use three-point crosses to order genes because this allows us to
  - control for dosage compensation.
  - control for genomic imprinting.
  - detect multiple recombination events, and these infrequent events give us the order.
  - detect multiple recombination events, and these frequent events give us the order.
- During the process of spermatogenesis, a nondisjunction event that occurs during the second division would be
  - worse than the first division because all four meiotic products would be aneuploid.
  - better than the first division because only two of the four meiotic products would be aneuploid.
  - the same outcome as the first division with all four products aneuploid.
  - the same outcome as the first division as only two products would be aneuploid.

### SYNTHESIZE

- Color blindness is caused by a sex-linked, recessive gene. If a woman, whose father was color blind, marries a man with normal color vision, what percentage of their children will be color blind? What percentage of male children? Of female children?
- Assume that the genes for seed color and seed shape are located on the same chromosome. A plant heterozygous for both genes is testcrossed wrinkled green with the following results:

green, wrinkled	645
green, round	36
yellow, wrinkled	29
yellow, round	590

What were the genotypes of the parents, and how far apart are these genes?

- Is it possible to have a calico cat that is male? Why or why not?

## Chapter 14

# DNA: The Genetic Material

## Chapter Outline

- 14.1 The Nature of the Genetic Material
- 14.2 DNA Structure
- 14.3 Basic Characteristics of DNA Replication
- 14.4 Prokaryotic Replication
- 14.5 Eukaryotic Replication
- 14.6 DNA Repair

## Introduction

The realization that patterns of heredity can be explained by the segregation of chromosomes in meiosis raised a question that occupied biologists for over 50 years: What is the exact nature of the connection between hereditary traits and chromosomes? This chapter describes the chain of experiments that led to our current understanding of DNA, modeled in the picture, and of the molecular mechanisms of heredity. These experiments are among the most elegant in science. And, just as in a good detective story, each discovery has led to new questions. But however erratic and lurching the course of the experimental journey may appear, our picture of heredity has become progressively clearer, the image more sharply defined.

### 14.1 The Nature of the Genetic Material

#### Learning Outcomes

1. Describe the phenomenon of transformation.
2. Evaluate the evidence for DNA as genetic material.

In the previous two chapters, you learned about the nature of inheritance and how genes, which contain the information to specify traits, are located on chromosomes. This finding led to the question of what part of the chromosome actually contains the genetic information. Specifically, biologists wondered about the chemical identity of the genetic information. They knew that chromosomes are composed primarily of both protein and DNA. Which of these organic molecules actually makes up the genes?

Starting in the late 1920s and continuing for about 30 years, a series of investigations addressed this question. DNA

consists of four chemically similar nucleotides. In contrast, protein contains 20 different amino acids that are much more chemically diverse than nucleotides. These characteristics seemed initially to indicate greater informational capacity in protein than in DNA.

However, experiments began to reveal evidence in favor of DNA. We describe three of those major findings in this section.

## Griffith finds that bacterial cells can be transformed

The first clue came in 1928 with the work of the British microbiologist Frederick Griffith. Griffith was trying to make a vaccine that would protect against influenza, which was thought at the time to be caused by the bacteria *Streptococcus pneumoniae*. There are two forms of this bacteria: The normal virulent form that causes pneumonia, and a mutant, nonvirulent form that does not. The normal virulent form of this bacterium is referred to as the S form because it forms smooth colonies on a culture dish. The mutant, nonvirulent form, which lacks an enzyme needed to manufacture the polysaccharide coat, is called the R form because it forms rough colonies.

Griffith performed a series of simple experiments in which mice were infected with these bacteria, then monitored for disease symptoms (figure 14.1). Mice infected with the virulent S form died from pneumonia, whereas infection with the nonvirulent R form had no effect. This result shows that the polysaccharide coat is necessary for virulence. If the virulent

S form is first heat-killed, infection does not harm the mice, showing that the coat itself is not sufficient to cause disease. Lastly, infecting mice with a mixture of heat-killed S form with live R form caused pneumonia and death in the mice. This was unexpected as neither treatment alone caused disease. Furthermore, high levels of live S form bacteria were found in the lungs of the dead mice.

Somehow, the information specifying the polysaccharide coat had passed from the dead, virulent S bacteria to the live, coatless R bacteria in the mixture, permanently altering the coatless R bacteria into the virulent S variety. Griffith called this transfer of virulence from one cell to another, **transformation**. Our modern interpretation is that genetic material was actually transferred between the cells.

## Avery, MacLeod, and McCarty identify the transforming principle

The agent responsible for transforming *Streptococcus* went undiscovered until 1944. In a classic series of experiments, Oswald Avery and his coworkers Colin MacLeod and Maelyn McCarty identified the substance responsible for transformation in Griffith's experiment.

They first prepared the mixture of dead S *Streptococcus* and live R *Streptococcus* that Griffith had used. Then they removed as much of the protein as they could from their preparation, eventually achieving 99.98% purity. They found that despite the removal of nearly all protein, the transforming activity was not reduced.

**Figure 14.1 Griffith's experiment.** Griffith was trying to make a vaccine against pneumonia and instead discovered transformation. **a.** Injecting live virulent bacteria into mice produces pneumonia. Injection of nonvirulent bacteria (**b**) or heat-killed virulent bacteria (**c**) had no effect. **d.** However, a mixture of heat-killed virulent and live nonvirulent bacteria produced pneumonia in the mice. This indicates the genetic information for virulence was transferred from dead, virulent cells to live, nonvirulent cells, transforming them from nonvirulent to virulent.

Moreover, the properties of this substance resembled those of DNA in several ways:

1. The elemental composition agreed closely with that of DNA.
2. When spun at high speeds in an ultracentrifuge, it migrated to the same level (density) as DNA.
3. Extracting lipids and proteins did not reduce transforming activity.
4. Protein-digesting enzymes did not affect transforming activity, nor did RNA-digesting enzymes.
5. DNA-digesting enzymes destroyed all transforming activity.

These experiments supported the identity of DNA as the substance transferred between cells by transformation and indicated that the genetic material, at least in this bacterial species, is DNA.

## Hershey and Chase demonstrate that phage genetic material is DNA

Avery's results were not widely accepted at first because many biologists continued to believe that proteins were the repository

of hereditary information. But additional evidence supporting Avery's conclusion was provided in 1952 by Alfred Hershey and Martha Chase, who experimented with viruses that infect bacteria. These viruses are called **bacteriophages**, or more simply, **phages**.

Viruses, described in more detail in chapter 27, are much simpler than cells; they generally consist of genetic material (DNA or RNA) surrounded by a protein coat. The phage used in these experiments is called a *lytic* phage because infection causes the cell to burst, or lyse. When such a phage infects a bacterial cell, it first binds to the cell's outer surface and then injects its genetic information into the cell. There, the viral genetic information is expressed by the bacterial cell's machinery, leading to production of thousands of new viruses. The buildup of viruses eventually causes the cell to lyse, releasing progeny phage.

The phage used by Hershey and Chase contains only DNA and protein, and therefore it provides the simplest possible system to differentiate the roles of DNA and protein. Hershey and Chase set out to identify the molecule that the phage injects into the bacterial cells. To do this, they needed a method to label both DNA and protein in unique ways that would allow them to be distinguished. Nucleotides

### SCIENTIFIC THINKING

**Hypothesis:** DNA is the genetic material in bacteriophage.

**Prediction:** The phage life cycle requires reprogramming the cell to make phage proteins. The information for this must be introduced into the cell during infection.

**Test:** DNA can be specifically labeled using radioactive phosphate ( $^{32}\text{P}$ ), and protein can be specifically labeled using radioactive sulfur ( $^{35}\text{S}$ ). Phage are grown on either  $^{35}\text{S}$  or  $^{32}\text{P}$ , then used to infect cells in two experiments. The phage heads remain attached to the outside of the cell and can be removed by brief agitation in a blender. The cell suspension can be collected by centrifugation, leaving the phage heads in the supernatant.

**Result:** When the experiment is done, only  $^{32}\text{P}$  makes it into the cell in any significant quantity.

**Conclusion:** Thus, DNA must be the molecule that is used to reprogram the cell.

**Further Experiments:** How does this experiment complement or extend the work of Avery on the identity of the transforming principle?

**Figure 14.2** Hershey–Chase experiment showed DNA is genetic material for phage.

## 14.2 DNA Structure

### Learning Outcomes

1. Describe the data available to Watson and Crick.
2. Explain the details of the Watson and Crick structure.
3. Explain the importance of complementarity for DNA structure and function.

contain phosphorus, but proteins do not, and some amino acids contain sulfur, but DNA does not. Thus, the radioactive  $^{32}\text{P}$  isotope can be used to label DNA specifically, and the isotope  $^{35}\text{S}$  can be used to label proteins specifically. The two isotopes are easily distinguished based on the particles they emit when they decay.

Two experiments were performed (figure 14.2). In one, viruses were grown on a medium containing  $^{32}\text{P}$ , which was incorporated into DNA; in the other, viruses were grown on medium containing  $^{35}\text{S}$ , which was incorporated into coat proteins. Each group of labeled viruses was then allowed to infect separate bacterial cultures.

After infection, the bacterial cell suspension was agitated in a blender to remove the infecting viral particles from the surfaces of the bacteria. This step ensured that only the part of the virus that had been injected into the bacterial cells—that is, the genetic material—would be detected.

Each bacterial suspension was then centrifuged to produce a pellet of cells for analysis. In the  $^{32}\text{P}$  experiment, a large amount of radioactive phosphorus was found in the cell pellet, but in the  $^{35}\text{S}$  experiment, very little radioactive sulfur was found in the pellet (see figure 14.2). Hershey and Chase deduced that DNA, and not protein, constituted the genetic information that viruses inject into bacteria.

A Swiss chemist, Friedrich Miescher, discovered DNA in 1869, only four years after Mendel's work was published—although it is unlikely that Miescher knew of Mendel's experiments.

Miescher extracted a white substance from the nuclei of human cells and fish sperm. The proportion of nitrogen and phosphorus in the substance was different from that found in any other known constituent of cells, which convinced Miescher that he had discovered a new biological substance. He called this substance “nuclein” because it seemed to be specifically associated with the nucleus. Because Miescher's nuclein was slightly acidic, it came to be called *nucleic acid*.

### Learning Outcomes Review 14.1

Experiments with pneumonia-causing bacteria showed that virulence could be passed from one cell to another, a phenomenon termed transformation. When the factor responsible for transformation was purified, it was shown to be DNA. Labeling experiments with phage also indicated that the genetic material was DNA and not protein.

- Why was protein an attractive candidate for the genetic material?

### DNA's components were known, but its three-dimensional structure was a mystery

Although the three-dimensional structure of the DNA molecule was not elucidated until Watson and Crick, it was known that it contained three main components (figure 14.3):

1. a five-carbon sugar
2. a phosphate ( $\text{PO}_4$ ) group

Nitrogenous Base		
Purines		Adenine
		Guanine
Pyrimidines		Cytosine (both DNA and RNA)
		Thymine (DNA only)
		Uracil (RNA only)

**Figure 14.3 Nucleotide subunits of DNA and RNA.** The nucleotide subunits of DNA and RNA are composed of three components: a five-carbon sugar (deoxyribose in DNA and ribose in RNA); a phosphate group; and a nitrogenous base (either a purine or a pyrimidine).

**Figure 14.4** A phosphodiester bond.

3. a nitrogen-containing (nitrogenous) base. The base may be a **purine** (adenine, A, or guanine, G), a two-ringed structure; or a **pyrimidine** (thymine, T, or cytosine, C), a single-ringed structure. RNA contains the pyrimidine uracil (U) in place of thymine.

The convention in organic chemistry is to number the carbon atoms of a molecule and then to use these numbers to refer to any functional group attached to a carbon atom (see chapter 3). In the ribose sugars found in nucleic acids, four of the carbon atoms together with an oxygen atom form a five-membered ring. As illustrated in figure 14.3, the carbon atoms are numbered 1' to 5', proceeding clockwise from the oxygen atom; the prime symbol (') indicates that the number refers to a carbon in a sugar rather than to the atoms in the bases attached to the sugars.

Under this numbering scheme, the phosphate group is attached to the 5' carbon atom of the sugar, and the base is attached to the 1' carbon atom. In addition, a free hydroxyl (—OH) group is attached to the 3' carbon atom.

The 5' phosphate and 3' hydroxyl groups allow DNA and RNA to form long chains of nucleotides by the process of dehydration synthesis (see chapter 3). The linkage is called a **phosphodiester bond** because the phosphate group is now linked to the two sugars by means of a pair of ester bonds (figure 14.4). Many thousands of nucleotides can join together via these linkages to form long nucleic acid polymers.

Linear strands of DNA or RNA, no matter how long, almost always have a free 5' phosphate group at one end and a free 3' hydroxyl group at the other. Therefore, every DNA and RNA molecule has an intrinsic polarity, and we can refer unambiguously to each end of the molecule. By convention, the sequence of bases is usually written in the 5'-to-3' direction.

## Chargaff, Franklin, and Wilkins obtained some structural evidence

To understand the model that Watson and Crick proposed, we need to review the evidence that they had available to construct their model.

### Chargaff's rules

A careful study carried out by Erwin Chargaff showed that the nucleotide composition of DNA molecules varied in complex ways, depending on the source of the DNA. This strongly suggested that DNA was not a simple repeating polymer and that it might have the information-encoding properties genetic material requires. Despite DNA's complexity, however, Chargaff observed an important underlying regularity in the ratios of the bases found in native DNA: *The amount of adenine present in DNA always equals the amount of thymine, and the amount of guanine always equals the amount of cytosine.* These findings are commonly referred to as *Chargaff's rules*:

1. The proportion of A always equals that of T, and the proportion of G always equals that of C, or:  $A = T$ , and  $G = C$ .
2. It follows that there is always an equal proportion of purines (A and G) and pyrimidines (C and T).

As mounting evidence indicated that DNA stored the hereditary information, investigators began to puzzle over how such a seemingly simple molecule could carry out such a complex coding function.

### Franklin: X-ray diffraction patterns of DNA

Another line of evidence provided more direct information about the possible structure of DNA. The British chemist Rosalind Franklin (figure 14.5a) used the technique of X-ray diffraction to analyze DNA. In X-ray diffraction, a molecule is bombarded with a beam of X-rays. The rays are bent, or

**Figure 14.5** Rosalind Franklin's X-ray diffraction patterns. *a.* Rosalind Franklin. *b.* This X-ray diffraction photograph of DNA fibers, made in 1953 by Rosalind Franklin was interpreted to show the helical structure of DNA.

**Figure 14.6 The DNA double helix.** James Watson (*left*) and Francis Crick (*right*) deduced the structure of DNA in 1953 from Chargaff's rules, knowing the proper tautomeric forms of the bases and using Franklin's diffraction studies.

diffracted, by the molecules they encounter, and the diffraction pattern is recorded on photographic film. The patterns resemble the ripples created by tossing a rock into a smooth lake (figure 14.5*b*). When analyzed mathematically, the diffraction pattern can yield information about the three-dimensional structure of a molecule.

X-ray diffraction works best on substances that can be prepared as perfectly regular crystalline arrays. At the time Franklin conducted her analysis, it was impossible to obtain true crystals of natural DNA, so she had to use DNA in the form of fibers. Maurice Wilkins, another researcher working in the same laboratory, had been able to prepare more uniformly oriented DNA fibers than anyone else at the time. Using these fibers, Franklin succeeded in obtaining crude diffraction information on natural DNA. The diffraction patterns she obtained suggested that the DNA molecule had the shape of a helix, or corkscrew, with a consistent diameter of about 2 nm and a complete helical turn every 3.4 nm.

### Tautomeric forms of bases

One piece of evidence important to Watson and Crick was the form of the bases themselves. Because of the alternating double and single bonds in the bases, they actually exist in equilibrium between two different forms when in solution. The different forms have to do with keto ( $\text{C}=\text{O}$ ) versus enol ( $\text{C}-\text{OH}$ ) groups and amino ( $-\text{NH}_2$ ) versus imino ( $=\text{NH}$ ) groups that are attached to the bases. These structural forms are called *tautomers*.

The importance of this distinction is that the two forms exhibit very different hydrogen-bonding possibilities. The predominant forms of the bases contain the keto and amino groups (see figure 14.3), but a prominent biochemistry text of the time actually contained the opposite, and incorrect, information. Legend has it that Watson learned the correct forms while having lunch with a biochemist friend.

## The Watson–Crick model fits the available evidence

Learning informally of Franklin's results before they were published in 1953, James Watson and Francis Crick, two young investigators at Cambridge University, quickly worked out a likely structure for the DNA molecule (figure 14.6), which we now know was substantially correct. Watson and Crick did not perform a single experiment themselves related to DNA structure; rather, they built detailed molecular models based on the information available.

The key to the model was their understanding that each DNA molecule is actually made up of *two* chains of nucleotides that are intertwined—the double helix.

### The phosphodiester backbone

The two strands of the double helix are made up of long polymers of nucleotides, and as described earlier, each strand is made up of repeating sugar and phosphate units joined by phosphodiester bonds (figure 14.7). We call this the *phosphodiester backbone* of the

**Figure 14.7 Structure of a single strand of DNA.** The phosphodiester backbone is composed of alternating sugar and phosphate groups. The bases are attached to each sugar.

**Figure 14.8 The double helix.** Shown with the phosphodiester backbone as a ribbon on top and a space-filling model on the bottom. The bases protrude into the interior of the helix where they hold it together by base-pairing. The backbone forms two grooves, the larger major groove and the smaller minor groove.

molecule. The two strands of the backbone are then wrapped about a common axis forming a double helix (figure 14.8). The helix is often compared to a spiral staircase, in which the two strands of the double helix are the handrails on the staircase.

### Complementarity of bases

Watson and Crick proposed that the two strands were held together by formation of hydrogen bonds between bases on opposite strands. These bonds would result in specific **base-pairs**: Adenine (A) can form two hydrogen bonds with thymine (T) to form an A–T base-pair, and guanine (G) can form three hydrogen bonds with cytosine (C) to form a G–C base-pair (figure 14.9).

Note that this configuration also pairs a two-ringed purine with a single-ringed pyrimidine in each case, so that the diameter of each base-pair is the same. This consistent diameter is indicated by the X-ray diffraction data.

We refer to this pattern of base-pairing as *complementary*, which means that although the strands are not identical, they each can be used to specify the other by base-pairing. If the sequence of one strand is ATGC, then the complementary strand sequence must be TACG. This characteristic becomes critical for DNA replication and expression, as you will see later in this chapter.

The Watson–Crick model also explained Chargaff’s results: In a double helix, adenine forms two hydrogen bonds with thymine, but it will not form hydrogen bonds properly with cytosine. Similarly, guanine forms three hydrogen bonds with cytosine, but it will not form hydrogen bonds properly with thymine. Because of this base-pairing, adenine and thymine always occur in the same proportions in any DNA molecule, as do guanine and cytosine.

**Figure 14.9 Base-pairing holds strands together.** The hydrogen bonds that form between A and T and between G and C are shown with dashed lines. These produce AT and GC base-pairs that hold the two strands together. This always pairs a purine with a pyrimidine, keeping the diameter of the double helix constant.

### Inquiry question

Does the Watson–Crick model account for all of the data discussed in the text?

### Antiparallel configuration

As stated earlier, a single phosphodiester strand has an inherent polarity, meaning that one end terminates in a 3' OH and the other end terminates in a 5' PO<sub>4</sub>. Strands are thus referred to as having either a 5'-to-3' or a 3'-to-5' polarity. Two strands could be put together in two ways: with the polarity the same in each (parallel) or with the polarity opposite (antiparallel). Native double-stranded DNA always has the antiparallel configuration, with one strand running 5' to 3' and the other running 3' to 5' (see figure 14.8). In addition to its complementarity, this antiparallel nature also has important implications for DNA replication.

### The Watson–Crick DNA molecule

In the Watson and Crick model, each DNA molecule is composed of two complementary phosphodiester strands that each form a helix with a common axis. These strands are antiparallel, with the bases extending into the interior of the helix. The bases from opposite strands form base-pairs with each other to join the two complementary strands (see figures 14.8 and 14.9).

Although the hydrogen bonds between each individual base-pair are low-energy bonds, the sum of bonds between the many base-pairs of the polymer has enough energy that the entire molecule is stable. To return to our spiral staircase analogy—the backbone is the handrails, the base-pairs are the steps.

Although the Watson–Crick model provided a rational structural for DNA, researchers had to answer further questions about how DNA could be replicated, a crucial step in cell division, and also about how cells could repair damaged or otherwise altered DNA. We explore these questions in the rest of this chapter. (In the following chapter, we continue with the genetic code and the connection between the code and protein synthesis.)

#### Learning Outcomes Review 14.2

Chargaff showed that in DNA, the amount of adenine was equal to the amount of thymine, and the amount of guanosine was equal to that of cytosine. X-ray diffraction studies by Franklin and Wilkins indicated that DNA formed a helix. Watson and Crick built a model consisting of two antiparallel strands wrapped in a helix about a common axis. The two strands are held together by hydrogen bonds between the bases: adenine pairs with thymine and guanine pairs with cytosine. The two strands are thus complementary to each other.

- Why was information about the proper tautomeric form of the bases critical?

## 14.3 Basic Characteristics of DNA Replication

#### Learning Outcomes

1. Explain the basic mechanism of DNA replication.
2. Describe the requirements for DNA replication.

The accurate replication of DNA prior to cell division is a basic and crucial function. Research has revealed that this complex process requires the participation of a large number of cellular proteins. Before geneticists could look for these details, however, they needed to perform some groundwork on the general mechanisms.

### Meselson and Stahl demonstrate the semiconservative mechanism

The Watson–Crick model immediately suggested that the basis for copying the genetic information is complementarity. One chain of the DNA molecule may have any conceivable base sequence, but this sequence completely determines the sequence of its partner in the duplex.

In replication, the sequence of parental strands must be duplicated in daughter strands. That is, one parental helix with two strands must yield two daughter helices with four strands. The two daughter molecules are then separated during the course of cell division.

Three models of DNA replication are possible (figure 14.10):

1. In a *conservative model*, both strands of the parental duplex would remain intact (conserved), and new DNA copies would consist of all-new molecules. Both daughter strands would contain all-new molecules.

**Figure 14.10** Three possible models for DNA replication. The conservative model produces one entirely new molecule and conserves the old. The semiconservative model produces two hybrid molecules of old and new strands. The dispersive model produces hybrid molecules with each strand a mixture of old and new.

- In a **semiconservative model**, one strand of the parental duplex remains intact in daughter strands (semiconserved); a new complementary strand is built for each parental strand consisting of new molecules. Daughter strands would consist of one parental strand and one newly synthesized strand.
- In a *dispersive model*, copies of DNA would consist of mixtures of parental and newly synthesized strands; that is, the new DNA would be dispersed throughout each strand of both daughter molecules after replication.

Notice that these three models suggest general mechanisms of replication, without specifying any molecular details of the process.

### The Meselson–Stahl experiment

The three models for DNA replication were evaluated in 1958 by Matthew Meselson and Franklin Stahl. To distinguish between these models, they labeled DNA and then followed the labeled DNA through two rounds of replication (figure 14.11).

The label Meselson and Stahl used was a heavy isotope of nitrogen ( $^{15}\text{N}$ ), not a radioactive label. Molecules containing  $^{15}\text{N}$  have a greater density than those containing the common  $^{14}\text{N}$  isotope. Ultracentrifugation can be used to separate molecules that have different densities.

Bacteria were grown in a medium containing  $^{15}\text{N}$ , which became incorporated into the bases of the bacterial DNA. After several generations, the DNA of these bacteria was denser than that of bacteria grown in a medium containing the normally available  $^{14}\text{N}$ . Meselson and Stahl then transferred the bacteria from the  $^{15}\text{N}$  medium to  $^{14}\text{N}$  medium and collected the DNA at various time intervals.

The DNA for each interval was dissolved in a solution containing a heavy salt, cesium chloride. This solution was spun at very high speeds in an ultracentrifuge. The enormous centrifugal forces caused cesium ions to migrate toward the bottom of the centrifuge tube, creating a gradient of cesium concentration, and thus of density. Each DNA strand floated or sank in the gradient until it reached the point at which its density exactly matched the density of the cesium at that location. Because  $^{15}\text{N}$  strands are denser than  $^{14}\text{N}$  strands, they migrated farther down the tube.

The DNA collected immediately after the transfer of bacteria to new  $^{14}\text{N}$  medium was all of one density equal to that of  $^{15}\text{N}$  DNA alone. However, after the bacteria completed a first round of DNA replication, the density of their DNA had decreased to a value intermediate between  $^{14}\text{N}$  DNA alone and  $^{15}\text{N}$  DNA. After the second round of replication, two density classes of DNA were observed: one intermediate and one equal to that of  $^{14}\text{N}$  DNA (see figure 14.11).

### Interpretation of the Meselson–Stahl findings

Meselson and Stahl compared their experimental data with the results that would be predicted on the basis of the three models.

- The conservative model was not consistent with the data because after one round of replication, two densities should have been observed: DNA strands would either be all-heavy (parental) or all-light (daughter). This model is rejected.
- The semiconservative model is consistent with all observations: After one round of replication, a single

**Figure 14.11 The Meselson–Stahl experiment.** Bacteria grown in heavy  $^{15}\text{N}$  medium are shifted to light  $^{14}\text{N}$  medium and grown for two rounds of replication. Samples are taken at time points corresponding to zero, one, and two rounds of replication and centrifuged in cesium chloride to form a gradient. The actual data are shown at the bottom with the interpretation of semiconservative replication shown schematically.

density would be predicted because all DNA molecules would have a light strand and a heavy strand. After two rounds of replication, half of the molecules would have two light strands, and half would have a light strand and a heavy strand—and so two densities would be observed. Therefore, the results support the semiconservative model.

- The dispersive model was consistent with the data from the first round of replication, because in this model, every DNA helix would consist of strands that are mixtures of  $\frac{1}{2}$  light (new) and  $\frac{1}{2}$  heavy (old) molecules. But after two rounds of replication, the dispersive model would still yield only a single density; DNA strands would be composed of  $\frac{3}{4}$  light and  $\frac{1}{4}$  heavy molecules. Instead, two densities were observed. Therefore, this model is also rejected.

The basic mechanism of DNA replication is semiconservative. At the simplest level, then, DNA is replicated by opening up a DNA helix and making copies of both strands to produce two daughter helices, each consisting of one old strand and one new strand.

## DNA replication requires a template, nucleotides, and a polymerase enzyme

Replication requires three things: something to copy, something to do the copying, and the building blocks to make the copy. The parental DNA molecules serve as a template, enzymes perform the actions of copying the template, and the building blocks are nucleoside triphosphates.

The process of replication can be thought of as having a beginning where the process starts; a middle where the majority of building blocks are added; and an end where the process is finished. We use the terms *initiation*, *elongation*, and *termination* to describe a biochemical process. Although this may seem overly simplistic, in fact, discrete functions are usually required for initiation and termination that are not necessary for elongation.

A number of enzymes work together to accomplish the task of assembling a new strand, but the enzyme that actually matches the existing DNA bases with complementary nucleotides and then links the nucleotides together to make the new strand is **DNA polymerase** (figure 14.12). All DNA

**Figure 14.12 Action of DNA polymerase.** DNA polymerases add nucleotides to the 3' end of a growing chain. The nucleotide added depends on the base that is in the template strand. Each new base must be complementary to the base in the template strand. With the addition of each new nucleoside triphosphate, two of its phosphates are cleaved off as pyrophosphate.

### Inquiry question

Why do you think it is important that the sugar–phosphate backbone of DNA is held together by covalent bonds, and the cross-bridges between the two strands are held together by hydrogen bonds?

polymerases that have been examined have several common features. They all add new bases to the 3' end of existing strands. That is, they synthesize in a 5'-to-3' direction by extending a strand base-paired to the template. All DNA polymerases also require a *primer* to begin synthesis; they cannot begin without a strand of RNA or DNA base-paired to the template. RNA polymerases do not have this requirement, so they usually synthesize the primers.

### Learning Outcomes Review 14.3

Meselson and Stahl showed that the basic mechanism of replication is semiconservative: Each new DNA helix is composed of one old strand and one new strand. The process of replication requires a template to copy, nucleoside triphosphate building blocks, and the enzyme DNA polymerase. DNA polymerases synthesize DNA in a 5'-to-3' direction from a primer, usually RNA.

- In the Meselson–Stahl experiment, what would the results be if the DNA was denatured prior to separation by ultracentrifugation?

## 14.4 Prokaryotic Replication

### Learning Outcomes

1. Describe the functions of *E. coli* DNA polymerases.
2. Explain why replication is discontinuous on one strand.
3. Diagram the functions found at the replication fork.

To build up a more detailed picture of replication, we first concentrate on prokaryotic replication using *E. coli* as a model. We can then look at eukaryotic replication primarily in how it differs from the prokaryotic system.

**Figure 14.13** Replication is bidirectional from a unique origin. Replication initiates from a unique origin. Two separate replisomes are loaded onto the origin and initiate synthesis in the opposite directions on the chromosome. These two replisomes continue in opposite directions until they come to a unique termination site.

### Prokaryotic replication starts at a single origin

Replication in *E. coli* initiates at a specific site, the origin (called *oriC*), and ends at a specific site, the terminus. The sequence of *oriC* consists of repeated nucleotides that bind an initiator protein and an AT-rich sequence that can be opened easily during initiation of replication. (A–T base-pairs have only two hydrogen bonds, compared with the three hydrogen bonds in G–C base-pairs.)

After initiation, replication proceeds bidirectionally from this unique origin to the unique terminus (figure 14.13). We call the DNA controlled by an origin a **replicon**. In this case, the chromosome plus the origin forms a single replicon.

### *E. coli* has at least three different DNA polymerases

As mentioned earlier, DNA polymerase refers to a group of enzymes responsible for the building of a new DNA strand from the template. The first DNA polymerase isolated in *E. coli* was given the name **DNA polymerase I (Pol I)**. At first, investigators assumed this polymerase was responsible for the bulk synthesis of DNA during replication. A mutant was isolated, however, that had no Pol I activity, but could still replicate its chromosome. Two additional polymerases were isolated from this strain of *E. coli* and were named **DNA polymerase II (Pol II)** and **DNA polymerase III (Pol III)**. As with all other known polymerases, all three of these enzymes synthesize polynucleotide strands only in the 5'-to-3' direction and require a primer.

Many DNA polymerases have additional enzymatic activity that aids their function. This activity is a nuclease activity, or the ability to break phosphodiester bonds between nucleotides. Nucleases are classified as either **endonucleases** (which cut DNA internally) or **exonucleases** (which chew away at an end of DNA). DNA Pol I, Pol II, and Pol III have 3'-to-5' exonuclease activity, which serves as a proofreading function because it allows the enzyme to remove a mispaired base. In addition, the DNA Pol I enzyme also has a 5'-to-3' exonuclease activity, the importance of which will become clear shortly.

The three different polymerases have different roles in the replication process. DNA Pol III is the main replication enzyme; it is responsible for the bulk of DNA synthesis. DNA Pol I acts on the lagging strand to remove primers and replace them with DNA. The Pol II enzyme does not appear to play a role in replication but is involved in DNA repair processes.

For many years, these three polymerases were thought to be the only DNA polymerases in *E. coli*, but recently several

**Figure 14.14 Unwinding the helix causes torsional strain.** If the ends of a linear DNA molecule are constrained, as they are in the cell, unwinding the helix produces torsional strain. This can cause the double helix to further coil in space (supercoiling). The enzyme DNA gyrase can relieve supercoiling.

new ones have been identified. There are now five known polymerases, although not all are active in DNA replication.

### Unwinding DNA requires energy and causes torsional strain

Although some DNA polymerases can unwind DNA as they synthesize new DNA, another class of enzymes has the single

function of unwinding DNA strands to make this process more efficient. Enzymes that use energy from ATP to unwind the DNA template are called **helicases**.

The single strands of DNA produced by helicase action are unstable because the process exposes the hydrophobic bases to water. Cells solve this problem by using a protein, called single-strand-binding protein (SSB), to coat exposed single strands.

The unwinding of the two strands introduces torsional strain in the DNA molecule. Imagine two rubber bands twisted together. If you now unwind the rubber bands, what happens? The rubber bands, already twisted about each other, will further coil in space. When this happens with a DNA molecule it is called **supercoiling** (figure 14.14). The branch of mathematics that studies how forms twist and coil in space is called *topology*, and therefore we describe this coiling of the double helix as the *topological state* of DNA. This state describes how the double helix itself coils in space. You have already seen an example of this coiling with DNA wrapped about histone proteins in the nucleosomes of eukaryotic chromosomes (see chapter 10).

Enzymes that can alter the topological state of DNA are called **topoisomerases**. Topoisomerase enzymes act to relieve the torsional strain caused by unwinding and to prevent this supercoiling from happening. **DNA gyrase** is the topoisomerase involved in DNA replication (see figure 14.14).

### Replication is semidiscontinuous

Earlier, DNA was described as being antiparallel—meaning that one strand runs in the 3'-to-5' direction, and its complementary strand runs in the 5'-to-3' direction. The antiparallel nature of DNA combined with the nature of the polymerase enzymes puts constraints on the replication process. Because polymerases can synthesize DNA in only one direction, and the two DNA strands run in opposite directions, polymerases on the two strands must be synthesizing DNA in opposite directions (figure 14.15).

The requirement of DNA polymerases for a primer means that on one strand primers need to be added as the helix

**Figure 14.15 Replication is semidiscontinuous.** The 5'-to-3' synthesis of the polymerase and the antiparallel nature of DNA mean that only one strand, the leading strand, can be synthesized continuously. The other strand, the lagging strand, must be made in pieces, each with its own primer.

is opened up (see figure 14.15). This means that one strand can be synthesized in a continuous fashion from an initial primer, but the other strand must be synthesized in a discontinuous fashion with multiple priming events and short sections of DNA being assembled. The strand that is continuous is called the **leading strand**, and the strand that is discontinuous is the **lagging strand**. DNA fragments synthesized on the lagging strand are named **Okazaki fragments** in honor of the man who first experimentally demonstrated discontinuous synthesis. They introduce a need for even more enzymatic activity on the lagging strand, as is described next.

## Synthesis occurs at the replication fork

The partial opening of a DNA helix to form two single strands has a forked appearance, and is thus called the **replication fork**. All of the enzymatic activities that we have discussed plus a few more are found at the replication fork (table 14.1). Synthesis on the leading strand and on the lagging strand proceed in different ways, however.

### Priming

The primers required by DNA polymerases during replication are synthesized by the enzyme *DNA primase*. This enzyme is an RNA polymerase that synthesizes short stretches of RNA 10–20 bp (base-pairs) long that function as primers for DNA polymerase. Later on, the RNA primer is removed and replaced with DNA.

### Leading-strand synthesis

Synthesis on the leading strand is relatively simple. A single priming event is required, and then the strand can be extended indefinitely by the action of DNA Pol III. If the enzyme re-

mains attached to the template, it can synthesize around the entire circular *E. coli* chromosome.

The ability of a polymerase to remain attached to the template is called *processivity*. The Pol III enzyme is a large multi-subunit enzyme that has high processivity due to the action of one subunit of the enzyme, called the  $\beta$  subunit (figure 14.16a).

The  $\beta$  subunit is made up of two identical protein chains that come together to form a circle. This circle can be loaded onto the template like a clamp to hold the Pol II enzyme to the DNA (figure 14.16b). This structure is therefore referred to as the “sliding clamp,” and a similar structure is found in eukaryotic polymerases as well. For the clamp to function, it must be opened and then closed around the DNA. A multisubunit protein called the clamp loader accomplishes this task. This function is also found in eukaryotes.

### Lagging-strand synthesis

The discontinuous nature of synthesis on the lagging strand requires the cell to do much more work than on the leading strand (see figure 14.15). Primase is needed to synthesize primers for each Okazaki fragment, and then all these RNA primers need to be removed and replaced with DNA. Finally, the fragments need to be stitched together.

DNA Pol II accomplishes the synthesis of Okazaki fragments. The removal and replacement of primer segments, however, is accomplished by DNA Pol I. Using its 5'-to-3' exonuclease activity, it can remove primers in front and then replace them by using its usual 5'-to-3' polymerase activity. The synthesis is primed by the previous Okazaki fragment, which is composed of DNA and has a free 3' OH that can be extended.

TABLE 14.1 DNA Replication Enzymes of <i>E. coli</i>			
Protein	Role	Size (kDa)	Molecules per Cell
Helicase	Unwinds the double helix	300	20
Primase	Synthesizes RNA primers	60	50
Single-strand binding protein	Stabilizes single-stranded regions	74	300
DNA gyrase	Relieves torque	400	250
DNA polymerase III	Synthesizes DNA	≈900	20
DNA polymerase I	Erases primer and fills gaps	103	300
DNA ligase	Joins the ends of DNA segments; DNA repair	74	300

**Figure 14.16** The DNA polymerase sliding clamp. *a.* The  $\beta$  subunit forms a ring that can encircle DNA. *b.* The  $\beta$  subunit is shown attached to the DNA. This forms the “sliding clamp” that keeps the polymerase attached to the template.

**Figure 14.17 Lagging-strand synthesis.** The action of primase synthesizes the primers needed by DNA polymerase III (not shown). These primers are removed by DNA polymerase I using its 5'-to-3' exonuclease activity, then extending the previous Okazaki fragment to replace the RNA. The nick between Okazaki fragments after primer removal is sealed by DNA ligase.

This leaves only the last phosphodiester bond to be formed where synthesis by Pol I ends. This is done by **DNA ligase**, which seals this “nick,” eventually joining the Okazaki fragments into complete strands. All of this activity on the lagging strand is summarized in figure 14.17.

**Figure 14.18 The replication fork.** A model for the structure of the replication fork with two polymerase III enzymes held together by a large complex of accessory proteins. These include the “clamp loader,” which loads the  $\beta$  subunit sliding clamp periodically on the lagging strand. The polymerase III on the lagging strand periodically releases its template and reassociates along with the  $\beta$  clamp. The loop in the lagging-strand template allows both polymerases to move in the same direction despite DNA being antiparallel. Primase, which makes primers for the lagging-strand fragments, and helicase are also associated with the central complex. Polymerase I removes primers and ligase joins the fragments together.

## Inquiry question

What is the role of DNA ligase? What would happen to DNA replication in a cell where this enzyme is not functional?

### Termination

Termination occurs at a specific site located roughly opposite *oriC* on the circular chromosome. The last stages of replication produce two daughter molecules that are intertwined like two rings in a chain. These intertwined molecules are unlinked by the same enzyme that relieves torsional strain at the replication fork—DNA gyrase.

## The replisome contains all the necessary enzymes for replication

The enzymes involved in DNA replication form a macromolecular assembly called the **replisome**. This assembly can be thought of as the “replication organelle,” just as the ribosome is the organelle that synthesizes protein. The replisome has two main subcomponents: the *primosome*, and a complex of two DNA Pol III enzymes, one for each strand. The primosome is composed of primase and helicase, along with a number of accessory proteins. The need for constant priming on the lagging strand explains the need for the primosome complex as part of the replisome.

The two Pol III complexes include two synthetic core subunits, each with its own  $\beta$  subunit. The entire replisome complex is held together by a number of proteins that includes the clamp loader. The clamp loader is required to periodically load a  $\beta$  subunit on the lagging strand and to transfer the Pol III to this new  $\beta$  subunit (figure 14.18).

1. A DNA polymerase III enzyme is active on each strand. Primase synthesizes new primers for the lagging strand.

4. The clamp loader attaches the  $\beta$  clamp and transfers this to polymerase III, creating a new loop in the lagging-strand template. DNA ligase joins the fragments after DNA polymerase I removes the primers.

2. The "loop" in the lagging-strand template allows replication to occur 5'-to-3' on both strands, with the complex moving to the left.

5. After the  $\beta$  clamp is loaded, the DNA polymerase III on the lagging strand adds bases to the next Okazaki fragment.

3. When the polymerase III on the lagging strand hits the previously synthesized fragment, it releases the  $\beta$  clamp and the template strand. DNA polymerase I attaches to remove the primer.

Even given the difficulties with lagging-strand synthesis, the two Pol III enzymes in the replisome are active on both leading and lagging strands simultaneously. How can the two strands be synthesized in the same direction when the strands are antiparallel? The model first proposed, still with us in some form, involves a loop formed in the lagging strand, so that the polymerases can move in the same direction (see figure 14.18). Current evidence also indicates that this replication complex is probably stationary, with the DNA strand moving through it like thread in a sewing machine, rather than the complex moving along the DNA strands. This stationary complex also pushes the newly synthesized DNA outward, which may aid in chromosome segregation. This process is summarized in figure 14.19.

#### Learning Outcomes Review 14.4

*E. coli* has three DNA polymerases: DNA Pol I, II, and III. Synthesis on one strand is discontinuous because DNA is antiparallel, and polymerases only synthesize in the 5'-to-3' direction. Replication occurs at the replication fork, where the two strands are separated. Assembled here is a massive complex, the replisome, containing DNA polymerase III, primase, helicase, and other proteins. The lagging strand requires DNA polymerase I to remove the primers and replace them with DNA, and ligase to join Okazaki fragments.

- How are the nuclease functions of the different polymerases used during replication?

**Figure 14.19 DNA synthesis by the replisome.** The semidiscontinuous synthesis of DNA is illustrated in stages using the model from figure 14.18.

## 14.5 Eukaryotic Replication

### Learning Outcomes

1. Compare eukaryotic replication with prokaryotic.
2. Explain the function of telomeres.
3. Identify the link between telomerase and cell division.

Eukaryotic replication is complicated by two main factors: the larger amount of DNA organized into multiple chromosomes, and the linear structure of the chromosomes. This process requires new enzymatic activities only for dealing with the ends of chromosomes; otherwise the basic enzymology is the same.

### Eukaryotic replication requires multiple origins

The sheer amount of DNA and how it is packaged constitute a problem for eukaryotes (figure 14.20). Eukaryotes usually have multiple chromosomes that are each larger than the *E. coli*

**Figure 14.20** DNA of a single human chromosome. This chromosome has been relieved of most of its packaging proteins, leaving the DNA in its native form. The residual protein scaffolding appears as the dark material in the lower part of the micrograph.

chromosome. If only a single unique origin existed for each chromosome, the length of time necessary for replication would be prohibitive. This problem is solved by the use of multiple origins of replication for each chromosome, resulting in multiple *replicons*.

The origins are not as sequence-specific as *oriC*, and their recognition seems to depend on chromatin structure as well as on sequence. The number of origins used can also be adjusted during the course of development, so that early on, when cell divisions need to be rapid, more origins are activated. Each origin must be used only once per cell cycle.

### The enzymology of eukaryotic replication is more complex

The replication machinery of eukaryotes is similar to that found in bacteria, but it is larger and more complex. The initiation phase of replication requires more factors to assemble both helicase and primase complexes onto the template, then load the polymerase with its sliding clamp unit.

The eukaryotic primase is interesting in that it is a complex of both an RNA polymerase and a DNA polymerase. It first makes short RNA primers, then extends these with DNA to produce the final primer. The reason for this added complexity is unclear.

The main replication polymerase itself is also a complex of two different enzymes that work together. One is called *DNA polymerase epsilon* (pol  $\epsilon$ ) and the other *DNA polymerase delta* (pol  $\delta$ ). The sliding clamp subunit that allows the enzyme complex to stay attached to the template is called PCNA (for proliferating cell nuclear antigen). This unusual name reflects the fact that PCNA was first identified as an antibody-inducing protein in proliferating (dividing) cells. The PCNA sliding clamp forms a trimer, but this structure is similar to the  $\beta$  subunit sliding clamp. The clamp loader is also similar to the bacterial structure. Despite the additional complexity, the action of the replisome is similar to that described earlier for *E. coli*, and the replication fork has essentially the same components.

### Archaeal replication proteins are similar to eukaryotic proteins

Despite their lack of a membrane-bounded nucleus, Archaeal replication proteins are more similar to eukaryotes than to bacterial. The main replication polymerase is most similar to eukaryotic pol  $\delta$ , and the sliding clamp is similar to the PCNA protein. The clamp loading complex is also more similar to eukaryotic than bacterial. The most interesting conclusion from all of these data are that all three domains of life have similar functions involved in replicating chromosomes. All three domains assemble similar protein complexes with clamp loader, sliding clamp, two polymerases, helicase, and primase at the replication fork.

### Linear chromosomes have specialized ends

The specialized structures found on the ends of eukaryotic chromosomes are called **telomeres**. These structures protect

**Figure 14.21 Replication of the end of linear DNA.** Only one end is shown for simplicity; the problem exists at both ends. The leading strand can be completely replicated, but the lagging strand cannot be finished. When the last primer is removed, it cannot be replaced. During the next round of replication, when this shortened template is replicated, it will produce a shorter chromosome.

the ends of chromosomes from nucleases and maintain the integrity of linear chromosomes. These telomeres are composed of specific DNA sequences, but they are not made by the replication complex.

### Replicating ends

The very structure of a linear chromosome causes a cell problems in replicating the ends. The directionality of polymerases, combined with their requirement for a primer, create this problem.

Consider a simple linear molecule like the one in figure 14.21. Replication of one end of each template strand is simple, namely the 5' end of the leading-strand template. When the polymerase reaches this end, synthesizing in the 5'-to-3' direction, it eventually runs out of template and is finished.

But on the other strand's end, the 3' end of the lagging strand, removal of the last primer on this end leaves a gap. This gap cannot be primed, meaning that the polymerase complex cannot finish this end properly. The result would be a gradual shortening of chromosomes with each round of cell division (see figure 14.21).

### The action of telomerase

When the sequence of telomeres was determined, they were found to be composed of short repeated sequences of DNA. This repeating nature is easily explained by their synthesis. They are made by an enzyme called **telomerase**, which uses an internal RNA as a template and not the DNA itself (figure 14.22).

**Figure 14.22 Action of telomerase.** Telomerase contains an internal RNA that the enzyme uses as a template to extend the DNA of the chromosome end. Multiple rounds of synthesis by telomerase produce repeated sequences. This single strand is completed by normal synthesis using it as a template (not shown).

## 14.6 DNA Repair

The use of the internal RNA template allows short stretches of DNA to be synthesized, composed of repeated nucleotide sequences complementary to the RNA of the enzyme. The other strand of these repeated units is synthesized by the usual action of the replication machinery copying the strand made by telomerase.

### Telomerase, aging, and cancer

A gradual shortening of the ends of chromosomes occurs in the absence of telomerase activity. During embryonic and childhood development in humans, telomerase activity is high, but it is low in most somatic cells of the adult. The exceptions are cells that must divide as part of their function, such as lymphocytes. The activity of telomerase in somatic cells is kept low by preventing the expression of the gene encoding this enzyme.

Evidence for the shortening of chromosomes in the absence of telomerase was obtained by producing mice with no telomerase activity. These mice appear to be normal for up to six generations, but they show steadily decreasing telomere length that eventually leads to nonviable offspring.

This finding indicates a relationship between cell senescence (aging) and telomere length. Normal cells undergo only a specified number of divisions when grown in culture. This limit is at least partially based on telomere length.

Support for the relationship between senescence and telomere length comes from experiments in which telomerase was introduced into fibroblasts in culture. These cells have their lifespan increased relative to controls that have no added telomerase. Interestingly, these cells do not show the hallmarks of malignant cells, indicating that activation of telomerase alone does not make cells malignant.

A relationship has been found, however, between telomerase and cancer. Cancer cells do continue to divide indefinitely, and this would not be possible if their chromosomes were being continually shortened. Cancer cells generally show activation of telomerase, which allows them to maintain telomere length; but this is clearly only one aspect of conditions that allow them to escape normal growth controls.

### Inquiry question

? How does the structure of eukaryotic genomes affect replication? Does this introduce problems that are not faced by prokaryotes?

### Learning Outcomes Review 14.5

Eukaryotic replication is complicated by a large amount of DNA organized into chromosomes, and by the linear nature of chromosomes. Eukaryotes replicate a large amount of DNA in a short time by using multiple origins of replication. Linear chromosomes end in telomeres, and the length of telomeres is correlated with the ability of cells to divide. The enzyme telomerase synthesizes the telomeres. Cancer cells show activation of telomerase, which extends the ability of the cells to divide.

- What might be the result of abnormal shortening of telomeres or a lack of telomerase activity?

### Learning Outcomes

1. Explain why DNA repair is critical for cells.
2. Describe the different forms of DNA repair.

As you learned earlier, many DNA polymerases have 3'-to-5' exonuclease activity that allows "proofreading" of added bases. This action increases the accuracy of replication, but errors still occur. Without error correction mechanisms, cells would accumulate errors at an unacceptable rate, leading to high levels of deleterious or lethal mutations. A balance must exist between the introduction of new variation by mutation, and the effects of deleterious mutations on the individual.

### Cells are constantly exposed to DNA-damaging agents

In addition to errors in DNA replication, cells are constantly exposed to agents that can damage DNA. These agents include radiation, such as UV light and X-rays, and chemicals in the environment. Agents that damage DNA can lead to mutations, and any agent that increases the number of mutations above background levels is called a **mutagen**.

The number of potentially mutagenic agents that organisms encounter is huge. Sunlight itself includes radiation in the UV range and is thus mutagenic. Ozone normally screens out much of the harmful UV radiation in sunlight, but some remains. The relationship between sunlight and mutations is shown clearly by the increase in skin cancer in regions of the southern hemisphere that are underneath a seasonal "ozone hole."

Organisms also may encounter mutagens in their diet in the form of either contaminants in food or natural plant products that can damage DNA. When a simple test was designed to detect mutagens, screening of possible sources indicated an amazing diversity of mutagens in the environment and in natural sources. As a result, consumer products are now screened to reduce the load of mutagens we are exposed to, but we cannot escape natural sources.

### DNA repair restores damaged DNA

Cells cannot escape exposure to mutagens, but systems have evolved that enable cells to repair some damage. These DNA repair systems are vital to continued existence, whether a cell is a free-living, single-celled organism or part of a complex multicellular organism.

The importance of DNA repair is indicated by the multiplicity of repair systems that have been discovered and characterized. All cells that have been examined show multiple pathways for repairing damaged DNA and for reversing errors that occur during replication. These systems are not perfect, but they do reduce the mutational load on organisms to an acceptable level. In the rest of this section, we illustrate the action of DNA repair by concentrating on two examples drawn from these multiple repair pathways.

## Repair can be either specific or nonspecific

DNA repair falls into two general categories: specific and nonspecific. Specific repair systems target a single kind of lesion in DNA and repair only that damage. Nonspecific forms of repair use a single mechanism to repair multiple kinds of lesions in DNA.

### Photorepair: A specific repair mechanism

Photorepair is specific for one particular form of damage caused by UV light, namely the *thymine dimer*. Thymine dimers are formed by a photochemical reaction of UV light and adjacent thymine bases in DNA. The UV radiation causes the thymines to react, covalently linking them together: a thymine dimer (figure 14.23).

Repair of these thymine dimers can be accomplished by multiple pathways, including photorepair. In photorepair, an en-

**Figure 14.23** Repair of thymine dimer by photorepair.

UV light can catalyze a photochemical reaction to form a covalent bond between two adjacent thymines, thereby creating a thymine dimer. A photolyase enzyme recognizes the damage and binds to the thymine dimer. The enzyme absorbs visible light and uses the energy to cleave the thymine dimer.

zyme called a *photolyase* absorbs light in the visible range and uses this energy to cleave the thymine dimer. This action restores the two thymines to their original state (see figure 14.23). It is interesting that sunlight in the UV range can cause this damage, and sunlight in the visible range can be used to repair the damage. Photorepair does not occur in cells deprived of visible light.

The photolyase enzyme has been found in many different species, ranging from bacteria, to single-celled eukaryotes, to humans. The ubiquitous nature of this enzyme illustrates the importance of this form of repair. For as long as cells have existed on Earth, they have been exposed to UV light and its potential to damage DNA.

### Excision repair: A nonspecific repair mechanism

A common form of nonspecific repair is **excision repair**. In this pathway, a damaged region is removed, or excised, and is then replaced by DNA synthesis (figure 14.24). In *E. coli*, this action is accomplished by proteins encoded by the *uvr A*, *B*, and

**Figure 14.24** Repair of damaged DNA by excision repair.

Damaged DNA is recognized by the *uvr* complex, which binds to the damaged region and removes it. Synthesis by DNA polymerase replaces the damaged region. DNA ligase finishes the process (not shown).

C genes. Although these genes were identified based on mutations that increased sensitivity of the cell to UV light (hence the “uvr” in their names), their proteins can act on damage due to other mutagens.

Excision repair follows three steps: (1) recognition of damage, (2) removal of the damaged region, and (3) resynthesis using the information on the undamaged strand as a template (see figure 14.24). Recognition and excision are accomplished by the UvrABC complex. The UvrABC complex binds to damaged DNA and then cleaves a single strand on either side of the damage, removing it. In the synthesis stage, DNA pol I or pol II replaces the damaged DNA. This restores the original information in the damaged strand by using the information in the complementary strand.

### Other repair pathways

Cells have other forms of nonspecific repair, and these fall into two categories: error-free and error-prone. It may seem strange to have an error-prone pathway, but it can be thought of as a last-ditch effort to save a cell that has been exposed to such massive damage that it has overwhelmed the error-free systems. In fact, this system in *E. coli* is part of what is called the “SOS response.”

Cells can also repair damage that produces breaks in DNA. These systems use enzymes related to those that are in-

involved in recombination during meiosis (see chapter 11). It is thought that recombination uses enzymes that originally evolved for DNA repair.

The number of different systems and the wide spectrum of damage that can be repaired illustrate the importance of maintaining the integrity of the genome. Accurate replication of the genome is useless if a cell cannot reverse errors that can occur during this process or repair damage due to environmental causes.

### Inquiry question

Cells are constantly exposed to DNA-damaging agents, ranging from UV light to by-products of oxidative metabolism. How does the cell deal with this, and what would happen if the cell had no way of dealing with this?

### Learning Outcomes Review 14.6

The ability to repair DNA is critical because of replication errors and the constant presence of damaging agents that can cause mutation. Cells have multiple repair pathways; some of these systems are specific for a single type of damage, such as photorepair that reverses thymine dimers caused by UV light. Other systems are nonspecific, such as excision repair that removes and replaces damaged regions.

- Could a cell survive with no form of DNA repair?

## Chapter Review

### 14.1 The Nature of the Genetic Material

#### Griffith finds that bacterial cells can be transformed.

Nonvirulent *S. pneumoniae* could take up an unknown substance from a virulent strain and become virulent.

#### Avery, MacLeod, and McCarty identify the transforming principle.

The transforming substance could be inactivated by DNA-digesting enzymes, but not by protein-digesting enzymes.

#### Hershey and Chase demonstrate that phage genetic material is DNA.

Radioactive labeling showed that the infectious agent of phage is its DNA, and not its protein.

### 14.2 DNA Structure

#### DNA's components were known, but its three-dimensional structure was a mystery.

The nucleotide building blocks for DNA contain deoxyribose and the bases adenine (A), guanine (G), cytosine (C), and thymine (T). Phosphodiester bonds are formed between the 5' phosphate of one nucleotide and the 3' hydroxyl of another nucleotide (see figure 14.4).

#### Chargaff, Franklin, and Wilkins obtained some structural evidence.

Chargaff found equal amounts of adenine and thymine, and of cytosine and guanine, in DNA. The bases exist primarily in keto and enol forms that exhibit hydrogen bonding. X-ray diffraction

studies by Franklin and Wilkins indicated that DNA had a helical structure.

#### The Watson-Crick model fits the available evidence (see figures 14.8 and 14.9).

DNA consists of two antiparallel polynucleotide strands wrapped about a common helical axis. These strands are held together by hydrogen bonds forming specific base pairs (A/T and G/C). The two strands are complementary; one strand can specify the other.

### 14.3 Basic Characteristics of DNA Replication

#### Meselson and Stahl demonstrate the semiconservative mechanism (see figure 14.11).

Semiconservative replication uses each strand of a DNA molecule to specify the synthesis of a new strand. Meselson and Stahl showed this by using a heavy isotope of nitrogen and separating the replication products. Replication produces two new molecules each composed of one new strand and one old strand.

#### DNA replication requires a template, nucleotides, and a polymerase enzyme.

All new DNA molecules are produced by DNA polymerase copying a template. All known polymerases synthesize new DNA in the 5'-to-3' direction. These enzymes also require a primer. The building blocks used in replication are deoxynucleotide triphosphates with high-energy bonds; they do not require any additional energy.

## 14.4 Prokaryotic Replication

### *Prokaryotic replication starts at a single origin.*

The *E. coli* origin has AT-rich sequences that are easily opened. The chromosome and its origin form a replicon.

### *E. coli has at least three different DNA polymerases.*

Some DNA polymerases can also degrade DNA from one end, called exonuclease activity. Pol I, II, and III all have 3'-to-5' exonuclease activity that can remove mispaired bases. Pol I can remove bases in the 5'-to-3' direction, important to removing RNA primers.

### *Unwinding DNA requires energy and causes torsional strain.*

DNA helicase uses energy from ATP to unwind DNA. The torsional strain introduced is removed by the enzyme DNA gyrase.

### *Replication is semidiscontinuous.*

Replication is discontinuous on one strand (see figure 14.15). The continuous strand is called the leading strand, and the discontinuous strand is called the lagging strand.

### *Synthesis occurs at the replication fork.*

The partial opening of a DNA strand forms two single-stranded regions called the replication fork. At the fork, synthesis on the leading strand requires a single primer, and the polymerase stays attached to the template because of the  $\beta$  subunit that acts as a sliding clamp. On the lagging strand, DNA primase adds primers periodically, and DNA Pol III synthesizes the Okazaki fragments. DNA Pol I removes primer segments, and DNA ligase joins the fragments.

### *The replisome contains all the necessary enzymes for replication.*

The replisome consists of two copies of Pol III, DNA primase, DNA helicase, and a number of accessory proteins. It moves in one direction by creating a loop in the lagging strand, allowing the antiparallel template strands to be copied in the same direction (see figures 14.18 and 14.19).

## 14.5 Eukaryotic Replication

### *Eukaryotic replication requires multiple origins.*

The sheer size and organization of eukaryotic chromosomes requires multiple origins of replication to be able to replicate DNA in the time available in S phase.

### *The enzymology of eukaryotic replication is more complex.*

The eukaryotic primase synthesizes a short stretch of RNA and then switches to making DNA. This primer is extended by the main replication polymerase, which is a complex of two enzymes. The sliding clamp subunit was originally identified as protein produced by proliferating cells and is called PCNA.

### *Archaeal replication proteins are similar to eukaryotic proteins.*

The replication proteins of archaea, including the sliding clamp, clamp loader, and DNA polymerases, are more similar to those of eukaryotes than to prokaryotes.

### *Linear chromosomes have specialized ends.*

The ends of linear chromosomes are called telomeres. They are made by telomerase, not by the replication complex. Telomerase contains an internal RNA that acts as a template to extend the DNA of the chromosome end. Adult cells lack telomerase activity, and telomere shortening correlates with senescence.

## 14.6 DNA Repair

### *Cells are constantly exposed to DNA-damaging agents.*

Errors from replication and damage induced by agents such as UV light and chemical mutagens can lead to mutations.

### *DNA repair restores damaged DNA.*

Without repair mechanisms, cells would accumulate mutations until inviability occurred.

### *Repair can be either specific or nonspecific.*

The enzyme photolyase uses energy from visible light to cleave thymine dimers caused by UV light. Excision repair is nonspecific. In prokaryotes, the *uvr* system can remove a damaged region of DNA.

## Review Questions

### UNDERSTAND

- What was the key finding from Griffith's experiments using live and heat-killed pathogenic bacteria?
  - Bacteria with a smooth coat could kill mice.
  - Bacteria with a rough coat are not lethal.
  - DNA is the genetic material.
  - Genetic material can be transferred from dead to live bacteria.
- Which of the following is *not* a component of DNA?
  - The pyrimidine uracil
  - Five-carbon sugars
  - The purine adenine
  - Phosphate groups
- Chargaff studied the composition of DNA from different sources and found that
  - the number of phosphate groups always equals the number of five-carbon sugars.
  - the proportions of A equal that of C and G equals T.
  - the proportions of A equal that of T and G equals C.
  - purines bind to pyrimidines.
- The bonds that hold two complementary strands of DNA together are
  - hydrogen bonds.
  - peptide bonds.
  - ionic bonds.
  - phosphodiester bonds.

5. The basic mechanism of DNA replication is semiconservative with two new molecules,
  - a. each with new strands.
  - b. one with all new strands and one with all old strands.
  - c. each with one new and one old strand.
  - d. each with a mixture of old and new strands.
6. One common feature of all DNA polymerases is that they
  - a. synthesize DNA in the 3'-to-5' direction.
  - b. synthesize DNA in the 5'-to-3' direction.
  - c. synthesize DNA in both directions by switching strands.
  - d. do not require a primer.
7. Which of the following is *not* part of the Watson–Crick model of the structure of DNA?
  - a. DNA is composed of two strands.
  - b. The two DNA strands are oriented in parallel (5'-to-3').
  - c. Purines bind to pyrimidines.
  - d. DNA forms a double helix.
6. Successful DNA synthesis requires all of the following *except*
  - a. helicase.
  - b. endonuclease.
  - c. DNA primase.
  - d. DNA ligase.
7. The synthesis of telomeres
  - a. uses DNA polymerase, but without the sliding clamp.
  - b. uses enzymes involved in DNA repair.
  - c. requires telomerase, which does not need a template.
  - d. requires telomerase, which uses an internal RNA as a template.
8. Which type of enzyme is involved in excision repair?
  - a. Photolyase
  - b. DNA polymerase III
  - c. Endonuclease
  - d. Telomerase

## APPLY

1. If one strand of a DNA is: 5' ATCGTTAAGCGAGTCA 3', then the complementary strand would be:
  - a. 5' TAGCAATTCGCTCAGT 3'.
  - b. 5' ACTGAGCGAATTGCTA 3'.
  - c. 5' TGA CTGCTTAACGAT 3'.
  - d. 5' ATCGTTAAGCGAGTCA 3'.
2. Hershey and Chase used radioactive phosphorus and sulfur to
  - a. label DNA and protein with the same molecule.
  - b. differentially label DNA and protein.
  - c. identify the transforming principle.
  - d. Both (b) and (c) are correct.
3. The Meselson and Stahl experiment used a density label to be able to
  - a. determine the directionality of DNA replication.
  - b. differentially label DNA and protein.
  - c. distinguish between newly replicated and old strands.
  - d. distinguish between replicated DNA and RNA primers.
4. The difference in leading- versus lagging-strand synthesis is a consequence of
  - a. only the physical structure of DNA.
  - b. only the activity of DNA polymerase enzymes.
  - c. both the physical structure of DNA and the action of polymerase enzyme.
  - d. the larger size of the lagging strand.
5. If the activity of DNA ligase was removed from replication, this would have a greater affect on
  - a. synthesis on the lagging strand versus the leading strand.
  - b. synthesis on the leading strand versus the lagging strand.
  - c. priming of DNA synthesis versus actual DNA synthesis.
  - d. photorepair of DNA versus DNA replication.

## SYNTHESIZE

1. The work by Griffith provided the first indication that DNA was the genetic material. Review the four experiments outlined in figure 14.1. Predict the likely outcome for the following variations on this classic research.
  - a. Heat-killed pathogenic and heat-killed nonpathogenic
  - b. Heat-killed pathogenic and live nonpathogenic in the presence of an enzyme that digests proteins (proteases)
  - c. Heat-killed pathogenic and live nonpathogenic in the presence of an enzyme that digests DNA (endonuclease)
2. In the Meselson–Stahl experiment, a control experiment was done to show that the hybrid bands after one round of replication were in fact two complete strands, one heavy and one light. Using the same experimental setup as detailed in the text, how can this be addressed?
3. Enzyme function is critically important for the proper replication of DNA. Predict the consequence of a loss of function for each of the following enzymes.
  - a. DNA gyrase
  - b. DNA polymerase III
  - c. DNA ligase
  - d. DNA polymerase I

# Chapter 15

## Genes and How They Work

### Chapter Outline

- 15.1 The Nature of Genes
- 15.2 The Genetic Code
- 15.3 Prokaryotic Transcription
- 15.4 Eukaryotic Transcription
- 15.5 Eukaryotic pre-mRNA Splicing
- 15.6 The Structure of tRNA and Ribosomes
- 15.7 The Process of Translation
- 15.8 Summarizing Gene Expression
- 15.9 Mutation: Altered Genes

### Introduction

You've seen how genes specify traits and how those traits can be followed in genetic crosses. You've also seen that the information in genes resides in the DNA molecule; the picture above shows all the DNA within the entire *E. coli* chromosome. Information in DNA is replicated by the cell and then partitioned equally during the process of cell division. The information in DNA is much like a blueprint for a building. The construction of the building uses the information in the blueprint, but requires building materials and carpenters and other skilled laborers using a variety of tools working together to actually construct the building. Similarly, the information in DNA requires nucleotide and amino acid building blocks, multiple forms of RNA, and many proteins acting in a coordinated fashion to make up the structure of a cell.

We now turn to the nature of the genes themselves and how cells extract the information in DNA in the process of gene expression. Gene expression can be thought of as the conversion of genotype into the phenotype.

### 15.1 The Nature of Genes

#### Learning Outcomes

1. Describe the evidence for the one-gene/one-polypeptide hypothesis.
2. Distinguish between transcription and translation.
3. List the roles played by RNA in gene expression.

We know that DNA encodes proteins, but this knowledge alone tells us little about how the information in DNA can control cellular functions. Researchers had evidence that genetic mutations affected proteins, and in particular enzymes, long before the structure and code of DNA was known. In this section we review the evidence of the link between genes and enzymes.

#### Garrod concluded that inherited disorders can involve specific enzymes

In 1902, the British physician Archibald Garrod noted that certain diseases among his patients seemed to be more prevalent in

particular families. By examining several generations of these families, he found that some of the diseases behaved as though they were the product of simple recessive alleles. Garrod concluded that these disorders were Mendelian traits, and that they had resulted from changes in the hereditary information in an ancestor of the affected families.

Garrod investigated several of these disorders in detail. In alkaptonuria, patients produced urine that contained homogentisic acid (alkapton). This substance oxidized rapidly when exposed to air, turning the urine black. In normal individuals, homogentisic acid is broken down into simpler substances. With considerable insight, Garrod concluded that patients suffering from alkaptonuria lack the enzyme necessary to catalyze this breakdown. He speculated that many other inherited diseases might also reflect enzyme deficiencies.

### Beadle and Tatum showed that genes specify enzymes

From Garrod's finding, it took but a short leap of intuition to surmise that the information encoded within the DNA of chromosomes acts to specify particular enzymes. This point was not actually established, however, until 1941, when a series of experiments by George Beadle and Edward Tatum at Stanford University provided definitive evidence. Beadle and Tatum deliberately set out to create mutations in chromosomes and verified that they behaved in a Mendelian fashion in crosses. These alterations to single genes were analyzed for their effects on the organism (figure 15.1).

#### *Neurospora crassa*, the bread mold

One of the reasons Beadle and Tatum's experiments produced clear-cut results was their choice of experimental organism, the bread mold *Neurospora crassa*. This fungus can be grown readily in the laboratory on a defined medium consisting of only a carbon source (glucose), a vitamin (biotin), and inorganic salts. This type of medium is called "minimal" because it represents the minimal requirements to support growth. Any cells that can grow on minimal medium must be able to synthesize all necessary biological molecules.

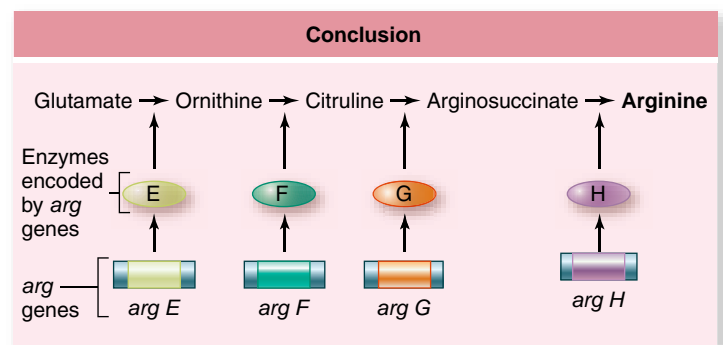

Beadle and Tatum exposed *Neurospora* spores to X-rays, expecting that the DNA in some of the spores would experience damage in regions encoding the ability to make compounds needed for normal growth (see figure 15.1). Such a mutation would cause cells to be unable to grow on minimal medium. Such mutations are called **nutritional mutations** because cells carrying them grow only if the medium is supplemented with additional nutrients.

#### Nutritional mutants

To identify mutations causing metabolic deficiencies, Beadle and Tatum placed subcultures of individual fungal cells grown on a rich medium onto minimal medium. Any cells that had lost the ability to make compounds necessary for growth would not grow on minimal medium. Using this approach, Beadle and Tatum succeeded in isolating and identifying many nutritional mutants.

Results				
Mutation in Enzyme	Plus Ornithine	Plus Citruline	Plus Arginosuccinate	Plus Arginine
E	Growth	Growth	Growth	Growth
F	No growth	Growth	Growth	Growth
G	No growth	No growth	Growth	Growth
H	No growth	No growth	No growth	Growth

**Figure 15.1** The Beadle and Tatum experiment.

Wild-type *Neurospora* were mutagenized with X-rays to produce mutants deficient in the synthesis of arginine (top panel). The specific defect in each mutant was identified by growing on medium supplemented with intermediates in the biosynthetic pathway for arginine (middle panel). A mutant will grow only on media supplemented with an intermediate produced after the defective enzyme in the pathway for each mutant. The enzymes in the pathway can then be correlated with genes on chromosomes (bottom panel).

Next, the researchers supplemented the minimal medium with different compounds known to be intermediates in this biochemical pathway to identify the deficiency in each mutant. This step allowed them to pinpoint the nature of the strain's biochemical deficiency. They concentrated in particular on mutants that would grow only in the presence of the amino acid arginine, dubbed *arg* mutants. These were shown to define four genes they named *argE*, *argF*, *argG*, and *argH*. When their chromosomal positions were located, the *arg* mutations were found to cluster in three areas.

### One gene/one polypeptide

The next step was to determine where each mutation was blocked in the biochemical pathway for arginine biosynthesis. To do this, they supplemented the medium with each intermediate in the pathway to see which intermediate would support a mutant's growth. If the mutation affects an enzyme in the pathway that acts prior to the intermediate used as a supplement, then growth should be supported—but not if the mutation affects a step after the intermediate used (see figure 15.1). For each enzyme in the arginine biosynthetic pathway, Beadle and Tatum were able to isolate a mutant strain with a defective form of that enzyme. The mutation was always located at one of a few specific chromosomal sites, and each mutation had a unique location. Thus, each of the mutants they examined had a defect in a single enzyme, caused by a mutation at a single site on a chromosome.

Beadle and Tatum concluded that genes specify the structure of enzymes, and that each gene encodes the structure of one enzyme (see figure 15.1). They called this relationship the *one-gene/one-enzyme hypothesis*. Today, because many enzymes contain multiple polypeptide subunits, each encoded by a separate gene, the relationship is more commonly referred to as the **one-gene/one-polypeptide hypothesis**. This hypothesis clearly states the molecular relationship between genotype and phenotype.

As you learn more about genomes and gene expression, you'll find that this clear relationship is overly simple. As described later in this chapter, eukaryotic genes are more complex than those of prokaryotes. In addition, some enzymes are composed, at least in part, of RNA, itself an intermediate in the production of proteins. Nevertheless, this one-gene/one-polypeptide concept is a useful starting point for thinking about gene expression.

## The central dogma describes information flow in cells as DNA to RNA to protein

The conversion of genotype to phenotype requires information stored in DNA to be converted to protein. The nature of information flow in cells was first described by Francis Crick as the **central dogma of molecular biology**. Information passes in one direction from the gene (DNA) to an RNA copy of the gene, and the RNA copy directs the sequential assembly of a chain of amino acids into a protein (figure 15.2). Stated briefly,

The central dogma provides an intellectual framework that describes information flow in biological systems. We call the

**Figure 15.2** The central dogma of molecular biology.

DNA is transcribed to make mRNA, which is translated to make a protein.

DNA-to-RNA step **transcription** because it produces an exact copy of the DNA, much as a legal transcription contains the exact words of a court proceeding. The RNA-to-protein step is termed **translation** because it requires translating from the nucleic acid to the protein “languages.”

Since the original formulation of the central dogma, a class of viruses called **retroviruses** was discovered that can convert their RNA genome into a DNA copy, using the viral enzyme **reverse transcriptase**. This conversion violates the direction of information flow of the central dogma, and the discovery forced an updating of the possible flow of information to include this “reverse” flow from RNA to DNA.

### Transcription makes an RNA copy of DNA

The process of transcription produces an RNA copy of the information in DNA. That is, transcription is the DNA-directed synthesis of RNA by the enzyme RNA polymerase (figure 15.3). This process uses the principle of complementarity, described in chapter 14, to use DNA as a template to make RNA.

Because DNA is double-stranded and RNA is single-stranded, only one of the two DNA strands needs to be copied. We call the strand that is copied the **template strand**. The RNA transcript's sequence is complementary to the template strand. The strand of DNA not used as a template is called the **coding strand**. It has the same sequence as the RNA transcript,

**Figure 15.3 RNA polymerase.** In this electron micrograph, the dark circles are RNA polymerase molecules synthesizing RNA from a DNA template.

except that U (uracil) in the RNA is T (thymine) in the DNA-coding strand. Another naming convention for the two strands of the DNA is to call the coding strand the sense strand, as it has the same “sense” as the RNA. The template strand would then be the antisense strand.

The RNA transcript used to direct the synthesis of polypeptides is termed *messenger RNA (mRNA)*. Its name reflects its use by the cell to carry the DNA message to the ribosome for processing.

### Inquiry question

It is widely accepted that RNA polymerase has no proofreading capacity. Would you expect high or low levels of error in transcription compared with DNA replication? Why do you think it is more important for DNA polymerase than for RNA polymerase to proofread?

## Translation uses information in RNA to synthesize proteins

The process of translation is by necessity much more complex than transcription. In this case, RNA cannot be used as a direct template for a protein because there is no complementarity—that is, a sequence of amino acids cannot be aligned to an RNA template based on any kind of “chemical fit.” Molecular geneticists suggested that some kind of adapter molecule must exist that can interact with both RNA and amino acids, and *transfer RNA (tRNA)* was found to fill this role. This need for an intermediary adds a level of complexity to the process that is not seen in either DNA replication or transcription of RNA.

Translation takes place on the ribosome, the cellular protein-synthesis machinery, and it requires the participation of multiple kinds of RNA and many proteins. Here we provide an outline of the processes; all are described in detail in the sections that follow.

## RNA has multiple roles in gene expression

All RNAs are synthesized from a DNA template by transcription. Gene expression requires the participation of multiple kinds of RNA, each with different roles in the overall process. Here is a brief summary of these roles, which are described in detail later.

**Messenger RNA.** Even before the details of gene expression were unraveled, geneticists recognized that there must be an intermediate form of the information in DNA that can be transported out of the eukaryotic nucleus to the cytoplasm for ribosomal processing. This hypothesis was called the “messenger hypothesis,” and we retain this language in the name *messenger RNA (mRNA)*.

**Ribosomal RNA.** The class of RNA found in ribosomes is called **ribosomal RNA (rRNA)**. There are multiple forms of rRNA, and rRNA is found in both ribosomal subunits. This rRNA is critical to the function of the ribosome.

**Transfer RNA.** The intermediary adapter molecule between mRNA and amino acids, as mentioned earlier, is **transfer RNA (tRNA)**. Transfer RNA molecules have amino acids covalently attached to one end and an anticodon that can base-pair with an mRNA codon at the other. The tRNAs act to interpret information in mRNA and to help position the amino acids on the ribosome.

**Small nuclear RNA.** **Small nuclear RNAs (snRNAs)** are part of the machinery that is involved in nuclear processing of eukaryotic “pre-mRNA.” We discuss this splicing reaction later in the chapter.

**SRP RNA.** In eukaryotes, where some proteins are synthesized by ribosomes on the rough endoplasmic reticulum (RER), this process is mediated by the **signal recognition particle**, or **SRP**, described later in the chapter. The SRP contains both RNA and proteins.

**Micro-RNA.** This class of RNA was discovered relatively recently. These very short RNAs, called **micro-RNAs**, or **miRNA**, have gone from unknown to a major class of regulatory molecules in a very short period of time.

### Learning Outcomes Review 15.1

Garrod showed that altered enzymes can cause metabolic disorders. Beadle and Tatum demonstrated that each gene encodes a unique enzyme. Genetic information flows from DNA (genes) to protein (enzymes) using messenger RNA as an intermediate. Transcription converts information in DNA into an RNA transcript, and translation converts this information into protein. RNA comes in several varieties having different functions; these include mRNA (the transcript), tRNA (the intermediary), and rRNA (in ribosomes), as well as snRNA, SNP RNA, and micro-RNA.

- Why do cells need an adapter molecule like tRNA between RNA and protein?

## 15.2 The Genetic Code

### Learning Outcomes

1. Summarize the experiments that revealed the genetic code.
2. Describe the characteristics of the genetic code.
3. Identify the relationship between codons and amino acids.

How does the order of nucleotides in a DNA molecule encode the information that specifies the order of amino acids in a polypeptide? The answer to this essential question came in 1961, through an experiment led by Francis Crick and Sydney Brenner. That experiment was so elegant and the result so critical to understanding the genetic code that we describe it here in detail.

### The code is read in groups of three

Crick and Brenner reasoned that the genetic code most likely consisted of a series of blocks of information called **codons**, each corresponding to an amino acid in the encoded protein. They further hypothesized that the information within one codon was probably a sequence of three nucleotides. With four DNA nucleotides (G, C, T, and A), using two in each codon can produce only  $4^2$ , or 16, different codons—not enough to code for 20 amino acids. However, three nucleotides results in  $4^3$ , or 64, different combinations of three, more than enough.

### Spaced or unspaced codons?

In theory, the sequence of codons in a gene could be punctuated with nucleotides between the codons that are not used, like the spaces that separate the words in this sentence. Alternatively, the codons could lie immediately adjacent to each other, forming a continuous sequence of nucleotides.

If the information in the genetic message is separated by spaces, then altering any single word would not affect the entire sentence. In contrast, if all of the words are run together but read in groups of three, then any alteration that is not in groups of three would alter the entire sentence. These two ways of using information in DNA imply different methods of translating the information into protein.

### Determining that codons are unspaced

To choose between these alternative mechanisms, Crick and his colleagues used a chemical to create mutations that caused single-base insertions or deletions from a viral DNA molecule. They then showed that combining an insertion with a deletion restored function even though either one individually displayed loss of function. In this case, only the region between the insertion or deletion would be altered. By choosing a region of the gene that encoded a part of the protein not critical to function, this small change did not cause a change in phenotype.

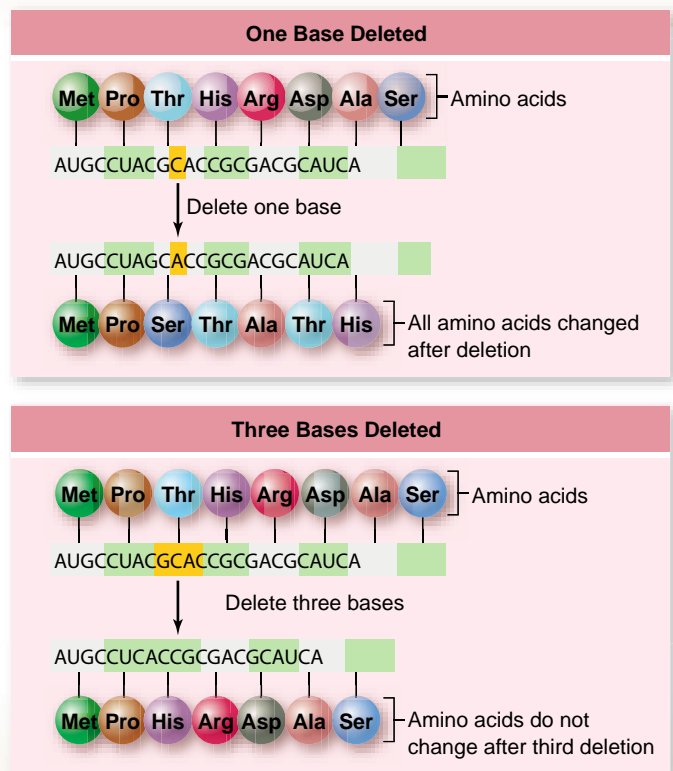

When they combined a single deletion or two deletions near each other, the genetic message shifted, altering all of the amino acids after the deletion. When they made three deletions,

### SCIENTIFIC THINKING

**Hypothesis:** The genetic code is read in groups of three bases.

**Prediction:** If the genetic code is read in groups of three, then deletion of one or two bases would shift the reading frame after the deletion. Deletion of three bases, however, would produce a protein with a single amino acid deleted but no change downstream.

**Test:** Single-base deletion mutants are collected, each of which exhibits a mutant phenotype. Three of these deletions in a single region are combined to assess the effect of deletion of three bases.

**Result:** The combination of three deletions does not have the same drastic effect as the loss of one or two bases.

**Conclusion:** The genetic code is read in groups of three.

**Further Experiments:** If you also had mutants with one base additions, what would be the effect of combining a deletion and an addition?

**Figure 15.4** The genetic code is triplet.

however, the protein after the deletions was normal. They obtained the same results when they made additions to the DNA consisting of 1, 2, or 3 nt (nucleotides).

Thus, Crick and Brenner concluded that the genetic code is read in increments of three nucleotides (in other words, it is a triplet code), and that reading occurs continuously without punctuation between the 3-nt units (figure 15.4).

These experiments indicate the importance of the **reading frame** for the genetic message. Because there is no punctuation, the reading frame established by the first codon in the sequence determines how all subsequent codons are read. We now call the kinds of mutations that Crick and Brenner used **frameshift mutations** because they alter the reading frame of the genetic message.

## Nirenberg and others deciphered the code

The determination of which of the 64 possible codons encoded each particular amino acid was one of the greatest triumphs of 20th-century biochemistry. Accomplishing this decryption required two main developments to succeed: (1) cell-free biochemical systems that would support protein synthesis from a defined RNA and (2) the ability to produce synthetic, defined RNAs that could be used in the cell-free system.

During a five-year period from 1961 to 1966, work performed primarily in Marshall Nirenberg's laboratory led to the elucidation of the genetic code. Nirenberg's group first showed that adding the synthetic RNA molecule polyU (an RNA molecule consisting of a string of uracil nucleotides) to their cell-free systems

produced the polypeptide polyphenylalanine (a string of phenylalanine amino acids). Therefore, UUU encodes phenylalanine.

Next they used enzymes to produce RNA polymers with more than one nucleotide. These polymers allowed them to infer the composition of many of the possible codons, but not the order of bases in each codon.

The researchers then were able to use enzymes to synthesize defined 3-base sequences that could be tested for binding to the protein-synthesis machinery. This so-called *triplet-binding assay* allowed them to identify 54 of the 64 possible triplets.

The organic chemist H. Gobind Khorana provided the final piece of the puzzle by using organic synthesis to produce artificial RNA molecules of defined sequence, and then examining what polypeptides they directed in cell-free systems. The combination of all of these methods allowed the determination of all 64 possible 3-nt sequences, and the full genetic code was determined (table 15.1).

## The code is degenerate but specific

Some obvious features of the code jump out of table 15.1. First, 61 of the 64 possible codons are used to specify amino acids. Three codons, UAA, UGA, and UAG, are reserved for another function: they signal “stop” and are known as **stop codons**. The only other form of “punctuation” in the code is that AUG is used to signal “start” and is therefore the **start codon**. In this case the codon has a dual function because it also encodes the amino acid methionine (Met).

**TABLE 15.1** The Genetic Code

		S E C O N D L E T T E R								
First Letter	U		C		A		G		Third Letter	
U	UUU	<b>Phe</b> Phenylalanine	UCU	<b>Ser</b> Serine	UAU	<b>Tyr</b> Tyrosine	UGU	<b>Cys</b> Cysteine	U	
	UUC		UCC		UAC		UGC			C
	UUA	<b>Leu</b> Leucine	UCA		<b>UAA</b> “Stop”	<b>UGA</b> “Stop”			A	
	UUG		UCG		<b>UAG</b> “Stop”	UGG	<b>Trp</b> Tryptophan		G	
C	CUU	<b>Leu</b> Leucine	CCU	<b>Pro</b> Proline	CAU	<b>His</b> Histidine	CGU	<b>Arg</b> Arginine	U	
	CUC		CCC		CAC		CGC		C	
	CUA		CCA		CAA	<b>Gln</b> Glutamine	CGA		A	
	CUG		CCG		CAG		CGG		G	
A	AUU	<b>Ile</b> Isoleucine	ACU	<b>Thr</b> Threonine	AAU	<b>Asn</b> Asparagine	AGU	<b>Ser</b> Serine	U	
	AUC		ACC		AAC		AGC		C	
	AUA		ACA		AAA	<b>Lys</b> Lysine	AGA		A	
	<b>AUG</b> <b>Met</b> Methionine; “Start”	ACG	AAG		AGG		<b>Arg</b> Arginine		G	
G	GUU	<b>Val</b> Valine	GCU	<b>Ala</b> Alanine	GAU	<b>Asp</b> Aspartate	GGU	<b>Gly</b> Glycine	U	
	GUC		GCC		GAC		GGC		C	
	GUA		GCA		GAA	<b>Glu</b> Glutamate	GGA		A	
	GUG		GCG		GAG		GGG		G	

A codon consists of three nucleotides read in the sequence shown. For example, ACU codes for threonine. The first letter, A, is in the First Letter column; the second letter, C, is in the Second Letter column; and the third letter, U, is in the Third Letter column. Each of the mRNA codons is recognized by a corresponding anticodon sequence on a tRNA molecule. Many amino acids are specified by more than one codon. For example, threonine is specified by four codons, which differ only in the third nucleotide (ACU, ACC, ACA, and ACG).

**Figure 15.5 Transgenic pig.** The piglet on the right is a conventional piglet. The piglet on the left was engineered to express a gene from jellyfish that encodes green fluorescent protein. The color of this piglet's nose is due to expression of this introduced gene. Such transgenic animals indicate the universal nature of the genetic code.

You can see that 61 codons are more than enough to encode 20 amino acids. That leaves lots of extra codons. One way to deal with this abundance would be to use only 20 of the 61 codons, but this is not what cells do. In reality, all 61 codons are used, making the code **degenerate**, which means that some amino acids are specified by more than one codon. The reverse, however, in which a single codon would specify more than one amino acid, is never found.

This degeneracy is not uniform. Some amino acids have only one codon, and some have up to six. In addition, the degenerate base usually occurs in position 3 of a codon, such that the first two positions are the same, and two or four of the possible nucleotides at position 3 encode the same amino acid. (The nature of protein synthesis on ribosomes explains how this codon usage works, and it is discussed later.)

### The code is practically universal, but not quite

The genetic code is the same in almost all organisms. The universality of the genetic code is among the strongest evidence that all living things share a common evolutionary heritage. Because the code is universal, genes can be transferred from one organism to another and can be successfully expressed in their new host (figure 15.5). This universality of gene expression is central to many of the advances of genetic engineering discussed in chapter 17.

In 1979, investigators began to determine the complete nucleotide sequences of the mitochondrial genomes in humans, cattle, and mice. It came as something of a shock when these investigators learned that the genetic code used by these mammalian mitochondria was not quite the same as the “universal code” that has become so familiar to biologists.

In the mitochondrial genomes, what should have been a stop codon, UGA, was instead read as the amino acid tryptophan; AUA was read as methionine rather than as isoleucine; and AGA and AGG were read as stop codons rather than as arginine. Furthermore, minor differences from the universal code have also been found in the genomes of chloroplasts and in ciliates (certain types of protists).

Thus, it appears that the genetic code is not quite universal. Some time ago, presumably after they began their endo-

symbiotic existence, mitochondria and chloroplasts began to read the code differently, particularly the portion associated with “stop” signals.

### Inquiry question

- ? The genetic code is almost universal. Why do you think it is nearly universal?

### Learning Outcomes Review 15.2

The genetic code was shown to be nucleotide base triplets with two forms of punctuation and no spaces: three bases code for an amino acid, and the groups of three are read in order. Sixty-one codons specify amino acids, one of which also codes for “start,” and three codons indicate “stop,” for 64 total. Because some amino acids are specified by more than one codon, the code is termed degenerate. All codons encode only one amino acid, however.

- What would be the outcome if a codon specified more than one amino acid?

## 15.3 Prokaryotic Transcription

### Learning Outcomes

1. Describe the transcription process in bacteria.
2. Differentiate features of initiation from those of elongation.
3. Define the unique features of prokaryotic transcription.

We begin an examination of gene expression by describing the process of transcription in prokaryotes. The later description of eukaryotic transcription will concentrate on their differences from prokaryotes.

**Figure 15.6 Bacterial RNA polymerase and transcription initiation.** *a.* RNA polymerase has two forms: core polymerase and holoenzyme. *b.* The  $\sigma$  subunit of the holoenzyme recognizes promoter elements at  $-35$  and  $-10$  and binds to the DNA. The helix is opened at the  $-10$  region, and transcription begins at the start site at  $+1$ .

*a.*

## Prokaryotes have a single RNA polymerase

The single **RNA polymerase** of prokaryotes exists in two forms: the *core polymerase* and the *holoenzyme*. The core polymerase can synthesize RNA using a DNA template, but it cannot initiate synthesis accurately. The holoenzyme can accurately initiate synthesis.

The core polymerase is composed of four subunits: two identical  $\alpha$  subunits, a  $\beta$  subunit, and a  $\beta'$  subunit (figure 15.6a). The two  $\alpha$  subunits help to hold the complex together and can bind to regulatory molecules. The active site of the enzyme is formed by the  $\beta$  and  $\beta'$  subunits, which bind to the DNA template and the ribonucleotide triphosphate precursors.

The *holoenzyme*, which can properly initiate synthesis, is formed by the addition of a  $\sigma$  (sigma) subunit to the core polymerase (see figure 15.6a). Its ability to recognize specific signals in DNA allows RNA polymerase to locate the beginning of genes, which is critical to its function. Note that initiation of mRNA synthesis does not require a primer, in contrast to DNA replication.

## Initiation occurs at promoters

Accurate initiation of transcription requires two sites in DNA: one called a **promoter** that forms a recognition and binding site for the RNA polymerase, and the actual **start site**. The polymerase also needs a signal to end transcription, which we call a **terminator**. We then refer to the region from promoter to terminator as a **transcription unit**.

The action of the polymerase moving along the DNA can be thought of as analogous to water flowing in a stream. We can speak of sites on the DNA as being “upstream” or “downstream” of the start site. We can also use this comparison to form a simple system for numbering bases in DNA to refer to positions in the transcription unit. The first base transcribed is called +1, and this numbering continues downstream until the last base is transcribed. Any bases upstream of the start site receive negative numbers, starting at -1.

The promoter is a short sequence found upstream of the start site and is therefore not transcribed by the polymerase. Two 6-base sequences are common to bacterial promoters: One

is located 35 nt upstream of the start site (-35), and the other is located 10 nt upstream of the start site (-10) (figure 15.6b). These two sites provide the promoter with asymmetry; they indicate not only the site of initiation, but also the direction of transcription.

The binding of RNA polymerase to the promoter is the first step in transcription. Promoter binding is controlled by the  $\sigma$  subunit of the RNA polymerase holoenzyme, which recognizes the -35 sequence in the promoter and positions the RNA polymerase at the correct start site, oriented to transcribe in the correct direction.

Once bound to the promoter, the RNA polymerase begins to unwind the DNA helix at the -10 site (see figure 15.6b). The polymerase covers a region of about 75 bp but only unwinds about 12–14 bp.

### Inquiry question

The prokaryotic promoter has two distinct elements that are not identical. How is this important to the initiation of transcription?

## Elongation adds successive nucleotides

In prokaryotes, the transcription of the RNA chain usually starts with ATP or GTP. One of these forms the 5' end of the chain, which grows in the 5'-to-3' direction as ribonucleotides are added. As the RNA polymerase molecule leaves the promoter region, the  $\sigma$  factor is no longer required, although it may remain in association with the enzyme.

This process of leaving the promoter, called *clearance*, or *escape*, involves more than just synthesizing the first few nucleotides of the transcript and moving on, because the enzyme has made strong contacts to the DNA during initiation. It is necessary to break these contacts with the promoter region to be able to move progressively down the template. The enzyme goes through conformational changes during this clearance stage, and subsequently contacts less of the DNA than it does during the initial promoter binding.

The region containing the RNA polymerase, the DNA template, and the growing RNA transcript is called the **transcription bubble** because it contains a locally unwound

b.

“bubble” of DNA (figure 15.7). Within the bubble, the first 9 bases of the newly synthesized RNA strand temporarily form a helix with the template DNA strand. This stabilizes the positioning of the 3' end of the RNA so it can interact with an incoming ribonucleotide triphosphate. The enzyme itself covers about 50 bp of DNA around this transcription bubble.

The transcription bubble created by RNA polymerase moves down the bacterial DNA at a constant rate, about 50 nt/sec, with the growing RNA strand protruding from the bubble. After the transcription bubble passes, the now-transcribed DNA is rewound as it leaves the bubble.

## Termination occurs at specific sites

The end of a bacterial transcription unit is marked by terminator sequences that signal “stop” to the polymerase. Reaching these sequences causes the formation of phosphodiester bonds to cease, the RNA–DNA hybrid within the transcription bubble to dissociate, the RNA polymerase to release the DNA, and the DNA within the transcription bubble to rewind.

The simplest terminators consist of a series of G–C base-pairs followed by a series of A–T base-pairs. The RNA transcript of this stop region can form a double-stranded structure in the GC region called a *hairpin*, which is followed by four or more uracil (U) ribonucleotides (figure 15.8). Formation of the hairpin causes the RNA polymerase to pause,

**Figure 15.7 Model of a transcription bubble.** The DNA duplex is unwound by the RNA polymerase complex, rewinding at the end of the bubble. One of the strands of DNA functions as a template, and nucleotide building blocks are added to the 3' end of the growing RNA. There is a short region of RNA–DNA hybrid within the bubble.

**Figure 15.8 Bacterial transcription terminator.** The self-complementary G–C region forms a double-stranded stem with a single-stranded loop called a hairpin. The stretch of U's forms a less stable RNA–DNA hybrid that falls off the enzyme.

placing it directly over the run of four uracils. The pairing of U with the DNA's A is the weakest of the four hybrid base-pairs, and it is not strong enough to hold the hybrid strands when the polymerase pauses. Instead, the RNA strand dissociates from the DNA within the transcription bubble, and transcription stops. A variety of protein factors also act at these terminators to aid in terminating transcription.

## Prokaryotic transcription is coupled to translation

In prokaryotes, the mRNA produced by transcription begins to be translated before transcription is finished—that is, they are *coupled* (figure 15.9). As soon as a 5' end of the mRNA becomes available, ribosomes are loaded onto this to begin translation. (This coupling cannot occur in eukaryotes because transcription occurs in the nucleus, and translation occurs in the cytoplasm.)

Another difference between prokaryotic and eukaryotic gene expression is that the mRNA produced in prokaryotes may contain multiple genes. Prokaryotic genes are often organized such that genes encoding related functions are clustered together. This grouping of functionally related genes is referred to as an **operon**. An operon is a single transcription unit that encodes multiple enzymes necessary for a biochemical pathway. By clustering genes by function, they can be regulated together, a topic that we return to in the next chapter.

**Figure 15.9** Transcription and translation are coupled in prokaryotes. In this micrograph of gene expression in *E. coli*, translation is occurring during transcription. The arrows point to RNA polymerase enzymes, and ribosomes are attached to the mRNAs extending from the polymerase. Polypeptides being synthesized by ribosomes, which are not visible in the micrograph, have been added to the last mRNA in the drawing.

### Learning Outcomes Review 15.3

Transcription in bacteria is accomplished by RNA polymerase, which has two forms: a core polymerase and a holoenzyme. Initiation is accomplished by the holoenzyme form, which can accurately recognize promoter sequences. Elongation consists of RNA synthesis by the core enzyme, which adds RNA nucleotides in sequence until it reaches a terminator where synthesis stops, then the transcript is released. In prokaryotes, translation of the RNA transcript begins before transcription is finished, making the processes coupled.

- *Yeast are unicellular organism like bacteria; would you expect them to have the same transcription/translation coupling?*

## 15.4 Eukaryotic Transcription

### Learning Outcomes

1. List the different eukaryotic RNA polymerases.
2. Distinguish between the promoters of the RNA polymerases.
3. Define the processing that occurs to eukaryotic transcripts.

The basic mechanism of transcription by RNA polymerase is the same in eukaryotes as in prokaryotes; however, the details of the two processes differ enough that it is necessary to consider them separately. Here we concentrate only on how eukaryotic systems differ from prokaryotic systems, such as the bacterial system just discussed. All other features may be assumed to be the same.

### Eukaryotes have three RNA polymerases

Unlike prokaryotes, which have a single RNA polymerase enzyme, eukaryotes have three different RNA polymerases, which are distinguished in both structure and function. The enzyme **RNA polymerase I** transcribes rRNA, **RNA polymerase II** transcribes mRNA and some small nuclear RNAs, and **RNA polymerase III** transcribes tRNA and some other small RNAs. Together, these three enzymes accomplish all transcription in the nucleus of eukaryotic cells.

### Each polymerase has its own promoter

The existence of three different RNA polymerases requires different signals in the DNA to allow each polymerase to recognize where to begin transcription. Each polymerase recognizes a different promoter structure.

#### RNA polymerase I promoters

RNA polymerase I promoters at first puzzled biologists, because comparisons of rRNA genes between species showed no similarities outside the coding region. The current view is that these promoters are also specific for each species, and for this reason, cross-species comparisons do not yield similarities.

#### RNA polymerase II promoters

The RNA polymerase II promoters are the most complex of the three types, probably a reflection of the huge diversity of genes that are transcribed by this polymerase. When the first eukaryotic genes were isolated, many had a sequence called the **TATA box** upstream of the start site. This sequence was similar to the prokaryotic  $-10$  sequence, and it was assumed that the TATA box was the primary promoter element. With the sequencing of entire genomes, many more genes have been analyzed, and this assumption has proved too simple. It has been replaced by the idea of a “core promoter” that can be composed of a number of different elements, including the TATA box. Additional control elements allow for tissue-specific and developmental time-specific expression (see chapter 16).

#### RNA polymerase III promoters

Promoters for RNA polymerase III also were a source of surprise for biologists in the early days of molecular biology who were examining the control of eukaryotic gene expression. A common technique for analyzing regulatory regions was to make successive deletions from the 5' end of genes until enough was deleted to abolish specific transcription. The logic followed experiences with prokaryotes, in which the regulatory regions had been found at the 5' end of genes. But in the case of tRNA genes, the 5' deletions had no effect on

**Figure 15.10 Eukaryotic initiation complex.** Unlike transcription in prokaryotic cells, in which the RNA polymerase recognizes and binds to the promoter, eukaryotic transcription requires the binding of transcription factors to the promoter before RNA polymerase II binds to the DNA. The association of transcription factors and RNA polymerase II at the promoter is called the initiation complex.

expression! The promoters were found to actually be internal to the gene itself. This has not proved to be the case for all polymerase III genes, but appears to be for most.

### Initiation and termination differ from that in prokaryotes

The initiation of transcription at RNA polymerase II promoters is analogous to prokaryotic initiation but is more complex. Instead of a single factor allowing promoter recognition, eukaryotes use a host of **transcription factors**. These proteins are necessary to get the RNA polymerase II enzyme to a promoter and to initiate gene expression. A number of these transcription factors interact with RNA polymerase II to form an *initiation complex* at the promoter (figure 15.10). We explore this complex in detail in chapter 16 when we describe the control of gene expression.

The termination of transcription for RNA polymerase II also differs from that in prokaryotes. Although termination

sites exist, they are not as well defined as are prokaryotic terminators. The end of the mRNA is also not formed by RNA polymerase II because the primary transcript is modified after transcription.

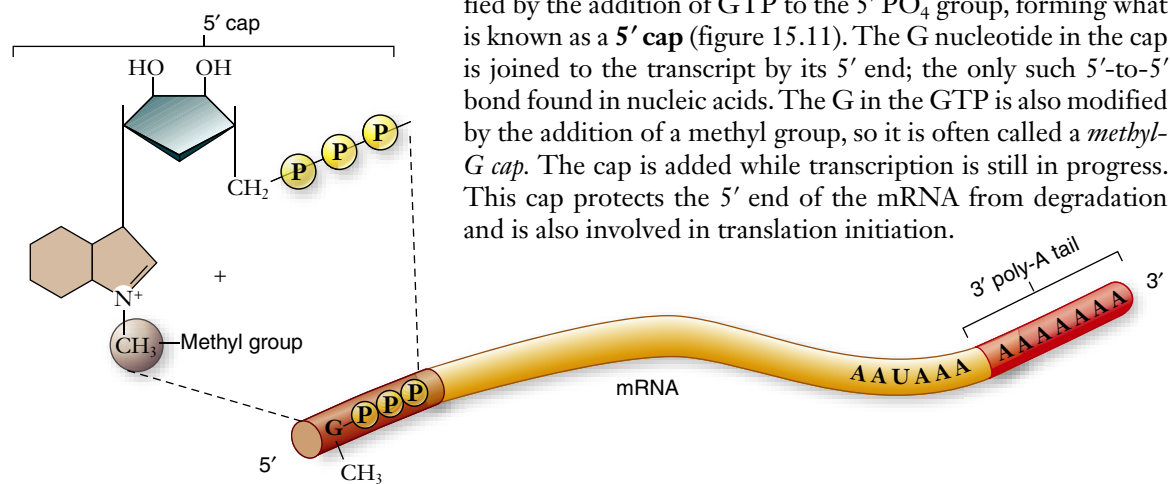

### Eukaryotic transcripts are modified

A primary difference between prokaryotes and eukaryotes is the fate of the transcript itself. Between transcription in the nucleus and export of a mature mRNA to the cytoplasm, a number of modifications occur to the initial transcripts made by RNA polymerase II. We call the RNA synthesized by RNA polymerase II the **primary transcript** and the final processed form the **mature mRNA**.

#### The 5' cap

Eukaryotic transcripts have an unusual structure that is added to the 5' end of mRNAs. The first base in the transcript is usually an adenine (A) or a guanine (G), and this is further modified by the addition of GTP to the 5' PO<sub>4</sub> group, forming what is known as a **5' cap** (figure 15.11). The G nucleotide in the cap is joined to the transcript by its 5' end; the only such 5'-to-5' bond found in nucleic acids. The G in the GTP is also modified by the addition of a methyl group, so it is often called a *methyl-G cap*. The cap is added while transcription is still in progress. This cap protects the 5' end of the mRNA from degradation and is also involved in translation initiation.

**Figure 15.11 Posttranscriptional modifications to 5' and 3' ends.** Eukaryotic mRNA molecules are modified in the nucleus with the addition of a methylated GTP to the 5' end of the transcript, called the 5' cap, and a long chain of adenine residues to the 3' end of the transcript, called the 3' poly-A tail.

### The 3' poly-A tail

A major difference between transcription in prokaryotes and eukaryotes is that in eukaryotes, the end of the transcript is not the end of the mRNA. The eukaryotic transcript is cleaved downstream of a specific site (AAUAAA) prior to the termination site for transcription. A series of adenine (A) residues, called the **3' poly-A tail**, is added after this cleavage by the enzyme poly-A polymerase. Thus the end of the mRNA is not created by RNA polymerase II and is not the end of the transcript (see figure 15.11).

The enzyme poly-A polymerase is part of a complex that recognizes the poly-A site, cleaves the transcript, then adds 100–200 A's to the end. The poly-A tail appears to play a role in the stability of mRNAs by protecting them from degradation (see chapter 16).

### Splicing of primary transcripts

Eukaryotic genes may contain noncoding sequences that have to be removed to produce the final mRNA. This process, called pre-mRNA splicing, is accomplished by an organelle called the *spliceosome*. This complex topic is discussed in the next section.

#### Learning Outcomes Review 15.4

Eukaryotes have three RNA polymerases called polymerase I, II, and III. Each synthesizes a different RNA and recognizes its own promoter. The RNA polymerase I promoter is species-specific. The polymerase II promoter is complex, but often includes a sequence called the TATA box. The polymerase III promoter is internal to the gene, rather than close to the 5' end. Polymerase II is responsible for mRNA synthesis. The primary mRNA transcript is modified by addition of a 5' cap and a 3' poly-A tail consisting of 100–200 adenines. Noncoding regions are removed by splicing.

- Does the complexity of the eukaryotic genome require three polymerases?

## 15.5 Eukaryotic pre-mRNA Splicing

#### Learning Outcomes

1. Explain the concept of colinearity of genes and proteins and how it applies in prokaryotes and eukaryotes.
2. Describe the splicing reaction for pre-mRNA.
3. Illustrate how splicing changes the nature of genes.

The first genes isolated were prokaryotic genes found in *E. coli* and its viruses. A clear picture of the nature and some of the control of gene expression emerged from these systems before any eukaryotic genes were isolated. It was assumed that although details would differ, the outline of gene expression in eukaryotes would be similar. The world of biology was in for a shock with the isolation of the first genes from eukaryotic organisms.

### Eukaryotic genes may contain interruptions

Many eukaryotic genes appeared to contain sequences that were not represented in the mRNA. It is hard to exaggerate how unexpected this finding was. A basic tenet of molecular biology based on *E. coli* was that a gene was *colinear* with its protein product, that is, the sequence of bases in the gene corresponds to the sequence of bases in the mRNA, which in turn corresponds to the sequence of amino acids in the protein.

In the case of eukaryotes, genes can be interrupted by sequences that are not represented in the mRNA and the protein. The term “split genes” was used at the time, but the nomenclature that has stuck describes the unexpected nature of these sequences. We call the noncoding DNA that interrupts the sequence of the gene “intervening sequences,” or **introns**, and we call the coding sequences **exons** because they are expressed (figure 15.12).

### The spliceosome is the splicing organelle

It is still true that the mature eukaryotic mRNA is colinear with its protein product, but a gene that contains introns is not. Imagine looking at an interstate highway from a satellite. Scattered randomly along the thread of concrete would be cars,

a.

b.

c.

#### Figure 15.12 Eukaryotic genes contain introns and exons.

**a.** Eukaryotic genes contain sequences that form the coding sequence called exons and intervening sequences called introns. **b.** An electron micrograph showing hybrids formed with the mRNA and the DNA of the ovalbumin gene, which has seven introns. Introns within the DNA sequence have no corresponding sequence in the mRNA and thus appear as seven loops. **c.** A schematic drawing of the micrograph.

#### Inquiry question

How can the same gene encode different transcripts?

some moving in clusters, others individually; most of the road would be bare. That is what a eukaryotic gene is like—scattered exons embedded within much longer sequences of introns.

In humans, only 1 to 1.5% of the genome is devoted to the exons that encode proteins; 24% is devoted to the noncoding introns within which these exons are embedded.

### The splicing reaction

The obvious question is—How do eukaryotic cells deal with the noncoding introns? The answer is that the primary transcript is cut and put back together to produce the mature mRNA. The latter process is referred to as **pre-mRNA splicing**, and it occurs in the nucleus prior to the export of the mRNA to the cytoplasm.

The intron–exon junctions are recognized by **small nuclear ribonucleoprotein particles**, called **snRNPs** (pronounced “snurps”). The snRNPs are complexes composed of snRNA and protein. These snRNPs then cluster together with other associated proteins to form a larger complex called the **spliceosome**, which is responsible for the splicing, or removal, of the introns.

For splicing to occur accurately, the spliceosome must be able to recognize intron–exon junctions. Introns all begin with the same 2-base sequence and end with another 2-base sequence that tags them for removal. In addition, within the intron there is a conserved A nucleotide, called the *branch point*, which is important for the splicing reaction (figure 15.13).

The splicing process begins with cleavage of the 5' end of the intron. This 5' end becomes attached to the 2' OH of the branch point A, forming a branched structure called a *lariat* due to its resemblance to a cowboy's lariat in a rope (see figure 15.13). The 3' end of the first exon is then used to displace the 3' end of the intron, joining the two exons together and releasing the intron as a lariat.

The processes of transcription and RNA processing do not occur in a linear sequence, but are rather all part of a concerted process that produces the mature mRNA. The capping reaction occurs during transcription, as does the splicing process. The RNA polymerase II enzyme itself helps to recruit the other factors necessary for modification of the primary transcript, and in this way the process of transcription and pre-mRNA processing are coupled.

### Distribution of introns

No rules govern the number of introns per gene or the sizes of introns and exons. Some genes have no introns; others may have 50. The sizes of exons range from a few nucleotides to 7500 nt, and the sizes of introns are equally variable. The presence of introns partly explains why so little of a eukaryotic genome is actually composed of “coding sequences” (see chapter 18 for results from the Human Genome Project).

One explanation for the existence of introns suggests that exons represent functional domains of proteins, and that the intron–exon arrangements found in genes represent the shuffling of these functional units over long periods of evolutionary time. This hypothesis, called *exon shuffling*, was proposed soon after the discovery of introns and has been the subject of much debate over the years.

The recent flood of genomic data has shed light on this issue by allowing statistical analysis of the placement of introns and on intron–exon structure. This analysis has provided support for the exon shuffling hypothesis for many genes; however, it is

**Figure 15.13 Pre-mRNA splicing by the spliceosome.**

Particles called snRNPs contain snRNA that interacts with the 5' end of an intron and with a branch site internal to the intron. Several snRNPs come together with other proteins to form the spliceosome. As the intron forms a loop, the 5' end is cut and linked to a site near the 3' end of the intron. The intron forms a lariat that is excised, and the exons are spliced together. The spliceosome then disassembles and releases the spliced mRNA.

also clearly not universal, because all proteins do not show this kind of pattern. It is possible that introns do not have a single origin, and therefore cannot be explained by a single hypothesis.

### Splicing can produce multiple transcripts from the same gene

One consequence of the splicing process is greater complexity in gene expression in eukaryotes. A single primary transcript can be spliced into different mRNAs by the inclusion of different sets of exons, a process called **alternative splicing**.

Evidence indicates that the normal pattern of splicing is important to an organism's function. It has been estimated that 15% of known human genetic disorders are due to altered splicing. Mutations in the signals for splicing can introduce new splice sites or can abolish normal patterns of splicing. (In chapter 16 we consider how alternative splicing can be used to regulate gene expression.)

Although many cases of alternative splicing have been documented, the recent completion of the reference sequence of the human genome, along with other large data sets of expressed sequences, now allow large-scale comparisons between sequences found in mRNAs and in the genome. Three different computer-based analyses have been performed, producing results that are in rough agreement. These initial genomic assessments indicate a range of 35 to 59% for human genes that exhibit some form of alternative splicing. If we pick the middle ground of around 40%, this result still vastly increases the number of potential proteins encoded by the 25,000 genes in the human genome.

It is important to note that these analyses are primarily computer-based, and the functions of the possible spliced products have been investigated for only a small part of the potentially spliced genes. These analyses, however, do explain how the 25,000 genes of the human genome can encode the more than 80,000 different mRNAs reported to exist in human cells. The emerging field of proteomics addresses the number and functioning of proteins encoded by the human genome.

### Learning Outcomes Review 15.5

In prokaryotes, genes appear to be colinear with their protein products. Eukaryotic genes, by contrast, contain exon regions, which are expressed, and intron sequences, which interrupt the exons. The introns are removed by the spliceosome in a process that leaves the exons joined together. Alternative splicing can generate different mRNAs, and thus different proteins, from the same gene. Recent estimates are that as many as half of human genes may be alternatively spliced.

- What advantages would alternative splicing confer on an organism?

### Learning Outcomes

1. Explain why the tRNA charging reaction is critical to translation.
2. Identify the tRNA-binding sites in the ribosome.

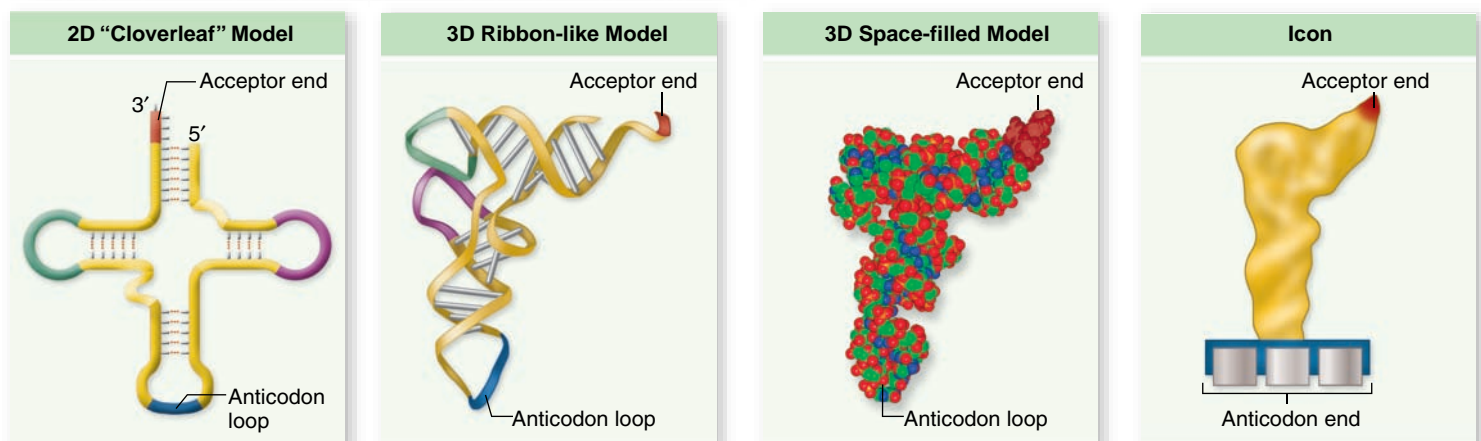

The ribosome is the key organelle in translation, but it also requires the participation of mRNA, tRNA and a host of other factors. Critical to this process is the interaction of the ribosomes with tRNA and mRNA. To understand this, we first examine the structure of the tRNA adapter molecule and the ribosome itself.

## Aminoacyl-tRNA synthetases attach amino acids to tRNA

Each amino acid must be attached to a tRNA with the correct anticodon for protein synthesis to proceed. This covalent attachment is accomplished by the action of activating enzymes called **aminoacyl-tRNA synthetases**. One of these enzymes is present for each of the 20 common amino acids.

### tRNA structure

Transfer RNA is a bifunctional molecule that must be able to interact with mRNA and with amino acids. The structure of tRNAs is highly conserved in all living systems, and it can be formed into a cloverleaf type of structure based on intramolecular base-pairing that produces double-stranded regions. This primary structure is then folded in space to form an L-shaped molecule that has two functional ends: the **acceptor stem** and the **anticodon loop** (figure 15.14).

**Figure 15.14 The structure of tRNA.** Base-pairing within the molecule creates three stem and loop structures in a characteristic cloverleaf shape. The loop at the bottom of the cloverleaf contains the anticodon sequence, which can base-pair with codons in the mRNA. Amino acids are attached to the free, single-stranded —OH end of the acceptor stem. In its final three-dimensional structure, the loops of tRNA are folded into the final L-shaped structure.

The acceptor stem is the 3' end of the molecule, which always ends in 5' CCA 3'. The amino acid is attached to this end of the molecule. The anticodon loop is the bottom loop of the cloverleaf, and it can base-pair with codons in mRNA.

### The charging reaction

The aminoacyl-tRNA synthetases must be able to recognize specific tRNA molecules as well as their corresponding amino acids. Although 61 codons code for amino acids, there are actually not 61 tRNAs in cells, although the number varies from species to species. Therefore, some aminoacyl-tRNA synthetases must be able to recognize more than one tRNA—but each recognizes only a single amino acid.

The reaction catalyzed by the enzymes is called the tRNA **charging reaction**, and the product is an amino acid joined to a tRNA, now called a *charged tRNA*. An ATP molecule provides energy for this endergonic reaction. The charged tRNA produced by the reaction is an activated intermediate that can undergo the peptide bond-forming reaction without an additional input of energy.

The charging reaction joins the acceptor stem to the carboxyl terminus of an amino acid (figure 15.15). Keeping this directionality in mind is critical to understanding the function of the ribosome, because each peptide bond will be formed between the amino group of one amino acid and the carboxyl group of another amino acid.

The correct attachment of amino acids to tRNAs is important because the ribosome does not verify this attachment. Ribosomes can only ensure that the codon–anticodon pairing is correct. In an elegant experiment, cysteine was converted chemically to alanine after the charging reaction, when the amino acid was already attached to tRNA. When this charged tRNA was used in an in vitro protein synthesis system, alanine was in-

corporated in the place of cysteine, showing that the ribosome cannot “proofread” the amino acids attached to tRNA.

In a very real sense, therefore, the charging reaction is the real translation step; amino acids are incorporated into a peptide based solely on the tRNA anticodon and its interaction with the mRNA.

### The ribosome has multiple tRNA-binding sites

The synthesis of any biopolymer can be broken down into initiation, elongation, and termination—you have seen this division for DNA replication as well as for transcription. In the case of translation, or protein synthesis, all three of these steps take place on the ribosome, a large macromolecular assembly consisting of rRNA and proteins. Details of the process by which the two ribosome subunits are assembled during initiation are described shortly.

For the ribosome to function it must be able to bind to at least two charged tRNAs at once so that a peptide bond can be formed between their amino acids, as described in the previous overview. The bacterial ribosome contains three binding sites, summarized in figure 15.16:

- The **P site** (peptidyl) binds to the tRNA attached to the growing peptide chain.
- The **A site** (aminoacyl) binds to the tRNA carrying the next amino acid to be added.
- The **E site** (exit) binds the tRNA that carried the previous amino acid added (see figure 15.16).

Transfer RNAs move through these sites successively during the process of elongation. Relative to the mRNA, the sites are arranged 5' to 3' in the order E, P, and A. The incoming

1. In the first step of the reaction, the amino acid is activated. The amino acid reacts with ATP to produce an intermediate with the carboxyl end of the amino acid attached to AMP. The two terminal phosphates (pyrophosphates) are cleaved from ATP in this reaction.

2. The amino acid-AMP complex remains bound to the enzyme. The tRNA next binds to the enzyme.

3. The second step of the reaction transfers the amino acid from AMP to the tRNA, producing a charged tRNA and AMP. The charged tRNA consists of a specific amino acid attached to the 3' acceptor stem of its RNA.

**Figure 15.15 tRNA charging reaction.** There are 20 different aminoacyl-tRNA synthetase enzymes each specific for one amino acid, such as tryptophan (Trp). The enzyme must also recognize and bind to the tRNA molecules with anticodons specifying that amino acid, ACC for tryptophan. The reaction uses ATP and produces an activated intermediate that will not require further energy for peptide bond formation.

**Figure 15.16** Ribosomes have two subunits.

Ribosome subunits come together and apart as part of a ribosome cycle. The smaller subunit fits into a depression on the surface of the larger one. Ribosomes have three tRNA-binding sites: aminoacyl site (A), peptidyl site (P), and empty site (E).

charged tRNAs enter the ribosome at the A site, transit through the P site, and then leave via the E site.

### The ribosome has both decoding and enzymatic functions

The two functions of the ribosome involve decoding the transcribed message and forming peptide bonds. The decoding function resides primarily in the small subunit of the ribosome. The formation of peptide bonds requires the enzyme **peptidyl transferase**, which resides in the large subunit.

**Figure 15.17** 3-D structure of prokaryotic ribosome.

The complete atomic structure of a prokaryotic large ribosomal subunit has been determined at 2.4-Å resolution. Bases of RNA are white, the polynucleotide backbone is red, and proteins are blue. The faces of each ribosomal subunit are lined with rRNA such that their interaction with tRNAs, amino acids, and mRNA all involve rRNA. Proteins are absent from the active site but abundant everywhere on the surface. The proteins stabilize the structure by interacting with adjacent RNA strands.

Our view of the ribosome has changed dramatically over time. Initially, molecular biologists assumed that the proteins in the ribosome carried out its function and that the rRNA was a structural scaffold necessary to hold the proteins in the correct position. Now this view has mostly been reversed; the ribosome is seen instead as rRNAs that are held in place by proteins. The faces of the two subunits that interact with each other are lined with rRNA, and the parts of both subunits that interact with mRNA, tRNA, and amino acids are also primarily rRNA (figure 15.17). It is now thought that the peptidyl transferase activity resides in an rRNA in the large subunit.

### Learning Outcomes Review 15.6

Transfer RNA has two functional regions, one that bonds with an amino acid, and the other that can base-pair with mRNA. The tRNA charging reaction joins the carboxyl end of an amino acid to the 3' acceptor stem of its tRNA; without charged tRNAs, translation cannot take place. This reaction is catalyzed by 20 different aminoacyl-tRNA synthetases, one for each amino acid. The ribosome has three different binding sites for tRNA, one for the tRNA adding to the growing peptide chain (P site), one for the next charged tRNA (A site), and one for the previous tRNA, which is now without an amino acid (E site). The ribosome can be thought of as having both a decoding function and an enzymatic function.

- What would be the effect on translation of a mutant tRNA that has an anticodon complementary to a STOP codon?

## 15.7 The Process of Translation

### Learning Outcomes

1. Distinguish between translation initiation and elongation.
2. Explain the elongation cycle.
3. Compare translation on the RER and in the cytoplasm.

The process of translation is one of the most complex and energy-expensive tasks that cells perform. An overview of the process, as you saw earlier, is perhaps deceptively simple: The mRNA is threaded through the ribosome, while tRNAs carrying amino acids bind to the ribosome, where they interact with mRNA by base-pairing with the mRNA's codons. The ribosome and tRNAs position the amino acids such that peptide bonds can be formed between each new amino acid and the growing polypeptide.

### Initiation requires accessory factors

As mentioned earlier, the start codon is AUG, which also encodes the amino acid methionine. The ribosome usually uses the first AUG it encounters in an mRNA strand to signal the start of translation.

**Figure 15.18 Initiation of translation.** In prokaryotes, initiation factors play key roles in positioning the small ribosomal subunit, the initiator tRNA<sup>fMet</sup>, and the mRNA. When the tRNA<sup>fMet</sup> is positioned over the first AUG codon of the mRNA, the large ribosomal subunit binds, forming the E, P, and A sites where successive tRNA molecules bind to the ribosomes, and polypeptide synthesis begins. Ribosomal subunits are shown as a cutaway sectioned through the middle.

### Prokaryotic initiation

In prokaryotes, the **initiation complex** includes a special **initiator tRNA** molecule charged with a chemically modified methionine, *N-formylmethionine*. The initiator tRNA is shown as tRNA<sup>fMet</sup>. The initiation complex also includes the small ribosomal subunit and the mRNA strand (figure 15.18). The small subunit is positioned correctly on the mRNA due to a conserved sequence in the 5' end of the mRNA called the

**ribosome-binding sequence (RBS)** that is complementary to the 3' end of a small subunit rRNA.

A number of initiation factors mediate this interaction of the ribosome, mRNA, and tRNA<sup>fMet</sup> to form the initiation complex. These factors are involved in initiation only and are not part of the ribosome.

Once the complex of mRNA, initiator tRNA, and small ribosomal subunit is formed, the large ribosomal subunit is added, and

**Figure 15.19 Peptide bond formation.** Peptide bonds are formed between a “new” charged tRNA in the A site and the growing chain attached to the tRNA in the P site. The bond forms between the amino group of the new amino acid and the carboxyl group of the growing chain. This breaks the bond between the growing chain and its tRNA, transferring it to the A site as the new amino acid remains attached to its tRNA.

translation can begin. With the formation of the complete ribosome, the initiator tRNA is bound to the P site with the A site empty.

### Eukaryotic initiation

Initiation in eukaryotes is similar, although it differs in two important ways. First, in eukaryotes, the initiating amino acid is methionine rather than *N*-formylmethionine. Second, the initiation complex is far more complicated than in prokaryotes, containing nine or more protein factors, many consisting of several subunits. Eukaryotic mRNAs also lack an RBS. The small subunit binds to the mRNA initially by binding to the 5' cap of the mRNA.

### Elongation adds successive amino acids

When the entire ribosome is assembled around the initiator tRNA and mRNA, the second charged tRNA can be brought to the ribosome and bind to the empty A site. This requires an **elongation factor** called **EF-Tu**, which binds to the charged tRNA and to GTP.

A peptide bond can then form between the amino acid of the initiator tRNA and the newly arrived charged tRNA in the A site. The geometry of this bond relative to the two charged tRNAs is critical to understanding the process. Remember that an amino acid is attached to a tRNA by its carboxyl terminus. The peptide bond is formed between the amino end of the incoming amino acid (in the A site) and the carboxyl end of the growing chain (in the P site) (figure 15.19).

The addition of successive amino acids is a series of events that occur in a cyclic fashion. Figure 15.20 shows the details of the elongation cycle.

1. **Matching tRNA anticodon with mRNA codon.** Each new charged tRNA comes to the ribosome bound to EF-Tu and GTP. The charged tRNA binds to the A site if its anticodon is complementary to the mRNA codon in the A site.

After binding, GTP is hydrolyzed, and EF-Tu-GDP dissociates from the ribosome where it is recycled by another factor. This two-step binding and hydrolysis of GTP is thought to increase the accuracy of translation.

**Figure 15.20 Elongation cycle.**

Numbering of the cycle corresponds to the numbering in the text. The cycle begins when a new charged tRNA with anticodon matching the codon of the mRNA in the A site arrives with EF-Tu. The EF-Tu hydrolyzes GTP and dissociates from the ribosome. A peptide bond is formed between the amino acid in the A site and the growing chain in the P site, transferring the growing chain to the A site, and leaving the tRNA in the P site empty. Ribosome translocation requires another elongation factor and GTP hydrolysis. This moves the tRNA in the A site into the P site, the next codon in the mRNA into the A site, and the empty tRNA into the E site.

**Figure 15.21 Termination of protein synthesis.** There is no tRNA with an anticodon complementary to any of the three termination signal codons. When a ribosome encounters a termination codon, it stops translocating. A specific protein release factor facilitates the release of the polypeptide chain by breaking the covalent bond that links the polypeptide to the P site tRNA.

- 2. Peptide bond formation.** Peptidyl transferase, located in the large subunit, catalyzes the formation of a peptide bond between the amino group of the amino acid in the A site and the carboxyl group of the growing chain. This also breaks the bond between the growing chain and the tRNA in the P site leaving it empty (no longer charged). The overall result of this is to transfer the growing chain to the tRNA in the A site.
- 3. Translocation of the ribosome.** After the peptide bond has been formed, the ribosome moves relative to the mRNA and the tRNAs. The next codon in the mRNA shifts into the A site, and the tRNA with the growing chain moves to the P site. The uncharged tRNA formerly in the P site is now in the E site, and it will be ejected in the next cycle. This translocation step requires the accessory factor EF-G and the hydrolysis of another GTP.

This elongation cycle continues with each new amino acid added. The ribosome moves down the mRNA in a 5'-to-3' direction, reading successive codons. The tRNAs move through the ribosome in the opposite direction, from the A site to the P site and finally the E site, before they are ejected as empty tRNAs, which can be charged with another amino acid and then used again.

### Wobble pairing

As mentioned, there are fewer tRNAs than codons. This situation is easily rationalized because the pairing between the 3' base of the codon and the 5' base of the anticodon is less stringent than normal. In some tRNAs, the presence of modified bases with less accurate pairing in the 5' position of the anticodon enhances this flexibility. This effect is referred to as

### Figure 15.22 Synthesis of proteins on RER.

Proteins that are synthesized on RER arrive at the ER because of sequences in the peptide itself. A signal sequence in the amino terminus of the polypeptide is recognized by the signal recognition particle (SRP). This complex docks with a receptor associated with a channel in the ER. The peptide passes through the channel into the lumen of the ER as it is synthesized.

**wobble pairing** because these tRNAs can “wobble” a bit on the mRNA, so that a single tRNA can “read” more than one codon in the mRNA.

### Inquiry question

? How is the wobble phenomenon related to the number of tRNAs and the degeneracy of the genetic code?

### Termination requires accessory factors

Elongation continues in this fashion until a chain-terminating stop codon is reached (for example, UAA in figure 15.21). These stop codons do not bind to tRNA; instead, they are recognized by release factors, proteins that release the newly made polypeptide from the ribosome.

### Proteins may be targeted to the ER

In eukaryotes, translation can occur either in the cytoplasm or on the RER. Proteins that are translated on the RER are targeted there based on their own initial amino acid sequence. The ribosomes found on the RER are actively translating and are not permanently bound to the ER.

A polypeptide that starts with a short series of amino acids called a **signal sequence** is specifically recognized and bound by a cytoplasmic complex of proteins called the *signal recognition particle (SRP)*. The complex of signal sequence and SRP is in turn recognized by a receptor protein in the ER membrane. The binding of the ER receptor to the signal sequence/SRP complex holds the ribosome engaged in translation of the protein on the ER membrane, a process called *docking* (figure 15.22).

As the protein is assembled, it passes through a channel formed by the docking complex and into the interior ER compartment, the cisternal space. This is the basis for the docking metaphor—the ribosome is not actually bound to the ER itself, but with the newly synthesized protein entering the ER, the ribosome is like a boat tied to a dock with a rope.

The basic mechanism of protein translocation across membranes by the SRP and its receptor and channel complex has been conserved across all three cell types: eukaryotes, bacteria, and archaea. Given that only eukaryotic cells have an endomembrane system, this universality may seem curious; however, bacteria and archaea both export proteins through their plasma membrane, and the mechanism used is similar to the way in which eukaryotes move proteins into the cisternal space of the ER.

Once within the ER cisternal space, or lumen, the newly synthesized protein can be modified by the addition of sugars (glycosylation) and transported by vesicles to the Golgi apparatus (see chapter 4). This is the beginning of the protein-trafficking pathway that can lead to other intracellular targets, to incorporation into the plasma membrane, or to release outside of the cell itself.

### Learning Outcomes Review 15.7

Translation initiation involves the interaction of the small ribosomal subunit with mRNA and a charged initiator tRNA. The elongation cycle involves bringing in new charged tRNAs to the ribosome's A site, forming peptide bonds between amino acids, and translocating the ribosome along the mRNA chain. The tRNAs transit through the ribosome from A to P to E sites during the process. In eukaryotes, signal sequences of a newly forming polypeptide may target it and its ribosome to be moved to the RER. Polypeptides formed on the RER enter the cisternal space rather than being released into the cytoplasm.

- What stages of translation require energy?

## 15.8 Summarizing Gene Expression

Because of the complexity of the process of gene expression, it is worth stepping back to summarize some key points:

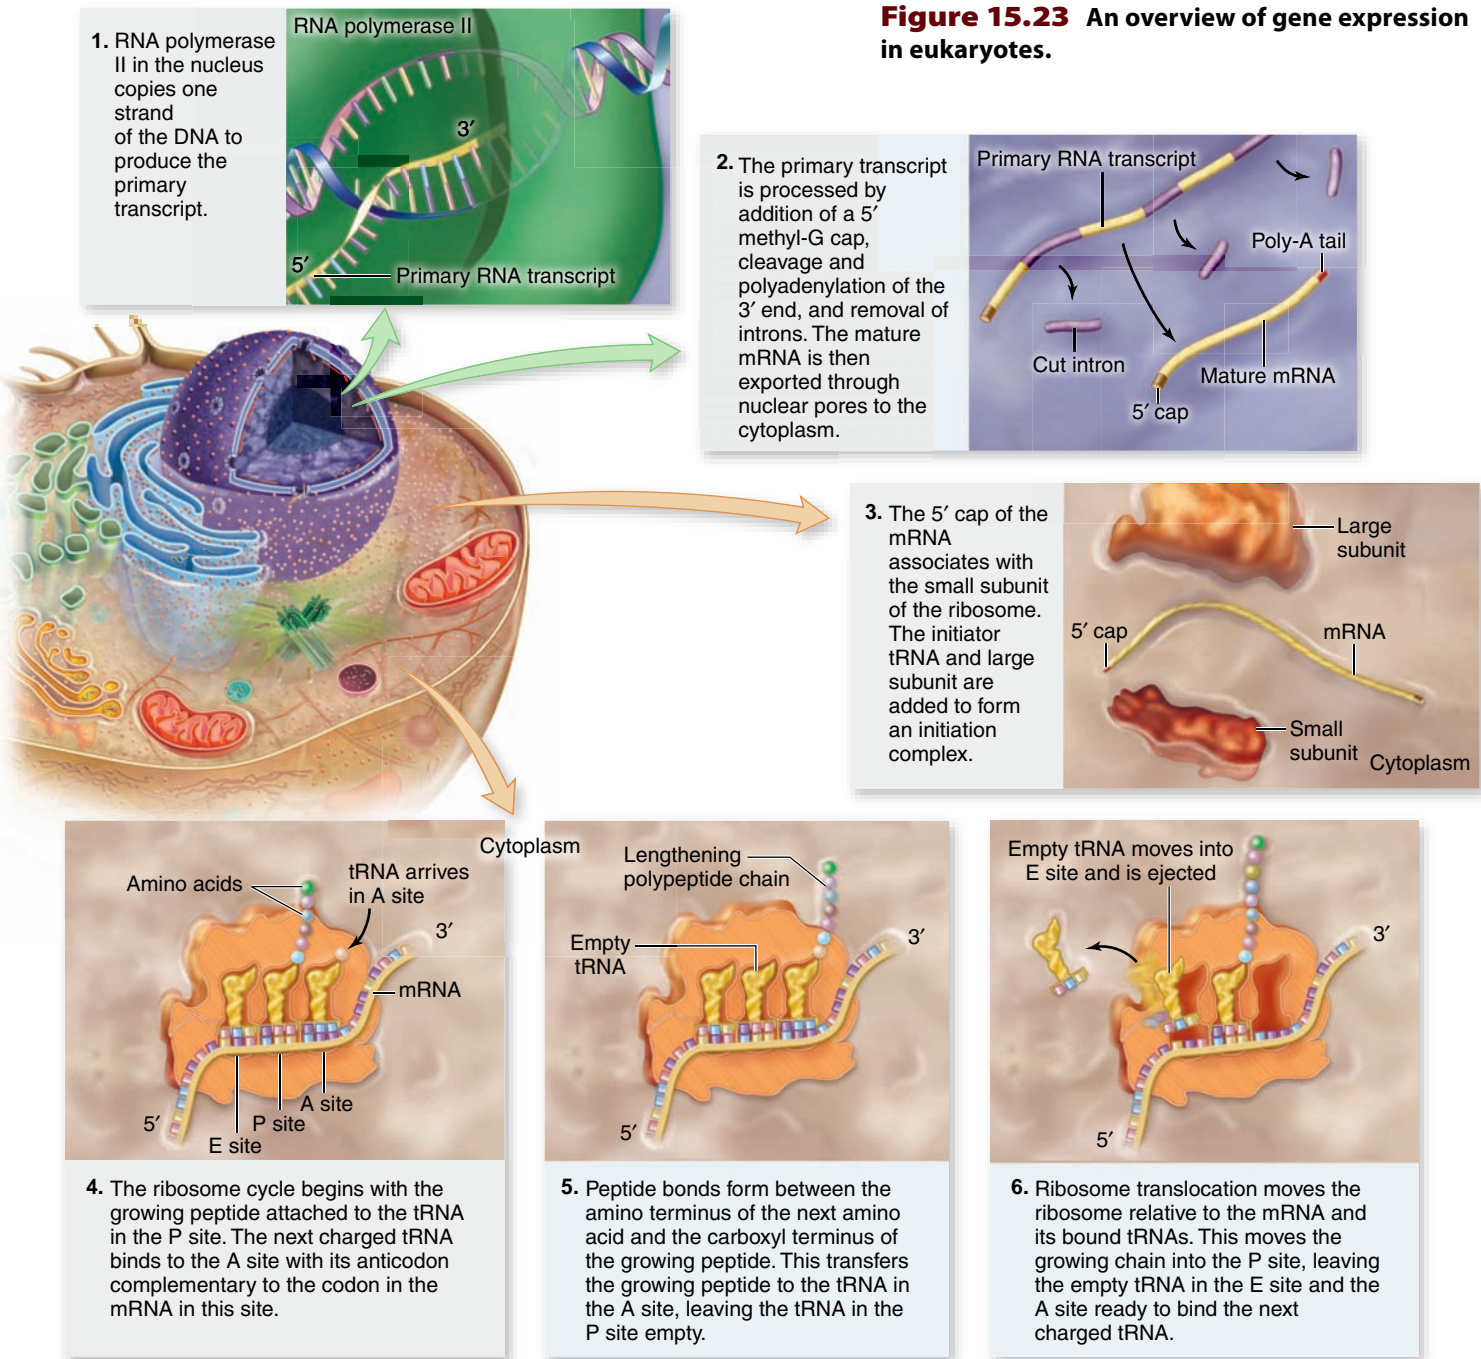

- The process of gene expression converts information in the genotype into the phenotype.
- A copy of the gene in the form of mRNA is produced by transcription, and the mRNA is used to direct the synthesis of a protein by translation.
- Both transcription and translation can be broken down into initiation, elongation, and termination cycles that produce their respective polymers. (The same is true for DNA replication.)
- Eukaryotic gene expression is much more complex than that of prokaryotes.

The nature of eukaryotic genes with their intron and exon components greatly complicates the process of gene expression by requiring additional steps between transcription and translation. The production and processing of eukaryotic mRNAs also takes place in the nucleus, whereas translation takes place in the cytoplasm. This necessitates the transport of the mRNA through the nuclear pores to the cytoplasm before translation can take place. The entire eukaryotic process is summarized in figure 15.23.

A number of differences can be highlighted between gene expression in prokaryotes and in eukaryotes. Table 15.2 (on p. 298) summarizes these main points.

### Learning Outcome Review 15.8

The greater complexity of eukaryotic gene expression is related to the functional organization of the cell, with DNA in the nucleus and ribosomes in the cytoplasm. The differences in gene expression between prokaryotes and eukaryotes is mainly in detail, but some differences have functional significance.

**Figure 15.23** An overview of gene expression in eukaryotes.

<b>TABLE 15.2</b> Differences Between Prokaryotic and Eukaryotic Gene Expression		
<b>Characteristic</b>	<b>Prokaryotes</b>	<b>Eukaryotes</b>
Introns	No introns, although some archaeal genes possess them.	Most genes contain introns.
Number of genes in mRNA	Several genes may be transcribed into a single mRNA molecule. Often these have related functions and form an operon, which helps coordinate regulation of biochemical pathways.	Only one gene per mRNA molecule; regulation of pathways accomplished in other ways.
Site of transcription and translation	No membrane-bounded nucleus, transcription and translation are coupled.	Transcription in nucleus; mRNA is transported to the cytoplasm for translation.
Initiation of translation	Begins at AUG codon preceded by special sequence that binds the ribosome.	Begins at AUG codon preceded by the 5' cap (methylated GTP) that binds the ribosome.
Modification of mRNA after transcription	None; translation begins before transcription is completed. Transcription and translation are coupled.	A number of modifications while the mRNA is in the nucleus: Introns are removed and exons are spliced together; a 5' cap is added; a poly-A tail is added.

## 15.9 Mutation: Altered Genes

### Learning Outcomes

1. Describe the effects of different point mutations.
2. Explain the nature of triplet repeat expansion.
3. List the different chromosomal mutations and their effects.

One way to analyze the function of genes is to find or to induce mutations in a gene to see how this affects its function. In terms of the organism, however, inducing mutations is usually negative; most mutations have deleterious effects on the phenotype of the organism. In chapter 13, you saw how a number of genetic diseases, such as sickle cell anemia, are due to single base changes. We now consider mutations from the perspective of how the DNA itself is altered. Mutational changes range from the alteration of a single base to the loss of genetic material (deletion) to the loss of an entire chromosome. The change of a single base can result in changing a single amino acid in a protein, and this in turn can lead to a debilitating clinical phenotype. This is illustrated for the case of sickle cell anemia in figure 15.24. In the sickle cell allele, a single A is changed to a T resulting in a glutamic acid being replaced with a valine. The substitution of non-polar valine causes the beta chains to aggregate into polymers, and this alters the shape of the cells, leading to the disease state.

### Point mutations affect a single site in the DNA

A mutation that alters a single base is termed a **point mutation**. The mutation can be either the substitution of one base for another, or the deletion or addition of a single base (or a small number of bases).

#### Base substitution

The substitution of one base pair for another in DNA is called a **base substitution mutation**. Because of the degenerate nature

of the genetic code, base substitution may or may not alter the amino acid encoded. If the new codon from the base substitution still encodes the same amino acid, we say the mutation is *silent* (figure 15.25*b*). When base substitution changes an amino acid in a protein, it is also called a **missense mutation** as the “sense” of the codon produced after transcription of the mutant gene will be altered (figure 15.25*c*). These fall into two classes, *transitions* and *transversions*. A transition does not change the type of bases in the base pair, that is, a pyrimidine is substituted for a pyrimidine, or purine for purine. In contrast, a transversion does change the type of bases in a base pair, that is, pyrimidine to purine or the reverse. A variety of human genetic diseases, including sickle cell anemia, are caused by base substitutions.

#### Nonsense mutations

A special category of base substitution arises when a base is changed such that the transcribed codon is converted to a stop codon (see figure 15.25*d*). We call these **nonsense mutations** because the mutation does not make “sense” to the translation apparatus. The stop codon results in premature termination of translation and leads to a truncated protein. How short the resulting protein is depends on where a stop codon has been introduced in the gene.

#### Frameshift mutations

The addition or deletion of a single base has much more profound consequences than does the substitution of one base for another. These mutations are called *frameshift mutations* because they alter the reading frame in the mRNA downstream of the mutation. This class of mutations was used by Crick and Brenner, as described earlier in the chapter, to infer the nature of the genetic code.

Changing the reading frame early in a gene, and thus in its mRNA transcript, means that the majority of the protein will be altered. Frameshifts also can cause premature termination of translation because 3 in 64 codons are stop codons, which represents a high probability in the sequence that has been randomized by the frameshift.

**Figure 15.24** Sickle cell anemia is caused by an altered protein. Hemoglobin is composed of a tetramer of two  $\alpha$ -globin and two  $\beta$ -globin chains. The sickle cell allele of the  $\beta$ -globin gene contains a single base change resulting in the substitution of Val for Glu. This creates a hydrophobic region on the surface of the protein that is “sticky” leading to their association into long chains that distort the shape of the red blood cells.

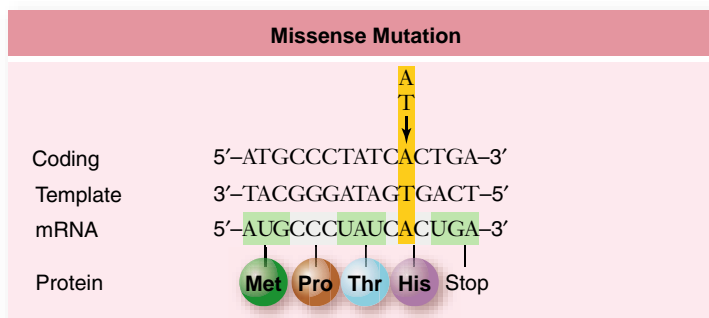

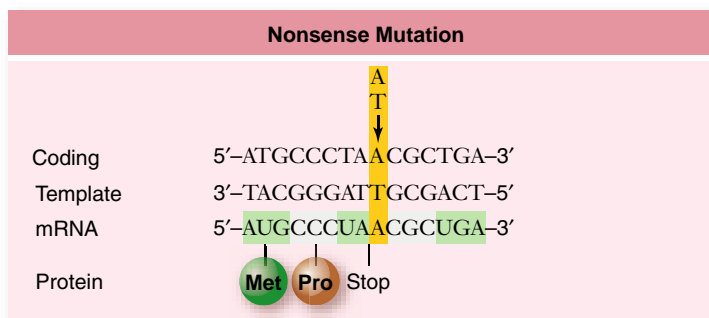

a.

b.

c.

d.

**Figure 15.25 Types of mutations.** *a.* A hypothetical gene is shown with encoded mRNA and protein. Arrows above the gene indicate sites of mutations described in the rest of the figure. *b.* Silent mutation. A change in the third position of a codon is often silent due to degeneracy in the genetic code. In this case T/A to C/G mutation does not change the amino acid encoded (proline). *c.* Missense mutation. The G/C to A/T mutation changes the amino acid encoded from arginine to histidine. *d.* Nonsense mutation. The T/A to A/T mutation produces a UAA stop codon in the mRNA.

### Triplet repeat expansion mutations

Given the long history of molecular genetics, and the relatively short time that molecular analysis has been possible on humans, it is surprising that a new kind of mutation was discovered in humans. However, one of the first genes isolated that was associated with human disease, the gene for *Huntington disease*, provided a new kind of mutation. The gene for Huntington contains a triplet sequence of DNA that is repeated, and this repeat unit is expanded in the disease allele relative to the normal allele. Since this initial discovery, at least 20 other human genetic diseases appear to be due to this mechanism. The prevalence of this kind of mutation is unknown, but at present humans and mice are the only organisms in which they have been observed, implying that they may be limited to vertebrates, or even mammals. No such mutation has ever been found in *Drosophila* for example.

The expansion of the triplet can occur in the coding region or in noncoding transcribed DNA. In the case of Huntington disease, the repeat unit is actually in the coding region of the gene where the triplet encodes glutamine, and expansion results in a polyglutamine region in the protein. A number of other neurodegenerative disorders also show this kind of mutation. In the case of fragile-X syndrome, an inherited form of mental retardation, the repeat is in noncoding DNA.

### Chromosomal mutations change the structure of chromosomes

Point mutations affect a single site in a chromosome, but more extensive changes can alter the structure of the chromosome itself, resulting in **chromosomal mutations**. Many human cancers are associated with chromosomal abnormalities, so these are of great clinical relevance. We briefly consider possible alterations to chromosomal structure, all of which are summarized in figure 15.26.

#### Deletions

A **deletion** is the loss of a portion of a chromosome. Frameshifts can be caused by one or more small deletions, but much larger regions of a chromosome may also be lost. If too much information is lost, the deletion is usually fatal to the organism.

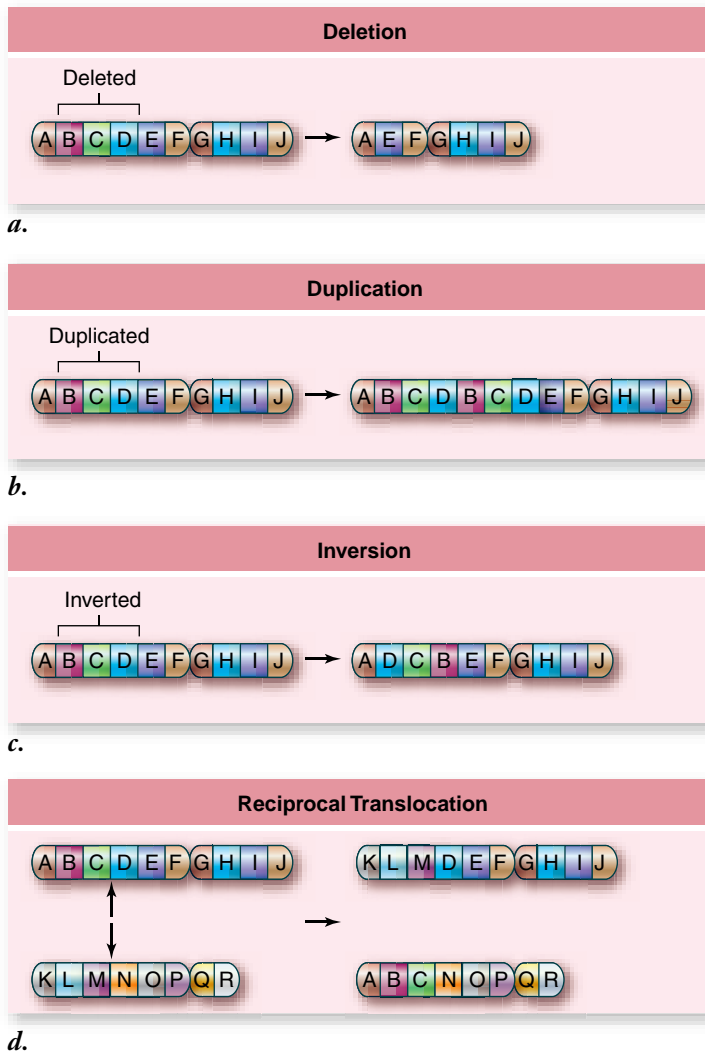

One human syndrome that is due to a deletion is *cri-du-chat*, which is French for “cry of the cat” after the noise made by children with this syndrome. Cri-du-chat syndrome is caused by a large deletion from the short arm of chromosome 5. It usually results in early death, although many affected individuals show a normal lifespan. It has a variety of effects, including respiratory problems.

#### Duplications

The **duplication** of a region of a chromosome may or may not lead to phenotypic consequences. Effects depend upon the location of the “breakpoints” where the duplication occurred. If the duplicated region does not lie within a gene, there may be no effect. If the duplication occurs next to the original region, it is termed a *tandem duplication*. These tandem duplications are important in the evolution of families of related genes, such as the globin family that encode the protein hemoglobin.

#### Inversions

An **inversion** results when a segment of a chromosome is broken in two places, reversed, and put back together. An inversion

**Figure 15.26 Chromosomal mutations.** Larger-scale changes in chromosomes are also possible. Material can be deleted (a), duplicated (b), and inverted (c). Translocations occur when one chromosome is broken and becomes part of another chromosome. This often occurs where both chromosomes are broken and exchange material, an event called a reciprocal translocation (d).

may not have an effect on phenotype if the sites where the inversion occurs do not break within a gene. In fact, although humans all have the “same” genome, the order of genes in all individuals in a population is not precisely the same due to inversions that occur in different lineages.

### Translocations

If a piece of one chromosome is broken off and joined to another chromosome, we call this a **translocation**. Translocations are complex because they can cause problems during meiosis, particularly when two different chromosomes try to pair with each other during meiosis I.

Translocations can also move genes from one chromosomal region to another in a manner that changes the expression of genes in the region involved. Two forms of leukemia have been shown to be associated with translocations that move oncogenes into regions of a chromosome where they are expressed inappropriately in blood cells.

## Mutations are the starting point of evolution

If no changes occurred in genomes over time, then there could be no evolution. Too much change, however, is harmful to the individual with a greatly altered genome. Thus a delicate balance must exist between the amount of new variation that arises in a species and the health of individuals in the species. This topic is explored in more detail later in the book when we consider evolution and population genetics (chapter 20).

The larger scale alteration of chromosomes has also been important in evolution, although its role is poorly understood. It is clear that gene families arise by the duplication of an ancestral gene, followed by the functional divergence of the duplicated copies. It is also clear that even among closely related species, the number and arrangements of genes on chromosomes can differ. Large-scale rearrangements may have occurred.

## Our view of the nature of genes has changed with new information

In this and the preceding chapters, we have seen multiple views of genes. Mendel used crosses to follow traits determined by what we now call genes. The behavior of these genes can be predicted based on the behavior of chromosomes during meiosis. Morgan and others learned to map the location of genes on chromosomes. These findings led to the view of genes as abstract entities that could be followed through generations and mapped to chromosomal locations like “beads on a string,” with the beads being genes and the string the chromosome.

The original molecular analysis of genes led to the simple one-gene/one-polypeptide paradigm. This oversimplification was changed when geneticists observed the alternative splicing of eukaryotic genes, which can lead to multiple protein products from the same genetic information. Furthermore, some genes do not encode proteins at all, but only RNA, which can either be a part of the gene expression machinery (rRNA, tRNA, and other forms) or can itself act as an enzyme. Other stretches of DNA are important for regulating genes but are not expressed. All of these findings make a simple definition of genes difficult.

We are left with the rich complexity of the nature of genes, which defies simple definition. To truly understand the nature of genes we must consider both their molecular nature as well as their phenotypic expression. This brings us full circle, back to the relationship between genotype and phenotype, with a much greater appreciation for the complexity of this relationship.

### Learning Outcomes Review 15.9

Point mutations (single-base changes, additions, or deletions) include missense mutations that cause substitution of one amino acid for another, nonsense mutations that halt transcription, and frameshift mutations that throw off the correct reading of codons. Triplet repeat expansion is the abnormal duplication of a codon with each round of cell division. Mutations affecting chromosomes include deletions, duplications, inversions, and translocations.

- **Would an inversion or duplication always be expected to have a phenotype?**

## Chapter Review

### 15.1 The Nature of Genes

**Garrod concluded that inherited disorders can involve specific enzymes.**

Garrod found that alkaptonuria is due to an altered enzyme.

**Beadle and Tatum showed that genes specify enzymes.**

*Neurospora* mutants unable to synthesize arginine were found to lack specific enzymes. Beadle and Tatum advanced the “one gene/one polypeptide” hypothesis (figure 15.1).

**The central dogma describes information flow in cells as DNA to RNA to protein (figure 15.2).**

We call the DNA strand copied to mRNA the template (antisense) strand; the other the coding (sense) strand.

**Transcription makes an RNA copy of DNA.**

**Translation uses information in RNA to synthesize proteins.**

An adapter molecule, tRNA, is required to connect the information in mRNA into the sequence of amino acids.

**RNA has multiple roles in gene expression.**

### 15.2 The Genetic Code

**The code is read in groups of three.**

Crick and Brenner showed that the code is nonoverlapping and is read in groups of three. This finding established the concept of reading frame.

**Nirenberg and others deciphered the code.**

A codon consists of 3 nucleotides, so there are 64 possible codons. Three codons signal “stop,” and one codon signals “start” and also encodes methionine. Thus 61 codons encode the 20 amino acids.

**The code is degenerate but specific.**

Many amino acids have more than one codon, but each codon specifies only a single amino acid.

**The code is practically universal, but not quite.**

In some mitochondrial and protist genomes, a STOP codon is read as an amino acid; otherwise the code is universal.

### 15.3 Prokaryotic Transcription

**Prokaryotes have a single RNA polymerase.**

Prokaryotic RNA polymerase exists in two forms: core polymerase, which can synthesize mRNA; and holoenzyme, core plus  $\sigma$  factor, which can accurately initiate synthesis (figure 15.6).

**Initiation occurs at promoters.**

Initiation requires a start site and a promoter. The promoter is upstream of the start site, and binding of RNA polymerase holoenzyme to its  $-35$  region positions the polymerase properly.

**Elongation adds successive nucleotides.**

Transcription proceeds in the 5'-to-3' direction. The transcription bubble contains RNA polymerase, the locally unwound DNA template, and the growing mRNA transcript (figure 15.7).

**Termination occurs at specific sites.**

Terminators consist of complementary sequences that form a double-stranded hairpin loop where the polymerase pauses (figure 15.8).

**Prokaryotic transcription is coupled to translation.**

Translation begins while mRNAs are still being transcribed.

### 15.4 Eukaryotic Transcription

**Eukaryotes have three RNA polymerases.**

RNA polymerase I transcribes rRNA; polymerase II transcribes mRNA and some snRNAs; polymerase III transcribes tRNA.

**Each polymerase has its own promoter.**

**Initiation and termination differ from that in prokaryotes.**

Unlike prokaryotic promoters, RNA polymerase II promoters require a host of transcription factors. Although termination sites exist, the end of the mRNA is modified after transcription.

**Eukaryotic transcripts are modified (figure 15.11).**

After transcription, a methyl-GTP cap is added to the 5' end of the transcript. A poly-A tail is added to the 3' end. Noncoding internal regions are also removed by splicing.

### 15.5 Eukaryotic pre-mRNA Splicing

**Eukaryotic genes may contain interruptions.**

Coding DNA (an exon) is interrupted by noncoding introns. These introns are removed by splicing (figure 15.13).

**The spliceosome is the splicing organelle.**

snRNPs recognize intron–exon junctions and recruit spliceosomes. The spliceosome ultimately joins the 3' end of the first exon to the 5' end of the next exon.

**Splicing can produce multiple transcripts from the same gene.**

### 15.6 The Structure of tRNA and Ribosomes

**Aminoacyl-tRNA synthetases attach amino acids to tRNA.**

The tRNA charging reaction attaches the carboxyl terminus of an amino acid to the 3' end of the correct tRNA (figure 15.15).

**The ribosome has multiple tRNA-binding sites (figure 15.16).**

A charged tRNA first binds to the A site, then moves to the P site where its amino acid is bonded to the peptide chain, and finally, without its amino acid, moves to the E site from which it is released.

**The ribosome has both decoding and enzymatic functions.**

Ribosomes hold tRNAs and mRNA in position for a ribosomal enzyme to form peptide bonds.

### 15.7 The Process of Translation

**Initiation requires accessory factors.**

In prokaryotes, initiation-complex formation is aided by the ribosome-binding sequence (RBS) of mRNA, complementary to a small subunit. Eukaryotes use the 5' cap for the same function.

**Elongation adds successive amino acids (figure 15.20).**

As the ribosome moves along the mRNA, new amino acids from charged tRNAs are added to the growing peptide (figure 15.19).

**Termination requires accessory factors.**

Stop codons are recognized by termination factors.

**Proteins may be targeted to the ER.**

In eukaryotes, proteins with a signal sequence in their amino terminus bind to the SRP, and this complex docks on the ER. (15.8 Summary is omitted.)

### 15.9 Mutation: Altered Genes

**Point mutations affect a single site in the DNA.**

Base substitutions exchange one base for another, and frameshift mutations involve the addition or deletion of a base. Triplet repeat expansion mutations can cause genetic diseases.

**Chromosomal mutations change the structure of chromosomes.**

Chromosomal mutations include additions, deletions, inversions, or translocations.

**Mutations are the starting point of evolution.**

**Our view of the nature of genes has changed with new information.**

## Review Questions

### UNDERSTAND

- The experiments with nutritional mutants in *Neurospora* by Beadle and Tatum provided evidence that
  - bread mold can be grown in a lab on minimal media.
  - X-rays can damage DNA.
  - cells need enzymes.
  - genes specify enzymes.
- What is the *central dogma* of molecular biology?
  - DNA is the genetic material.
  - Information passes from DNA directly to protein.
  - Information passes from DNA to RNA to protein.
  - One gene encodes only one polypeptide.
- In the genetic code, one codon
  - consists of three bases.
  - specifies a single amino acid.
  - specifies more than one amino acid.
  - both a & b
- Eukaryotic transcription differs from prokaryotic in that
  - eukaryotes have only one RNA polymerase.
  - eukaryotes have three RNA polymerases.
  - prokaryotes have three RNA polymerases.
  - both a & c
- An anticodon would be found on which of the following types of RNA?
  - snRNA (small nuclear RNA)
  - mRNA (messenger RNA)
  - tRNA (transfer RNA)
  - rRNA (ribosomal RNA)
- RNA polymerase binds to a \_\_\_\_\_ to initiate \_\_\_\_\_.
  - mRNA; translation
  - promoter; transcription
  - primer; transcription
  - transcription factor; translation
- During translation, the codon in mRNA is actually “read” by
  - the A site in the ribosome.
  - the P site in the ribosome.
  - the anticodon in a tRNA.
  - the anticodon in an amino acid.

### APPLY

- Which of the following functions as a “stop” signal for a prokaryotic RNA polymerase?
  - A specific sequence of bases called a terminator
  - The Poly-A site
  - Addition of a 5' cap
  - A region of the mRNA that can base-pair to form a hairpin
- The splicing process
  - occurs in prokaryotes.
  - joins introns together.
  - can produce multiple mRNAs from the same transcript.
  - only joins exons for each gene in one way.

- During translation, the ribosome must move along the mRNA. This movement
  - requires the ribosome to come apart into subunits.
  - requires an accessory factor and energy.
  - does not require energy, but requires the ribosome to change conformation.
  - requires accessory factors and uses energy from peptide bond formation.
- In comparing transcription in prokaryotes and eukaryotes the mRNAs
  - differ in that eukaryotic mRNAs often encode more than one protein.
  - differ in that prokaryotic mRNAs often encode more than one protein.
  - are similar in that both are always colinear with their genes.
  - are similar in that neither is colinear with their genes.
- A nonsense mutation
  - results in large scale change to a chromosome.
  - will lead to the premature termination of transcription.
  - will lead to the premature termination of translation.
  - is the same as a transversion.
- An inversion will
  - necessarily cause a mutant phenotype.
  - only cause a mutant phenotype if the inversion breakpoints fall within a gene.
  - halt transcription in the inverted region because the chromosome is now backwards.
  - interfere with translation of genes in the inverted region.
- What is the relationship between mutations and evolution?
  - Mutations make genes better.
  - Mutations can create new alleles.
  - Mutations happened early in evolution, but not now.
  - There is no relationship between evolution and genetic mutations.

### SYNTHESIZE

- A template strand of DNA has the following sequence:  
3' – CGTTACCCGAGCCGTACGATTAGG – 5'  
Use the sequence information to determine
  - the predicted sequence of the mRNA for this gene.
  - the predicted amino acid sequence of the protein.
- Frameshift mutations often result in truncated proteins. Explain this observation based on the genetic code.
- Describe how each of the following mutations will affect the final protein product (protein begins with START codon). Name the type of mutation.  
Original template strand:  
3' – CGTTACCCGAGCCGTACGATTAGG – 5'
  - 3' – CGTTACCCGAGCCGTAACGATTAGG – 5'
  - 3' – CGTTACCCGATCCGTACGATTAGG – 5'
  - 3' – CGTTACCCGAGCCGTTTCGATTAGG – 5'
- There are a number of features that are unique to bacteria, and others that are unique to eukaryotes. Could any of these features offer the possibility to control gene expression in a way that is unique to either eukaryotes or bacteria?

# Control of Gene Expression

## Chapter Outline

- 16.1 Control of Gene Expression
- 16.2 Regulatory Proteins
- 16.3 Prokaryotic Regulation
- 16.4 Eukaryotic Regulation
- 16.5 Eukaryotic Chromatin Structure
- 16.6 Eukaryotic Posttranscriptional Regulation
- 16.7 Protein Degradation

## Introduction

*In a symphony, various instruments play their own parts at different times; the musical score determines which instruments play when. Similarly, in an organism, different genes are expressed at different times, with a “genetic score,” written in regulatory regions of the DNA, determining which genes are active when. The picture shows the expanded “puff” of this *Drosophila* chromosome, which represents genes that are being actively expressed. Gene expression and how it is controlled is our topic in this chapter.*

## 16.1 Control of Gene Expression

### Learning Outcomes

1. Identify the point at which control of gene expression usually occurs.
2. Describe the usual action of regulatory proteins.
3. List differences between control of gene expression in prokaryotes and that in eukaryotes.

Control of gene expression is essential to all organisms. In prokaryotes, it allows the cell to take advantage of changing environmental conditions. In multicellular eukaryotes, it is critical for directing development and maintaining homeostasis.

### Control usually occurs at the level of transcription initiation

You learned in the previous chapter that gene expression is the conversion of genotype to phenotype—the flow of information from DNA to produce functional proteins that control cellular activities. We could envision controlling this process at any point

along the way, and in fact, examples of control occur at most steps. The most logical place to control this process, however, is at the beginning: production of mRNA from DNA by transcription.

Transcription itself could be controlled at any step, but again, the beginning is the most logical place. Although cells do not always behave in ways that conform to human logic, control of the initiation of transcription is common.

RNA polymerase is key to transcription, and it must have access to the DNA helix and must be capable of binding to the gene's promoter for transcription to begin. **Regulatory proteins** act by modulating the ability of RNA polymerase to bind to the promoter. This idea of controlling the access of RNA polymerase to a promoter is common to both prokaryotes and eukaryotes, but the details differ greatly, as you will see.

These regulatory proteins bind to specific nucleotide sequences on the DNA that are usually only 10–15 nt in length. (Even a large regulatory protein has a “footprint,” or binding area, of only about 20 nt.) Hundreds of these regulatory sequences have been characterized, and each provides a binding site for a specific protein that is able to recognize the sequence. Binding of the protein either *blocks* transcription by getting in the way of RNA polymerase or *stimulates* transcription by facilitating the binding of RNA polymerase to the promoter.

## Control strategies in prokaryotes are geared to adjust to environmental changes

Control of gene expression is accomplished very differently in prokaryotes than it is in eukaryotes. Prokaryotic cells have been shaped by evolution to grow and divide as rapidly as possible, enabling them to exploit transient resources. Proteins in prokaryotes turn over rapidly, allowing these organisms to respond quickly to changes in their external environment by changing patterns of gene expression.

In prokaryotes, the primary function of gene control is to adjust the cell's activities to its immediate environment. Changes in gene expression alter which enzymes are present in response to the quantity and type of available nutrients and the amount of oxygen. Almost all of these changes are fully reversible, allowing the cell to adjust its enzyme levels up or down in response to environment changes.

## Control strategies in eukaryotes are aimed at maintaining homeostasis

The cells of multicellular organisms, in contrast, have been shaped by evolution to be protected from transient changes in their immediate environment. Most of them experience fairly constant conditions. Indeed, *homeostasis*—the maintenance of a constant internal environment—is considered by many to be the hallmark of multicellular organisms. Cells in such organisms respond to signals in their immediate environment (such as growth factors and hormones) by altering gene expression, and in doing so they participate in regulating the body as a whole.

Some of these changes in gene expression compensate for changes in the physiological condition of the body. Others mediate the decisions that actually produce the body, ensuring that the correct genes are expressed in the right cells at the right time during development. Later chapters deal with the details,

but for now we can simplify by saying that the growth and development of multicellular organisms entail a long series of biochemical reactions, each catalyzed by a specific enzyme. Once a particular developmental change has occurred, these enzymes cease to be active, lest they disrupt the events that must follow.

To produce this sequence of enzymes, genes are transcribed in a carefully prescribed order, each for a specified period of time, following a fixed genetic program that may even lead to programmed cell death (**apoptosis**). The one-time expression of the genes that guide a developmental program is fundamentally different from the reversible metabolic adjustments prokaryotic cells make in response to the environment. In all multicellular organisms, changes in gene expression within particular cells serve the needs of the whole organism, rather than the survival of individual cells.

Unicellular eukaryotes also use different control mechanisms from those of prokaryotes. All eukaryotes have a membrane-bounded nucleus, use similar mechanisms to condense DNA into chromosomes, and have the same gene expression machinery, all of which differ from those of prokaryotes.

### Learning Outcomes Review 16.1

Gene expression is usually controlled at the level of transcription initiation. Regulatory proteins bind to specific DNA sequences and affect the binding of RNA polymerase to promoters. Individual protein may either prevent or stimulate transcription. In prokaryotes, regulation is focused on adjusting the cell's activities to the environment to ensure viability. In multicellular eukaryotes, regulation is geared to maintaining internal homeostasis, and even in unicellular forms, this control has mechanisms to deal with a bounded nucleus and multiple chromosomes.

- *Would you expect the control of gene expression in a unicellular eukaryote like yeast to be more like that of humans or E. coli?*

## 16.2 Regulatory Proteins

### Learning Outcomes

1. *Explain how proteins can interact with base pairs without unwinding the helix.*
2. *Describe the common features of DNA-binding motifs.*

The ability of certain proteins to bind to *specific* DNA regulatory sequences provides the basic tool of gene regulation—the key ability that makes transcriptional control possible. To understand how cells control gene expression, it is first necessary to gain a clear picture of this molecular recognition process.

## Proteins can interact with DNA through the major groove

In the past, molecular biologists thought that the DNA helix had to unwind before proteins could distinguish one DNA

sequence from another; only in this way, they reasoned, could regulatory proteins gain access to the hydrogen bonds between base-pairs. We now know it is unnecessary for the helix to unwind because proteins can bind to its outside surface, where the edges of the base-pairs are exposed.

Careful inspection of a DNA molecule reveals two helical grooves winding around the molecule, one deeper than the other. Within the deeper groove, called the **major groove**, the nucleotides' hydrogen bond donors and acceptors are accessible. The pattern created by these chemical groups is unique for each of the four possible base-pair arrangements, providing a ready way for a protein nestled in the groove to read the sequence of bases (figure 16.1).

## DNA-binding domains interact with specific DNA sequences

Protein–DNA recognition is an area of active research; so far, the structures of over 30 regulatory proteins have been analyzed. Although each protein is unique in its fine details, the part of the protein that actually binds to the DNA is much less variable. Almost all of these proteins employ one of a small set of **DNA-binding motifs**. A motif, as described in chapter 3, is a form of three-dimensional substructure that is found in many proteins. These DNA-binding motifs share the property of interacting with specific sequences of bases, usually through the major groove of the DNA helix.

DNA-binding motifs are the key structure within the DNA-binding domain of these proteins. This domain is a functionally distinct part of the protein necessary to bind to DNA in a sequence-specific manner. Regulatory proteins also need to be able to interact with the transcription apparatus, which is accomplished by a different regulatory domain.

Note that two proteins that share the same DNA-binding domain do not necessarily bind to the same DNA sequence. The similarities in the DNA-binding motifs appear in their three-dimensional structure, and not in the specific contacts that they make with DNA.

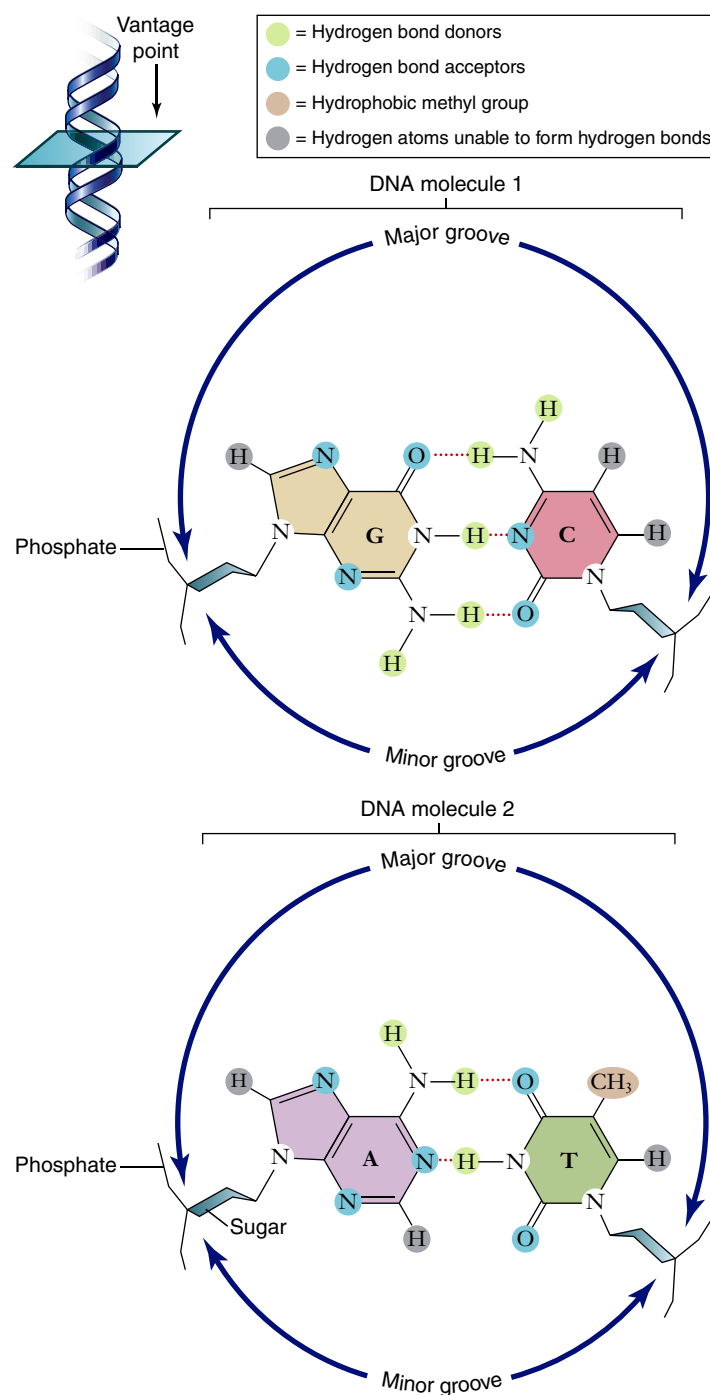

## Several common DNA-binding motifs are shared by many proteins

A limited number of common DNA-binding motifs are found in a wide variety of different proteins. Four of the best known are detailed in the following sections to give the sense of how DNA-binding proteins interact with DNA.

### The helix-turn-helix motif

The most common DNA-binding motif is the **helix-turn-helix**, constructed from two  $\alpha$ -helical segments of the protein linked by a short, nonhelical segment, the “turn” (figure 16.2*a*). As the first motif recognized, the helix-turn-helix motif has since been identified in hundreds of DNA-binding proteins.

A close look at the structure of a helix-turn-helix motif reveals how proteins containing such motifs interact with the major groove of DNA. The helical segments of the motif interact with one another, so that they are held at roughly right angles. When this motif is pressed against DNA, one of the helical

**Figure 16.1** Reading the major groove of DNA. Looking down into the major groove of a DNA helix, we can see the edges of the bases protruding into the groove. Each of the four possible base-pair arrangements (two are shown here) extends a unique set of chemical groups into the groove, indicated in this diagram by differently colored circles. A regulatory protein can identify the base-pair arrangement by this characteristic signature.

segments (called the *recognition helix*) fits snugly in the major groove of the DNA molecule, and the other butts up against the outside of the DNA molecule, helping to ensure the proper positioning of the recognition helix.

Most DNA-regulatory sequences recognized by helix-turn-helix motifs occur in symmetrical pairs. Such sequences

are bound by proteins containing two helix-turn-helix motifs separated by 3.4 nanometers (nm), the distance required for one turn of the DNA helix (see figure 16.2*a*). Having *two* protein–DNA-binding sites doubles the zone of contact between protein and DNA and greatly strengthens the bond between them.

### The homeodomain motif

A special class of helix-turn-helix motifs, the **homeodomain**, plays a critical role in development in a wide variety of eukaryotic organisms, including humans. These motifs were discovered when researchers began to characterize a set of homeotic mutations in *Drosophila* (mutations that cause one body part to be replaced by another). They found that the mutant genes encoded regulatory proteins. Normally these proteins would initiate key stages of development by binding to developmental switch-point genes. More than 50 of these regulatory proteins have been analyzed, and they all contain a nearly identical sequence of 60 amino acids, which was termed the *homeodomain*. The most conserved part of the homeodomain contains a recognition helix of a helix-turn-helix motif. The rest of the homeodomain forms the other two helices of this motif.

### The zinc finger motif

A different kind of DNA-binding motif uses one or more zinc atoms to coordinate its binding to DNA. Called **zinc fingers**, these motifs exist in several forms. In one form, a zinc atom links an  $\alpha$ -helical segment to a  $\beta$ -sheet segment (see chapter 3) so that the helical segment fits into the major groove of DNA.

This sort of motif often occurs in clusters, the  $\beta$  sheets spacing the helical segments so that each helix contacts the major groove. The effect is like a hand wrapped around the DNA with the fingers lying in the major groove. The more zinc fingers in the cluster, the stronger the protein binds to the DNA.

### The leucine zipper motif

In yet another DNA-binding motif, two different protein subunits cooperate to create a single DNA-binding site. This motif is created where a region on one subunit containing several hydrophobic amino acids (usually leucines) interacts with a similar region on the other subunit. This interaction holds the two subunits together at those regions, while the rest of the subunits remain separated. Called a **leucine zipper**, this structure has the shape of a Y, with the two arms of the Y being helical regions that fit into the major groove of DNA (figure 16.2*b*). Because the two subunits can contribute quite different helical regions to the motif, leucine zippers allow for great flexibility in controlling gene expression.

### Learning Outcomes Review 16.2

A DNA helix exhibits a major groove and a minor groove; regulatory proteins interact with DNA by accessing bases along the major groove. These proteins all contain DNA-binding motifs, and they often include one or two  $\alpha$ -helical segments. These motifs form the active part of the DNA-binding domain, and another domain of the protein interacts with the transcription apparatus.

- What would be the effect of a mutation in a helix-turn-helix protein that altered the spacing of the two helices?

**Figure 16.2 Major DNA-binding motifs.** Two different DNA-binding motifs are pictured interacting with DNA. *a*. The helix-turn-helix motif binds to DNA using one  $\alpha$  helix, the recognition helix, to interact with the major groove. The other helix positions the recognition helix. Proteins with this motif are usually dimers, with two identical subunits, each containing the DNA-binding motif. The two copies of the motif (red) are separated by 3.4 nm, precisely the spacing of one turn of the DNA helix. *b*. The leucine zipper acts to hold two subunits in a multisubunit protein together, thereby allowing  $\alpha$ -helical regions to interact with DNA.

## 16.3 Prokaryotic Regulation

### Learning Outcomes

1. Compare how control by induction differs from control by repression.
2. Explain control of gene expression in the *lac operon*.
3. Explain control of gene expression in the *trp operon*.

The details of regulation can be revealed by examining mechanisms used by prokaryotes to control the initiation of transcription. Prokaryotes and eukaryotes share some common themes, but they have some profound differences as well. Later on we discuss eukaryotic systems and concentrate on how they differ from the simpler prokaryotic systems.

### Control of transcription can be either positive or negative

Control at the level of transcription initiation can be either positive or negative. **Positive control** increases the frequency of initiation, and **negative control** decreases the frequency of initiation. Each of these forms of control are mediated by regulatory proteins, but the proteins have opposite effects.

#### Negative control by repressors

Negative control is mediated by proteins called **repressors**. Repressors are proteins that bind to regulatory sites on DNA called **operators** to prevent or decrease the initiation of transcription. They act as a kind of roadblock to prevent the polymerase from initiating effectively.

Repressors do not act alone; each responds to specific effector molecules. Effector binding can alter the conformation of the repressor to either enhance or abolish its binding to DNA. These repressor proteins are allosteric proteins with an active site that binds DNA and a regulatory site that binds effectors. Effector binding at the regulatory site changes the ability of the repressor to bind DNA (see chapter 6 for more details on allosteric proteins).

#### Positive control by activators

Positive control is mediated by another class of regulatory, allosteric proteins called **activators** that can bind to DNA and stimulate the initiation of transcription. These activators enhance the binding of RNA polymerase to the promoter to increase the level of transcription initiation.

Activators are the logical and physical opposites of repressors. Effector molecules can either enhance or decrease activator binding.

### Prokaryotes adjust gene expression in response to environmental conditions

Changes in the environments that bacteria and archaea encounter often result in changes in gene expression. In general, genes encoding proteins involved in catabolic pathways (breaking down mole-

cules) respond oppositely from genes encoding proteins involved in anabolic pathways (building up molecules). In the discussion that follows, we describe enzymes in the catabolic pathway that transports and utilizes the sugar lactose. Later we describe the anabolic pathway that synthesizes the amino acid tryptophan.

As mentioned in the preceding chapter, prokaryotic genes are often organized into operons, multiple genes that are part of a single transcription unit having a single promoter. Genes that are involved in the same metabolic pathway are often organized in this fashion. The proteins necessary for the utilization of lactose are encoded by the ***lac operon***, and the proteins necessary for the synthesis of tryptophan are encoded by the ***trp operon***.

### Inquiry question

- ? What advantage might a bacterium get by linking into a single operon several genes, all of the products of which contribute to a single biochemical pathway?

#### Induction and repression

If a bacterium encounters lactose, it begins to make the enzymes necessary to utilize lactose. When lactose is not present, however, there is no need to make these proteins. Thus, we say that the synthesis of the proteins is *induced* by the presence of lactose. **Induction** therefore occurs when enzymes for a certain pathway are produced in response to a substrate.

When tryptophan is available in the environment, a bacterium will not synthesize the enzymes necessary to make tryptophan. If tryptophan ceases to be available, then the bacterium begins to make these enzymes. **Repression** occurs when bacteria capable of making biosynthetic enzymes do not produce them. In the case of both induction and repression, the bacterium is adjusting to produce the enzymes that are optimal for its immediate environment.

#### Negative control

Knowing that gene expression is probably controlled at the level of initiation of transcription does not tell us whether that control is positive or negative. On the surface, repression may appear to be negative and induction positive; but in the case of both the *lac* and *trp* operons, control is negative by a repressor protein. The key is that the effector proteins have opposite effects on the repressor in induction with those seen in repression.

**Figure 16.3** The *lac* region of the *Escherichia coli* chromosome. The *lac* operon consists of a promoter, an operator, and three genes (*lac Z*, *Y*, and *A*) that encode proteins required for the metabolism of lactose. In addition, there is a binding site for the catabolite activator protein (CAP), which affects RNA polymerase binding to the promoter. The *I* gene encodes the repressor protein, which can bind the operator and block transcription of the *lac* operon.

For either mechanism to work, the molecule in the environment, such as lactose or tryptophan, must produce the proper effect on the gene being regulated. In the case of *lac* induction, the presence of lactose must *prevent* a repressor protein from binding to its regulatory sequence. In the case of *trp* repression, by contrast, the presence of tryptophan must *cause* a repressor protein to bind to its regulatory sequence.

These responses are opposite because the needs of the cell are opposite in anabolic versus catabolic pathways. Each pathway is examined in detail in the following sections to show how protein–DNA interactions allow the cell to respond to environmental conditions.

## The *lac* operon is negatively regulated by the *lac* repressor

The control of gene expression in the *lac* operon was elucidated by the pioneering work of Jaques Monod and François Jacob.

The *lac* operon consists of the genes that encode functions necessary to utilize lactose:  $\beta$ -galactosidase (*lacZ*), lactose per-

mease (*lacY*), and lactose transacetylase (*lacA*), plus the regulatory regions necessary to control the expression of these genes (figure 16.3). In addition, the gene for the *lac* repressor (*lacI*) is linked to the rest of the *lac* operon and is thus considered part of the operon although it has its own promoter. The arrangement of the control regions upstream of the coding region is typical of most prokaryotic operons, although the linked repressor is not.

### Action of the repressor

Initiation of transcription of the *lac* operon is controlled by the *lac* repressor. The repressor binds to the operator, which is adjacent to the promoter (figure 16.4a). This binding prevents RNA polymerase from binding to the promoter. This DNA binding is sensitive to the presence of lactose: The repressor binds DNA in the absence of lactose, but not in the presence of lactose.

### Interaction of repressor and inducer

In the absence of lactose, the *lac* repressor binds to the operator, and the operon is repressed (see figure 16.4a). The effector that controls the DNA binding of the repressor is a metabolite of

**Figure 16.4 Induction of the *lac* operon.** *a.* In the absence of lactose the *lac* repressor binds to DNA at the operator site, thus preventing transcription of the operon. When the repressor protein is bound to the operator site, the *lac* operon is shut down (repressed). *b.* The *lac* operon is transcribed (induced) when CAP is bound and when the repressor is not bound. Allolactose binding to the repressor alters the repressor's shape so it cannot bind to the operator site and block RNA polymerase activity.

lactose, allolactose, which is produced when lactose is available. Allolactose binds to the repressor, altering its conformation so that it no longer can bind to the operator (figure 16.4b). The operon is now induced. Since allolactose allows induction of the operon, it is usually called the inducer.

As the level of lactose falls, allolactose will no longer be available to bind to the repressor, allowing the repressor to bind to DNA again. Thus this system of negative control by the *lac* repressor and its inducer, allolactose, allows the cell to respond to changing levels of lactose in the environment.

Even in the absence of lactose, the *lac* operon is expressed at a very low level. When lactose becomes available, it is transported into the cell and enough allolactose is produced that induction of the operon can occur.

## The presence of glucose prevents induction of the *lac* operon

**Glucose repression** is the preferential use of glucose in the presence of other sugars such as lactose. If bacteria are grown in the presence of both glucose and lactose, the *lac* operon is

not induced. When the glucose is used up, the *lac* operon is induced, allowing lactose to be used as an energy source.

Despite the name *glucose repression*, this mechanism involves an activator protein that can stimulate transcription from multiple catabolic operons, including the *lac* operon. This activator, **catabolite activator protein (CAP)**, is an allosteric protein with cAMP as an effector. This protein is also called **cAMP response protein (CRP)** because it binds cAMP, but we will use the name CAP to emphasize its role as a positive regulator. CAP alone does not bind to DNA, but binding of the effector cAMP to CAP changes its conformation such that it can bind to DNA (figure 16.5). The level of cAMP in cells is reduced in the presence of glucose so that no stimulation of transcription from CAP-responsive operons takes place.

The CAP–cAMP system was long thought to be the sole mechanism of glucose repression. But more recent research has indicated that the presence of glucose inhibits the transport of lactose into the cell. This deprives the cell of the *lac* operon inducer, allolactose, allowing the repressor to bind to the operator. This mechanism, called **inducer exclusion**, is now thought to be the main form of glucose repression of the *lac* operon.

a.

**Figure 16.5 Effect of glucose on the *lac* operon.** Expression of the *lac* operon is controlled by a negative regulator (repressor) and a positive regulator (CAP). The action of CAP is sensitive to glucose levels. **a.** For CAP to bind to DNA, it must bind to cAMP. When glucose levels are low, cAMP is abundant and binds to CAP. The CAP–cAMP complex causes the DNA to bend around it. This brings CAP into contact with RNA polymerase (not shown) making polymerase binding to the promoter more efficient. **b.** High glucose levels produce two effects: cAMP is scarce so CAP is unable to activate the promoter, and the transport of lactose is blocked (inducer exclusion).

b.

Given that inducer exclusion occurs, the role of CAP in the absence of glucose seems superfluous. But in fact, the action of CAP–cAMP allows maximal expression of the operon in the absence of glucose. The positive control of CAP–cAMP is necessary because the promoter of the *lac* operon alone is not efficient in binding RNA polymerase. This inefficiency is overcome by the action of the positive control of the CAP–cAMP activator (see figure 16.5).

## The *trp* operon is controlled by the *trp* repressor

Like the *lac* operon, the *trp* operon consists of a series of genes that encode enzymes involved in the same biochemical path-

way. In the case of the *trp* operon these enzymes are necessary for synthesizing tryptophan. The regulatory region that controls transcription of these genes is located upstream of the genes. The *trp* operon is controlled by a repressor encoded by a gene located outside the *trp* operon. The *trp* operon is continuously expressed in the absence of tryptophan and is not expressed in the presence of tryptophan.

The *trp* repressor is a helix-turn-helix protein that binds to the operator site located adjacent to the *trp* promoter (figure 16.6). This repressor behaves in a manner opposite to the *lac* repressor. In the absence of tryptophan, the *trp* repressor does not bind to its operator, allowing expression of the operon, and production of the enzymes necessary to make tryptophan.

a.

b.

**Figure 16.6** How the *trp* operon is controlled. The tryptophan operon encodes the enzymes necessary to synthesize tryptophan. **a.** The tryptophan repressor alone cannot bind to DNA. The promoter is free to function, and RNA polymerase transcribes the operon. **b.** When tryptophan is present, it binds to the repressor, altering its conformation so it now binds DNA. The tryptophan–repressor complex binds tightly to the operator, preventing RNA polymerase from initiating transcription.

When levels of tryptophan rise, then tryptophan (the *corepressor*) binds to the repressor and alters its conformation, allowing it to bind to its operator. Binding of the repressor–corepressor complex to the operator prevents RNA polymerase from binding to the promoter. The actual change in repressor structure due to tryptophan binding is an alteration of the orientation of a pair of helix–turn–helix motifs that allows their recognition helices to fit into adjacent major grooves of the DNA (figure 16.7).

When tryptophan is present and bound to the repressor and this complex is bound to the operator, the operon is said to be *repressed*. As tryptophan levels fall, the repressor alone cannot bind to the operator, allowing expression of the operon. In this state, the operon is said to be **derepressed**, distinguishing this state from induction (see figure 16.6).

The key to understanding how both induction and repression can be due to negative regulation is knowledge of the behavior of repressor proteins and their effectors. In induction, the repressor alone can bind to DNA, and the inducer prevents DNA binding. In the case of repression, the repressor only binds DNA when bound to the corepressor. Induction and repression are excellent examples of how interactions of molecules can affect their structures, and how molecular structure is critical to function.

**Figure 16.7** How the tryptophan repressor works. The binding of tryptophan to the repressor increases the distance between the two recognition helices in the repressor, allowing the repressor to fit snugly into two adjacent portions of the major groove in DNA.

### Learning Outcomes Review 16.3

Induction occurs when expression of genes in a pathway is turned on in response to a substrate; repression occurs when expression is prevented in response to a substrate. The *lac* operon is negatively controlled by a repressor protein that binds to DNA, thus preventing transcription. When lactose is present, the operon is turned on; allolactose binds to the repressor, which then no longer binds to DNA. This operon is also positively regulated by an activator protein. The *trp* operon is negatively controlled by a repressor protein that must be bound to tryptophan in order to bind to DNA. In the absence of tryptophan, the repressor cannot bind DNA, and the operon is derepressed.

- What would be the effect on regulation of the *trp* operon of a mutation in the *trp* repressor that can still bind to *trp*, but no longer bind to DNA?

## 16.4 Eukaryotic Regulation

### Learning Outcomes

1. Distinguish between the role of general and specific transcription factors.
2. Describe events necessary for Pol II to bind to the promoter.
3. Explain how transcription factors can have an effect from a distance in the DNA.

The control of transcription in eukaryotes is much more complex than in prokaryotes. The basic concepts of protein–DNA interactions are still valid, but the nature and number of interacting proteins is much greater due to some obvious differences. First, eukaryotes have their DNA organized into chromatin, complicating protein–DNA interactions considerably.

Second, eukaryotic transcription occurs in the nucleus, and translation occurs in the cytoplasm; in prokaryotes, these processes are spatially and temporally coupled. This provides more opportunities for regulation in eukaryotes than in prokaryotes.

Because of these differences, the amount of DNA involved in regulating eukaryotic genes is much greater. The need for a fine degree of flexible control is especially important for multicellular eukaryotes, with their complex developmental programs and multiple tissue types. General themes, however, emerge from this complexity.

### Transcription factors can be either general or specific

In the preceding chapter we introduced the concept of transcription factors. Eukaryotic transcription requires a variety of

these protein factors, which fall into two categories: *general transcription factors* and *specific transcription factors*. General factors are necessary for the assembly of a transcription apparatus and recruitment of RNA polymerase II to a promoter. Specific factors increase the level of transcription in certain cell types or in response to signals.

### General transcription factors

Transcription of RNA polymerase II templates (the majority being genes that encode protein products) requires more than just RNA polymerase II to initiate transcription. A host of **general transcription factors** are also necessary to establish productive initiation. These factors are required for transcription to occur, but they do not increase the rate above this basal rate.

General transcription factors are named with letter designations that follow the abbreviation TFII, for “transcription factor RNA polymerase II.” The most important of these factors, TFIID, contains the TATA-binding protein that recognizes the TATA box sequence found in many eukaryotic promoters (figure 16.8).

Binding of TFIID is followed by binding of TFIIE, TFIIF, TFIIA, TFIIB, and TFIIF and a host of accessory factors called *transcription-associated factors*, TAFs. The *initiation complex* that results (figure 16.9) is clearly much more complex than the bacterial RNA polymerase holoenzyme binding to a promoter. And there is yet another level of complexity: The initiation complex, although capable of initiating synthesis at a basal level, does not achieve transcription at a high level without the participation of other, specific factors.

### Specific transcription factors

**Specific transcription factors** act in a tissue- or time-dependent manner to stimulate higher levels of transcription than the basal level. The number and diversity of these factors are overwhelm-

**Figure 16.8 A eukaryotic promoter.** This promoter is for the gene encoding the enzyme thymidine kinase. Formation of the transcription initiation complex begins with a general transcription factor binding to the TATA box. There are three other DNA sequences that direct the binding of other specific transcription factors.

### Figure 16.9 Formation of a eukaryotic initiation complex.

The general transcription factor, TFIID, binds to the TATA box and is joined by the other general factors, TFIIE, TFIIF, TFIIA, TFIIB, and TFIIF. This complex is added to by a number of transcription-associated factors (TAFs) that together recruit the RNA pol II molecule to the core promoter.

ing. Some sense can be made of this proliferation of factors by concentrating on the DNA-binding motif, as opposed to the specific factors.

A key common theme that emerges from the study of these factors is that specific transcription factors, called *activators*, have a domain organization. Each factor consists of a DNA-binding domain and a separate activating domain that interacts with the transcription apparatus, and these domains are essentially independent in the protein. If the DNA-binding domains are “swapped” between different factors the binding specificity for the factors is switched without affecting their ability to activate transcription.

### Promoters and enhancers are binding sites for transcription factors

Promoters, as mentioned in the preceding chapter, form the binding sites for general transcription factors. These factors then mediate the binding of RNA polymerase II to the promoter (and also the binding of RNA polymerases I and III to their specific promoters). In contrast, the holoenzyme portion of the RNA polymerase of prokaryotes can directly recognize a promoter and bind to it.

**Enhancers** were originally defined as DNA sequences necessary for high levels of transcription that can act independently of position or orientation. At first, this concept seemed counterintuitive, especially since molecular biologists had been conditioned by prokaryotic systems to expect control regions to be immediately upstream of the coding region. It turns out that enhancers are the binding site of

DNA loops around so that the activator comes into contact with the RNA polymerase.

The activator triggers RNA polymerase activation, and transcription begins. DNA unloops.

**Figure 16.10 DNA looping caused by proteins.** When the bacterial activator NtrC binds to an enhancer, it causes the DNA to loop over to a distant site where RNA polymerase is bound, thereby activating transcription. Although such enhancers are rare in prokaryotes, they are common in eukaryotes.

the specific transcription factors. The ability of enhancers to act over large distances was at first puzzling, but investigators now think this action is accomplished by DNA bending to form a loop, positioning the enhancer closer to the promoter.

Although more important in eukaryotic systems, this looping was first demonstrated using prokaryotic DNA-binding proteins (figure 16.10). The important point is that the linear distance separating two sites on the chromosome does not have to translate to great physical distance, because the flexibility of DNA allows bending and looping. An activator bound to an enhancer can thus be brought into contact with the transcription factors bound to a distant promoter (figure 16.11).

### Coactivators and mediators link transcription factors to RNA polymerase II

Other factors specifically mediate the action of transcription factors. These *coactivators* and *mediators* are also necessary for activation of transcription by the transcription factor. They act by binding the transcription factor and then binding to another part of the transcription apparatus. Mediators are essential to the function of some transcription factors, but not all transcription

**Figure 16.11 How enhancers work.** The enhancer site is located far away from the gene being regulated. Binding of an activator (*gray*) to the enhancer allows the activator to interact with the transcription factors (*blue*) associated with RNA polymerase, stimulating transcription.

factors require them. The number of coactivators is much smaller than the number of transcription factors because the same coactivator can be used with multiple transcription factors.

## The transcription complex brings things together

Although a few general principles apply to a broad range of situations, nearly every eukaryotic gene—or group of genes with coordinated regulation—represents a unique case. Virtually all genes that are transcribed by RNA polymerase II need the same suite of general factors to assemble an initiation complex, but the assembly of this complex and its ultimate level of transcription depend on specific transcription factors that in combination make up the **transcription complex** (figure 16.12).

The makeup of eukaryotic promoters, therefore, is either very simple, if we consider only what is needed for the initiation complex, or very complicated, if we consider all factors that may bind in a complex and affect transcription. This kind of combinatorial gene regulation leads to great flexibility because it can respond to the many signals a cell may receive affecting transcription, allowing integration of these signals.

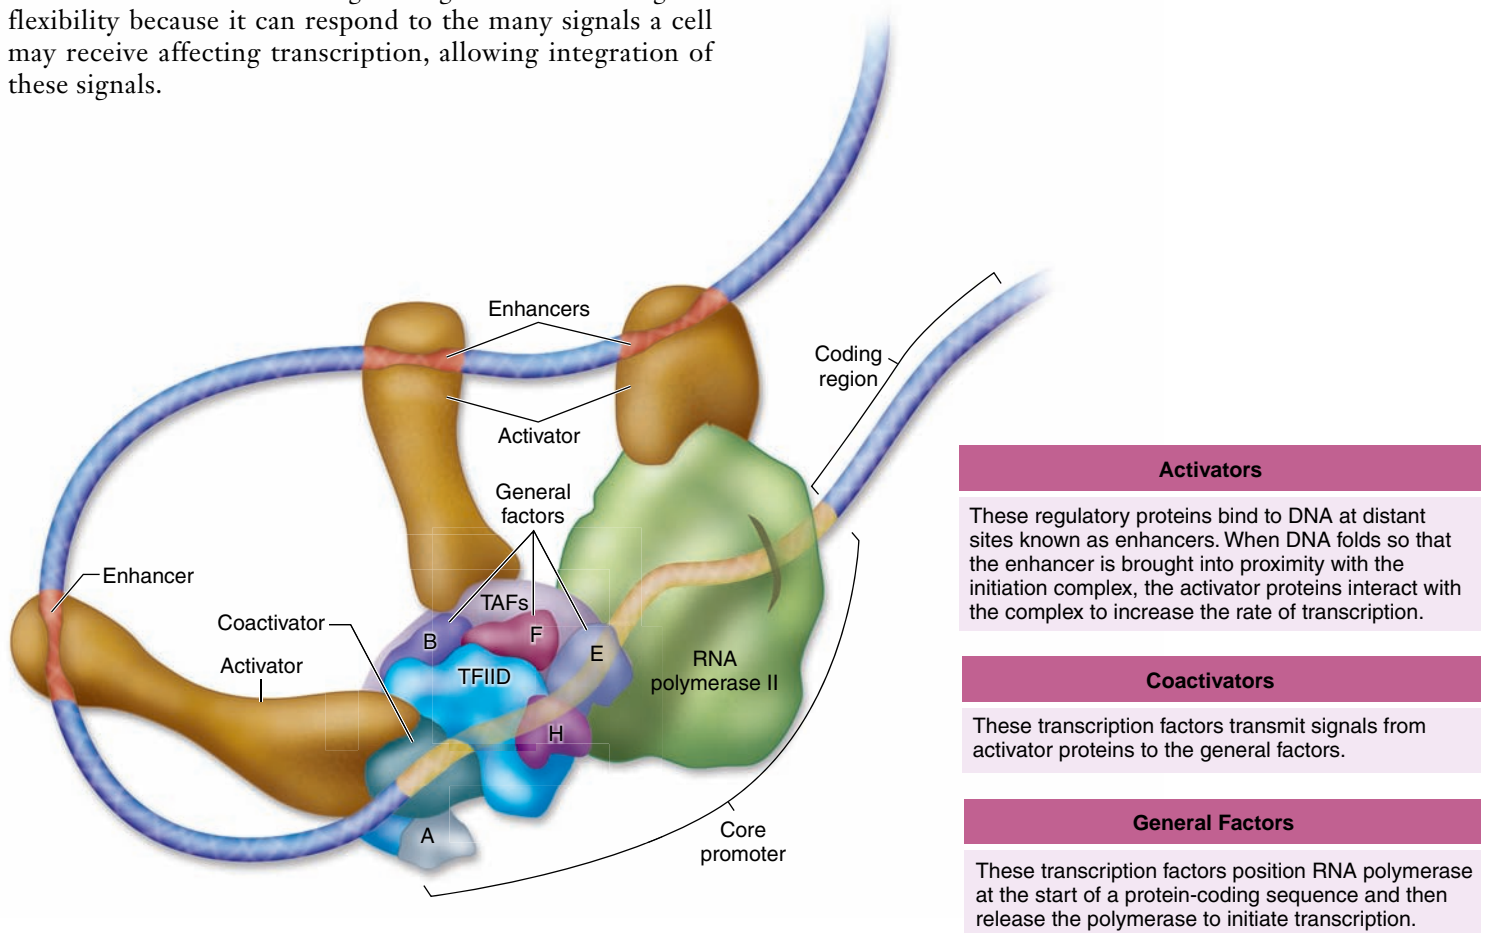

### Inquiry question

? How do eukaryotes coordinate the activation of many genes whose transcription must occur at the same time?

### Learning Outcomes Review 16.4

In eukaryotes, initiation requires general transcription factors that bind to the promoter and recruit RNA polymerase II to form an initiation complex. General factors produce the basal level of transcription. Specific transcription factors, which bind to enhancer sequences, can increase the level of transcription. Enhancers can act at a distance because DNA can loop, bringing an enhancer and a promoter closer together. Additional coactivators and mediators link certain specific transcription factors to RNA polymerase II.

- What would be the effect of a mutation that results in the loss of a general transcription factor versus the loss of a specific factor?

**Figure 16.12 Interactions of various factors within the transcription complex.** All specific transcription factors bind to enhancer sequences that may be distant from the promoter. These proteins can then interact with the initiation complex by DNA looping to bring the factors into proximity with the initiation complex. As detailed in the text, some transcription factors, called activators, can directly interact with the RNA polymerase II or the initiation complex, whereas others require additional coactivators.

## 16.5 Eukaryotic Chromatin Structure

### Learning Outcomes

1. Describe how chromatin structure can affect gene expression.
2. Explain the function of chromatin remodeling complexes.

Eukaryotes have the additional gene expression hurdle of possessing DNA that is packaged into chromatin. The packaging of DNA first into nucleosomes and then into higher order chromatin structures is now thought to be directly related to the control of gene expression.

Chromatin structure at its lowest level is the organization of DNA and histone proteins into *nucleosomes* (see chapter 10). These nucleosomes may block binding of transcription factors and RNA polymerase II at the promoter.

The higher order organization of chromatin, which is not completely understood, appears to depend on the state of the histones in nucleosomes. Histones can be modified to result in a greater condensation of chromatin, making promoters even less accessible for protein–DNA interactions. A chromatin remodeling complex exists that can make DNA more accessible.

### Both DNA and histone proteins can be modified

Chemical *methylation* of the DNA was once thought to play a major role in gene regulation in vertebrate cells. The addition of a methyl group to cytosine creates 5-methylcytosine, but this change has no effect on its base-pairing with guanine (figure 16.13). Similarly, the addition of a methyl group to uracil produces thymine, which clearly does not affect base-pairing with adenine.

Many inactive mammalian genes are methylated, and it was tempting to conclude that methylation caused the inactivation. But methylation is now viewed as having a less direct role, blocking the accidental transcription of “turned-off” genes. Vertebrate cells apparently possess a protein that binds to clus-

**Figure 16.13 DNA methylation.** Cytosine is methylated, creating 5-methylcytosine. Because the methyl group (*green*) is positioned to the side, it does not interfere with the hydrogen bonds of a G—C base-pair, but it can be recognized by proteins.

ters of 5-methylcytosine, preventing transcriptional activators from gaining access to the DNA. DNA methylation in vertebrates thus ensures that once a gene is turned off, it stays off.

The histone proteins that form the core of the nucleosome (chapter 10) can also be modified. This modification is correlated with active versus inactive regions of chromatin, similar to the methylation of DNA just described. Histones can also be methylated, and this alteration is generally found in inactive regions of chromatin. Finally, histones can be modified by the addition of an acetyl group, and this addition is correlated with active regions of chromatin.

### Some transcription activators alter chromatin structure

The control of eukaryotic transcription requires the presence of many different factors to activate transcription. Some activators seem to interact directly with the initiation complex or with coactivators that themselves interact with the initiation complex, as described earlier. Other cases are not so clear. The emerging consensus is that some coactivators have been shown to be histone acetylases. In these cases, it appears that transcription is increased by removing higher order chromatin structure that would prevent transcription (figure 16.14). Some corepressors have been shown to be histone deacetylases as well.

These observations have led to the suggestion that a “histone code” might exist, analogous to the genetic code.

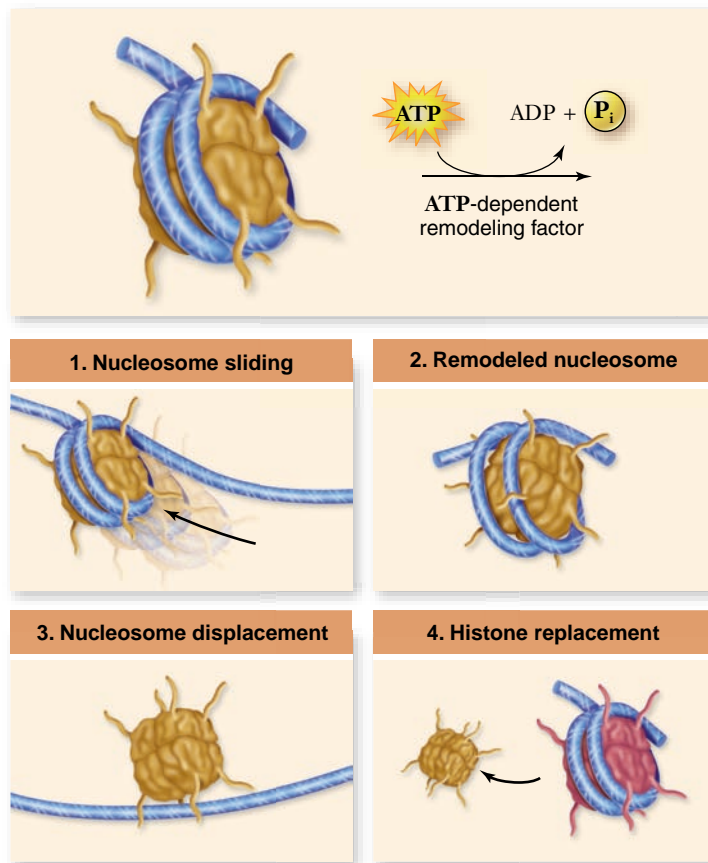

**Figure 16.14 Histone modification affects chromatin structure.** DNA in eukaryotes is organized first into nucleosomes and then into higher order chromatin structures. The histones that make up the nucleosome core have amino tails that protrude. These amino tails can be modified by the addition of acetyl groups. The acetylation alters the structure of chromatin, making it accessible to the transcription apparatus.

This histone code is postulated to underlie the control of chromatin structure and, thus, of access of the transcription machinery to DNA.

## Chromatin-remodeling complexes also change chromatin structure

The outline of how alterations to chromatin structure can regulate gene expression are beginning to emerge. A key discovery is the existence of so-called **chromatin-remodeling complexes**. These large complexes of proteins include enzymes that modify histones and DNA and that also change chromatin structure itself.

One class of these remodeling factors, ATP-dependent chromatin remodeling factors, function as molecular motors that affect DNA and histones. These ATP-dependent remodeling factors use energy from ATP to alter the relationships between histones and DNA. They can catalyze four different changes in histone/DNA binding (figure 16.15): 1) nucleosome sliding along DNA, which changes the position of a nucleosome on the DNA; 2) create a remodeled state where DNA is more

**Figure 16.15** Function of ATP-dependent remodeling factors. ATP dependent remodeling factors use the energy from ATP to alter chromatin structure. They can (1) slide nucleosomes along DNA to reveal binding sites for proteins; (2) create a remodeled state of chromatin where the DNA is more accessible; (3) completely remove nucleosomes from DNA; and (4) replace histones in nucleosomes with variant histones.

accessible; 3) removal of nucleosomes from DNA; and 4) replacement of histones with variant histones. These functions all act to make DNA more accessible to regulatory proteins that in turn, affect gene expression.

### Learning Outcomes Review 16.5

Eukaryotic DNA is packaged into chromatin, adding another structural challenge to transcription. Changes in chromatin structure correlate with modification of DNA and histones, and access to DNA by transcriptional regulators requires changes in chromatin structure. Some transcriptional activators modify histones by acetylation. Large chromatin-remodeling complexes include enzymes that alter the structure of chromatin, making DNA more accessible to regulatory proteins.

- Genes that are turned on in all cells are called “housekeeping” genes. Explain the idea behind this name.

## 16.6 Eukaryotic Posttranscriptional Regulation

### Learning Outcomes

1. Explain how small RNAs can affect gene expression.
2. Differentiate between the different kinds of posttranscriptional regulation.

The separation of transcription in the nucleus and translation in the cytoplasm in eukaryotes provides possible points of regulation that do not exist in prokaryotes. For many years we thought of this as “alternative” forms of regulation, but it now appears that they play a much more central role than previously suspected. In this section we will consider several of these mechanisms to control gene expression beginning with the exciting new area of regulation by small RNAs.

### Small RNAs act after transcription to control gene expression

The study of development has led to a number of important insights into the regulation of gene expression. A striking example is the discovery of small RNAs that affect gene expression. A mutant isolated in the worm *C. elegans* called *lin-4* was known to alter developmental timing, a so-called heterochronic mutant. Genetic studies had shown that this gene regulated another gene, *lin-14*. When the *lin-4* gene was isolated by Ambros, Lee, and Feinbaum in 1992, they showed that it did not encode a protein product. Instead, the *lin-4* gene encoded only two small RNA molecules, one of 22 nt and one of 61 nt. Further the 22 nt RNA was derived from the longer 61 nt RNA. Further work showed that this small RNA was complementary to a region in another heterochronic gene, *lin-14*. A model was developed where the *lin-4* RNA acted as a translational repressor of the *lin-14* mRNA

(figure 16.16). Although it was not called that at the time, this was the first identified micro RNA, or miRNA.

A completely different line of inquiry involved the use of double-stranded RNAs to turn off gene expression. This has been shown to act via another class of small RNA called small interfering RNAs, or siRNAs. These may be experimentally introduced, derived from invading viruses, or even encoded in the genome. The use of siRNA to control gene expression re-

vealed the existence of cellular mechanisms for the control of gene expression via small RNAs.

Since its discovery, gene silencing by small RNAs has been a source of great interest for both its experimental uses, and as an explanation for posttranslational control of gene expression. As these small RNAs have been studied in a variety of systems, it has led to a proliferation of terms to describe them. Recent research has uncovered a wealth of new types of small RNAs, but we will confine ourselves to the two classes of miRNA and siRNA as these are well established and illustrate the RNA silencing machinery.

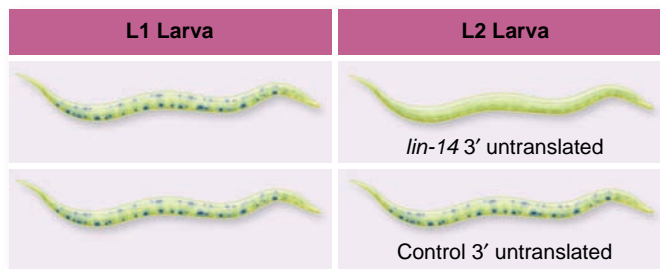

## SCIENTIFIC THINKING

**Hypothesis:** The region of the *lin-14* gene complementary to the *lin-4* miRNA controls *lin-14* expression.

**Prediction:** If the *lin-4* complementary region of the *lin-14* gene is spliced into a reporter gene, then this reporter gene should show regulation similar to *lin-14*.

**Test:** Recombinant DNA is used to make two versions of a reporter gene ( $\beta$ -galactosidase). In transgenic worms (*C. elegans*), expression of the reporter gene produces a blue color.

1. The  $\beta$ -galactosidase gene with the *lin-14* 3' untranslated region containing the *lin-4* complementary region
2. The  $\beta$ -galactosidase gene with a control 3' untranslated region lacking the *lin-4* complementary region

### Result:

1. Transgenic worms with reporter gene plus *lin-14* 3' untranslated region show expression in L1 but not L2 stage larvae. This is the pattern expected for the *lin-14* gene, which is controlled by *lin-4*.
2. Transgenic worms with reporter gene plus control 3' untranslated region do not show expression pattern expected for control by *lin-4*.

**Conclusion:** The 3' untranslated region from *lin-14* is sufficient to turn off gene expression in L2 larvae.

**Further Experiments:** What expression pattern would you predict for these constructs in a mutant that lacks *lin-4* function?

## miRNA genes

The discovery of the role of miRNAs in gene expression initially appeared to be confined to nematodes as the *lin-4* gene did not have any obvious homologs in other systems. Seven years later, a second gene, *let-7*, was discovered in the same pathway in *C. elegans*. The *let-7* gene also encoded a 22 nt RNA that could influence translation. In this case, homologs for *let-7* were immediately found in both *Drosophila* and in humans.

As an increasing number of miRNAs were discovered in different organisms, miRNA gene discovery has turned to computer searching and high throughput methods such as microarrays and new high throughput sequencing. A database devoted to miRNAs currently lists 695 known human miRNA sequences.

Genes for miRNA are found in a variety of locations including the introns of expressed genes, and they are often clustered with multiple miRNAs in a single transcription unit. They are also found in regions of the genome that were previously considered transcriptionally silent. This finding is particularly exciting because other work looking at transcription across animal genomes has found that much we thought was transcriptionally silent, is actually not.

## miRNA biogenesis and function

The production of a functional miRNA begins in the nucleus, and ends in the cytoplasm with a ~22 nt RNA that functions to repress gene expression (figure 16.17). The initial transcript of an miRNA gene is by RNA polymerase II producing a transcript called the Pri-miRNA. The region of this transcript containing the miRNA can fold back on itself and base-pair to form a stem and loop structure. This is cleaved in the nucleus by a nuclease called Drosha that trims the miRNA to just the stem and loop structure, which is now called the pre-miRNA. This pre-miRNA is exported from the nucleus through a nuclear pore bound to the protein exportin 5. Once in the cytoplasm the pre-miRNA is further cleaved by another nuclease called Dicer to produce a short double-stranded RNA containing the miRNA. The miRNA is loaded into a complex of proteins called an RNA induced silencing complex, or RISC. The RISC includes the RNA-binding protein Argonaute (Ago), which interacts with the miRNA. The complementary strand is either removed by a nuclease, or is removed during the loading process.

At this point, the RISC is targeted to repress the expression of other genes based on sequence complementarity to the miRNA. The complementary region is usually in the 3' untranslated region of genes, and the result can be cleavage of the mRNA or inhibition of translation. It appears that in animals,

**Figure 16.16 Control of *lin-14* gene expression.** The *lin-14* gene is controlled by the *lin-4* gene. This is mediated by a region of the 3' untranslated region of the *lin-14* mRNA that is complementary to *lin-4* miRNA.

**Figure 16.17 Biogenesis and function of miRNA.** Genes for miRNAs are transcribed by RNA polymerase II to produce a Pri-miRNA. This is processed by the Droscha nuclease to produce the Pre-miRNA, which is exported from the nucleus bound to export factor Exportin 5. Once in the cytoplasm, the pre-miRNA is processed by Dicer nuclease to produce the mature miRNA. The miRNA is loaded into a RISC, which can act to either cleave target mRNAs, or to inhibit translation of target mRNAs.

the inhibition of translation is more common than the cleavage of the mRNA, although the precise mechanism of this inhibition is still unclear. In plants, the cleavage of the mRNA by the RISC is common and seems to be related to the more precise complementarity found between plant miRNAs and their targets compared to animal systems.

## RNA interference

Small RNA mediated gene silencing has been known for a number of years. There has been some confusion created by observations in different systems leading to multiple names for similar phenomenon. Thus RNA interference, cosuppression, and posttranscriptional gene silencing all act through similar biochemical mechanisms. The term RNA interference is currently the most common and involves the production of siRNAs.

The production of siRNAs is similar to miRNAs except that they arise from a long double-stranded RNA (figure 16.18). This can be either a very long region of self complementarity, or from two complementary RNAs. These long double-stranded RNAs are processed by Dicer to yield multiple siRNAs that are loaded into an Ago containing RISC. The siRNAs usually have near-perfect complementarity to their target mRNAs, and the result is cleavage of the mRNA by the siRNA containing RISC.

The source of the double-stranded RNA to produce siRNAs can be either from the cell, or from outside the cell. From the cell itself, there are genes that produce RNAs with long regions of self-complementarity that fold back to produce a substrate for Dicer in the cytoplasm. They can also arise from repeated regions of the genome that contain transposable elements. Exogenous double-stranded RNAs can be introduced

**Figure 16.18 Biogenesis and function of siRNA.** SiRNAs can arise from a variety of sources that all produce long double-stranded regions of RNA. The double-stranded RNA is processed by Dicer nuclease to produce a number of siRNAs that are each loaded onto their own RISC. The RISC then cleaves target mRNA.

experimentally, or by infection with a virus. The last origin for double-stranded RNAs may point to the evolution of the RNA silencing machinery as a form of antiviral defense.

### **Distinguishing miRNAs and siRNAs**

The biogenesis of both miRNA and siRNA involves cleavage by Dicer, and incorporation into a RISC complex. The main thing that distinguishes these two types of molecules is their targets: miRNAs tend to repress genes different from their origin, while endogenous siRNAs tend to repress the genes they were derived from. Additionally siRNAs are used experimentally to turn off the expression of genes. This takes advantage of the cellular machinery to turn off a gene based with a double-stranded RNA corresponding to the gene of interest.

There are other differences between the two classes of small RNA. When multiple species are examined, miRNAs tend to be evolutionarily conserved while siRNAs do not. While the biogenesis is similar in terms of the nucleases involved, the actual structure of the double-stranded RNAs is not the same. The transcript of miRNA genes form stem-loop structures containing the miRNA while the double-stranded RNAs generating siRNAs may be bimolecular, or very long stem-loops. These longer double-stranded regions lead to multiple siRNAs while there is only a single miRNA generated from a pre-miRNA.

### **Small RNAs can mediate heterochromatin formation**

RNA silencing pathways have also been implicated in the formation of heterochromatin in fission yeast, plants, and *Drosophila*. In fission yeast, centromeric heterochromatin formation is driven by siRNAs produced by the action of the Dicer nuclease. This heterochromatin formation also involves modification of histone proteins, and thus connects RNA interference with chromatin remodeling complexes in this system. It is not yet clear how widespread this is.

In *Drosophila*, there is genetic evidence for the involvement of the RNA interference machinery in the formation of heterochromatin. This is particularly clear in the germ line where a specific class of small RNA appears to be involved in silencing transposons during spermatogenesis and oogenesis. There is also evidence that a similar mechanism may act in vertebrates.

Plants are an interesting case in that they have a variety of small RNA species. The RNA interference pathway is more complex than in animals with multiple forms of Dicer nuclease proteins and Argonaute RNA binding proteins. One class of endogenous siRNA can lead to heterochromatin formation by DNA methylation and histone modification.

### **Alternative splicing can produce multiple proteins from one gene**

As noted in the preceding chapter, splicing of pre-mRNA is one of the processes leading to mature mRNA. Many of these splicing events may produce different mRNAs from a single primary transcript by alternative splicing. This mechanism allows another level of control of gene expression.

Alternative splicing can change the splicing events that occur during different stages of development or in different tissues. An example of developmental differences is found in *Drosophila*, in which sex determination is the result of a complex series of alternative splicing events that differ in males and females.

An excellent example of tissue-specific alternative splicing in action is found in two different human organs: the thyroid gland and the hypothalamus. The thyroid gland is responsible for producing hormones that control processes such as metabolic rate. The hypothalamus, located in the brain, collects information from the body (for example, salt balance) and releases hormones that in turn regulate the release of hormones from other glands, such as the pituitary gland. (You'll learn more about these glands in chapter 46.)

These two organs produce two distinct hormones: *calcitonin* and *CGRP* (calcitonin gene-related peptide) as part of their function. Calcitonin controls calcium uptake and the balance of calcium in tissues such as bones and teeth. CGRP is involved in a number of neural and endocrine functions. Although these two hormones are used for very different physiological purposes, they are produced from the same transcript (figure 16.19).

The synthesis of one product versus another is determined by tissue-specific factors that regulate the processing of the primary transcript. In the case of calcitonin and CGRP, pre-mRNA splicing is controlled by different factors that are present in the thyroid and in the hypothalamus.

### **RNA editing alters mRNA after transcription**

In some cases, the editing of mature mRNA transcripts can produce an altered mRNA that is not truly encoded in the genome—an unexpected possibility. RNA editing was first discovered as the insertion of uracil residues into some RNA transcripts in protozoa, and it was thought to be an anomaly.

RNA editing of a different sort has since been found in mammalian species, including humans. In this case, the editing involves chemical modification of a base to change its base-pairing properties, usually by deamination. For example, both deamination of cytosine to uracil and deamination of adenine to inosine have been observed (inosine pairs as G would during translation).

#### **Apolipoprotein B**

The human protein apolipoprotein B is involved in the transport of cholesterol and triglycerides. The gene that encodes this protein, *apoB*, is large and complex, consisting of 29 exons scattered across almost 50 kilobases (kb) of DNA.

The protein exists in two isoforms: a full-length APOB100 form and a truncated APOB48 form. The truncated form is due to an alteration of the mRNA that changes a codon for glutamine to one that is a stop codon. Furthermore, this editing occurs in a tissue-specific manner; the edited form appears only in the intestine, whereas the liver makes only the full-length form. The full-length APOB100 form is part of the low-density lipoprotein (LDL) particle that carries cholesterol. High levels of serum LDL are thought

**Figure 16.19 Alternative splicing.** Many primary transcripts can be spliced in different ways to give rise to multiple mRNAs. In this example, in the thyroid the primary transcript is spliced to contain four exons encoding the protein calcitonin. In the hypothalamus the fourth exon, which contains the poly-A site used in the thyroid, is skipped and two additional exons are added to encode the protein calcitonin-gene-related peptide (CGRP).

to be a major predictor of atherosclerosis in humans. It does not appear that editing has any effect on the levels of the intestine-specific transcript.

### The 5-HT serotonin receptor

RNA editing has also been observed in some brain receptors for opiates in humans. One of these receptors, the serotonin (5-HT) receptor, is edited at multiple sites to produce a total of 12 different isoforms of the protein.

It is unclear how widespread these forms of RNA editing are, but they are further evidence that the information encoded within genes is not the end of the story for protein production.

## mRNA must be transported out of the nucleus for translation

Processed mRNA transcripts exit the nucleus through the nuclear pores (described in chapter 4). The passage of a transcript across the nuclear membrane is an active process that requires the transcript to be recognized by receptors lining the interior of the pores. Specific portions of the transcript, such as the poly-A tail, appear to play a role in this recognition.

There is little hard evidence that gene expression is regulated at this point, although it could be. On average, about 10% of primary transcripts consists of exons that will make up mRNA sequences, but only about 5% of the total mRNA produced as primary transcript ever reaches the cytoplasm. This observation suggests that about half of the exons in primary transcripts never leave the nucleus, but it is unclear whether the disappearance of this mRNA is selective.

## Initiation of translation can be controlled

The translation of a processed mRNA transcript by ribosomes in the cytoplasm involves a complex of proteins called *translation factors*. In at least some cases, gene expression is regulated by modification of one or more of these factors. In other instances, **translation repressor proteins** shut down translation

by binding to the beginning of the transcript, so that it cannot attach to the ribosome.

In humans, the production of ferritin (an iron-storing protein) is normally shut off by a translation repressor protein called aconitase. Aconitase binds to a 30-nt sequence at the beginning of the ferritin mRNA, forming a stable loop to which ribosomes cannot bind. When iron enters the cell, the binding of iron to aconitase causes the aconitase to dissociate from the ferritin mRNA, freeing the mRNA to be translated and increasing ferritin production 100-fold.

## The degradation of mRNA is controlled

Another aspect that affects gene expression is the stability of mRNA transcripts in the cell cytoplasm. Unlike prokaryotic mRNA transcripts, which typically have a half-life of about 3 min, eukaryotic mRNA transcripts are very stable. For example,  $\beta$ -globin gene transcripts have a half-life of over 10 hr, an eternity in the fast-moving metabolic life of a cell.

The transcripts encoding regulatory proteins and growth factors, however, are usually much less stable, with half-lives of less than 1 hr. What makes these particular transcripts so unstable? In many cases, they contain specific sequences near their 3' ends that make them targets for enzymes that degrade mRNA. A sequence of A and U nucleotides near the 3' poly-A tail of a transcript promotes removal of the tail, which destabilizes the mRNA.

Loss of the poly-A tail leads to rapid degradation by 3' to 5' RNA exonucleases. Another consequence of this loss is the stimulation of decapping enzymes that remove the 5' cap leading to degradation by 5' to 3' RNA exonucleases.

Other mRNA transcripts contain sequences near their 3' ends that are recognition sites for endonucleases, which cause these transcripts to be digested quickly. The short half-lives of the mRNA transcripts of many regulatory genes are critical to the function of those genes because they enable the levels of regulatory proteins in the cell to be altered rapidly.

A review of various methods of posttranscriptional control of gene expression is provided in figure 16.20.

**Figure 16.20** Mechanisms for control of gene expression in eukaryotes.

### Learning Outcomes Review 16.6

Small RNAs control gene expression by either selective degradation of mRNA, inhibition of translation, or alteration of chromatin structure. Multiple mRNAs can be formed from a single gene via alternative splicing, which can be tissue- and developmentally specific. The sequence of an mRNA transcript can also be altered by RNA editing.

- How could the phenomenon of RNA interference be used in drug design?

## 16.7 Protein Degradation

### Learning Outcomes

1. Describe the role of ubiquitin in the degradation of proteins.
2. Explain the function of the proteasome.

If all of the proteins produced by a cell during its lifetime remained in the cell, serious problems would arise. Protein labeling studies in the 1970s indicated that eukaryotic cells turn over proteins in a controlled manner. That is, proteins are continually being synthesized and degraded. Although this protein turnover is not as rapid as in prokaryotes, it indicates that a system regulating protein turnover is important.

Proteins can become altered chemically, rendering them nonfunctional; in addition, the need for any particular protein may be transient. Proteins also do not always fold correctly, or they may become improperly folded over time. These changes can lead to loss of function or other chemical behaviors, such as aggregating into insoluble complexes. In fact, a number of neurodegenerative diseases, such as Alzheimer dementia, Parkinson disease, and mad cow disease, are related to proteins that aggregate, forming characteristic plaques in brain cells. Thus, in addition to normal turnover of proteins, cells need a mechanism to get rid of old, unused, and incorrectly folded proteins.

Enzymes called **proteases** can degrade proteins by breaking peptide bonds, converting a protein into its constituent amino acids. Although there is an obvious need for these enzymes, they clearly cannot be floating around in the cytoplasm active at all times.

One way that eukaryotic cells handle such problems is to confine destructive enzymes to a specific cellular compartment. You may recall from chapter 4 that lysosomes are vesicles that contain digestive enzymes, including proteases. Lysosomes are used to remove proteins and old or nonfunctional organelles, but this system is not specific for particular proteins. Cells need another regulated pathway to remove proteins that are old or unused, but leave the rest of cellular proteins intact.

### Addition of ubiquitin marks proteins for destruction

Eukaryotic cells solve this problem by marking proteins for destruction, then selectively degrading them. The mark that cells use is the attachment of a **ubiquitin** molecule. Ubiquitin, so named because it is found in essentially all eukaryotic cells (that is, it is ubiquitous), is a 76-amino-acid protein that can exist as an isolated molecule or in longer chains that are attached to other proteins.

The longer chains are added to proteins in a stepwise fashion by an enzyme called *ubiquitin ligase* (figure 16.21). This reaction requires ATP and other proteins, and it takes place in a multistep, regulated process. Proteins that have a ubiquitin chain attached are called *polyubiquitinated*, and this state is a signal to the cell to destroy this protein.

Two basic categories of proteins become ubiquitinated: those that need to be removed because they are improperly folded or nonfunctional, and those that are produced and degraded in a controlled fashion by the cell. An example of the latter are the cyclin proteins that help to drive the cell cycle (chapter 10). When these proteins have fulfilled their role in active division of the cell, they become polyubiquitinated and are removed. In this way, a cell can control entry into cell division or maintain a nondividing state.

**Figure 16.21 Ubiquitination of proteins.** Proteins that are to be degraded are marked with ubiquitin. The enzyme ubiquitin ligase uses ATP to add ubiquitin to a protein. When a series of these have been added, the polyubiquitinated protein is destroyed.

### The proteasome degrades polyubiquitinated proteins

The cellular organelle that degrades proteins marked with ubiquitin is the **proteasome**, a large cylindrical complex that proteins enter at one end and exit the other as amino acids or peptide fragments (figure 16.22).

The proteasome complex contains a central region that has protease activity and regulatory components at each end. Although not membrane-bounded, this organelle can be thought of as a form of compartmentalization on a very small scale. By using a two-step process, first to mark proteins for destruction, then to process them through a large complex, proteins to be degraded are isolated from the rest of the cytoplasm.

**Figure 16.22 The *Drosophila* proteasome.** The central complex contains the proteolytic activity, and the flanking regions act as regulators. Proteins enter one end of the cylinder and are cleaved to peptide fragments that exit the other end.

The process of ubiquitination followed by degradation by the proteasome is called the *ubiquitin–proteasome pathway*. It can be thought of as a cycle in that the ubiquitin added to proteins is not itself destroyed in the proteasome. As the proteins are degraded, the ubiquitin chain itself is simply cleaved back into ubiquitin units that can then be reused (figure 16.23).

### Learning Outcomes Review 16.7

Control of protein degradation in eukaryotes involves addition of the protein ubiquitin, which marks the protein for destruction. The proteasome, a cylindrical complex with protease activity in its center, recognizes ubiquitinated proteins and breaks them down, much like a shredder destroys documents. Ubiquitin is recycled unchanged.

- If the ubiquitination process was not tightly controlled, what effect would this have on a cell?

**Figure 16.23** Degradation by the ubiquitin–proteasome pathway. Proteins are first ubiquitinated, then enter the proteasome to be degraded. In the proteasome, the polyubiquitin is removed and then is later “deubiquitinated” to produce single ubiquitin molecules that can be reused.

### Inquiry question

- ? What are two reasons a cell would polyubiquitinate a polypeptide?

## Chapter Review

### 16.1 Control of Gene Expression

**Control usually occurs at the level of transcription initiation.**

Transcription is controlled by regulatory proteins that modulate the ability of RNA polymerase to bind to the promoter. These may either block transcription or stimulate it.

**Control strategies in prokaryotes are geared to adjust to environmental changes.**

**Control strategies in eukaryotes are aimed at maintaining homeostasis.**

### 16.2 Regulatory Proteins

**Proteins can interact with DNA through the major groove.**

A DNA double helix exhibits a major groove and a minor groove; bases in the major groove are accessible to regulatory proteins.

**DNA-binding domains interact with specific DNA sequences.**

A region of the regulatory protein that can bind to the DNA is termed a DNA-binding motif (see figure 16.2).

**Several common DNA-binding motifs are shared by many proteins.**

Common motifs include the helix–turn–helix motif, the homeodomain motif, the zinc finger motif, and the leucine zipper.

### 16.3 Prokaryotic Regulation

**Control of transcription can be either positive or negative.**

Negative control is mediated by proteins called repressors that interfere with transcription. Positive control is mediated by a class of regulatory proteins called activators that stimulate transcription.

**Prokaryotes adjust gene expression in response to environmental conditions.**

The *lac* operon is induced in the presence of lactose; that is, the enzymes to utilize lactose are only produced when lactose is present. The *trp* operon is repressed; that is, the enzymes needed to produce tryptophan are turned off when tryptophan is present.

**The *lac* operon is negatively regulated by the *lac* repressor.**

The *lac* operon is induced when the effector (allolactose) binds to the repressor, altering its conformation such that it no longer binds DNA (see figure 16.4).

**The presence of glucose prevents induction of the *lac* operon**

Maximal expression of the *lac* operon requires positive control by catabolite activator protein (CAP) complexed with cAMP. When glucose is low, cAMP is high. Glucose repression involves both inducer exclusion, in which lactose is prevented from entering the cell, and the control of CAP function by the level of glucose.

**The *trp* operon is controlled by the *trp* repressor.**

The *trp* operon is repressed when tryptophan, acting as a corepressor, binds to the repressor, altering its conformation such that it can bind to DNA and turn off the operon. This prevents expression in the presence of excess *trp*.

## 16.4 Eukaryotic Regulation

**Transcription factors can be either general or specific.**

General transcription factors are needed to assemble the transcription apparatus and recruit RNA polymerase II at the promoter. Specific factors act in a tissue- or time-dependent manner to stimulate higher rates of transcription.

**Promoters and enhancers are binding sites for transcription factors.**

General factors bind to the promoter to recruit RNA polymerase. Specific factors bind to enhancers, which may be distant from the promoter but can be brought closer by DNA looping.

**Coactivators and mediators link transcription factors to RNA polymerase II (see figure 16.12).**

Some, but not all, transcription factors require a mediator. The number of coactivators is small because a single coactivator can be used with multiple transcription factors.

**The transcription complex brings things together.**

## 16.5 Eukaryotic Chromatin Structure

In eukaryotes, DNA is wrapped around proteins called histones, forming nucleosomes. These may block binding of transcription factors to promoters and enhancers.

**Both DNA and histone proteins can be modified.**

Methylation of DNA bases, primarily cytosine, correlates with genes that have been “turned off.” Methylation is associated with inactive regions of chromatin.

**Some transcription activators alter chromatin structure.**

Acetylation of histones results in active regions of chromatin.

**Chromatin-remodeling complexes also change chromatin structure.**

Chromatin-remodeling complexes contain enzymes that move, reposition, and transfer nucleosomes.

## 16.6 Eukaryotic Posttranscriptional Regulation

**Small RNAs act after transcription to control gene expression.**

RNA interference is mediated by siRNAs formed by cleavage of double-stranded RNA by the Dicer nuclease. The siRNA is bound to a protein, Argonaute, in an RNA Induced Silencing Complex (RISC). The RISC can cleave mRNA or inhibit translation. Another class of small RNA, miRNA, is formed by the action of two nucleases, Drosha and Dicer, on RNA stem-and-loop structures. These also form a RISC that can either degrade mRNA or stop translation.

**Small RNAs can mediate heterochromatin formation.**

In fission yeast, *Drosophila*, and plants, RNA interference pathways lead to the formation of heterochromatin.

**Alternative splicing can produce multiple proteins from one gene.**

In response to tissue-specific factors, alternative splicing of pre-mRNA from one gene can result in multiple proteins.

**RNA editing alters mRNA after transcription.**

**mRNA must be transported out of the nucleus for translation.**

**Initiation of translation can be controlled.**

Translation factors may be modified to control initiation; translation repressor proteins can bind to the beginning of a transcript so that it cannot attach to the ribosome.

**The degradation of mRNA is controlled.**

An mRNA transcript is relatively stable, but it may carry targets for enzymes that degrade it more quickly as needed by the cell.

## 16.7 Protein Degradation

**Addition of ubiquitin marks proteins for destruction.**

In eukaryotes, proteins targeted for destruction have ubiquitin added to them as a marker.

**The proteasome degrades polyubiquitinated proteins.**

A cell organelle—the cylindrical proteasome—degrades ubiquitinated proteins that pass through it.

## Review Questions

### UNDERSTAND

- In prokaryotes, control of gene expression usually occurs at the
  - splicing of pre-mRNA into mature mRNA.
  - initiation of translation.
  - initiation of transcription.
  - all of the above
- Regulatory proteins interact with DNA by
  - unwinding the helix and changing the pattern of base-pairing.
  - binding to the sugar-phosphate backbone of the double helix.
  - unwinding the helix and disrupting base-pairing.
  - binding to the major groove of the double helix and interacting with base-pairs.
- In *E. coli*, induction in the *lac* operon and repression in the *trp* operon are both examples of
  - negative control by a repressor.
  - positive control by a repressor.
  - negative control by an activator.
  - positive control by a repressor.
- The *lac* operon is controlled by two main proteins. These proteins
  - both act in a negative fashion.
  - both act in a positive fashion.
  - act in the opposite fashion, one negative and one positive.
  - act at the level of translation.
- In eukaryotes, binding of RNA polymerase to a promoter requires the action of
  - specific transcription factors.
  - general transcription factors.
  - repressor proteins.
  - inducer proteins.
- In eukaryotes, the regulation of gene expression occurs
  - only at the level of transcription.
  - only at the level of translation.
  - at the level of transcription initiation, or posttranscriptionally.
  - only posttranscriptionally.

7. In the *trp* operon, the repressor binds to DNA
  - a. in the absence of *trp*.
  - b. in the presence of *trp*.
  - c. in either the presence or absence of *trp*.
  - d. only when *trp* is needed in the cell.

### APPLY

1. The *lac* repressor, the *trp* repressor and CAP are all
  - a. negative regulators of transcription.
  - b. positive regulators of transcription.
  - c. allosteric proteins that bind to DNA and an effector.
  - d. proteins that can bind DNA or other proteins.
2. Specific transcription factors in eukaryotes interact with enhancers, which may be a long distance from the promoter. These transcription factors then
  - a. alter the structure of the DNA between enhancer and promoter.
  - b. do not interact with the transcription apparatus.
  - c. can interact with the transcription apparatus via DNA looping.
  - d. can interact with the transcription apparatus by removing the intervening DNA.
3. Repression in the *trp* operon and induction in the *lac* operon are both mechanisms that
  - a. would only be possible with positive regulation.
  - b. allow the cell to control the level of enzymes to fit environmental conditions.
  - c. would only be possible with negative regulation.
  - d. cause the cell to make the enzymes from these two operons all the time.
4. Regulation by small RNAs and alternative splicing are similar in that both
  - a. act after transcription.
  - b. act via RNA/protein complexes.
  - c. regulate the transcription machinery.
  - d. both a and b
5. Eukaryotic mRNAs differ from prokaryotic mRNAs in that they
  - a. usually contain more than one gene.
  - b. are colinear with the genes that encode them.
  - c. are not colinear with the genes that encode them.
  - d. both a and c
6. In the cell cycle, cyclin proteins are produced in concert with the cycle. This likely involves
  - a. control of initiation of transcription of cyclin genes, and ubiquitination of cyclin proteins.
  - b. alternative splicing of cyclin genes to produce different cyclin proteins.

- c. RNA editing to produce the different cyclin proteins.
  - d. transcription/translation coupling.
7. A mechanism of control in *E. coli* not discussed in this chapter involves pausing of ribosomes allowing a transcription terminator to form in the mRNA. In eukaryotic fission yeast, this mechanism should
  - a. be common since they are unicellular.
  - b. not be common since they are unicellular.
  - c. not occur as transcription occurs in the nucleus and translation in the cytoplasm.
  - d. not occur due to possibility of alternative splicing.

### SYNTHESIZE

1. You have isolated a series of mutants affecting regulation of the *lac* operon. All of these are constitutive, that is, they express the *lac* operon all the time. You also have both mutant and wild-type alleles for each mutant in all combinations, and on F' plasmids, which can be introduced into cells to make the cell diploid for the relevant genes. How would you use these tools to determine which mutants affect DNA binding sites on DNA, and which affect proteins that bind to DNA?
2. Examples of positive and negative control of transcription can be found in the regulation of expression of the bacterial operons *lac* and *trp*. Use these two operon systems to describe the difference between positive and negative regulation.
3. What forms of eukaryotic control of gene expression are unique to eukaryotes? Could prokaryotes use the mechanisms, or are they due to differences in these cell types?
4. The number and type of proteins found in a cell can be influenced by genetic mutation and regulation of gene expression. Discuss how these two processes differ.

# Biotechnology

## Chapter Outline

- 17.1 DNA Manipulation
- 17.2 Molecular Cloning
- 17.3 DNA Analysis
- 17.4 Genetic Engineering
- 17.5 Medical Applications
- 17.6 Agricultural Applications

## Introduction

Over the past decades, the development of new and powerful techniques for studying and manipulating DNA has revolutionized biology. The knowledge gained in the last 25 years is greater than that accrued during the history of biology. Biotechnology also affects more aspects of everyday life than any other area of biology. From the food on your table to the future of medicine, biotechnology touches your life.

Biotechnology is the application of molecular biology principles to numerous aspects of life. The ability to isolate specific DNA sequences arose from the study and use of small DNA molecules found in bacteria, like the plasmid pictured here. In this chapter, we explore these technologies and consider how they apply to specific problems of practical importance.

### 17.1 DNA Manipulation

#### Learning Outcomes

1. Relate endogenous roles of enzymes to their recombinant DNA applications.
2. Explain why DNA fragments can be separated with gel electrophoresis.

The ability to directly isolate and manipulate genetic material was one of the most profound changes in the field of biology in the late 20th century. The construction of **recombinant DNA**

molecules, that is, a single DNA molecule made from two different sources, began in the mid-1970s. The development of this technology, which has led to the entire field of biotechnology, is based on enzymes that can be used to manipulate DNA.

#### Restriction enzymes cleave DNA at specific sites

Enzymes called **restriction endonucleases** revolutionized molecular biology because of their ability to cleave DNA at specific sites. As described in chapter 14, nucleases are enzymes that degrade DNA, and many were known prior to the isolation of the first restriction enzyme (*HindII*) in 1970. If a DNA sequence were a rope, then restriction enzymes would be a knife that always cut that rope into specific pieces.

## Discovery and significance of restriction endonucleases

This site-specific cleavage activity, long sought by molecular biologists, was discovered from basic research into why bacterial viruses can infect some cells but not others. This phenomenon was termed *host restriction*. The bacteria produce enzymes that can cleave the invading viral DNA at specific sequences. The host cells protect their own DNA from cleavage by modifying it at the cleavage sites; the restriction enzymes do not cleave that modified DNA. Since the initial discovery of these restriction endonucleases, hundreds more have been isolated that recognize and cleave different **restriction sites**.

The ability to cut DNA at specific places is significant in two ways: First, it allows physical maps to be constructed based on the positioning of cleavage sites for restriction enzymes. These restriction maps provide crucial data for identifying and working with DNA molecules.

Second, restriction endonuclease cleavage allows the creation of recombinant molecules. The ability to construct recombinant molecules is critical to research, because many steps in the process of cloning and manipulating DNA require the ability to combine molecules from different sources.

## How restriction enzymes work

There are three types of restriction enzymes, but only type II cleaves at precise locations. Types I and III cleave with less precision and are not often used in cloning and manipulating DNA.

Type II enzymes allow creation of recombinant molecules; these enzymes recognize a specific DNA sequence, ranging from 4 bases to 12 bases, and cleave the DNA at a specific base within this sequence (figure 17.1).

The recognition sites for most type II enzymes are palindromes. A linguistic *palindrome* is a word or phrase that reads the same forward and in reverse, such as the sentence: “Madam I’m Adam.” The palindromic DNA sequence reads the same from 5' to 3' on one strand as it does on the complementary strand (see figure 17.1).

Given this kind of sequence, cutting the DNA at the same base on either strand can lead to staggered cuts that produce “sticky ends.” These short, unpaired sequences are the same for any DNA that is cut by this enzyme. Thus, these sticky ends allow DNAs from different sources to be easily joined together (see figure 17.1). While less common, some type II restriction enzymes, including *PvuII*, can cut both strands in the same position, producing blunt, not sticky, ends. Blunt cut ends can be joined with other blunt cut ends.

## DNA ligase allows construction of recombinant molecules

Because the two ends of a DNA molecule cut by a type II restriction enzyme have complementary sequences, the pair can form a duplex. An enzyme is needed, however, to join the two fragments together to create a stable DNA molecule. The enzyme DNA ligase accomplishes this by catalyzing the formation of a phosphodiester bond between adjacent phosphate and hydroxyl groups of DNA nucleotides. The action of ligase is to seal nicks in one or both strands (see figure 17.1). This is the

**Figure 17.1** Many restriction endonucleases produce DNA fragments with “sticky ends.”

The restriction endonuclease *EcoRI* always cleaves the sequence 5'GAATTC3' between G and A. Because the same sequence occurs on both strands, both are cut. However, the two sequences run in opposite directions on the two strands. As a result, single-stranded tails called “sticky ends” are produced that are complementary to each other. These complementary ends can then be joined to a fragment from another DNA that is cut with the same enzyme. These two molecules can then be joined by DNA ligase to produce a recombinant molecule.

same enzyme that joins Okazaki fragments on the lagging strand during DNA replication (see chapter 14).

## Gel electrophoresis separates DNA fragments

The fragments produced by restriction enzymes would not be of much use if we could not also easily separate them for analysis. The most common separation technique used is gel electrophoresis. This technique takes advantage of the negative charge on DNA molecules by using an electrical field to provide the force necessary to separate DNA molecules based on size.

The gel, which is made of either agarose or polyacrylamide and spread thinly on supporting material, provides a three-dimensional matrix that separates molecules based on size (figure 17.2). The gel is submerged in a buffer solution containing ions that can carry current and is subjected to an electrical field.

The strong negative charges from the phosphate groups in the DNA backbone cause it to migrate toward the positive pole (figure 17.2*b*). The gel acts as a sieve to separate DNA molecules based on size: The larger the molecule, the slower it will move through the gel matrix. Over a given period, smaller molecules migrate farther than larger ones. The DNA in gels can be visualized using a fluorescent dye that binds to DNA (figure 17.2*c, d*).

Electrophoresis is one of the most important methods in the toolbox of modern molecular biology, with uses ranging from DNA fingerprinting to DNA sequencing, both of which are described later on.

## Transformation allows introduction of foreign DNA into *E. coli*

The construction of recombinant molecules is the first step toward genetic engineering. It is also necessary to be able to

reintroduce these molecules into cells. In chapter 14 you learned that Frederick Griffith demonstrated that genetic material could be transferred between bacterial cells. This process, called *transformation*, is a natural process in the cells that Griffith was studying.

The bacterium *E. coli*, used routinely in molecular biology laboratories, does not undergo natural transformation; but artificial transformation techniques have been developed to allow introduction of foreign DNA into *E. coli*. Through temperature shifts or an electrical charge, the *E. coli* membrane becomes transiently permeable to the foreign DNA. In this way, recombinant molecules can be propagated in a cell that will make many copies of the constructed molecules.

In general, the introduction of DNA from an outside source into a cell is referred to as transformation. This process is important in *E. coli* for molecular cloning and the propagation of cloned DNA. Researchers also want to be able

**Figure 17.2 Gel electrophoresis.** *a.* Three restriction enzymes are used to cut DNA into specific pieces depending on each enzyme's recognition sequence. *b.* The fragments are loaded into a gel (agarose or polyacrylamide), and an electrical current is applied. The DNA fragments migrate through the gel based on size, with larger ones moving more slowly. *c.* This results in a pattern of fragments separated based on size, with the smaller fragments migrating farther than larger ones. *d.* The fragments can be visualized by staining with the dye ethidium bromide. When the gel is exposed to UV light, the DNA with bound dye fluoresces, appearing as pink bands in the gel. In the photograph, one band of DNA has been excised from the gel for further analysis and can be seen glowing in the tube the technician holds.

to reintroduce DNA into the original cells from which it was isolated. A transformed cell that can also be used to form all or part of an organism, is called a **transgenic** organism. Later in this chapter we explore the construction and uses of transgenic plants and animals.

### Learning Outcomes Review 17.1

Restriction endonucleases are part of bacterial cells' strategies to fight viral infection. Type II endonucleases cleave DNA at specific sites. DNA ligase can be used to link together fragments following action of restriction endonucleases. Gel electrophoresis employs electrical charge to separate DNA fragments according to size. Foreign DNA can be introduced into *E. coli* through artificial transformation, and then propagation can produce cloned DNA.

- Compare and contrast the endogenous roles of EcoRI and ligase in *E. coli* with their use in a molecular biology lab.

## 17.2 Molecular Cloning

### Learning Outcomes

1. Explain the role of a vector in molecular cloning.
2. Describe how a DNA library is constructed.

The term **clone** refers to a genetically identical copy. The technique of propagating plants by growing a new plant from a cutting of a donor plant is an early method of cloning widely used in agriculture and horticulture. The topic of cloning entire organisms is discussed in chapter 19. For now, we explore the idea of molecular cloning.

*Molecular cloning* involves the isolation of a specific sequence of DNA, usually one that encodes a particular protein product. This is sometimes called *gene cloning*, but the term *molecular cloning* is more accurate.

### Host–vector systems allow propagation of foreign DNA in bacteria

Although short sequences of DNA can be synthesized *in vitro* (in a test tube), the cloning of large unknown sequences requires propagation of recombinant DNA molecules *in vivo* (in a cell). The enzymes and methods described earlier allow biologists to produce, separate, and then introduce foreign DNA into cells.

The ability to propagate DNA in a host cell requires a **vector** (something to carry the recombinant DNA molecule) that can replicate in the host when it has been introduced. Such host–vector systems are crucial to molecular biology.

The most flexible and common host used for molecular cloning is the bacterium *E. coli*, but many other hosts are now possible. Investigators routinely reintroduce cloned eukaryotic DNA, using mammalian tissue culture cells, yeast cells, and insect cells as host systems. Each kind of host–vector system allows particular uses of the cloned DNA.

The two most commonly used vectors are plasmids and artificial chromosomes. *Plasmids* are small, circular extrachromosomal DNAs that are dispensable to the bacterial cell. Bacterial and eukaryotic artificial chromosomes are used to clone larger pieces of DNA.

### Plasmid vectors

Plasmid vectors (small, circular chromosomes) are typically used to clone relatively small pieces of DNA, up to a maximum of about 10 kilobases (kb). A plasmid vector must have three components:

1. An *origin of replication* to allow it to be replicated in *E. coli* independently of the host chromosome,
2. A *selectable marker*; usually antibiotic resistance, and
3. *One or more unique restriction sites* where foreign DNA can be added.

The selectable marker allows the presence of the plasmid to be easily identified through genetic selection. For example, cells that contain a plasmid with an antibiotic resistance gene continue to live when plated on antibiotic-containing growth media, whereas cells that lack the plasmid will die (they are killed by the antibiotic).

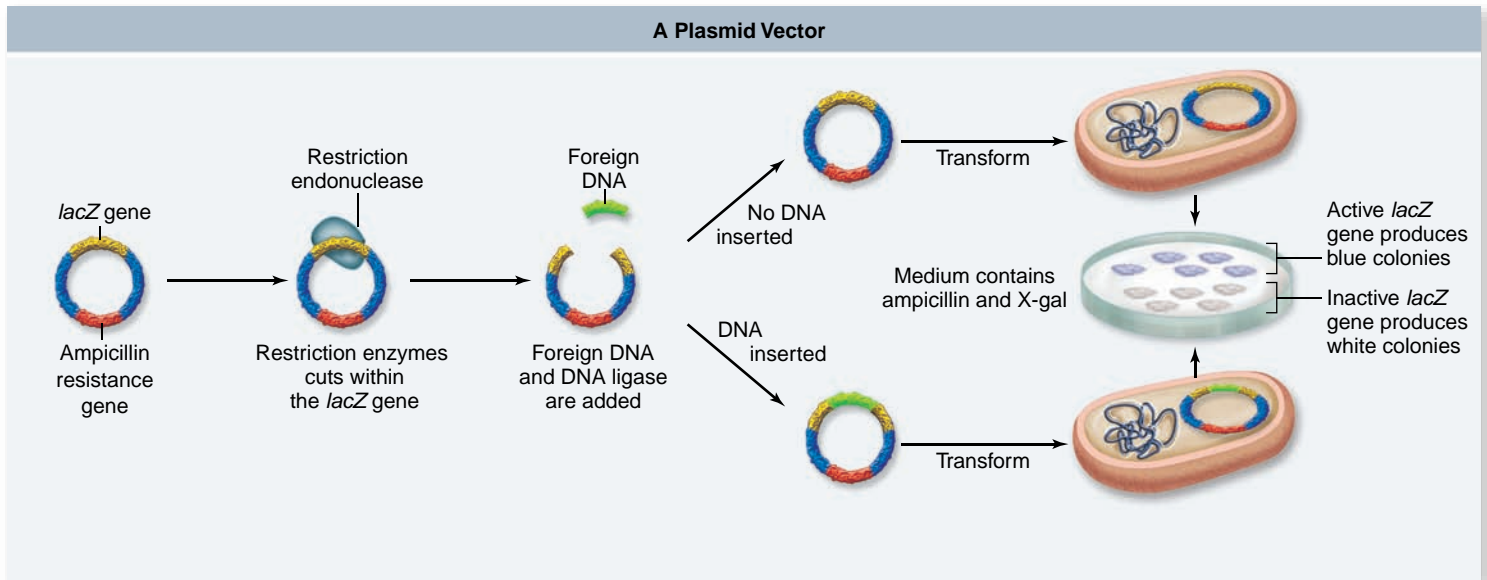

A fragment of DNA is inserted by the techniques described into a region of the plasmid with restriction sites called the multiple-cloning site (MCS). This region contains a number of unique restriction sites such that when the plasmid is cut with the relevant restriction enzymes, a linear plasmid results. When DNA of interest is cut with the same restriction enzyme, it can then be ligated into this site. The plasmid is then introduced into cells by transformation (see figure 17.3).

This region of the vector often has been engineered to contain another gene that becomes inactivated, so-called *insertional inactivation*, because it is now interrupted by the inserted DNA. One of the first cloning vectors, pBR322, used another antibiotic resistance gene for insertional activation; resistance to one antibiotic and sensitivity to the other indicated the presence of inserted DNA.

More recent vectors use the gene for  $\beta$ -galactosidase, an enzyme that cleaves galactoside sugars such as lactose. When the enzyme cleaves the artificial substrate X-gal, a blue color is produced. In these plasmids, insertion of foreign DNA interrupts the  $\beta$ -galactosidase gene, preventing a functional enzyme from being produced. When transformed cells are plated on medium containing both antibiotic (to select for plasmid-containing cells) and X-gal, they remain white, whereas transformed cells with no inserted DNA are blue (see figure 17.3).

### Artificial Chromosomes

The size of DNA molecules that can be cloned in plasmid vectors has limited the large-scale analysis of genomes. To deal

**Figure 17.3 Molecular cloning with vectors.** Plasmids are cut within the  $\beta$ -galactosidase gene (*lacZ*), and foreign DNA and DNA ligase are added. Foreign DNA inserted into *lacZ* interrupts the coding sequence, thus inactivating the gene. Plating cells on medium containing the antibiotic ampicillin selects for plasmid-containing cells. The medium also contains X-gal, and when *lacZ* is intact (*top*), the expressed enzyme cleaves the X-gal, producing blue colonies. When *lacZ* is inactivated (*bottom*), X-gal is not cleaved, and colonies remain white.

with this, geneticists decided to follow the strategy of cells and construct chromosomes, leading to the development of yeast artificial chromosomes (YACs) and bacterial artificial chromosomes (BACs). Progress has also been made on creating mammalian artificial chromosomes. Use of artificial chromosomes is described in the next chapter.

### Inquiry question

? An investigator wishes to clone a 32-kb recombinant molecule. What do you think is the best vector to use?

## DNA libraries contain the entire genome of an organism

The idea of molecular cloning depends on the ability to construct a representation of very complex mixtures in DNA, such as an entire genome, in a form that is easier to work with than the enormous chromosomes within a cell. If the huge DNA molecules in chromosomes can be converted into random fragments, and inserted into a vector such as plasmids, then when they are propagated in a host they will together represent the whole genome. This aggregate is termed a **DNA library**, a collection of DNAs in a vector that taken together represent the complex mixture of DNA (figure 17.4).

Conceptually the simplest possible kind of DNA library is a **genomic library**—a representation of the entire genome in a vector. This genome is randomly fragmented by partially digesting it with a restriction enzyme that cuts frequently. By not cutting the DNA to completion, not all sites are cleaved, and which sites are cleaved is random. The random fragments are

then inserted into a vector and introduced into host cells. Genomic libraries are usually constructed in bacterial artificial chromosomes (BACs).

A variety of different kinds of libraries can be made depending on the source DNA used. Any particular clone in the library contains only a single DNA, and all of them together make up the library. Keep in mind that unlike a library full of

**Figure 17.4 Creating DNA libraries.**

books, which is organized and catalogued, a DNA library is a random collection of overlapping DNA fragments. We explore how to find a sequence of interest in this random collection later in the chapter.

## Reverse transcriptase can make a DNA copy of RNA

In addition to genomic libraries, investigators often wish to isolate only the *expressed* part of genes. The structure of eukaryotic genes is such that the mRNA may be much smaller than the gene itself due to the presence of introns in the gene. After transcription by RNA polymerase II, the primary transcript is spliced to produce the mRNA (chapter 15). Because of this, genomic libraries are crucial to understanding the structure of the gene, but are not of much use if we want to express the gene in a bacterial species, whose genes do not contain introns and which has no mechanism for splicing.

A library of only expressed sequences represents a much smaller amount of DNA than the entire genome. The starting point for a cDNA library is isolated mRNA representing the genes expressed in a specific tissue at a specific developmental stage. Such a library of expressed sequences is made possible by the use of another enzyme: reverse transcriptase.

Reverse transcriptase was isolated from a class of viruses called retroviruses. The life cycle of a retrovirus requires making a DNA copy from its RNA genome. We can take advantage of the activity of the retrovirus enzyme to make DNA copies from isolated mRNA. DNA copies of mRNA are called **complementary DNA (cDNA)** (figure 17.5). A cDNA library is made by first isolating mRNA from genes being expressed and then using the reverse transcriptase enzyme to make cDNA from the mRNA. The cDNA is then used to make a library, as mentioned earlier. These cDNA libraries are extremely useful and are commonly made to represent the genes expressed in many different tissues or cells. While all genomic libraries made from an individual will be identical, cDNA libraries from the same cells at different developmental stages or different tissues will each be distinct.

### Inquiry question

? Suppose you wanted a copy of a section of a eukaryotic genome that included the introns and exons. Would the creation of cDNA be a good way to go about this?

## Hybridization allows identification of specific DNAs in complex mixtures

The technique of **molecular hybridization** is commonly used to identify specific DNAs in complex mixtures such as libraries. Hybridization, also called annealing, takes advantage of the specificity of base-pairing between the two strands of DNA. If a DNA molecule is denatured, that is, the two strands are separated, the strands can only reassociate with partners that have the correct complementary sequence. Molecular biologists can take advantage of this feature experimentally to

**Figure 17.5 The formation of cDNA.** A mature mRNA transcript is usually much smaller than the gene due to the loss of intron sequences by splicing. mRNA is isolated from the cytoplasm of a cell, which the enzyme reverse transcriptase uses as a template to make a DNA strand complementary to the mRNA. That newly made strand of DNA is the template for the enzyme DNA polymerase, which assembles a complementary DNA strand along it, producing cDNA—a double-stranded DNA version of the intron-free mRNA.

use a known, specific DNA molecule to find its partner in a complex mixture.

Any single-stranded nucleic acid (DNA or RNA) can be tagged with a radioactive label or with another detectable label, such as a fluorescent dye. This can then be used as a probe to identify its complement in a complex mixture of DNA or RNA. This renaturing is termed *hybridization* because the combination of labeled probe and unlabeled DNA form a hybrid molecule through base-pairing.

Probes have been made historically by a variety of techniques. One technique involved isolating a protein of interest

and then chemically sequencing the protein. With the protein sequence in hand, the DNA sequence could be predicted using the genetic code. This information can then be used to make a synthetic DNA for use as a probe.

## Specific clones can be isolated from a library

The isolation of a specific clone from the random collection that is a DNA library is akin to finding the proverbial needle in a haystack. It requires some information about the gene of interest. For example, many of the first genes isolated were those that are highly expressed in a specific cell type, such as the globin genes that encode the proteins found in the oxygen carrier hemoglobin.

Hybridization is the most common way of identifying a clone within a DNA library. This procedure is outlined for a DNA library in a plasmid vector in figure 17.6.

In the early days of molecular biology, individual investigators made their own DNA libraries, as is shown earlier in figure 17.4. Now, genomic and cDNA libraries are commercially available for a large number of organisms. Screening such a library involves growing the library on agar plates, making a replica of the library, and screening for the cloned sequence of interest.

### Stage 1: Plating the library

Physically, the library is either a collection of bacterial viruses that each contain an inserted DNA, or bacterial cells that each harbor a plasmid or artificial chromosome with inserted DNA. To find a specific clone, the library needs to be represented in an organized fashion. Figure 17.6 shows this representation for a plasmid vector. The library of bacteria containing plasmids is grown on agar plates at a high density, but not so high that individual colonies cannot be distinguished.

### Stage 2: Replicating the library

Once the library has been grown on plates, a replica can be made by laying a piece of filter paper on the plate; some of the viruses or cells in each colony will stick to the filter, and some will be left on the plate. The result is a copy of the library on a piece of filter paper. The DNA can be affixed to the filter paper by baking or by cross-linking it to the filter using UV light.

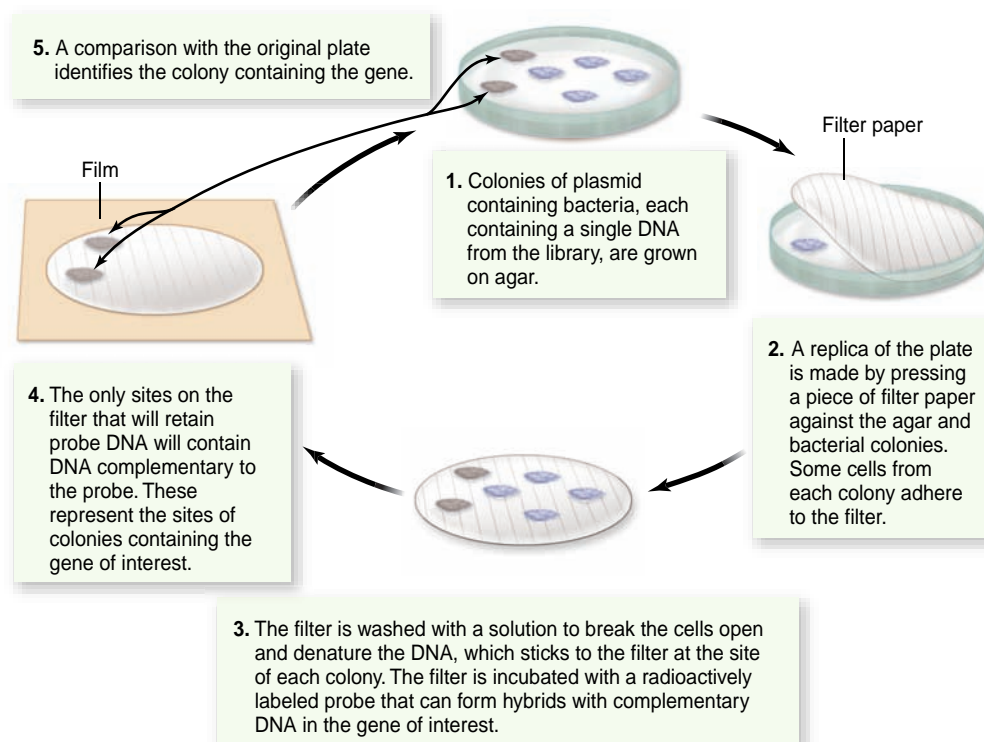

### Stage 3: Screening the library

Once a replica of the library has been formed on a filter, a specific clone can be identified by hybridization. The probe, which represents the specific sequence of interest, is labeled with a radioactive nucleotide. The probe is then added to the filters with the library replicated on them. Film sensitive to radioactive emissions is then placed in contact with the filters; where radioactivity is present, a dark spot appears on the film. When the film is aligned with the original plate, the clone of interest can be identified (see figure 17.6).

### Learning Outcomes Review 17.2

Molecular cloning is the isolation and amplification of a specific DNA sequence. A vector is a carrier into which a sequence of interest may be introduced. The most common vectors are plasmids and phages. The vector takes the sequence into a cell, which then multiplies, copying its own DNA along with that of the vector. DNA libraries are representations of complex mixtures of DNA, such as an entire genome, stored in a host-vector system. DNA libraries are often screened for specific clones using molecular hybridization.

- How does a gene's sequence in a cDNA library compare with the sequence of the gene itself?

**Figure 17.6 Screening a library using hybridization.** This technique takes advantage of DNA's ability to be denatured and renatured, with complementary strands finding each other. Cells containing the library are plated on agar gel. A replica of the plates is made using special filter paper, nitrocellulose or nylon, which binds to single-stranded DNA. The filter paper with replica colonies is treated to lyse the cells and denature the DNA, producing a pattern of DNA bound to the filter that corresponds to the pattern of colonies. When a radioactive probe is added, it finds complementary DNA and forms hybrids at the site of colonies that contained the gene of interest.

**Figure 17.7 The Southern blot procedure.**

Edwin M. Southern developed this procedure in 1975 to enable DNA fragments of interest to be visualized in a complex sample containing many other fragments of similar size. In steps 1–3, the DNA is separated on a gel, and then transferred (“blotted”) onto a solid support medium such as nitrocellulose paper or a nylon membrane. Sequences of interest can be detected by using a radioactively labeled probe. This probe (usually several hundred nucleotides in length) of single-stranded DNA (or an mRNA complementary to the gene of interest) is incubated with the filter containing the DNA fragments. All DNA fragments that contain nucleotide sequences complementary to the probe will form hybrids with the probe. Only a short segment of the probe and the complementary sequence are shown in panel 4. The fragments differ in size, with the smallest moving the farthest in the gel. The fragments of interest are then detected using photographic film. A representative image is shown in panel 5. The use of film for detection is being replaced by phosphor imagers, computer-controlled devices that have electronic sensors for light or radioactive emissions.

1. Electrophoresis is performed, using radioactively labeled markers as a size guide in the first lane.

2. The gel is covered with a sheet of nitrocellulose and placed in a tray of buffer on top of a sponge. Alkaline chemicals in the buffer denature the DNA into single strands. The buffer wicks its way up through the gel and nitrocellulose into a stack of paper towels placed on top of the nitrocellulose.

3. DNA in the gel is transferred, or “blotted,” onto the nitrocellulose.

4. Nitrocellulose with bound DNA is incubated with radioactively labeled nucleic acids and is then rinsed.

5. Photographic film is laid over the filter and is exposed only in areas that contain radioactivity (autoradiography). Bands on the film represent DNA in the gel that is complementary to the probe sequence.

## 17.3 DNA Analysis

### Learning Outcomes

1. Explain the Southern blotting method of identifying genes.
2. Compare endogenous DNA replication with sequencing and with the polymerase chain reaction.
3. Explain how the yeast system is used to study protein–protein interactions.

Molecular cloning provides specific DNA for further manipulation and analysis. The number of ways that DNA can be manipulated could fill the rest of this book, but for our purposes, we will highlight a few important methods of analysis and uses of molecular clones.

### Restriction maps provide molecular “landmarks”

If you are new to a city, the easiest way to find your way around is to obtain a map and compare that map with your surroundings. In a similar fashion, molecular biologists need maps to analyze and compare cloned DNAs.

The first kind of physical maps were restriction maps that included the location and order of sites cut by the battery of restriction enzymes available. Initially, these maps were created by cutting the DNA with different enzymes, separating the fragments by gel electrophoresis, and analyzing the resulting patterns. Although this method is still in use, many restriction maps are now generated by computer searching of known DNA sequences for the sites cut by restriction enzymes.

### Southern blotting reveals DNA differences

Once a gene has been cloned, it may be used as a probe to identify the same or a similar gene in DNA isolated from a cell or tissue (figure 17.7). In this procedure, called a **Southern blot**, DNA from the sample is cleaved into fragments with a restriction endonuclease, and the fragments are separated by gel electrophoresis. The double-stranded helix of each DNA fragment is then denatured into single strands by making the pH of the gel basic. Then the gel is “blotted” with a sheet of filter paper, transferring some of the DNA strands to the sheet.

Next, the filter is incubated with a labeled probe consisting of purified, single-stranded DNA corresponding to a specific gene (or mRNA transcribed from that gene). Any fragment that has a nucleotide sequence complementary to the probe’s sequence hybridizes with the probe (see figure 17.7).

This kind of blotting technique has also been adapted for use with RNA and proteins. When mRNA is separated by electrophoresis, the technique is called a **Northern blot**. The methodology is the same except for the starting material (mRNA instead of DNA) and that no denaturation step is required. Proteins can also be separated by electrophoresis and blotted by a procedure called a **Western blot**. In this case both the electrophoresis and the detection step are different from Southern blotting. The detection, in this case, requires an antibody that can bind to one protein.

The names of these techniques all go back to the original investigator, the British biologist Edwin M. Southern; the Northern and Western blotting names were word play on Southern’s name using the cardinal points of the compass.

### RFLP analysis

In some cases, an investigator wants to do more than find a specific gene, but instead is looking for variation in the genes of different individuals. One powerful way to do this is by analyzing **restriction fragment length polymorphisms**, or **RFLPs**, using Southern blotting (figure 17.8).

Point mutations that change the sequence of DNA can eliminate sequences recognized by restriction enzymes or create new recognition sequences, changing the pattern of fragments seen in a Southern blot. Sequence repetitions may also occur between the restriction endonuclease sites, and differences in repeat number between individuals can also alter the length of the DNA fragments. These differences can all be detected with Southern blotting.

When a genetic disease has an associated RFLP, the RFLP can be used to diagnose the disease. Huntington disease, cystic fibrosis, and sickle cell anemia all have associated RFLPs that have been used as molecular markers for diagnosis.

### DNA fingerprinting

RFLP analysis has been used in **DNA fingerprinting**. When a probe is made for DNA that is repetitive, it often detects a large number of fragments. These fragments are often not identical in different individuals. We say that the population is **polymorphic** for these molecular markers. These markers can be used as

**Figure 17.8** Restriction fragment length polymorphism (RFLP) analysis. *a.* Three samples of DNA differ in their restriction sites due to a single base-pair substitution in one case and a sequence duplication in another case. *b.* When the samples are cut with a restriction endonuclease, different numbers and sizes of fragments are produced. *c.* Gel electrophoresis separates the fragments, and different banding patterns result.

DNA “fingerprints” in criminal investigations and other identification applications.

Figure 17.9 shows the DNA fingerprints a prosecuting attorney presented in a rape trial in 1987. They consist of autoradiographs, parallel bars on X-ray film. These bars can be thought of as being similar to the product price codes on consumer goods in that they may provide unique identification. Each bar represents the position of a DNA restriction endonuclease fragment produced by techniques similar to those described in figures 17.7 and 17.8. The long dark lane with many bars in figure 17.9 represents a standardized control.

Two different probes were used to identify the restriction fragments. A vaginal swab had been taken from the victim within hours of her attack; from it, semen was collected and its DNA analyzed for restriction endonuclease patterns.

Compare the restriction endonuclease patterns of the semen to that of blood from the suspect. You can see that the suspect's two patterns match that of the rapist (and are not at all like those of the victim). The suspect was Tommie Lee Andrews, and on November 6, 1987, the jury returned a verdict of guilty. Andrews became the first person in the United States to be convicted of a crime based on DNA evidence.

Since the Andrews verdict, DNA fingerprinting evidence is now a determining factor in at least forty percent of the criminal cases in the United States. Although some probes highlight profiles shared by many people, others are quite rare. Using several probes, the probability of identity can be calculated or identity can be ruled out. Laboratory analyses of DNA samples, however, must be carried out properly—sloppy procedures could lead to a wrongful conviction. After widely publicized instances of questionable lab procedures, national standards are being developed.

DNA fingerprinting is also used to identify human remains. After the September 11, 2001 attacks on the World Trade Centers in New York, DNA fingerprinting was the only option for identifying some of the victims of the attack. By 2005, 1585 of the 2792 people who were missing had been identified using DNA fingerprinting. Advances in forensic

**Figure 17.9** Two of the DNA profiles that led to the conviction of Tommie Lee Andrews for rape in 1987. The two DNA probes seen here were used to characterize DNA isolated from the victim, the semen left by the rapist, and the suspect. The dark channels are multiband controls. There is a clear match between the suspect's DNA and the DNA of the rapist's semen in these two profiles.

**Figure 17.10** Ladder of fragments used in DNA sequencing. The photo shows the autoradiograph of the fragments generated by DNA-sequencing reactions. These fragments are generated by either organic reactions that cleave at specific bases or enzymatic reactions that terminate in specific bases. The gel can separate fragments that differ by a single base.

technology, including improved DNA isolation from very small amounts of tissue, have made it possible to identify additional individuals since 2005.

## DNA sequencing provides information about genes and genomes

The ultimate level of analysis is determination of the actual sequence of bases in a DNA molecule. The development of sequencing technology has paralleled the advancement of molecular biology. As it became possible to determine the sequence of an entire genome relatively rapidly, the field of genomics emerged.

The basic idea used in DNA sequencing is to generate a set of nested fragments that each begin with the same sequence and end in a specific base. When this set of fragments is separated by high-resolution gel electrophoresis, the result is a “ladder” of fragments (figure 17.10) in which each band consists of fragments that end in a specific base. By starting with the shortest fragment, one can then read the sequence by moving up the ladder.

The problem then became how to generate the sets of fragments that end in specific bases. In the early days of sequencing, both a chemical method and an enzymatic method were utilized. The chemical method involved organic reactions specific for the different bases that made breaks in the DNA chains at specific bases. The enzymatic method used DNA polymerase to synthesize chains, but it also included in the reaction modified nucleotides that could be incorporated but not extended: so-called *chain terminators*. The enzymatic method has proved more versatile, and it is easier to adapt to different uses.

### Enzymatic sequencing

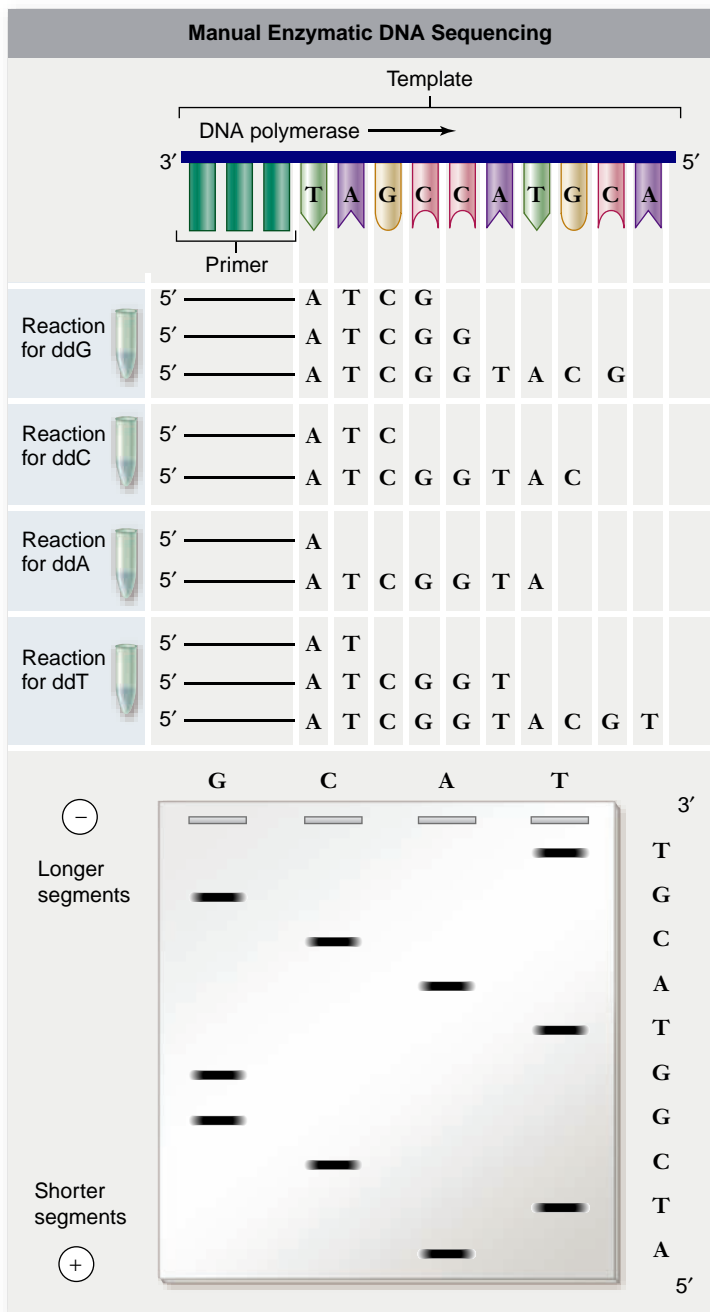

The enzymatic method of sequencing was developed by Frederick Sanger, who also was the first to determine the complete sequence of a protein. This method uses dideoxynucleotides as chain terminators in DNA synthesis reactions. A **dideoxynucleotide** has H in place of OH at both the 2' position and at the 3' position.

All DNA nucleotides lack —OH at the 2' carbon of the sugar, but dideoxynucleotides have no 3' —OH at which the enzyme can add new nucleotides. Thus the chain is terminated.

The experimenter must perform four separate reactions, each with a single dideoxynucleotide, to generate a set of fragments that terminate in specific bases. Thus all of the fragments produced in the A reaction incorporate dideoxy-

adenosine and must end in A, and the same for the other three reactions with different terminators. When these fragments are separated by high-resolution gel electrophoresis, each reaction is run in a different track, or lane, to generate a pattern of nested fragments that can be read from the smallest fragment to fragments that are each longer by one base (figure 17.11*a*).

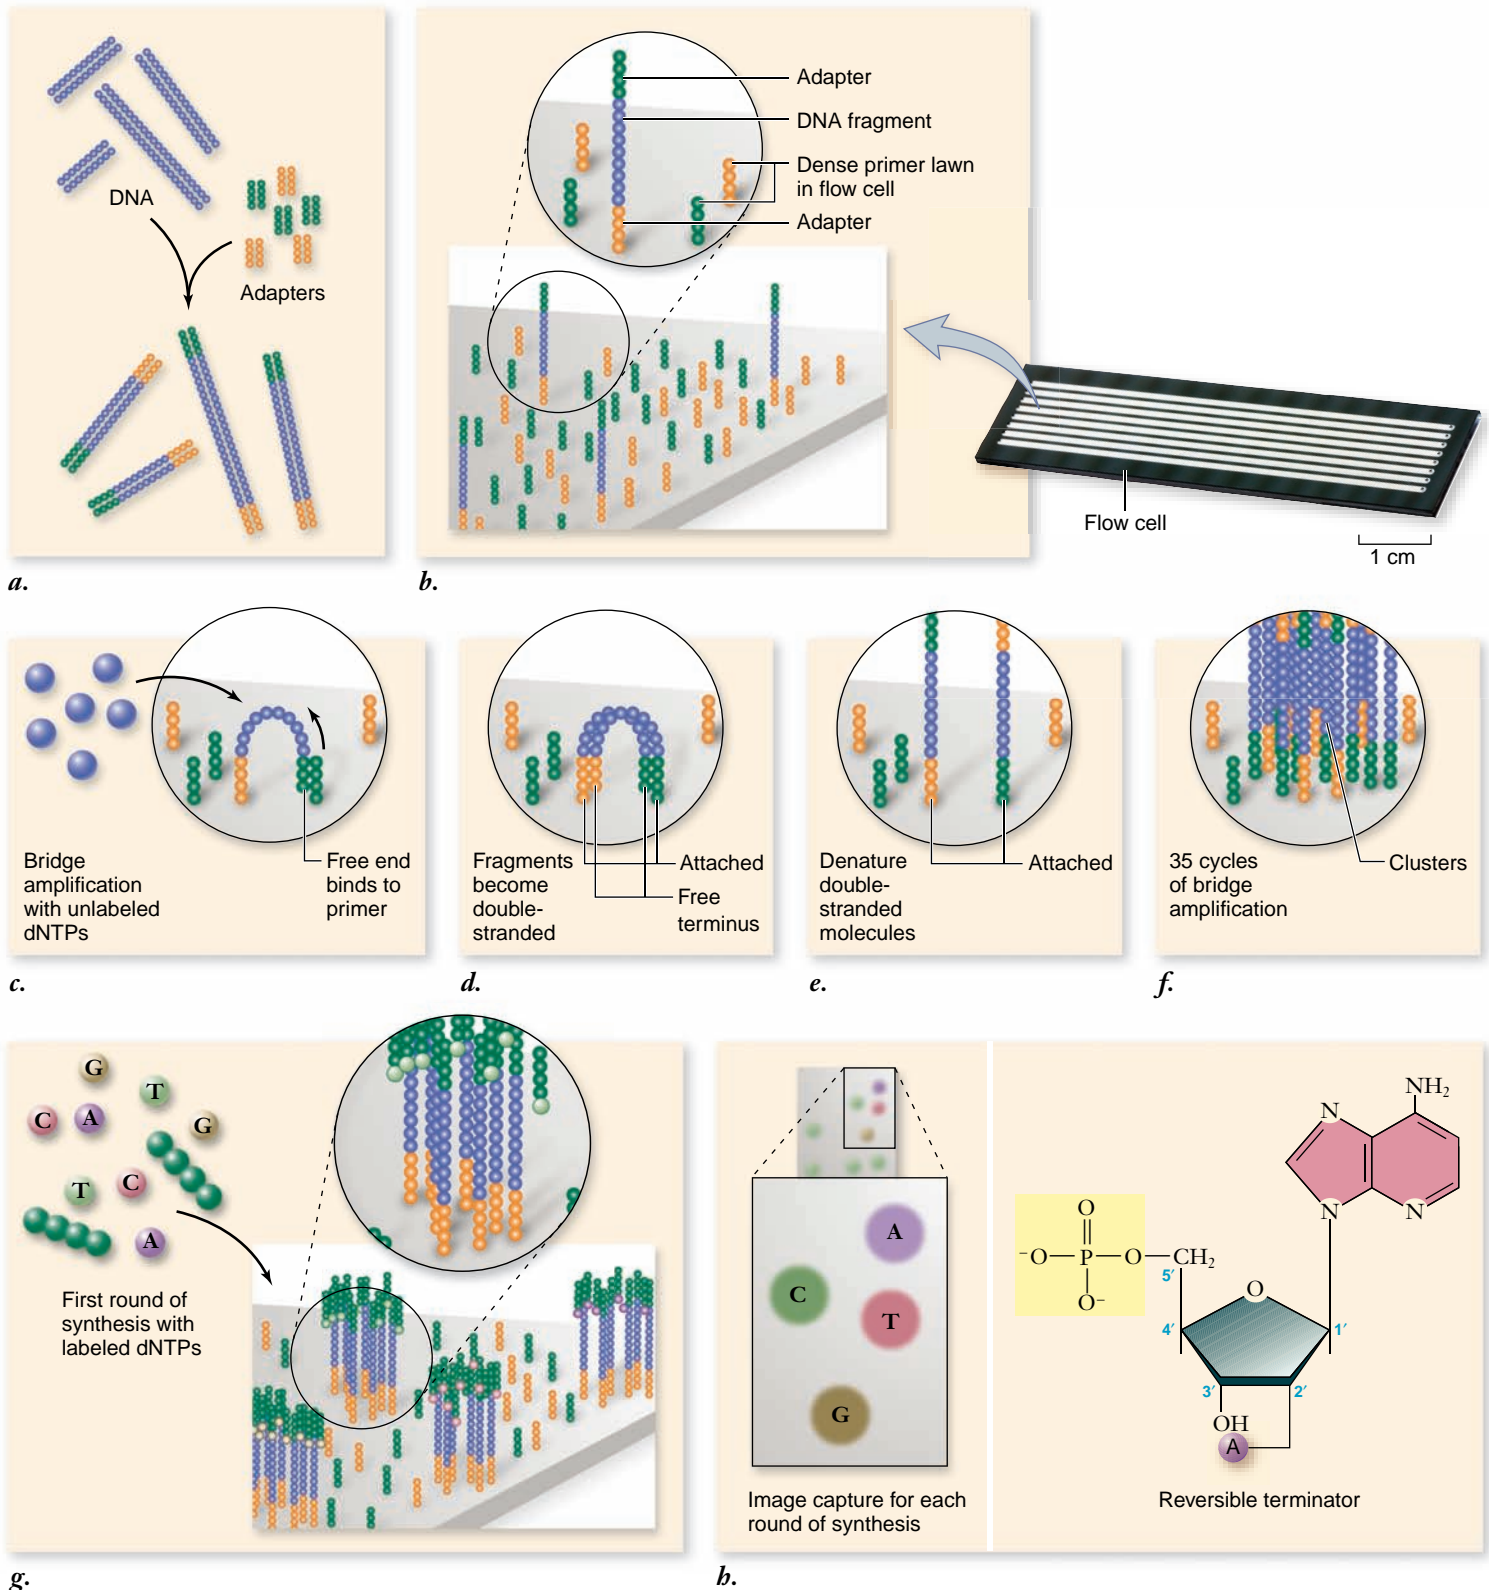

*a.*

*b.*

**Figure 17.11 Manual and automated enzymatic DNA sequencing.** The sequence to be determined is shown at the top as a template strand for DNA polymerase with a primer attached. *a.* In the manual method, four reactions were done, one for each nucleotide. For example, the A tube would contain dATP, dGTP, dCTP, dTTP, and ddATP. This leads to fragments that end in A due to the dideoxy terminator. The fragments generated in each reaction are shown along with the results of gel electrophoresis. *b.* In automated sequencing, each ddNTP is labeled with a different color fluorescent dye, which allows the reaction to be done in a single tube. The fragments generated by the reactions are shown. When these are electrophoresed in a capillary tube, a laser at the bottom of the tube excites the dyes, and each will emit a different color that is detected by a photodetector.

**Figure 17.12 New approach to sequencing.** DNA is cleaved into short fragments that will be sequenced. *a.* Adapters are added to the end of the DNA. *b.* DNA is denatured and the adapters bind to complementary primers in the flow cell. *c-f.* Individual fragments are amplified using dNTPs and polymerase. *g.* Fluorescently labeled dNTPs with cleavable dye that blocks the formation of additional phosphodiester bonds are added, and the first fluorescently labeled base is added. *h.* A CCD camera records the fluorescence pattern before the fluorescent dye is removed, and the next base is added to each DNA sequence.

Notice that since this is a DNA polymerase reaction, it requires a primer to begin synthesis. The vectors used for DNA sequencing have known regions next to the site where DNA is inserted. Short DNAs that are complementary to these regions are then synthesized and can be used as primers. This serves the dual purposes of providing a primer and ensuring that the first few bases sequenced are known because they are known in the vector itself. This allows the investigator to determine where the sequence of interest begins. As the sequence is generated, new primers can be designed near the end of the known sequence and DNA synthesized to use as a primer to extend the region sequenced in the next set of reactions.

### Automated sequencing

The technique of enzymatic sequencing is very powerful, but it is also labor-intensive and takes a significant amount of time. It requires a series of enzymatic manipulations, time for electrophoresis, then time to expose the gel to film. At the end of this, a skilled researcher can read around 300 bases of sequence reliably. The development of automated techniques made sequencing a much more practical and less human-intensive procedure.

Automated sequencing machines use fluorescent dyes instead of a radioactive label and separate the products of the sequencing reactions using gels in thin capillary tubes instead of the large slab gels. The tubes run in front of a laser that excites the dyes, causing them to fluoresce. With a different colored dye for each base, a photodetector can determine the identity of each base by its color.

The data are assembled by a computer that generates a visual image consisting of different colored peaks; these are converted into the raw sequence data (figure 17.11*b*). The sequence data come directly from the electrophoresis, eliminating the time needed for exposing gels to film and for manual reading of the sequences. The use of different colored dyes also reduces handling and allows more sequence to be produced at one time.

With increases in the number of samples per run and the length of sequences able to be read, along with decreases in handling time, the amount of sequence information that can be generated is limited mainly by the number of machines that can be run at once.

### New sequencing technology

For over 30 years, the basic chemistry of DNA sequencing did not change. Automation increased the speed of sequencing to the point that sequencing large eukaryotic genomes became possible. In the last few years, however, fundamentally new methods for sequencing have vastly accelerated the rate of sequence generation. Here we explore one new approach, which can generate 20 billion base pairs of sequence in a single run (figure 17.12). DNA is cleaved into smaller pieces, a few hundred base pairs, using a nebulizer—a device that converts the liquid to a very fine spray. Both ends are ligated to adapters that are complementary to specific primers. These DNA fragments are injected into a flow cell, which is like a microscope slide with seven channels, each containing a solid substrate with primers that complement the ligated ends of the DNA fragments. Millions of DNA fragments are placed in these channels, made single-stranded, and then amplified so there are

clusters of fragments. Amplification works like DNA replication where a polymerase is added that recognizes the primer and starts copying. The fragments are again denatured to yield single-stranded molecules. They are now ready for sequencing. As with Sanger sequencing, deoxyribonucleotide triphosphates (dNTPs) have a fluorescent tag, but it can be removed. Four colors are used to distinguish each base. The fluorescent tag is reversibly attached to the 2' position on the deoxyribose sugar and it blocks the 3' OH so that only a single phosphodiester bond forms, but the blocking group can be removed after each round of DNA extension so the DNA strands continue to elongate. Very powerful charge-coupled device (CCD) cameras, once used exclusively by astronomers, record the pattern of fluorescence in the flow cell after each round of elongation. The technology works because a solid material holds the DNA fragments in place while they are being synthesized so that the repeated CCD images can be compiled and provide information about the sequence of each cluster of fragments. The amount of data generated each time another round of base pairs is added is enormous, so digital storage space and computational power to make sense of the data are the limiting factors.

## The polymerase chain reaction accelerates the process of analysis

The next revolution in molecular biology was the development of the **polymerase chain reaction (PCR)**. Kary Mullis developed PCR in 1983 while he was a staff chemist at the Cetus Corporation; in 1993, he was awarded the Nobel Prize in chemistry for his discovery.

The idea of the polymerase chain reaction is simple: Two primers are used that are complementary to the opposite strands of a DNA sequence, oriented toward each other. When DNA polymerase acts on these primers and the sequence of interest, the primers produce complementary strands, each containing the other primer. If this procedure is done cyclically, the result is a large quantity of a sequence corresponding to the DNA that lies between the two primers (figure 17.13).

### The PCR procedure

Two developments turned this simple concept into a powerful technique. First, each cycle requires denaturing the DNA after each round of synthesis, which is easily done by raising the temperature; however, this destroys most polymerase enzymes. The solution was to isolate a DNA polymerase from a thermophilic, or heat-loving bacteria, *Thermus aquaticus*. This enzyme, called **Taq polymerase**, allows the reaction mixture to be repeatedly heated without destroying enzyme activity.

The second innovation was the development of machines with heating blocks that can be rapidly cycled over large temperature ranges with very accurate temperature control.

Thus each cycle of PCR involves three steps:

1. Denaturation (high temperature)
2. Annealing of primers (low temperature)
3. Synthesis (intermediate temperature)

Steps 1 to 3 are now repeated, and the two copies become four. It is not necessary to add any more polymerase, because

the heating step does not harm Taq polymerase. Each complete cycle, which takes only 1–2 min, doubles the number of DNA molecules. After 20 cycles, a single fragment produces more than one million ( $2^{20}$ ) copies!

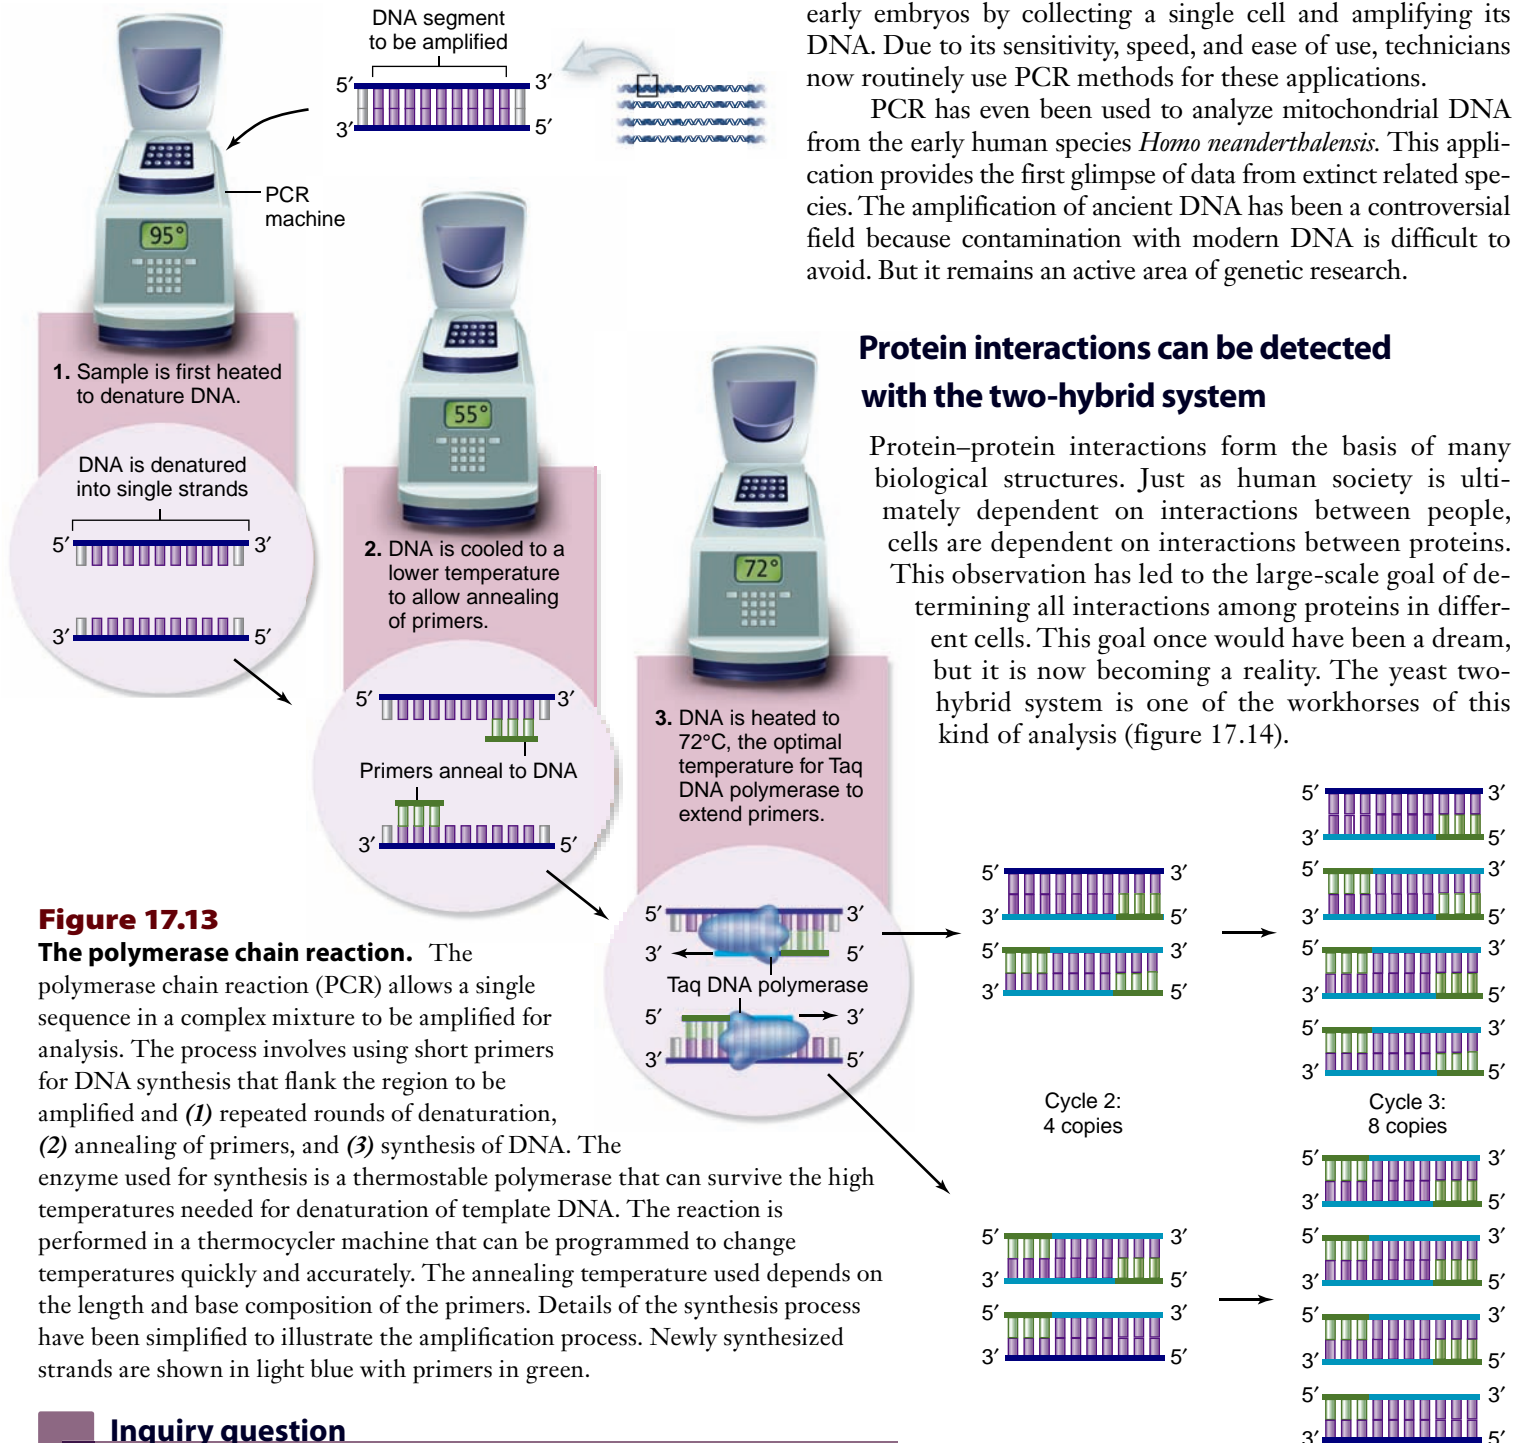

In this way, the process of PCR allows the amplification of a single DNA fragment from a small amount of a complex mixture of DNA. This result is similar to what is isolated using molecular cloning, but in the case of PCR, the DNA cannot be reintroduced directly into a cell. The PCR product can be analyzed using electrophoresis, cloned into a vector for other

manipulations, or directly sequenced. There are limitations on the size of the fragment that can be synthesized in this way, but it has been adapted for an amazing number of uses.

### Applications of PCR

PCR, now fully automated, has revolutionized many aspects of science and medicine because it allows the investigation of minute samples of DNA. In criminal investigations, DNA fingerprints can now be prepared from the cells in a tiny speck of dried blood or from the tissue at the base of a single human hair. In medicine, physicians can detect genetic defects in very early embryos by collecting a single cell and amplifying its DNA. Due to its sensitivity, speed, and ease of use, technicians now routinely use PCR methods for these applications.

PCR has even been used to analyze mitochondrial DNA from the early human species *Homo neanderthalensis*. This application provides the first glimpse of data from extinct related species. The amplification of ancient DNA has been a controversial field because contamination with modern DNA is difficult to avoid. But it remains an active area of genetic research.

**Figure 17.13**  
**The polymerase chain reaction.** The polymerase chain reaction (PCR) allows a single sequence in a complex mixture to be amplified for analysis. The process involves using short primers for DNA synthesis that flank the region to be amplified and (1) repeated rounds of denaturation, (2) annealing of primers, and (3) synthesis of DNA. The enzyme used for synthesis is a thermostable polymerase that can survive the high temperatures needed for denaturation of template DNA. The reaction is performed in a thermocycler machine that can be programmed to change temperatures quickly and accurately. The annealing temperature used depends on the length and base composition of the primers. Details of the synthesis process have been simplified to illustrate the amplification process. Newly synthesized strands are shown in light blue with primers in green.

### Protein interactions can be detected with the two-hybrid system

Protein–protein interactions form the basis of many biological structures. Just as human society is ultimately dependent on interactions between people, cells are dependent on interactions between proteins. This observation has led to the large-scale goal of determining all interactions among proteins in different cells. This goal once would have been a dream, but it is now becoming a reality. The yeast two-hybrid system is one of the workhorses of this kind of analysis (figure 17.14).

#### Inquiry question

? Could PCR be used to amplify mRNA?

The yeast two-hybrid system integrates much of the technology discussed in this chapter. It takes advantage of one feature of eukaryotic gene regulation, namely that the structure of proteins that turn on eukaryotic gene expression, transcription factors, have a modular structure.

The *Gal4* gene of yeast encodes a transcriptional activator with modular structure consisting of a DNA-binding domain that binds sequences in *Gal4*-responsive promoters, and an activation domain that interacts with the transcription apparatus to turn on transcription. The system uses two vectors: one containing a fragment of the *Gal4* gene that encodes the DNA-binding domain, and another containing a fragment of the *Gal4* gene that encodes the transcription activation domain. Neither of these alone can activate transcription.

**Figure 17.14** The yeast two-hybrid system detects interacting proteins. The Gal4 protein is a transcriptional activator (top). The *Gal4* gene has been split and engineered into two different vectors such that one will encode only the DNA-binding domain (bait vector) and the other the transcription-activating domain (prey vector). When other genes are spliced into these vectors, they produce fusion proteins containing part of Gal4 and the proteins to be tested. If the proteins being tested interact, this will restore *Gal4* function and activate expression of a reporter gene.

When cDNAs are inserted into each of these two vectors in the proper reading frame, they are expressed as a single protein consisting of the protein of interest and part of the Gal4 activator protein (see figure 17.13). These hybrid proteins are called *fusion proteins* since they are literally fused in the same polypeptide chain. The DNA-binding hybrid is called the *bait*, and the activating domain hybrid is called the *prey*.

These vectors are inserted into cells of different mating types that can be crossed. One of these vectors also contains a so-called *reporter gene* encoding a protein that can be assayed for enzymatic activity. The reporter gene is under control of a *Gal4*-responsive regulatory region, so that when active *Gal4* is present, the reporter gene is expressed and can be detected by an enzymatic assay.

The DNA-binding hybrid binds to DNA adjacent to the reporter gene. When the two proteins in bait and prey interact, the prey hybrid brings the activating domain into position to turn on gene expression from the reporter gene (see figure 17.13).

The beauty of this system is that it is both simple and flexible. It can be used with two known proteins or with a known protein in the bait vector and entire cDNA libraries in the prey vector. In the latter case, all of the possible interactions in a cell type can be mapped.

It is already clear that even more protein interactions occur in cells than anticipated. In the future these data will form the basis for understanding the networks of protein interactions that make up the normal activities of a cell.

### Learning Outcomes Review 17.3

The Southern blotting technique allows identification of a target DNA by separating single-stranded DNA fragments and hybridizing fragments of interest with a labeled probe. In living cells, DNA polymerase is a key enzyme in replication. DNA sequencing uses a modified DNA polymerase reaction that contains chain terminators, allowing fragments to be ordered in sequence. The polymerase chain reaction (PCR) produces a large amount of a specific DNA from a small amount of starting material. The yeast system for detecting protein–protein interactions involves a bait protein, a prey protein, and a reporter gene.

- What key component of PCR allows the rapid amplification of a sample?

## 17.4 Genetic Engineering

### Learning Outcome

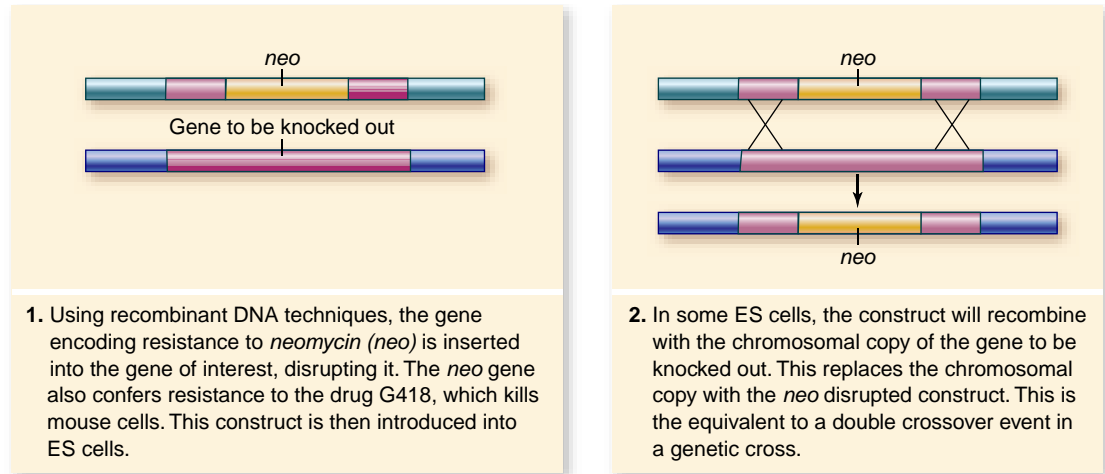

1. Describe three applications of cloning technology.

The ability to clone individual genes for analysis ushered in an era of unprecedented advancement in research. At the time, these advancements were not accompanied by grand announcements of potential medical breakthroughs and other applications. The ability to truly genetically engineer any kind of cell

## Figure 17.15

### Construction of a knockout mouse.

Steps in the construction of a knockout mouse. Some technical details have been omitted, but the basic concept is shown.

1. Using recombinant DNA techniques, the gene encoding resistance to neomycin (*neo*) is inserted into the gene of interest, disrupting it. The *neo* gene also confers resistance to the drug G418, which kills mouse cells. This construct is then introduced into ES cells.

2. In some ES cells, the construct will recombine with the chromosomal copy of the gene to be knocked out. This replaces the chromosomal copy with the *neo* disrupted construct. This is the equivalent to a double crossover event in a genetic cross.

or organism was a long way off. But we are now approaching this ability, and it has generated much excitement as well as controversy.

## Expression vectors allow production of specific gene products

A variety of specialized vectors have been constructed since the development of cloning technology. One very important type of vector are the **expression vectors**. These vectors contain the sequences necessary to drive expression of inserted DNA in a specific cell type, namely the correct sequences to permit transcription and translation of the sequences. The production of recombinant proteins in bacteria, for example, uses expression vectors with bacterial promoters and other control regions. The bacteria transformed by such vectors synthesize large amounts of the protein encoded by the inserted DNA. A number of pharmaceuticals have been produced in this way, the first of which was insulin, used to treat diabetes. (This type of application is discussed in more detail in the next section.)

## Genes can be introduced across species barriers

The ability to reintroduce genes into an original host cell, or to introduce genes into another host, is true genetic engineering. An animal containing a gene that has been introduced without the use of conventional breeding is called a **transgenic animal**. We will explore a number of uses of transgenic animals in medicine and agriculture, but it is important to realize that their original use was for basic research.

The ability to engineer genes in context or out of context allows an experimenter to ask questions that could never be asked otherwise. A dramatic example was the use of the *eyeless* gene from mice in *Drosophila*. When this mouse gene was introduced into *Drosophila*, it was shown to be able to substitute for a *Drosophila* gene in organizing the formation of eyes. It could even cause the formation of eyes in incorrect locations when expressed in tissue that did not normally form eyes. This amazing result shows that the formation of the compound eye in an

insect is not so different from the formation of the complex vertebrate eye. This example is discussed in more detail in chapter 25.

## Cloned genes can be used to construct “knockout” mice

One of the most important technologies for research purposes is **in vitro mutagenesis**—the ability to create mutations at any site in a cloned gene to examine their effect on function. Rather than depending on mutations induced by chemical agents or radiation in intact organisms, which is time- and labor-intensive, the DNA itself is directly manipulated. The ultimate use of this approach is to be able to replace the wild-type gene with a mutant copy to test the function of the mutated gene. Developed first in yeast, this technique has now been extended to the mouse.

In mice, this technique has produced **knockout mice** in which a known gene is inactivated (“knocked out”). The effect of loss of this function is then assessed in the adult mouse, or if it is lethal, the stage of development at which function fails can be determined. The idea is simple, but the technology is quite complex. A streamlined description of the steps in this type of experiment are outlined as follows and illustrated in figure 17.15:

1. The cloned gene is disrupted by replacing it with a marker gene using recombinant DNA techniques. The marker gene codes for resistance to the antibiotic neomycin in bacteria, which allows mouse cells to survive when grown in a medium containing the related drug G418. The construction is done such that the marker gene is flanked by the DNA normally flanking the gene of interest in the chromosome.
2. The interrupted gene is introduced into **embryonic stem cells (ES cells)**. These cells are derived from early embryos and can develop into different adult tissues. In these cells, the gene can recombine with the chromosomal copy of the gene based on the flanking DNA. This is the same kind of recombination used to map genes (chapter 13). The knockout gene with the drug resistance

3. The ES cells are placed on G418-containing medium. The G418 selects cells that have had a replacement event, and now contain a copy of the knocked out gene.

4. The ES cells containing the knocked out gene are injected into a blastocyst stage embryo and then implanted into a female to complete development.

5. Offspring will contain one chromosome with the gene of interest knocked out. Genetic crosses can then produce mice homozygous for the knocked out gene to assess the phenotype. This can range from lethality to no visible effect depending on the gene.

gene does not have an origin of replication, and thus it will be lost if no recombination occurs. Cells are grown in medium containing G418 to select for recombination events. (Only those containing the marker gene can grow in the presence of G418.)

- The ES cells containing the knocked-out gene are injected into a blastocyst stage embryo, which is then implanted into a pseudopregnant female (one that has been mated with a vasectomized male and as a result has a receptive uterus). The pups from this female have one copy of the gene of interest knocked out. Transgenic animals can then be crossed to generate homozygous lines. These homozygous lines can be analyzed for phenotypes.

In conventional genetics, genes are identified based on mutants that show a particular phenotype. Molecular genetic techniques are then used to find the gene and isolate a molecular clone for analysis. The use of knockout mice is an example of **reverse genetics**: A cloned gene of unknown function is used to make a mutant that is deficient in that gene. A geneticist can then assess the effect on the entire organism of eliminating a single gene.

Sometimes this approach leads to surprises, such as happened when the gene for the p53 tumor suppressor was knocked out. Because this protein is found mutated in many human cancers and plays a key role in the regulation of the cell cycle (chapter 10), it was thought to be essential—the knockout was expected to be lethal. Instead, the mice were born normal; that is, development had proceeded normally. These mice do have a phenotype, however; they exhibit an increased incidence of tumors in a variety of tissues as they age.

### Learning Outcome Review 17.4

Expression vectors that contain cloned genes allow the production of known proteins in different cells. This can be done for research purposes or to produce pharmaceuticals.

- Why is recombination an essential factor in creating a “knockout” mouse?

## 17.5 Medical Applications

### Learning Outcomes

- Explain how eukaryote proteins can be produced in bacterial cells.
- Evaluate potential problems of gene therapy.

The early days of genetic engineering led to a rash of startup companies, many of which are no longer in business. At the same time, all of the major pharmaceutical companies either began research in this area or actively sought to acquire smaller companies with promising technology. The number of applications of this technology are far too numerous to mention here, but we highlight a few; the section following discusses agricultural applications.

### Human proteins can be produced in bacteria

The first and perhaps most obvious commercial application of genetic engineering was the introduction of genes that encode clinically important proteins into bacteria. Because bacterial cells can be grown cheaply in bulk, bacteria that incorporate recombinant genes can synthesize large amounts of the proteins those genes specify, assuming the inserted gene has been designed to be expressed in a bacterial cell. This method has been used to produce several forms of human insulin and the immune system protein interferon, as well as other commercially valuable proteins, such as human growth hormone (figure 17.16) and erythropoietin, which stimulates red blood cell production.

Among the medically important proteins now manufactured by these approaches are **atrial peptides**, small proteins that may provide a new way to treat high blood pressure and kidney failure. Another is **tissue plasminogen activator (TPA)**, a human protein synthesized in minute amounts that causes blood clots to dissolve and that if used within the first

**Figure 17.16 Genetically engineered mouse with human growth hormone.** These two mice are from an inbred line and differ only in that the large one has one extra gene: the gene encoding human growth hormone. The gene was added to the mouse's genome and is now a stable part of the mouse's genetic endowment.

3 hr after an ischemic stroke (i.e., one that blocks blood to the brain) can prevent catastrophic disability.

A problem with this approach has been the difficulty of separating the desired protein from the others the bacteria make. The purification of proteins from such complex mixtures is both time-consuming and expensive, but it is still easier than

isolating the proteins from bulk processing of the tissues of animals, which is how such proteins used to be obtained. For example, insulin was previously extracted from hog pancreases because hog insulin was similar to human insulin.

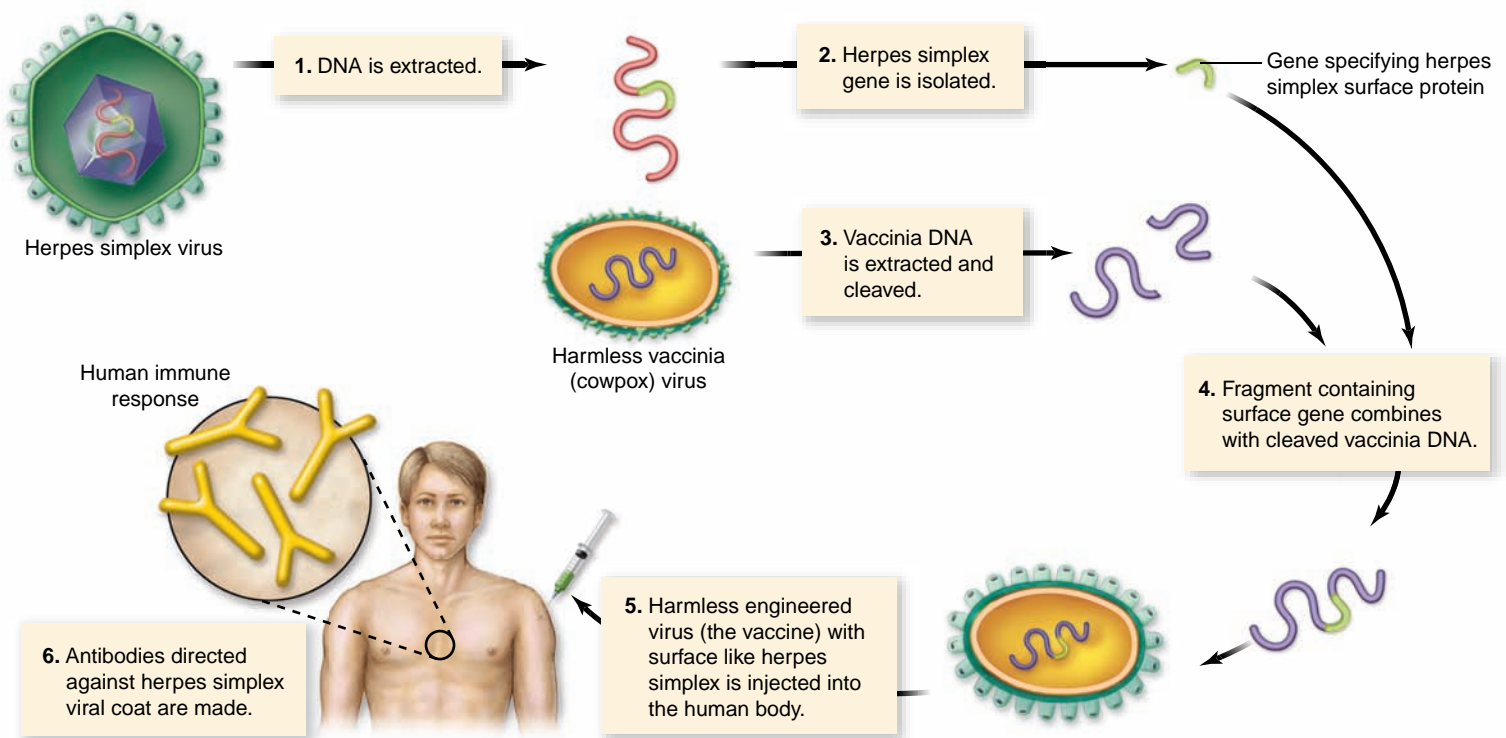

## Recombinant DNA may simplify vaccine production

Another area of potential significance involves the use of genetic engineering to produce vaccines against communicable diseases. Two types of vaccines are under investigation: *subunit vaccines* and *DNA vaccines*.

### Subunit vaccines

**Subunit vaccines** may be developed against viruses such as those that cause herpes and hepatitis. Genes encoding a part, or subunit, of the protein polysaccharide coat of the herpes simplex virus or hepatitis B virus are spliced into a fragment of the vaccinia (cowpox) virus genome (figure 17.17).

The vaccinia virus, which British physician Edward Jenner used more than 200 years ago in his pioneering vaccinations against smallpox, is now used as a vector to carry the herpes or hepatitis viral coat gene into cultured mammalian cells. These cells produce many copies of the recombinant vaccinia virus, which has the outside coat of a herpes or hepatitis virus. When this recombinant virus is injected into a mouse or rabbit, the immune system of the infected animal produces antibodies directed against the coat of the recombinant virus. The animal then develops an immunity to herpes or hepatitis virus.

**Figure 17.17 Strategy for constructing a subunit vaccine against herpes simplex.** Recombinant DNA techniques can be used to construct vaccines for a single protein from a virus or bacterium. In this example, the protein is a surface protein from the herpes simplex virus.

Vaccines produced in this way are harmless because the vaccinia virus is benign, and only a small fragment of the DNA from the disease-causing virus is introduced via the recombinant virus.

The great attraction of this approach is that it does not depend on the nature of the viral disease. In the future, similar recombinant viruses may be used in humans to confer resistance to a wide variety of viral diseases.

### DNA vaccines

In 1995, the first clinical trials began to test a novel new kind of **DNA vaccine**, one that depends not on antibodies but rather on the second arm of the body's immune defense, the so-called *cellular immune response*, in which blood cells known as killer T cells attack infected cells (chapter 52). The first DNA vaccines spliced an influenza virus gene encoding an internal nucleoprotein into a plasmid, which was then injected into mice. The mice developed a strong cellular immune response to influenza. Although new and controversial, the approach offers great promise.

## Gene therapy can treat genetic diseases directly

In 1990, researchers first attempted to combat genetic defects by the transfer of human genes. When a hereditary disorder is the result of a single defective gene, an obvious way to cure the disorder would be to add a working copy of the gene. This approach is being used in an attempt to combat cystic fibrosis, and it offers the potential of treating muscular dystrophy and a variety of other disorders (table 17.1).

**TABLE 17.1**

**Diseases Being Treated in Clinical Trials of Gene Therapy**

Disease
Cancer (melanoma, renal cell, ovarian, neuroblastoma, brain, head and neck, lung, liver, breast, colon, prostate, mesothelioma, leukemia, lymphoma, multiple myeloma)
SCID (severe combined immunodeficiency)
Cystic fibrosis
Gaucher disease
Familial hypercholesterolemia
Hemophilia
Purine nucleoside phosphorylase deficiency
$\alpha_1$ -Antitrypsin deficiency
Fanconi anemia
Hunter syndrome
Chronic granulomatous disease
Rheumatoid arthritis
Peripheral vascular disease
Acquired immunodeficiency syndrome (AIDS)
Duchenne muscular dystrophy
Macular degeneration (wet variety)
Batten disease (neurological disorder)

Clinical trials for treating macular degeneration, a genetic eye disease, using an RNAi vector (see chapter 16) are promising. Individuals with a certain type of macular degeneration lose their sight because of the uncontrolled proliferation of blood vessels under the retina. For the patient, it is a lot like looking through a car windshield with broken wipers in the middle of a thunderstorm. RNAi gene therapy involves injection of double-stranded RNA coding for a gene necessary for blood vessel proliferation. The RNAi mechanism has the counterintuitive effect of suppressing production of the protein needed for blood vessel development, preventing progression of the disease.

One disease that illustrates both the potential and the problems with gene therapy is **severe combined immunodeficiency disease (SCID)**. This disease has multiple forms, including an X-linked form (X-SCID) and a form that lacks the enzyme adenosine deaminase (ADA-SCID).

Recent trials for both of these forms showed great initial promise, with patients exhibiting restoration of immune function. But then problems arose in the case of the X-SCID trial when a patient developed a rare form of leukemia. Since that time, two other patients have developed the same leukemia, and it appears to be due to the gene therapy itself. The vector used to introduce the X-SCID gene integrated into the genome next to a proto-oncogene called *LMO2* in all three cases. Activation of this gene can cause childhood leukemias.

The insertion of a gene during gene therapy has always been a random event, and it has been a concern that the insertion could inactivate an essential gene, or turn on a gene inappropriately. That effect had not been observed prior to the X-SCID trial, despite a large number of genes introduced into blood cells in particular. For leukemia to occur in 15% of the patients treated implies that some influence of the genetic background associated with X-SCID potentiates this development. This possibility is supported by the observation that the ADA-SCID patients treated have not been affected thus far.

On the positive side, 15 children treated successfully are still alive, 14 of them after more than four years, with functioning immune systems. On the negative side, three other children treated have developed leukemia.

When we understand the basis of the preferential integration in the case of X-SCID, it should be possible to overcome this unfortunate result. In the meantime, the investigators have halted the trial and are working on new vectors to reduce the possibility of this preferential integration.

### Learning Outcomes Review 17.5

Recombinant DNA technology has allowed genes from eukaryotes, such as humans, to be isolated, inserted into vectors, and recombined into bacterial genomes, where the genes' products can be mass-produced. Gene therapy is the process of using genetic engineering to replace defective genes; however, in some cases unwanted effects result from random gene insertion.

- **What might be some undesirable effects of treating patients with human proteins manufactured in and isolated from other organisms?**

## 17.6 Agricultural Applications

### Learning Outcomes

1. Compare recombinant technology techniques in plants with those in bacteria.
2. Describe the controversial issues in the use of GM plants.

Perhaps no area of genetic engineering touches all of us so directly as the applications that are being used in agriculture today. Crops are being modified to resist disease, to be tolerant of herbicides, and for changes in nutritional and other content in a variety of ways. Plant systems are also being used to produce pharmaceuticals by “biopharming,” and domesticated animals are being genetically modified to produce biologically active compounds.

### The Ti plasmid can transform broadleaf plants

In plants, the primary experimental difficulty has been identifying a suitable vector for introducing recombinant DNA. Plant cells do not possess the many plasmids that bacteria have, so the choice of potential vectors is limited.

#### The Ti plasmid

The most successful results thus far have been obtained with the **Ti (tumor-inducing) plasmid** of the plant bacterium *Agrobacterium tumefaciens*, which normally infects broadleaf plants such as tomato, tobacco, and soybean. Part of the Ti plasmid integrates into the plant DNA, and researchers have succeeded in attaching other genes to this portion of the plasmid (figure 17.18). The characteristics of a number of plants

have been altered using this technique, which should be valuable in improving crops and forests.

Among the features scientists would like to affect are resistance to disease, frost, and other forms of stress; nutritional balance and protein content; and herbicide resistance. All of these traits have either been modified or are being modified. Unfortunately, *Agrobacterium* normally does not infect cereal plants such as corn, rice, and wheat, but alternative methods can be used to introduce new genes into them.

#### Other methods of gene insertion

For cereal plants that are not normally infected by *Agrobacterium*, other methods have been used. One popular method, “the gene gun,” uses bombardment with tiny gold or tungsten particles coated with DNA. This technique has the advantage of being usable for any species, but it does not allow as precise an engineering because the copy number of introduced genes is much harder to control.

Recently, modifications of the *Agrobacterium* system have allowed it to be used with cereal plants, so the gene gun technology may not be used much in the future. A new bacterium has also been manipulated to function like *Agrobacterium*, offering another potential alternative method of engineering cereal crops.

It is clear that genetic modification of crop plants of all sorts has become a mature technology, which should accelerate the production of a variety of transgenic crops.

### Herbicide-resistant crops allow no-till planting

Recently, broadleaf plants have been genetically engineered to be resistant to **glyphosate**, a powerful, biodegradable herbicide that kills most actively growing plants (figure 17.19). Glyphosate works by inhibiting an enzyme called 5-enolpyruvylshikimate-3-phosphate (EPSP) synthetase, which plants require to produce aromatic amino acids.

**Figure 17.18 The Ti plasmid.** This *Agrobacterium tumefaciens* plasmid is used in plant genetic engineering.

## SCIENTIFIC THINKING

**Hypothesis:** *Petunias can acquire tolerance to the herbicide glyphosate by overexpressing EPSP synthase.*

**Prediction:** *Transgenic petunia plants with a chimeric EPSP synthase gene with strong promoter will be glyphosate tolerant.*

**Test:**

1. Use restriction enzymes and ligase to “paste” the cauliflower mosaic virus promoter (35S) to the EPSP synthase gene and insert the construct in Ti plasmids.
2. Transform *Agrobacterium* with the recombinant plasmid.
3. Infect petunia cells and regenerate plants. Regenerate uninfected plants as controls.
4. Challenge plants with glyphosate.

**Result:** *Glyphosate kills control plants, but not transgenic plants.*

**Conclusion:** *Additional EPSP synthase provides glyphosate tolerance.*

**Further Experiments:** *The transgenic plants are tolerant, but not resistant (note bleaching at shoot tip). How could you determine if additional copies of the gene would increase tolerance? Can you think of any downsides to expressing too much EPSP synthase in petunia?*

**Figure 17.19** Genetically engineered herbicide resistance.

Humans do not make aromatic amino acids; we get them from our diet, so we are unaffected by glyphosate. To make glyphosate-resistant plants, scientists used a Ti plasmid to insert extra copies of the EPSP synthetase gene into plants. These engineered plants produce 20 times the normal level of EPSP synthetase, enabling them to synthesize proteins and grow despite glyphosate's suppression of the enzyme. In later experiments, a bacterial form of the EPSP synthetase gene that differs from the plant form by a single nucleotide was introduced into plants via Ti plasmids; the bacterial enzyme is not inhibited by glyphosate (see figure 17.19).

These advances are of great interest to farmers because a crop resistant to glyphosate would not have to be weeded—the field could simply be treated with the herbicide. Because glyphosate is a broad-spectrum herbicide, farmers would no longer need to employ a variety of different herbicides, most of which kill only a few kinds of weeds. Furthermore, glyphosate breaks down readily in the environment, unlike many other herbicides commonly used in agriculture. A plasmid is actively being sought for the introduction of the EPSP synthetase gene into cereal plants, making them also glyphosate-resistant.

At this point four important crop plants have been modified to be glyphosate-resistant: maize (corn), cotton, soybeans, and canola. The use of glyphosate-resistant soy has been especially popular, accounting for 60% of the global area of GM (genetically modified) crops grown in nine countries worldwide. In the United States, 90% of soy currently grown is GM soy. Global variation in the use of GM crops has occurred, with the Americas, led by the United States, the largest adopter. The area

currently with the largest growth in the use of GM crops is Asia, while Europe has been the slowest to move to their use.

### Bt crops are resistant to some insect pests

Many commercially important plants are attacked by insects, and the usual defense against such attacks has been to apply insecticides. Over 40% of the chemical insecticides used today are targeted against boll weevils, bollworms, and other insects that eat cotton plants. Scientists have produced plants that are resistant to insect pests, removing the need to use many externally applied insecticides.

The approach is to insert into crop plants genes encoding proteins that are harmful to the insects that feed on the plants, but harmless to other organisms. The most commonly used protein is a toxin produced by the soil bacterium *Bacillus thuringiensis* (*Bt toxin*). When insects ingest Bt toxin, endogenous enzymes convert it into an insect-specific toxin, causing paralysis and death. Because these enzymes are not found in other animals, the protein is harmless to them.

The same four crops that have been modified for herbicide resistance have also been modified for insect resistance using the Bt toxin. The use of Bt maize is the second most common GM crop globally, representing 14% of global area of GM crops in nine countries. The global distribution of these crops is also similar to the herbicide-resistant relatives.

Given the popularity of both of these types of crop modifications, it is not surprising that they have also been combined,

so-called *stacked GM crops*, in both maize and cotton. Stacked crops now represent 9% of global area of GM crops.

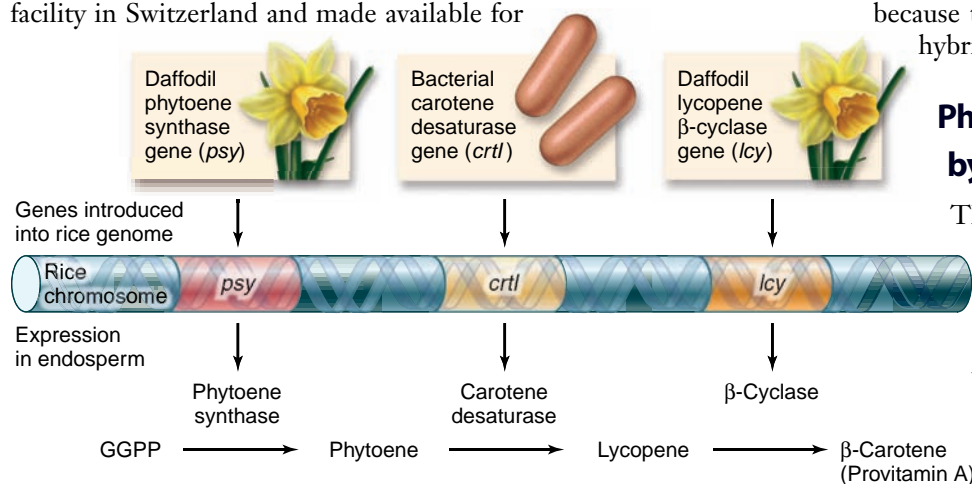

## Golden Rice shows potential of GM crops

One of the successes of GM crops is the development of Golden Rice. This rice has been genetically modified to produce  $\beta$ -carotene (provitamin A). The World Health Organization (WHO) estimates that vitamin A deficiency affects between 140 and 250 million preschool children worldwide. The deficiency is especially severe in developing countries where the major staple food is rice. Provitamin A in the diet can be converted by enzymes in the body to vitamin A, alleviating the deficiency.

Golden Rice is named for its distinctive color imparted by the presence of  $\beta$ -carotene in the endosperm (the outer layer of rice that has been milled). Rice does not normally make  $\beta$ -carotene in endosperm tissue, but does produce a precursor, geranyl geranyl diphosphate, that can be converted by three enzymes, phytoene synthase, phytoene desaturase, and lycopene  $\beta$ -cyclase, to  $\beta$ -carotene. These three genes were engineered to be expressed in endosperm and introduced into rice to complete the biosynthetic pathway producing  $\beta$ -carotene in endosperm (figure 17.20).

This is an interesting case of genetic engineering for two reasons. First, it introduces a new biochemical pathway in tissue of the transgenic plants. Second, it could not have been done by conventional breeding as no rice cultivar known produces these enzymes in endosperm. The original constructs used two genes from daffodil and one from a bacterium (see figure 17.20). There are many reasons to expect failure in the introduction of a biochemical pathway without disrupting normal metabolism. That the original form of Golden Rice makes significant amounts of  $\beta$ -carotene in an otherwise healthy plant is impressive. A second-generation version that makes much higher levels of  $\beta$ -carotene has also been produced by using the gene for phytoene synthase from maize in place of the original daffodil gene.

Golden Rice was originally constructed in a public facility in Switzerland and made available for

**Figure 17.20 Construction of Golden Rice.** Rice does not normally express the enzymes needed to synthesize  $\beta$ -carotene in endosperm. Three genes were added to the rice genome to allow expression of the pathway for  $\beta$ -carotene in endosperm. The source of the genes and the pathway for synthesis of  $\beta$ -carotene is shown. The result is Golden Rice, which contains enriched levels of  $\beta$ -carotene in endosperm.

free with no commercial entanglements. Since its inception, Golden Rice has been improved both by public groups and by industry scientists, and these improved versions are also being made available without commercial strings attached.

## GM crops raise a number of social issues

The adoption of GM crops has been resisted in some places for a variety of reasons. Some people have wondered about the safety of these crops for human consumption, the likelihood of introduced genes moving into wild relatives, and the possible loss of biodiversity associated with these crops.

Powerful forces have aligned on opposing sides in this debate. On the side in favor of the use of GM crops are the multinational companies that are utilizing this technology to produce seeds for the various GM crops. On the other side are a variety of political organizations that are opposed to genetically modified foods. Scientists can be found on both sides of the controversy.

The controversy originally centered on the safety of introduced genes for human consumption. In the United States, this issue has been “settled” for the crops already mentioned, and a large amount of GM soy and maize is consumed in this country. Although some opponents still raise the issue of long-term use and allergic reactions, no negative effects have been documented so far. Existing crops will be monitored for adverse effects, and each new modification will require regulatory approval for human consumption.

Another contention has been the fear that genes might spread outside of the GM crops into wild relatives, a process called introgression. But at this point there is no indication of that happening. One study showed no evidence for the movement of genes from GM crops into native species in Mexico, despite earlier studies indicating significant movement of introduced genes.

This finding does not mean that such movement is impossible, but it does indicate that it seems not to have occurred at present. It is clear that this area requires more study. This issue will likely have to be considered on a case-by-case basis because the number of wild relatives and the ease of hybridization varies greatly among crop plants.

## Pharmaceuticals can be produced by “biopharming”

The medicinal use of plants goes back as far as recorded history. In modern times, the pharmaceutical industry began by isolating biologically active compounds from plants. This approach began to change when in 1897, the Bayer company introduced acetyl salicylic acid, otherwise known as aspirin. This compound was a synthetic version of the compound salicylic acid, which was isolated from the bark of the white willow. The production of pharmaceuticals has since been dominated more by organic synthesis and less by the isolation of plant products.

One exception to this trend is cancer chemotherapeutic agents such as taxol, vinblastine, and vincristine, all of which were isolated from plant sources. In an interesting closing of

the historical loop, the industry is now looking at using transgenic plants for the production of useful compounds.

The first human protein to be produced in plants was human serum albumin, which was produced in 1990 by both genetically engineered tobacco and potato plants. Since that time more than 20 proteins have been produced in transgenic plants. This first crop of transgenic pharmaceuticals are now in the regulatory pipeline.

### Recombinant subunit vaccines

One promising aspect of plant genetic engineering is the production of recombinant subunit vaccines, which were discussed earlier. One of these, being produced in genetically modified potatoes, is a vaccine against Norwalk virus. Norwalk virus is not a common source of illness, but it reached the public consciousness when cruise ships were forced to cancel cruises due to outbreaks of the virus among passengers. The vaccine is now in clinical trials. A vaccine against rabies produced in transgenic spinach is also in clinical trials.

One obvious advantage of using plants for vaccine production is scalability. It has been estimated that 250 acres of greenhouse space could produce enough transgenic potato plants to supply Southeast Asia's need for hepatitis B vaccine.

### Recombinant antibodies

Molecular cloning and immunology can be combined to produce antibodies in transgenic plants that are normally made by blood cells in vertebrates. The synthesis of monoclonal antibodies in plant systems is a promising use of transgenic plants.

A number of potentially therapeutic antibodies are being produced in plants, and some of these have reached clinical trial stage. One interesting example is an antibody against the bacterium responsible for dental caries, commonly known as tooth decay. It would make a visit to the dentist more pleasant to have a topical antibody applied instead of a drill.

## Domesticated animals can also be genetically modified

Humans have been breeding and selecting domestic animals for thousands of years. With the advent of genetic engineering,

this process can be accelerated, and genes can be introduced from other species.

The production of transgenic livestock is in an early stage, and it is hard to predict where it will go. At this point, one of the uses of biotechnology is not to construct transgenic animals, but to use DNA markers to identify animals and to map genes that are involved in such traits as palatability in food animals, texture of hair or fur, and other features of animal products. Molecular techniques combined with the ability to clone domestic animals (chapter 19) could produce improved animals for economically desirable traits.

Transgenic animal technology has not been as successful as initially predicted. Early on, pigs were engineered to overproduce growth hormone in the hope that this would lead to increased and faster growth. These animals proved to have only slightly increased growth, and they had lower fat levels, which reduces flavor, as well as showing other deleterious effects. The main use thus far has been engineering animals to produce pharmaceuticals in milk—another example of the biopharming concept.

One interesting idea for transgenics is the EnviroPig. This animal has been engineered with the gene for phytase under the control of a salivary gland-specific promoter. The enzyme phytase breaks down phosphorus in the feed and can reduce phosphate excretion by up to 70%. Because phosphate is a major problem in pig waste, reducing its excretion could be a large environmental benefit.

As with GM crops, fears exist about the consumption of meat from transgenic animals. At this point, these fears do not seem to be based on sound science; nevertheless, every transgenic animal produced that is intended for consumption will need to be considered on a case-by-case basis.

### Learning Outcomes Review 17.6

Genes can be introduced into plants using the bacterial Ti plasmid and techniques similar to those for bacteria. To date, herbicide resistance, pathogen protection, nutritional enhancement, and vaccine and drug production have been targets of agricultural genetic engineering. Controversy regarding the use of GM plants has centered on the potential of unforeseen effects on human health and on the environment.

- How might a recombinant gene for Bt toxin production "escape" from a crop plant and move into wild plants?

## Calvin and Hobbes

by Bill Watterson

CALVIN AND HOBBS © 1995 Watterson. Dist. by Universal Press Syndicate. Reprinted with permission. All rights reserved.

### 17.1 DNA Manipulation

#### **Restriction enzymes cleave DNA at specific sites.**

DNA molecules fragmented by known type II restriction endonucleases can be ordered into a physical map of DNA.

#### **DNA ligase allows construction of recombinant molecules.**

Just as in DNA replication, DNA ligase catalyzes formation of a phosphodiester bond between nucleotides, forming a recombinant molecule.

#### **Gel electrophoresis separates DNA fragments.**

An electric field applied to a gel matrix causes DNA to migrate through the matrix. Smaller fragments migrate farther than large fragments (figure 17.2).

#### **Transformation allows introduction of foreign DNA into *E. coli*.**

Artificial transformation techniques introduce foreign DNA into *E. coli* cells, which are then termed transgenic.

### 17.2 Molecular Cloning

#### **Host–vector systems allow propagation of foreign DNA in bacteria.**

Plasmids, and artificial chromosomes can be used as vectors. Foreign DNA is inserted using restriction enzymes and DNA ligase; once the vector is inside the host cell, it is replicated during the cell cycle.

#### **DNA libraries contain the entire genome of an organism.**

A DNA library is a complex mixture of DNAs collected into vectors. These libraries may be probed for a sequence of interest.

#### **Reverse transcriptase can make a DNA copy of RNA.**

A library can also be created for the expressed parts of the genome by isolating RNA and converting it to cDNA using the enzyme reverse transcriptase (figure 17.5).

#### **Hybridization allows identification of specific DNAs in complex mixtures.**

DNA can be reversibly denatured and renatured, resulting in single- and then double-stranded DNA. Renaturation of complementary strands from different sources is called hybridization. Known DNA can be labeled to identify complementary strands.

#### **Specific clones can be isolated from a library.**

Hybridization is the most common way to identify a gene of interest in a library.

### 17.3 DNA Analysis

#### **Restriction maps provide molecular “landmarks.”**

The first physical maps of DNA molecules were based on the sites of restriction enzyme cleavage.

#### **Southern blotting reveals DNA differences.**

In Southern blotting, a complex mixture is separated by electrophoresis and transferred to filter paper. Specific sequences of DNA can then be identified by hybridization. Similar techniques can identify mRNA (Northern blot) and proteins (Western blot).

Restriction fragment length polymorphisms (RFLPs) identified by Southern blotting reveal individual differences in DNA. DNA fingerprinting uses probes to locate polymorphic DNA fragments.

#### **DNA sequencing provides information about genes and genomes.**

DNA sequencing uses chain-terminating reagents to identify the order of fragments and from this to infer the sequence of bases (figures 17.11, 17.12).

#### **The polymerase chain reaction accelerates the process of analysis.**

The polymerase chain reaction (PCR) amplifies a single small DNA fragment using two short primers that flank the region to be amplified. Cyclic replication is accomplished via heating and cooling; a key factor is Taq polymerase, which is not denatured at high temperature.

#### **Protein interactions can be detected with the two-hybrid system.**

The yeast two-hybrid system relies on fusion proteins and a reporter gene to study protein–protein interactions (figure 17.13).

### 17.4 Genetic Engineering

#### **Expression vectors allow production of specific gene products.**

Expression vectors contain the promoters and enhancers necessary to drive expression of the inserted DNA.

#### **Genes can be introduced across species barriers.**

Transgenic organisms can be constructed to express genes in a different species or to create mutations in genes to assess phenotype.

#### **Cloned genes can be used to construct “knockout” mice.**

In knockout mice, a gene is inactivated by replacing the wild-type version with a mutant copy (figure 17.15). In this way, the function of the gene can be analyzed and clarified.

### 17.5 Medical Applications

#### **Human proteins can be produced in bacteria.**

Bacterial production of human proteins such as insulin has allowed better results and has increased production to treat disease.

#### **Recombinant DNA may simplify vaccine production.**

Subunit vaccines produced in cultured cells have been shown to be effective in animals.

DNA vaccines, which alter the cellular immune response, are also promising. Both these approaches require further testing.

#### **Gene therapy can treat genetic diseases directly.**

Gene therapy involves inserting a normal gene to replace a defective one. Unfortunately, trials of two promising therapies had unintended and fatal consequences in 15% of patients.

### 17.6 Agricultural Applications

#### **The *Ti* plasmid can transform broadleaf plants.**

The tumor-inducing (*Ti*) plasmid from a plant bacterium is used to transfer genes into broad-leaf plants. A number of applications are currently in use.

#### **Herbicide-resistant crops allow no-till planting.**

#### ***Bt* crops are resistant to some insect pests.**

#### **Golden Rice shows potential of GM crops.**

#### **GM crops raise a number of social issues.**

Concerns about GM plants include unintended allergic reactions to proteins inserted from a different organism and spread of foreign genes into noncultivated plants in the environment.

#### **Pharmaceuticals can be produced by “biopharming.”**

#### **Domesticated animals can also be genetically modified.**

To date, results with transgenic animals have been mixed.

## Review Questions

### UNDERSTAND

- A recombinant DNA molecule is one that is
  - produced through the process of crossing over that occurs in meiosis.
  - constructed from DNA from different sources.
  - constructed from novel combinations of DNA from the same source.
  - produced through mitotic cell division.
- What is the basis of separation of different DNA fragments by gel electrophoresis?
  - The negative charge on DNA
  - The size of the DNA fragments
  - The sequence of the fragments
  - The presence of a dye
- The basic logic of enzymatic DNA sequencing is to produce
  - a nested set of DNA fragments produced by restriction enzymes.
  - a nested set of DNA fragments that each begin with different bases.
  - primers to allow PCR amplification of the region between the primers.
  - a nested set of DNA fragments that end with known bases.
- A DNA library is
  - an orderly array of all the genes within an organism.
  - a collection of vectors.
  - the collection of plasmids found within a single *E. coli*.
  - a collection of DNA fragments representing the entire genome of an organism.
- Molecular hybridization is used to
  - generate cDNA from mRNA.
  - introduce a vector into a bacterial cell.
  - screen a DNA library.
  - introduce mutations into genes.
- How does the yeast two-hybrid system detect protein–protein interactions?
  - Binding of fusion partners triggers a signal cascade that alters gene expression.
  - Fusion partners are detected using radioactive probes of Western blots.
  - Protein–protein binding of fusion partners triggers expression of a reporter gene.
  - Protein–protein binding of fusion partners triggers expression of the *Gal4* gene.
- In vitro mutagenesis is used to
  - produce large quantities of mutant proteins.
  - create mutations at specific sites within a gene.
  - create random mutations within multiple genes.
  - create organisms that carry foreign genes.
- Insertion of a gene for a surface protein from a medically important virus such as herpes into a harmless virus is an example of
  - a DNA vaccine.
  - reverse genetics.
  - gene therapy.
  - a subunit vaccine.
- What is a Ti plasmid?
  - A vector that can transfer recombinant genes into plant genomes
  - A vector that can be used to produce recombinant proteins in yeast
  - A vector that is specific to cereal plants like rice and corn
  - A vector that is specific to embryonic stem cells

### APPLY

- How is the gene for  $\beta$ -galactosidase used in the construction of a plasmid?
  - The gene is a promoter that is sensitive to the presence of the sugar, galactose.
  - It is an origin of replication.
  - It is a cloning site.
  - It is a marker for insertion of DNA.
- Which of the following statements is accurate for DNA replication in your cells, but not PCR?
  - DNA primers are required.
  - DNA polymerase is stable at high temperatures.
  - Ligase is essential.
  - dNTPs are necessary.
- What potential problems must be considered in creating a transgenic bacterium with the human insulin gene to produce insulin?
  - Introns in the human gene will not be processed after transcription.
  - The bacterial cell will be unable to post-translationally process the insulin peptide sequence.
  - There is no way to get the bacterium to transcribe high levels of a human gene.
  - Both a and b present problems.

### SYNTHESIZE

- Many human proteins, such as hemoglobin, are only functional as an assembly of multiple subunits. Assembly of these functional units occurs within the endoplasmic reticulum and Golgi apparatus of a eukaryotic cell. Discuss what limitations, if any exist to the large-scale production of genetically engineered hemoglobin.
- Enzymatic sequencing of a short strand of DNA was completed using dideoxynucleotides. Use the gel shown to determine the sequence of that DNA.

## Genomics

## Chapter Outline

- 18.1 Mapping Genomes
- 18.2 Whole-Genome Sequencing
- 18.3 Characterizing Genomes
- 18.4 Genomics and Proteomics
- 18.5 Applications of Genomics

## Introduction

The pace of discovery in biology in the last 30 years has been like the exponential growth of a population. Starting with the isolation of the first genes in the mid-1970s, researchers had accomplished the first complete genome sequence by the mid-1990s—that of the bacterial species *Haemophilus influenzae*, shown in the picture (genes with similar functions are shown in the same color). By the turn of the 21st century, the molecular biology community had completed a draft sequence of the human genome. Put another way, scientific accomplishments moved from cloning a single gene, to determining the sequence of a million base pairs in 20 years, then determining the sequence of a billion base pairs in another 5 years, and now sequencing 20 billion base pairs at one time. In the previous chapter you learned about the basic techniques of molecular biology. In this chapter you will see how those techniques have been applied to the analysis of whole genomes. This analysis integrates ideas from classical and molecular genetics with biotechnology, scaled and applied to whole genomes.

## 18.1 Mapping Genomes

### Learning Outcomes

1. Distinguish between a genetic map and a physical map.
2. Explain how genetic and physical maps can be linked.

We use maps to find our location, and depending on how accurately we wish to do this, we may use multiple maps with different resolutions. In genomics, we can locate a gene on a chromosome, in a subregion of a chromosome, and finally its precise location in the chromosome's DNA sequence. The DNA sequence level requires knowing the entire sequence of the genome, something that was once out of our reach technologically. Knowing the entire sequence is useless, however,

without other kinds of maps; finding a single gene within the sequence of the human genome is like trying to find your house on a map of the world.

To overcome this difficulty, maps of genomes are constructed at different levels of resolution and using different kinds of information. We can distinguish between *genetic maps* and *physical maps*. **Genetic maps** are abstract maps that place the relative location of genes on chromosomes based on recombination frequency (see chapter 13). **Physical maps** use landmarks within DNA sequences, ranging from restriction sites (described in the preceding chapter) to the ultimate level of detail: the actual DNA sequence.

## Different kinds of physical maps can be generated

To make sense of genome mapping, it is important to have physical landmarks on the genome that are at a lower level of resolution than the entire sequence. In fact, long before the Human Genome Project was even conceived, physical maps of DNA were needed as landmarks on cloned DNA. Two types of physical maps are (1) restriction maps, constructed using restriction enzymes and (2) chromosome-banding patterns, generated by cytological dye methods.

### Restriction maps

Distances between “landmarks” on a physical map are measured in base-pairs (1000 base-pairs [bp] equal 1 kilobase, kb). It is not necessary to know the DNA sequence of a segment of DNA in order to create a physical map, or to know whether the DNA encompasses information for a specific gene.

The first physical maps were created by cutting genomic DNA with different restriction enzymes, both singly and with combinations of enzymes (figure 18.1). The analysis of the patterns of fragments generated were used to generate a map.

In terms of larger pieces of DNA, this process is repeated and then used to put the pieces back together, based on size and overlap, into a contiguous segment of the genome, called a **contig**. Coincidentally, the very first restriction enzymes to be isolated came from *Haemophilus*, which was also the first free-living genome to be completely sequenced.

### Chromosome-banding patterns

Cytologists studying chromosomes with light microscopes found that by using different stains, they could produce reproducible patterns of bands on the chromosomes. In this way, they could identify all of the chromosomes and divide them into subregions based on banding pattern.

The use of different stains allows for the construction of a cytological map of the entire genome. These large-scale physical maps are like a map of an entire country, in that they encompass the whole genome, but at low resolution.

Cytological maps are used to characterize chromosomal abnormalities associated with human diseases, such as chronic myelogenous leukemia. In this disease, a reciprocal translocation occurs between chromosome 9 and chromosome 22 (figure 18.2a), resulting in an altered form of

1. Multiple copies of a segment of DNA are cut with restriction enzymes.

2. The fragments produced by enzyme A only, by enzyme B only, and by enzymes A and B together are run side-by-side on a gel, which separates them according to size.

3. The fragments are arranged so that the smaller ones produced by the simultaneous cut can be grouped to generate the larger ones produced by the individual enzymes.

4. A physical map is constructed.

**Figure 18.1** Restriction enzymes can be used to create a physical map. DNA is digested with two different restriction enzymes singly and in combination, then electrophoresed to separate the fragments. The location of sites can be deduced by comparing the sizes of fragments from the individual reactions with the combined reaction.

tyrosine kinase that is always turned on, causing white blood cell proliferation.

The use of hybridization with cloned DNA has added to the utility of chromosome-banding analysis. In this case, because the hybridization involves whole chromosomes, it is called *in situ hybridization*. It is done using fluorescently labeled probes, and so its complete name is **fluorescence in situ hybridization (FISH)** (figure 18.2b).

a.

b.

**Figure 18.2** Use of fluorescence in situ hybridization to correlate cloned DNA with cytological maps. *a.* Karyotype of human chromosomes showing the translocation between chromosomes 9 and 22. *b.* FISH using a *bcr* (green) and *abl* (red) probe. The yellow color indicates the fused genes (red plus green fluorescence combined). The *abl* gene and the fused *bcr-abl* gene both encode a tyrosine kinase, but the fused gene is always expressed.

### Inquiry question

? Why are there only three colored spots on the karyotype for two different genes?

## Sequence-tagged sites provide a common language for physical maps

The construction of a physical map for a large genome requires the efforts of many laboratories in different locations. A variety of difficulties arose in comparing data from different labs, as well as integrating different types of landmarks used on physical and genetic maps.

In the early days of the Human Genome Project, this problem was addressed by the creation of a common molecular language that could be used to describe the different types of landmarks.

### Defining common markers

Since all genetic information is ultimately based on DNA sequence, it was important for this common language to be

sequence-based, but not to require generating a large amount of sequence for any landmark. The solution was the **sequence-tagged site**, or **STS**. This site is a small stretch of DNA that is unique in the genome, that is, it only occurs once.

The boundary of the STS is defined by PCR primers, so the presence of the STS can be identified by PCR using any DNA as a template (see chapter 17). These sites need to be only 200–500 bp long, an amount of sequence that can be determined easily. The STS can contain any other kind of landmark—for example, part of a cloned gene that has been genetically mapped, or a restriction site that is polymorphic. Any marker that has been mapped can be converted to an STS by sequencing only 200–500 bp.

### The use of STSs

As maps are generated, new STSs are identified and added to a database, that indicates the sequence of the STS, its location in the genome, and the PCR primers needed to identify it. Any researcher is then able to identify the presence or absence of any STS in the DNA that he or she is analyzing.

Fragments of DNA can be pieced together using STSs by identifying overlapping regions in fragments. Because of the high density of STSs in the human genome and the relative ease of identifying an STS in a DNA clone, investigators were able to develop physical maps on the huge scale of the 3.2-gigabase genome in the mid-1990s (figure 18.3). STSs provide a scaffold for assembling genome sequences.

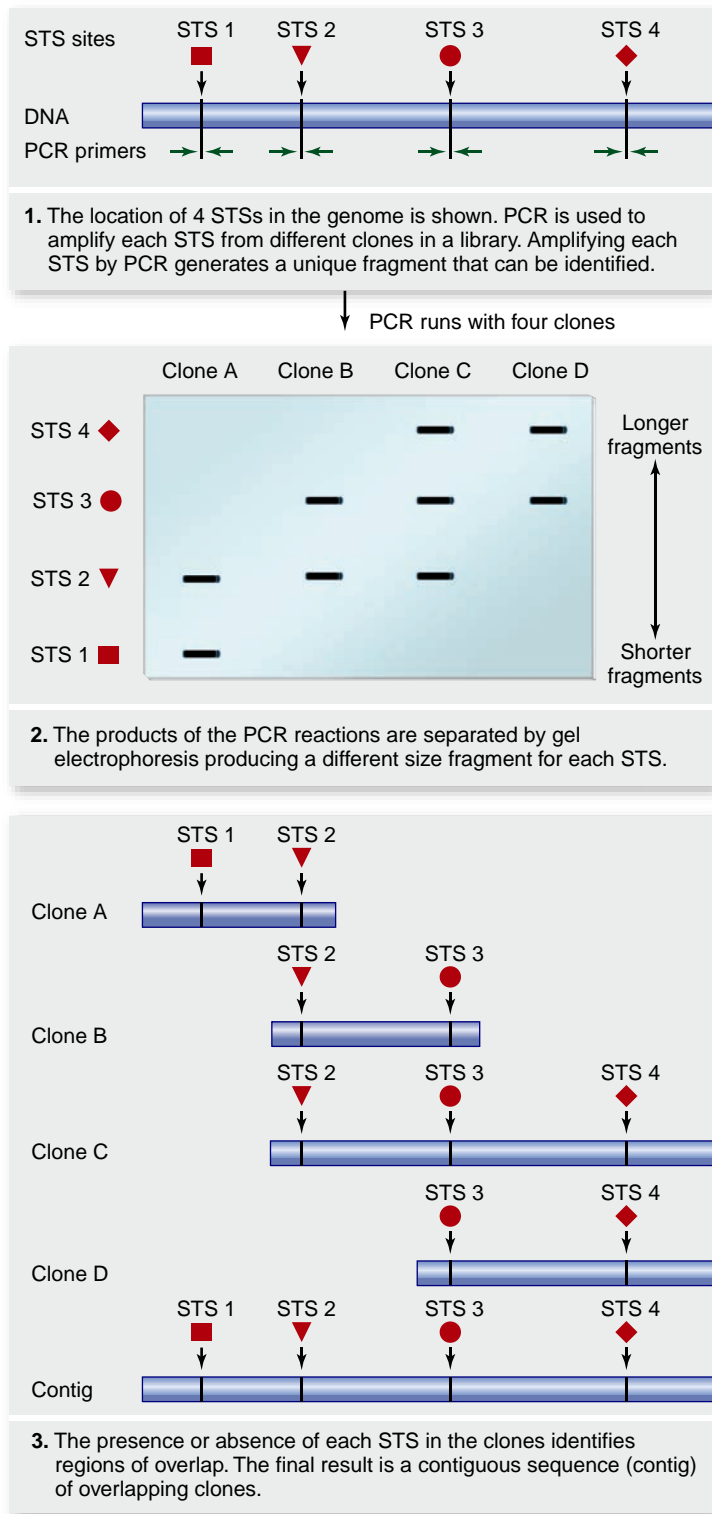

## Genetic maps provide a link to phenotypes

The first genetic (linkage) map was made in 1911 when Alfred Sturtevant mapped five genes in *Drosophila*. Distances on a genetic map reflect the frequency of recombination between genes and are measured in centimorgans (cM) in honor of the geneticist Thomas Hunt Morgan. One centimorgan corresponds to 1% recombination frequency between two loci. Over 14,000 genes have been mapped on the *Drosophila* genome.

Linkage mapping can be done without knowing the DNA sequence of a gene, as described in chapter 13. Computer programs make it possible to create a linkage map for a thousand genes at a time. But a few limitations to genetic maps still exist. One is that distances between genes determined by recombination frequencies do not directly correspond to physical distance on a chromosome. The conformation of DNA between genes varies, and this conformation can affect the frequency of recombination. Another limitation is that not all genes have obvious phenotypes that can be followed in segregating crosses.

The human genetic map is quite dense, with a marker roughly every 1 cM. This level of detail would have been unheard of 20 years ago, and it was made possible by development of molecular markers that do not cause a phenotype change.

The most common type of markers are short repeated sequences, called short tandem repeats, or STR loci, that differ in repeat length between individuals. These repeats are identified by using PCR to amplify the region containing the

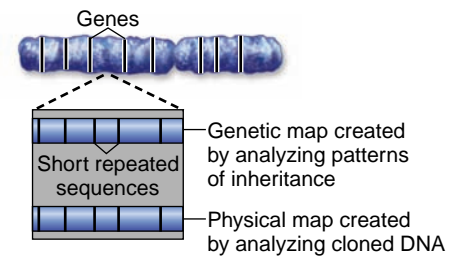

**Figure 18.3** Creating a physical map with sequence-tagged sites. The presence of landmarks called sequence-tagged sites, or STSs, in the human genome made it possible to begin creating a physical map large enough in scale to provide a foundation for sequencing the entire genome. (1) Primers (green arrows) that recognize unique STSs are added to cloned DNA, followed by DNA amplification via polymerase chain reaction (PCR). (2) PCR products are separated based on size on a DNA gel, and the STSs contained in each clone are identified. (3) Cloned DNA segments are aligned based on STSs to create a contig.

repeat, then analyzing the products using electrophoresis. Once a map is constructed using these markers, genes with alleles that cause a disease state can be mapped relative to the molecular landmarks. Thirteen of these STR loci form the basis for modern DNA fingerprinting developed by the FBI. The alleles for these 13 loci are what is cataloged in the Combined DNA Index System (CODIS) database used to identify criminal offenders.

## Physical maps can be correlated with genetic maps

We need to be able to correlate genetic maps with physical maps, particularly genome sequences, to aid in finding physical sequences for genes that have been mapped genetically.

The problem in finding genes is that the resolution of genetic maps at present is not nearly as fine-grained as the genome sequence. Markers that are 1 cM apart may be as much as a million base pairs apart.

Since the markers used to construct genetic maps are now primarily molecular markers, they can be easily located within a genome sequence. Similarly, any gene that has been cloned can be placed within the genome sequence and can also be mapped genetically. This provides an automatic correlation between the two maps. The problem of finding genes that have been mapped genetically but not isolated as molecular clones lies in the nature of genetic maps. Distances measured on genetic maps are not uniform due to variation in recombination frequency along the chromosome. So 1 cM of genetic distance translates to different numbers of base-pairs in different regions.

Different kinds of maps are stored in databases so they can be aligned and viewed. The National Center for Biotechnology Information (NCBI) is a branch of the National Library of Medicine, and it serves as the U.S. repository for these data and more. Similar databases exist in Europe and Japan, and all are kept current. An enormous storehouse of information is available for use by biological researchers worldwide.

### Learning Outcomes Review 18.1

Maps of genomes can be either physical maps or genetic maps. Physical maps include cytogenic maps of chromosome banding or restriction maps. Genetic maps are correlated with physical maps by using DNA markers such as sequence-tagged sites (STSs) unique to each genome.

- What accounts for the difference between the proximity of banding sites on a karyotype and the number of base-pairs separating the two sites?

## 18.2 Whole-Genome Sequencing

### Learning Outcomes

1. Characterize the main hurdle to sequencing an entire genome and how it has been overcome.
2. Differentiate between clone-by-clone sequencing and shotgun sequencing.

The ultimate physical map is the base-pair sequence of an entire genome. In the early days of molecular biology, all sequencing was done manually, and was therefore both time- and labor-intensive. As mentioned in chapter 17, the development of machines to automate this process increased the rate of sequence generation.

a.

b.

c.

**Figure 18.4 Automated sequencing.** *a.* This Sanger sequence facility runs multiple automated sequencers, each processing 96 samples at a time. *b.* The development of new sequencing technologies permit sequencing that is orders of magnitude faster and that can be done in a very small space. *c.* Over 20 billion different DNA segments can be sequenced simultaneously in a flow cell the size of a microscope slide.

Large-scale genome sequencing requires the use of high-throughput automated sequencing and computer analysis (figure 18.4). Genome sequencing is one case in which technology drove the science, rather than the other way around. In a few hours, an automated Sanger sequencer can sequence the same number of base-pairs that a technician could manually sequence in a year—up to 50,000 bp. With the current generation of sequencing technology described in the previous chapter, the rate of sequence generation is now five orders of magnitude greater than when the human genome was sequenced with automated Sanger sequencers. Without the automation of sequencing, it would have been impossible to sequence large, eukaryotic genomes like that of humans.

### Genome sequencing requires larger molecular clones

Although it would be ideal to isolate DNA from an organism, add it to a sequencer, and then come back in a week or two to pick up a computer-generated printout of the genome sequence, the process is not quite that simple. Sequencers provide accurate sequences for DNA segments up to 800 bp long. Even then, errors are possible. So, to reduce errors, each clone is sequenced 5–10 times.

Even with reliable sequence data in hand, each individual sequencing run produces a relatively small amount of sequence. Thus, the genome must be fragmented, and then individual molecular clones isolated for sequencing (see chapter 17).

### Artificial chromosomes

As described in chapter 17, the development of artificial chromosomes has allowed scientists to clone larger pieces of DNA. The first generation of these new vectors were yeast artificial chromosomes (YACs). These are constructed by using a yeast origin of replication and centromere sequence, then adding foreign DNA to it. The origin of replication allows the artificial chromosome to replicate independently of the rest of the genome, and the centromere sequences make the chromosome mitotically stable.

YACs were useful for cloning larger pieces of DNA but they had many drawbacks, including a tendency to rearrange, or to lose portions of DNA by deletion. Despite the difficulties, the YACs were used early on to construct physical maps by restriction enzyme digestion of the YAC DNA.

The artificial chromosomes most commonly used now, particularly for large-scale sequencing, are made in *E. coli*. These bacterial artificial chromosomes (BACs) are a logical extension of the use of bacterial plasmids. BAC vectors accept DNA inserts between 100 and 200 kb long. The downside of BAC vectors is that, like the bacterial chromosome, they are maintained as a single copy whereas plasmid vectors exist at high copy numbers.

### Human artificial chromosomes

Human artificial chromosomes can introduce large segments of human DNA into cultured cells. These artificial chromosomes are usually constructed by fragmentation of chromosomes with centromere sequence. Although circular, some can still segregate correctly during mitosis up to 98% of the time. Construction of linear human artificial chromosomes is not yet possible.

## Whole-genome sequencing is approached in two ways: clone-by-clone and shotgun

Sequencing an entire genome is an enormous task. Two ways of approaching this challenge have been developed: one that approaches the sequencing one step at a time, and another that attempts to take on the whole thing at once and depends on computers to sort out the data. The two techniques grew out of competing projects to sequence the human genome.

### Clone-by-clone sequencing

The cloning of large inserts in BACs facilitates the analysis of entire genomes. The strategy most commonly pursued is to construct a physical map first, and then use it to place the site of BAC clones for later sequencing.

Aligning large portions of a chromosome requires identifying regions that overlap between clones. This can be accomplished either by constructing restriction maps of each BAC clone, or by identifying STSs found in clones. If two BAC clones have the same STS, then they must overlap.

The alignment of a number of BAC clones results in a contiguous stretch of DNA called a *contig*. The individual BAC clones can then be sequenced 500 bp at a time to produce the sequence of the entire contig (figure 18.5a). This strategy of physical mapping followed by sequencing is called **clone-by-clone sequencing**.

### Shotgun sequencing

The idea of **shotgun sequencing** is simply to randomly cut the DNA into small fragments, sequence all cloned fragments, and then use a computer to put together the overlaps (figure 18.5b). This terminology actually goes back to the early days of molecular cloning when the construction of a library of randomly cloned fragments was referred to as *shotgun cloning*. This approach is much less labor-intensive than the clone-by-clone method, but it requires much greater computer power to assemble the final sequence and very efficient algorithms to find overlaps.

Unlike the clone-by-clone approach, shotgun sequencing does not tie the sequence to any other information about the genome (figure 18.5b). Many investigators have used both clone-by-clone and shotgun-sequencing techniques, and such hybrid approaches are becoming the norm. This combination has the strength of tying the sequence to a physical map while greatly reducing the time involved.

Assembler programs compare multiple copies of sequenced regions in order to assemble a **consensus sequence**, that is, a sequence that is consistent across all copies. Although computer assemblers are incredibly powerful, final human analysis is required after both clone-by-clone and shotgun sequencing to determine when a genome sequence is sufficiently accurate to be useful to researchers.

## The Human Genome Project used both sequencing methods

The vast scale of genomics ushered in a new way of doing biological research involving large teams. Although a single individual can isolate and manually sequence a molecular clone for

a.

b.

**Figure 18.5 Comparison of sequencing methods.** a. The clone-by-clone method uses large clones assembled into overlapping regions by STSs. Once assembled, these can be fragmented into smaller clones for sequencing. b. In the shotgun method the entire genome is fragmented into small clones and sequenced. Computer algorithms assemble the final DNA sequence based on overlapping nucleotide sequences.

a single gene, a huge genome like the human genome requires the collaborative efforts of hundreds of researchers.

The Human Genome Project originated in 1990 when a group of American scientists formed the International Human Genome Sequencing Consortium. The goal of this publicly funded effort was to use a clone-by-clone approach to sequence the human genome. Genetic and physical maps were used as scaffolding to sequence each chromosome.

In May, 1998, Craig Venter, whose research group had sequenced *Haemophilus influenzae*, announced his private company (Celera Genomics) would sequence the human genome. He proposed to shotgun-sequence the 3.2-gigabase genome in only two years. The Consortium rose to the challenge, and the race to sequence the human genome began. The upshot was a tie of sorts. On June 26, 2000, the groups jointly announced success, and each published its findings simultaneously in 2001. The Consortium's draft alone included 248 authors.

The draft sequence of the human genome was just the beginning. Gaps in the sequence are still being filled, and the

map is constantly being refined. The most recent “finished” human sequence is down to only 260 gaps, a 400-fold reduction in gaps, and it now includes 99% of the euchromatic sequence, up from 95%. The reference sequence has an error rate of 1 per 100,000 bases. Newer sequencing technologies are being used to close the remaining gaps. A few individuals, including James Watson who codiscovered the structure of DNA, have now had their personal genomes sequenced. The cost for having one’s genome sequenced is predicted to fall to \$1000 in the next few years, raising many questions about genome privacy.

Research on the whole genome can move ahead. Now that the ultimate physical map is in place and is being integrated with the genetic map, diseases that result from changes in more than one gene, such as diabetes, can be addressed. Comparisons with other genomes are already changing our understanding of genome evolution (see chapter 24).

### Learning Outcomes Review 18.2

Because of the enormous size of genomes, sequencing requires the use of automated sequencers running many samples in parallel. Two approaches have been developed for whole-genome sequencing: one that uses clones already aligned by physical mapping (clone-by-clone sequencing), and one that involves sequencing random clones and using a computer to assemble the final sequence (shotgun sequencing). In either case, significant computing power is necessary to assemble a final sequence.

- Why would data from a single copy of a genome likely be unreliable?

## 18.3 Characterizing Genomes

### Learning Outcomes

1. Describe the classes of DNA found in a genome.
2. Explain what an SNP is and why SNPs are helpful in characterizing genomes.

### Figure 18.6 Size and complexity of genomes.

In general, eukaryotic genomes are larger and have more genes than prokaryotic genomes, although the size of the organism is not the determining factor. The mouse genome is nearly as large as the human genome, and the rice genome contains more genes than the human genome.

Automated sequencing technology has produced huge amounts of sequence data, eventually sequencing entire genomes. This has allowed researchers studying complex problems to move beyond approaches restricted to the analysis of individual genes. Sequencing projects in themselves are descriptive analyses that tells us nothing about the organization of genomes, let alone the function of gene products and how they may be interrelated. Additional research and evaluation has given us both answers and new puzzles.

### The Human Genome Project found fewer genes than expected

For many years, geneticists had estimated the number of human genes to be around 100,000. This estimate, although based on some data, was really just a guess. Imagine researchers’ surprise when the number turned out to be only around 25,000! This represents only about twice as many genes as *Drosophila* and fewer genes than rice (figure 18.6). Clearly the complexity of an organism is not a simple function of the number of genes in its genome.

### Finding genes in sequence data requires computer searches

Once a genome has been sequenced, the next step is to determine which regions of the genome contain which genes, and what those genes do. A lot of information can be mined from the sequence data. Using markers from physical maps and information from genetic maps, it is possible to find the sequence of the small percentage of genes that are identified by mutations with an observable (phenotypic) effect. Genes can also be found by comparing expressed sequences to genomic sequences. The analysis of expressed sequences is discussed later in this section.

### Locating starts and stops

Information in the nucleotide sequence itself can also be used in the search for genes. A protein-coding gene begins with a start codon, such as ATG, and it contains no stop

codons (TAA, TGA, or TAG) for a distance long enough to encode a protein. This coding region is referred to as an **open reading frame (ORF)**. Although ORFs are likely to be genes, they may or may not actually be translated into a functional protein. Among putative genes, families of genes can be identified based on common domains. For example, genes in the HOX family have a conserved, 180-bp sequence called the homeobox, which encodes the homeodomain region of certain transcription factors. Sequences for potential genes need to be tested experimentally to determine whether they have a function.

The addition of information to the basic sequence information, like identifying ORFs, is called sequence **annotation**. This process is what converts simple sequence data into something that we can recognize based on landmarks such as regions that are transcribed and regions that are known or thought to encode proteins.

### **Inferring function across species: the BLAST algorithm**

It is also possible to search genome databases for sequences that are homologous to known genes in other species. A researcher who has isolated a molecular clone for a gene of unknown function can search the database for similar sequences to infer function. The tool that makes this possible is a search algorithm called BLAST (which stands for Basic Local Alignment Search Tool). Using a networked computer, one can submit a sequence to the BLAST server and get back a reply with all possible similar sequences contained in the sequence database.

Using these techniques, sequences that are not part of ORFs have been identified that have been conserved over millions of years of evolution. These sequences may be important for the regulation of the genes contained in the genome.

Using computer programs to search for genes, to compare genomes, and to assemble genomes are only a few of the new genomics approaches falling under the heading of **bioinformatics**.

## **Genomes contain both coding and noncoding DNA**

When genome sequences are analyzed, regions that encode proteins and other regions that do not encode proteins are revealed. For many years investigators had known of the latter, but they did not know the extent and nature of the noncoding DNA. We first consider the types of coding DNA that have been found, then move on to look at types of noncoding DNA.

### **Protein-encoding DNA in eukaryotes**

Four different classes of protein-encoding genes are found in eukaryotic genomes, differing largely in gene copy number.

**Single-copy genes.** Many genes exist as single copies on a particular chromosome. Most mutations in these genes result in recessive Mendelian inheritance.

**Segmental duplications.** Sometimes whole blocks of genes are copied from one chromosome to another, resulting

in *segmental duplication*. Blocks of similar genes in the same order are found throughout the human genome. Chromosome 19 seems to have been the biggest borrower, sharing blocks of genes with 16 other chromosomes.

**Multigene families.** As more has been learned about eukaryotic genomes, many genes have been found to exist as parts of *multigene families*, groups of related but distinctly different genes that often occur together in clusters. These genes appear to have arisen from a single ancestral gene that duplicated during an uneven meiotic crossover in which genes were added to one chromosome and subtracted from the other. These multigene families may include silent copies called *pseudogenes*, which are inactivated by mutation.

**Tandem clusters.** Identical copies of genes can also be found in *tandem clusters*. These genes are transcribed simultaneously, increasing the amount of mRNA available for protein production. Tandem clusters also include genes that do not encode proteins, such as clusters of rRNA genes.

### **Noncoding DNA in eukaryotes**

One of the most notable characteristics is the amount of noncoding DNA they possess. The Human Genome Project has revealed a particularly startling picture. Each of your cells has about 6 feet of DNA stuffed into it, but of that, less than 1 inch is devoted to genes! Nearly 99% of the DNA in your cells is non-protein coding DNA.

True genes are scattered about the human genome in clumps among the much larger amount of noncoding DNA, like isolated oases in a desert. Seven major sorts of noncoding human DNA have been described. (Table 18.1 shows the composition of the human genome, including noncoding DNA.)

**Noncoding DNA within genes.** As discussed in chapter 15, a human gene is not simply a stretch of DNA, like the letters of a word. Instead, a human gene is made up of numerous fragments of protein-encoding information (exons) embedded within a much larger matrix of noncoding DNA (introns). Together, introns make up about 24% of the human genome and exons less than 1.5%.

**Structural DNA.** Some regions of the chromosomes remain highly condensed, tightly coiled, and untranscribed throughout the cell cycle. Called *constitutive heterochromatin*, these portions tend to be localized around the centromere or located near the ends of the chromosome, at the telomeres.

**Simple sequence repeats.** Scattered about chromosomes are **simple sequence repeats (SSRs)**. An SSR is a 1- to 6-nt sequence such as CA or CGG, repeated like a broken record thousands and thousands of times. SSRs can arise from DNA replication errors. SSRs make up about 3% of the human genome.

**Segmental duplications.** Blocks of genomic sequences composed of from 10,000 to 300,000 bp have duplicated and moved either within a chromosome or to a nonhomologous chromosome.

TABLE 18.1

Classes of DNA Sequences Found in the Human Genome

Class	Estimated Frequency (%)	Description
Protein-encoding genes	1.5	Translated portions of the 25,000 genes scattered about the chromosomes
Introns	24	Noncoding DNA that constitutes the great majority of each human gene
Segmental duplications	5	Regions of the genome that have been duplicated
Pseudogenes (inactive genes)	2	Sequence that has characteristics of a gene but is not a functional gene
Structural DNA	20	Constitutive heterochromatin, localized near centromeres and telomeres
Simple sequence repeats	3	Stuttering repeats of a few nucleotides such as CGG, repeated thousands of times
Transposable elements	45	21%: Long interspersed elements (LINEs), which are active transposons 13%: Short interspersed elements (SINEs), which are active transposons 8%: Retrotransposons, which contain long terminal repeats (LTRs) at each end 3%: DNA transposon fossils
microRNA	0.03	Code for RNAs complementary to one or more mature mRNAs

**Pseudogenes.** These are inactive genes that may have lost function because of mutation.

**Transposable elements.** Fully 45% of the human genome consists of mobile bits of DNA called *transposable elements*. Some of these elements code for proteins, but many do not. Because of the significance of these elements, we describe them more fully in the following section.

**microRNA genes.** Hidden within the nonprotein-coding DNA lies an extraordinary mechanism for controlling gene expression and development. Compact regulatory RNAs have a much larger role in directing development in complex organisms than we imagined even a few years ago. Specifically, DNA that was once considered “junk” has been shown to encode microRNAs, or miRNAs, which are processed after transcription to lengths of 21 to 23 nt, but never translated. About 10,000 unique miRNAs have been identified that are complementary to one or more mature mRNAs.

### Transposable elements: mobile DNA

Discovered by Barbara McClintock in 1950, **transposable elements**, also termed *transposons* and *mobile genetic elements*, are bits of DNA that are able to move from one location on a chromosome to another. Barbara McClintock received the 1983 Nobel Prize in physiology or medicine for discovery of these elements and their unexpected ability to change location.

Transposable elements move around in different ways. In some cases, the transposon is duplicated, and the duplicated

DNA moves to a new place in the genome, so the number of copies of the transposon increases. Other types of transposons are excised without duplication and insert themselves elsewhere in the genome. The role of transposons in genome evolution is discussed in chapter 24.

Human chromosomes contain four sorts of transposable elements. Fully 21% of the genome consists of **long interspersed elements (LINEs)**. These ancient and very successful elements are about 6000 bp long, and they contain all the equipment needed for transposition. LINEs encode a reverse transcriptase enzyme that can make a cDNA copy of the transcribed LINE RNA. The result is a double-stranded segment that can reinsert into the genome rather than undergo translation into a protein. Since these elements use an RNA intermediate, they are termed *retrotransposons*.

**Short interspersed elements (SINEs)** are similar to LINEs, but they cannot transpose without using the transposition machinery of LINEs. Nested within the genome's LINEs are over half a million copies of a SINE element called Alu (named for a restriction enzyme that cuts within the sequence). The Alu SINE is 300 bp and represents 10% of the human genome. Like a flea on a dog, Alu moves with the LINE it resides within. Just as a flea sometimes jumps to a different dog, so Alu sometimes uses the enzymes of its LINE to move to a new chromosome location. Alu can also jump right into genes, causing harmful mutations.

Two other sorts of transposable elements are also found in the human genome: 8% of the human genome is devoted to retrotransposons called **long terminal repeats (LTRs)**. Although the transposition mechanism is a bit different from

that of LINEs, LTRs also use reverse transcriptase to ensure that copies are double-stranded and can reintegrate into the genome.

Some 3% of the genome is devoted to dead transposons, elements that have lost the signals for replication and can no longer move.

### Inquiry question

? How do you think these repetitive elements would affect the determination of gene order?

## Expressed sequence tags identify genes that are transcribed

Given the complexity of coding and noncoding DNA, it is important to be able to recognize regions of the genome that are actually expressed—that is, transcribed and then translated.

Because DNA is easier to work with than protein, one approach is to isolate mRNA, use this to make cDNA, then sequence one or both ends of as many cDNAs as possible. With automated sequencing, this task is not difficult, and these short sections of cDNA have been named **expressed sequence tags (ESTs)**. An EST is another form of STS, and thus it can be included in physical maps. This technique does not tell us anything about the function of any particular EST, but it does provide one view, at the whole-genome level, of what genes are expressed, at least as mRNAs.

ESTs have been used to identify 87,000 cDNAs in different human tissues. About 80% of these cDNAs were previously

unknown. You may wonder at this point how the estimated 25,000 genes of the human genome can result in 87,000 different cDNAs. The answer lies in the modularity of eukaryotic genes, which consist of exons interspersed with introns, as described in chapter 15.

Following transcription in eukaryotes, the introns are removed, and exons are spliced together. In some cells, some of the splice sites are skipped, and one or more exons is removed along with the introns. This process, called *alternative splicing* (figure 18.7), yields different proteins that can have different functions. Thus, the added complexity of proteins in the human genome comes not from additional genes, but from new ways to put existing parts of genes together.

## SNPs are single-base differences between individuals

One fact becoming clear from analysis of the human genome is that a huge amount of genetic variation exists in our species. This information has practical use.

Single-nucleotide polymorphisms (SNPs) are sites where individuals differ by only a single nucleotide. To be classified as a polymorphism, an SNP must be present in at least 1% of the population. SNPs occur about every 100 to 300 bp in the 3 billion bp human genome. As of January 2009, 1.5 million nonredundant human SNPs had been identified, about 10% of the variation available. These SNPs are being used to look for associations between genes. We expect that the genetic recombination occurring during meiosis randomizes all but the most tightly linked genes. We call the tendency for genes *not* to be randomized **linkage disequilibrium**. This kind of association can be used to map genes.

The preliminary analysis of SNPs shows that many are in linkage disequilibrium. This unexpected result has led to the idea of genomic **haplotypes**, or regions of chromosomes that are not being exchanged by recombination. The existence of haplotypes allows the genetic characterization of genomic regions by describing a small number of SNPs (figure 18.8). If these haplotypes stand up to further analysis, they could greatly aid in mapping the genetic basis of disease. The Human Genome Project is now working on a haplotype map of the genome.

**Figure 18.7** Alternative splicing can result in the production of different mRNAs from the same coding sequence. In some cells, exons can be excised along with neighboring introns, resulting in different proteins. Alternative splicing explains why 25,000 human genes can code for three to four times as many proteins.

### Figure 18.8 Construction of a haplotype map.

Single-nucleotide polymorphisms (SNPs) are single-base differences between individuals. Sections of DNA sequences from four individuals are shown in (a), with three SNPs indicated by arrows. b. These three SNPs are shown aligned along with 17 other SNPs from this chromosomal region. This represents a haplotype map for this region of the chromosome. Haplotypes are regions of the genome that are not exchanged by recombination during meiosis. c. Haplotypes can be identified using a small number of diagnostic SNPs that differ between the different haplotypes. In this case, 3 SNPs out of the 20 in this region are all that are needed to uniquely identify each haplotype. This greatly facilitates locating disease-causing genes, as haplotypes represent large regions of the genome that behave as a single site during meiosis.

### Learning Outcomes Review 18.3

Coding sequences in a genome can be found as a single copy, as repeated clusters, as part of segmental duplications, or as part of a gene family. A significant amount of noncoding DNA is found in all eukaryotic organisms. Transposable elements are capable of movement in the genome and are found in all eukaryotic genomes. Single-nucleotide polymorphisms (SNPs) provide a way of identifying individual variation, and they have also revealed cases of nonrandom recombination (genomic haplotypes).

- What explanation could you suggest, based on principles of natural selection, for the many repeated transposable elements in the human genome?

## 18.4 Genomics and Proteomics

### Learning Outcomes

- Describe the advances that have come from comparative genomics.
- Distinguish between genomics and proteomics.

To fully understand how genes work, we need to characterize the proteins they produce. This information is essential to understanding cell biology, physiology, development, and evolution. In many ways, we continue to ask the same questions that Mendel asked, but at a much different level of organization.

### Comparative genomics reveals conserved regions in genomes

With the large number of sequenced genomes, it is now possible to make comparisons at both the gene and genome level. The flood of information from different genomes has given rise to a new field: *comparative genomics*. One of the striking lessons learned from the sequence of the human genome is how very similar humans are to other organisms. More than half of the genes of *Drosophila* have human counterparts. Among mammals, the similarities are even greater. Humans have only 300 genes that have no counterpart in the mouse genome.

The use of comparative genomics to ask evolutionary questions is also a field of great promise. The comparison of the many prokaryotic genomes already indicates a greater degree of lateral gene transfer than was previously suspected. The latest round of animal genomes sequenced has included the chimpanzee, our closest living relative. The draft sequence of the

chimpanzee (*Pan troglodytes*) genome has just been completed, and comparisons between the chimpanzee and human genome may allow us to unravel what makes us uniquely human.

The early returns from this sequencing effort confirm that our genomes differ by only 1.23% in terms of nucleotide substitutions. At first glance, the largest difference between our genomes actually appears to be in transposable elements. In humans, the SINEs have been threefold more active than in the chimpanzee, but the chimpanzee has acquired two elements that are not found in the human genome. The differences due to insertion and deletion of bases are fewer than substitutions but account for about 1.5% of the euchromatic sequence being unique in each genome.

### Synteny allows comparison of unsequenced genomes

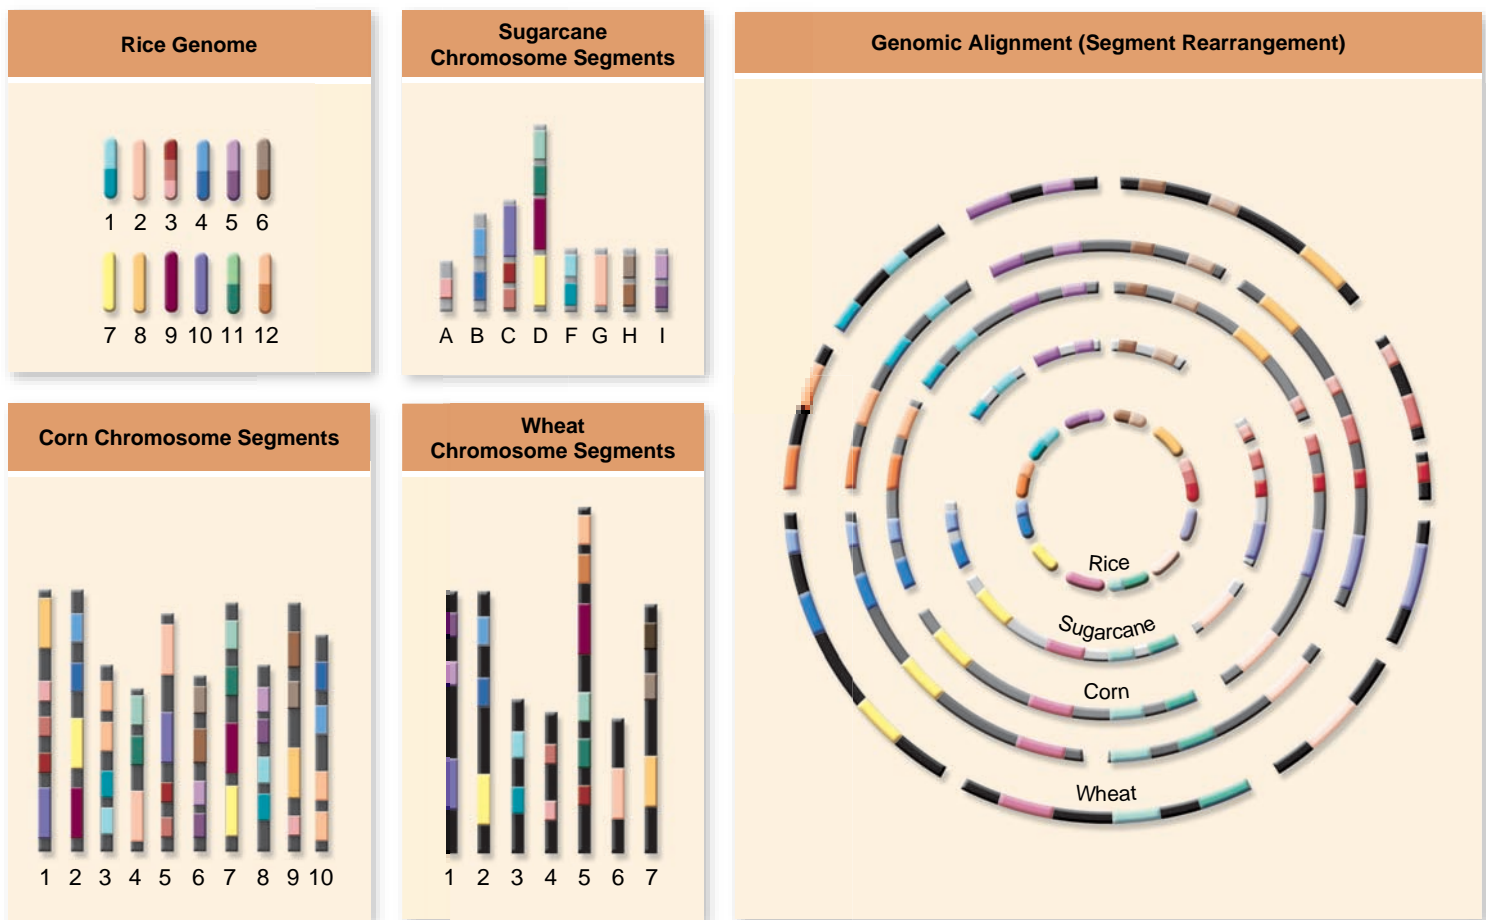

Similarities and differences between highly conserved genes can be investigated on a gene-by-gene basis between species. Genome science allows for a much larger scale approach to comparing genomes by taking advantage of synteny.

*Synteny* refers to the conserved arrangements of segments of DNA in related genomes. Physical mapping techniques can be used to look for synteny in genomes that have not been sequenced. Comparisons with the sequenced, syntenous segment in another species can be very helpful.

To illustrate this, consider rice, already sequenced, and its grain relatives maize, barley, and wheat, none of which have been fully sequenced. Even though these plants diverged more than 50 million years ago, the chromosomes of rice, corn, wheat, and other grass crops show extensive synteny (figure 18.9). In a genomic sense, “rice is wheat.”

By understanding the rice genome at the level of its DNA sequence, identification and isolation of genes from grains with larger genomes should be much easier. DNA sequence analysis of cereal grains could be valuable for identifying genes associated with disease resistance, crop yield, nutritional quality, and growth capacity.

As mentioned earlier, the rice genome has more genes than the human genome. However, rice still has a much smaller genome than its grain relatives, which also represent a major food source for humans.

**Figure 18.9** Grain genomes are rearrangements of similar chromosome segments. Shades of the same color represent pieces of DNA that are conserved among the different species but have been rearranged. By splitting the individual chromosomes of major grass species into segments and rearranging the segments, researchers have found that the genome components of rice, sugarcane, corn, and wheat are highly conserved. This implies that the order of the segments in the ancestral grass genome has been rearranged by recombination as the grasses have evolved.

## Organelle genomes have exchanged genes with the nuclear genome

Mitochondria and chloroplasts are considered to be descendants of ancient bacterial cells living in eukaryotes as a result of endosymbiosis (chapter 4). Their genomes have been sequenced in some species, and they are most like prokaryotic genomes. The chloroplast genome, having about 100 genes, is minute compared with the rice genome, with 32,000 to 55,000 genes.

### The chloroplast genome

The chloroplast, a plant organelle that functions in photosynthesis, can independently replicate in the plant cell because it has its own genome. The DNA in the chloroplasts of all land plants have about the same number of genes, and they are present in about the same order. In contrast to the evolution of the DNA in the plant cell nucleus, chloroplast DNA has evolved at a more conservative pace and therefore shows a more easily interpretable evolutionary pattern when scientists study DNA sequence similarities. Chloroplast DNA is also not subject to modification caused by transposable elements or to mutations due to recombination.

Over time, some genetic exchange appears to have occurred between the nuclear and chloroplast genomes. For example, Rubisco, the key enzyme in the Calvin cycle of photosynthesis (chapter 8), consists of large and small subunits. The small subunit is encoded in the nuclear genome. The protein it encodes has a targeting sequence that allows it to enter the chloroplast and combine with large subunits, which are coded for and produced by the chloroplast.

### The mitochondrial genome

Mitochondria are also constructed of components encoded by both the nuclear genome and the mitochondrial genome. For example, the electron transport chain (chapter 7) is made up of proteins that are encoded by both nuclear and mitochondrial genomes—and the pattern varies with different species. This observation implies a movement of genes from the mitochondria to the nuclear genome with some lineage-specific variation.

The evolutionary history of the localization of these genes is a puzzle. Comparative genomics and their evolutionary implications are explored in detail in chapter 24, after we have established the fundamentals of evolutionary theory.

## Functional genomics reveals gene function at the genome level

Bioinformatics takes advantage of high-end computer technology to analyze the growing gene databases, look for relationships among genomes, and then hypothesize functions of genes based on sequence. Genomics is now shifting gears and moving back to hypothesis-driven science, to **functional genomics**, the study of the function of genes and their products.

Like sequencing whole genomes, finding how these genomes work requires the efforts of a large team. For example,

an international community of researchers has come together with a plan to assign function to all of the 20,000–25,000 *Arabidopsis* genes by 2010 (Project 2010). One of the first steps is to determine when and where these genes are expressed. Each step beyond that will require additional improvements in technology.

### DNA microarrays

The earlier description of ESTs indicated that we could locate sequences that are transcribed on our DNA maps—but this tells us nothing about when and where these genes are turned on. To be able to analyze gene expression at the whole-genome level requires a representation of the genome that can be manipulated experimentally. This has led to the creation of **DNA microarrays**, or “gene chips” (figure 18.10).

**Preparation of a microarray** To prepare a particular microarray, fragments of DNA are deposited on a microscope slide by a robot at indexed locations (i.e., an array). Silicon chips instead of slides can also be arrayed. These chips can then be used in hybridization experiments with labeled mRNA from different sources. This gives a high-level view of genes that are active and inactive in specific tissues.

Researchers are currently using a chip with 24,000 *Arabidopsis* genes on it to identify genes that are expressed developmentally in certain tissues or in response to environmental factors. RNA from these tissues can be isolated and used as a probe for these microarrays. Only those sequences that are expressed in the tissues will be present and will hybridize to the microarray.

**Microarray analysis and cancer.** One of the most exciting uses of microarrays has been the profiling of gene expression patterns in human cancers. Microarray analysis has revealed that different cancers have different gene expression patterns. These findings are already being used to diagnose and design specific treatments for particular cancers.

From a large body of data, several patterns emerge:

1. Specific cancer types can be reliably distinguished from other cancer types and from normal tissue based on microarray data.
2. Subtypes of particular cancers often have different gene expression patterns in microarray data.
3. Gene expression patterns from microarray data can be used to predict disease recurrence, tendency to metastasize, and treatment response.

This represents an important step forward in both the diagnosis and treatment of human cancers.

### Microarray analysis and genome-wide association mapping

Genome-wide association (GWA) is an approach that compares SNPs throughout the genome between members in a population with and without a specific trait. The goal is to find a SNP that correlates with a specific trait as a way to map the trait. The dog genome exemplifies the value of GWA mapping. Using microarrays that distinguish between 15,000 SNP variants,

## SCIENTIFIC THINKING

**Hypothesis:** Flowers and leaves will express some of the same genes.

**Prediction:** When mRNAs isolated from *Arabidopsis* flowers and from leaves are used as probes on an *Arabidopsis* genome microarray, the two different probe sets will hybridize to both common and unique sequences.

**Test:**

1. Start with an *Arabidopsis* genome microarray. Unique, PCR-amplified *Arabidopsis* genome fragments (1, 2, 3, 4...) are contained in each well of a plate.

Plate containing genome fragments

2. DNA is printed onto a microscope slide.

3. Isolate mRNA from flowers and leaves, convert to cDNA, and label with fluorescent labels. Samples of mRNA are obtained from two different tissues. Probes for each sample are prepared using a different fluorescent nucleotide for each sample.

4. Probe microarray with labeled cDNA. The two probes are mixed and hybridized with the microarray. Fluorescent signals on the microarray are analyzed.

**Result:** Yellow spots represent sequences that hybridized to cDNA from both flowers and leaves. Red spots represent genes expressed only in flowers. Green spots represent genes expressed only in leaves.

**Conclusion:** Some *Arabidopsis* genes are expressed in both flowers and leaves, but there are genes expressed in flowers but not leaves and leaves but not flowers.

**Further Experiments:** How could you use microarrays to determine whether the genes expressed in both flowers and leaves are housekeeping genes or are unique to flowers and leaves?

**Figure 18.10** Microarrays.

disease alleles for a recessive trait can be mapped by comparing 20 purebred dogs exhibiting the disease with 20 healthy dogs.

### Transgenics

How can we determine whether two genes from different species having similar sequences have the same function? And,

how can we be sure that a gene identified by an annotation program actually functions as a gene in the organism? One way to address these questions is through transgenics—the creation of organisms containing genes from other species (transgenic organisms).

The technology for creating transgenic organisms was discussed in chapter 17; it is illustrated for plants in

figure 18.11. Different markers can be incorporated into the gene so that its protein product can be visualized or isolated in the transgenic plant, demonstrating that the inserted gene is being transcribed. In some cases, the transgene (inserted foreign gene) may affect a visible phenotype. Of course, transgenics are but one of many ways to address questions about gene function.

### Proteomics moves from genes to proteins

Proteins are much more difficult to study than DNA because of posttranslational modification and formation of protein complexes. And, as already mentioned, a single gene can code for multiple proteins using alternative splicing. Although all the DNA in a genome can be isolated from a single cell, only a portion of the proteome is expressed in a single cell or tissue.

**Proteomics** is the study of the **proteome**—all of the proteins encoded by the genome. Understanding the proteome for even a single cell will be a much more difficult task than determining the sequence of a genome. Because a single gene can produce more than one protein by alternative splicing, the first step is to characterize the **transcriptome**—all of the RNA that is present in a cell or tissue. Because of alternative splicing, both the transcriptome and the proteome are larger and more complex than the simple number of genes in the genome.

To make matters worse, a single protein can be modified posttranslationally to produce functionally different forms. The

function of a protein can also depend on its association with other proteins. Nonetheless, since proteins perform most of the major functions of cells, understanding their diversity is essential.

### Inquiry question

? Why is the “proteome” likely to be different from simply the predicted protein products found in the complete genome sequence?

### Predicting protein function

The use of new methods to quickly identify and characterize large numbers of proteins is the distinguishing feature between traditional protein biochemistry and proteomics. As with genomics, the challenge is one of scale.

Ideally, a researcher would like to be able to examine a nucleotide sequence and know what sort of functional protein the sequence specifies. Databases of protein structures in different organisms can be searched to predict the structure and function of genes known only by sequence, as identified in genome projects. Analysis of these data provides a clearer picture of how gene sequence relates to protein structure and function. Having a greater number of DNA sequences available allows for more extensive comparisons as well as identification of common structural patterns as groups of proteins continue to emerge.

Although there may be as many as a million different proteins, most are just variations on a handful of themes.

### Figure 18.11 Growth of a transgenic plant.

DNA containing a gene for herbicide resistance was transferred into wheat (*Triticum aestivum*). The DNA also contains the *GUS* gene, which is used as a tag or label. The *GUS* gene produces an enzyme that catalyzes the conversion of a staining solution from clear to blue. **a.** Embryonic tissue just prior to insertion of foreign DNA.

**b.** Following DNA transfer, callus cells containing the foreign DNA are indicated by color from the *GUS* gene (*blue spots*). **c.** Shoot formation in the transgenic plants growing on a selective medium. Here, the gene for herbicide resistance in the transgenic plants allows growth on the selective medium containing the herbicide.

**d.** Comparison of growth on the selection medium for transgenic plants bearing the herbicide resistance gene (*left*) and a nontransgenic plant (*right*).

The same shared structural motifs—barrels, helices, molecular zippers—are found in the proteins of plants, insects, and humans (figure 18.12; also see chapter 3 for more information on protein motifs). The maximum number of distinct motifs has been estimated to be fewer than 5000. About 1000 of these motifs have already been cataloged. Efforts are now under way to detail the shapes of all the common motifs.

### Protein microarrays

**Protein microarrays**, comparable to DNA microarrays, are being used to analyze large numbers of proteins simultaneously. Making a protein microarray starts with isolating the transcriptome of a cell or tissue. Then cDNAs are constructed and reproduced by cloning them into bacteria or viruses. Transcription and translation occur in the prokaryotic host, and micromolar quantities of protein are isolated and purified. These are then spotted onto glass slides.

Protein microarrays can be probed in at least three different ways. First, they can be screened with antibodies to specific proteins. Antibodies are labeled so that they can be detected, and the patterns on the protein array can be determined by computer analysis.

An array of proteins can also be screened with another protein to detect binding or other protein interactions. Thousands of interactions can be tested simultaneously. For example, calmodulin (which mediates  $\text{Ca}^{2+}$  function; see chapter 9) was labeled and used to probe a yeast proteome array with 5800 proteins. The screen revealed 39 proteins that bound calmodulin. Of those 39, 33 were previously unknown!

A third type of screen uses small molecules to assess whether they will bind to any of the proteins on the array. This approach shows promise for discovering new drugs that will inhibit proteins involved in disease.

### Large-scale screens reveal protein–protein interactions

We often study proteins in isolation, compared with their normal cellular context. This approach is obviously artificial. One immediate goal of proteomics, therefore, is to map all the physical interactions between proteins in a cell. This is a daunting task that requires tools that can be automated, similarly to the way that genome sequencing was automated.

One approach is to use the yeast two-hybrid system discussed in the preceding chapter. This system can be automated once libraries of known cDNAs are available in each of the two vectors used. The use of two-hybrid screens has been applied to budding yeast to generate a map of all possible interacting proteins. This method is difficult to apply to more complex multicellular organisms, but in a technical tour-de-force, it has been applied to *Drosophila melanogaster* as well.

For vertebrates, the two-hybrid system is being applied more selectively, by concentrating on a biologically significant process, such as signal transduction. The technique can then be used to map all of the interacting proteins in a specific signaling pathway.

**Figure 18.12** Computer-generated model of an enzyme. Searchable databases contain known protein structures, including human aldose reductase shown here. Secondary structural motifs are shown in different colors.

### Inquiry question

? What is the relationship among genome, transcriptome, and proteome?

### Learning Outcomes Review 18.4

Comparisons of different genomes allows geneticists to infer structural, functional, and evolutionary relationships between genes and proteins as well as relationships between species. Microarrays enable evaluation of gene expression for many genes at once. Proteomics involves similar analysis of all the proteins coded by a genome, that is, an organism's proteome. Because of alternative splicing, this task is much more complex.

- Why is establishment of a species' transcriptome an important step in studying its proteome?

## 18.5 Applications of Genomics

### Learning Outcomes

1. List ways in which genomics could be applied to infectious disease research.
2. Explain how genomics could enhance crop production and nutritional yield.
3. Evaluate the issues of genome ownership and privacy.

Space allows us to highlight only a few of the myriad applications of genomics to show the possibilities. The tools being developed truly represent a revolution in biology that will likely have a lasting influence on the way that we think about living systems.

## Genomics can help to identify infectious diseases

The genomics revolution has yielded millions of new genes to be investigated. The potential of genomics to improve human health is enormous. Mutations in a single gene can explain some, but not most, hereditary diseases. With entire genomes to search, the probability of unraveling human, animal, and plant diseases is greatly improved.

Although proteomics will likely lead to new pharmaceuticals, the immediate effect of genomics is being seen in diagnostics. Both improved technology and gene discovery are enhancing the diagnosis of genetic abnormalities.

Diagnostics are also being used to identify individuals. For example, short tandem repeats (STRs), discovered through genomic research, were among the forensic diagnostic tools used to identify remains of victims of the September 11, 2001, terrorist attack on the World Trade Center in New York City.

The September 11 attacks were followed by an increased awareness and concern about biological weapons. Five people died and 17 more were infected with anthrax after envelopes containing anthrax spores were sent through the U.S. mail. A massive FBI investigation initially focused on the wrong individual, Steven J. Hatfill, a government scientist. Genome sequencing allowed exploration of possible sources of the deadly bacteria. A difference of only 10 bp between strains allowed the FBI to trace the source to a single vial of the bacteria used in a vaccine research program at U.S. Army Medical Research Institute for Infectious Diseases. By 2008, Hatfield was exonerated. Another researcher, Bruce E. Ivins, committed suicide just before being formally charged by the FBI with criminal activity in the 2001 anthrax attacks. Ivins had been working on vaccine development. In addition, substantial effort has been turned toward the use of genomic tools to distinguish between naturally occurring infections and intentional outbreaks of disease. The Centers for Disease Control and Prevention (CDC) have ranked bacteria and viruses that are likely targets for bioterrorism (table 18.2).

## Genomics can help improve agricultural crops

Globally speaking, poor nutrition is the greatest impediment to human health. Much of the excitement about the rice genome project is based on its potential for improving the yield and nutritional quality of rice and other cereals worldwide. The development of Golden Rice (chapter 17) is an example of improved nutrition through genetic approaches. About one third of the world population obtains half its calories from rice (figure 18.13). In some regions, individuals consume up to 1.5 kg of rice daily. More than 500 million tons of rice is produced each year, but this may not be adequate to provide enough rice for the world in the future.

Pathogen	Disease	Genome*
<i>Variola major</i>	Smallpox	Complete
<i>Bacillus anthracis</i>	Anthrax	Complete
<i>Yersinia pestis</i>	Plague	Complete
<i>Clostridium botulinum</i>	Botulism	In progress
<i>Francisella tularensis</i>	Tularemia	Complete
Filoviruses	Ebola and Marburg hemorrhagic fever	Both are complete
Arenaviruses	Lassa fever and Argentine hemorrhagic fever	Both are complete

\*There are multiple strains of these viruses and bacteria. "Complete" indicates that at least one has been sequenced. For example, the Florida strain of anthrax was the first to be sequenced.

Due in large part to scientific advances in crop breeding and farming techniques, in the last 50 years world grain production has more than doubled, with an increase in cropland of only 1%. The world now farms a total area the size of South America, but without the scientific advances of the past 50 years, an area equal to the entire western hemisphere would need to be farmed to produce enough food for the world.

Unfortunately, water usage for crops has tripled in that time period, and quality farmland is being lost to soil erosion. Scientists are also concerned about the effects of global climate

**Figure 18.13 Rice field.** Most of the rice grown globally is directly consumed by humans and is the dietary mainstay of 2 billion people.

change on agriculture worldwide. Increasing the yield and quality of crops, especially on more marginal farmland, will depend on many factors—but genetic engineering, built on the findings of genomics projects, can contribute significantly to the solution.

Most crops grown in the United States produce less than half of their genetic potential because of environmental stresses (salt, water, and temperature), herbivores, and pathogens (figure 18.14). Identifying genes that can provide resistance to stress and pests is the focus of many current genomics research projects. Having access to entire genomic sequences will enhance the probability of identifying critical genes.

## Genomics raises ethical issues over ownership of genomic information

Genome science is also a source of ethical challenges and dilemmas. One example is the issue of gene patents. Actually, it is the use of a gene, not the gene itself, that is patentable. For a patent to be granted for a gene's use, the product and its function must be known.

The public genome consortia, supported by federal funding, have been driven by the belief that the sequence of genomes should be freely available to all and should not be patented. Private companies patent gene functions, but they often make sequence data available with certain restrictions. The physical sciences have negotiated the landscape of public and for-profit research for decades, but this is relatively new territory for biologists.

Another ethical issue involves privacy. How sequence data are used is the focus of thoughtful and ongoing discussions. The Universal Declaration on the Human Genome and Human Rights states, “The human genome underlies the fundamental unity of all members of the human family, as well as the recognition of their inherent dignity and diversity. In a symbolic sense, it is the heritage of humanity.”

Although we talk about “the” human genome, each of us has subtly different genomes that can be used to identify us. Genetic disorders such as cystic fibrosis and Huntington disease can already be identified by screening, but genomics will greatly increase the number of identifiable traits. The Genetic Information Nondiscrimination Act (GINA) was signed into law in 2008 to prevent discrimination based on genotype. Employers and health insurance companies may not request genetic tests or discriminate based on someone's genetic code. Life, disability, and long term care insurance are not covered by GINA. Members of the military are excluded from GINA's privacy protection. The U.S. Armed Forces require DNA samples from members of the military for possible casualty identification. The genome privacy debate continues.

Behavioral genomics is an area that is also rich with possibilities and dilemmas. Very few behavioral traits can be accounted for by single genes. Two genes have been associated with fragile-X mental retardation, and three with early-onset Alzheimer disease. Comparisons of multiple genomes will likely lead to the identification of multiple genes controlling a range of behaviors. Will this change the way we view acceptable behavior?

**Figure 18.14** Corn crop productivity well below its genetic potential due to drought stress. Corn production can be limited by water deficiencies due to the drought that occurs during the growing season in dry climates. Global climate change may increase drought stress in areas where corn is the major crop.

### Inquiry question

As of February 2008 a draft version of the corn genome has been sequenced. How could you use information from the corn and rice genome sequences to try to improve drought tolerance in corn?

In Iceland, the parliament has voted to have a private company create a database from pooled medical, genetic, and genealogical information about all Icelanders, a particularly fascinating population from a genetic perspective. Because minimal migration or immigration has occurred there over the last 800 years, the information that can be mined from the Icelandic database is phenomenal. Ultimately, the value of that information has to be weighed, however, against any possible discrimination or stigmatization of individuals or groups.

### Learning Outcomes Review 18.5

Genomics is one approach to better diagnosis, based on knowledge of infectious agents' genetic makeup; it also allows identification of individual disease strains. Genomics has enhanced DNA identification of remains. Agricultural crop yields and nutritional content could be improved if genes that confer disease resistance or increased synthesis can be identified.

- Suppose you produced an engineered form of potato that had twice the amount of protein. Would you seek a patent on this plant?

## Chapter Review

### 18.1 Mapping Genomes

#### **Different kinds of physical maps can be generated.**

Physical genetic maps include fully sequenced genomes, restriction maps, and maps of chromosome banding patterns.

#### **Sequence-tagged sites provide a common language for physical maps.**

Any physical site can be used as a sequence-tagged site (STS), based on a small stretch of a unique DNA sequence that allows unambiguous identification of a fragment.

#### **Genetic maps provide a link to phenotypes.**

Short tandem repeats (STRs) are the most common type of markers for distinguishing regions of the genome and assessing its phenotypic effects.

#### **Physical maps can be correlated with genetic maps.**

Physical and genetic maps can be correlated. Any gene that can be cloned can be placed within the genome sequence and mapped. However, absolute correspondence of distances cannot be accomplished.

### 18.2 Whole-Genome Sequencing

#### **Genome sequencing requires larger molecular clones.**

Yeast artificial chromosomes (YACs) have allowed cloning of larger pieces of DNA, although their use has some drawbacks. Bacterial artificial chromosomes (BACs) are most commonly used now.

#### **Whole-genome sequencing is approached in two ways: clone-by-clone and shotgun.**

Clone-by-clone sequencing starts with known clones, often in BACs that can be aligned with each other.

Shotgun sequencing involves sequencing random clones, then using a computer to assemble the finished sequence.

#### **The Human Genome Project used both sequencing methods.**

By 2004, the “finished” sequence was announced, and it includes 99% of the euchromatic human DNA sequence.

### 18.3 Characterizing Genomes

#### **The Human Genome Project found fewer genes than expected.**

Although eukaryotic genomes are larger and have more genes than those of prokaryotes, the size of the organism is not always correlated with the size of the genome. The human genome contains only around 25,000 genes, fewer than found in rice.

#### **Finding genes in sequence data requires computer searches.**

In a sequenced genome, protein-coding genes are identified by looking for open-reading frames (ORFs). An ORF begins with a start codon and contains no stop codon for a distance long enough to encode a protein. Genes are then grouped based on conserved regions.

#### **Genomes contain both coding and noncoding DNA.**

Protein-encoding DNA includes single-copy genes, segmental duplications, multigene families, and tandem clusters. Noncoding DNA in eukaryotes makes up about 99% of DNA. Approximately 45% of the human genome is composed of mobile transposable elements, including LINEs, SINEs, and LTRs.

#### **Expressed sequence tags identify genes that are transcribed.**

The number and location of expressed genes can be estimated by sequencing the ends of randomly selected cDNAs to produce expressed sequence tags (ESTs).

#### **SNPs are single-base differences between individuals.**

Single-nucleotide difference between individuals are called single-nucleotide polymorphisms (SNPs). To be classified as a polymorphism, an SNP must be present in at least 1% of the population. At least 50,000 SNPs are currently known in coding regions.

Genomic haplotypes are regions of chromosomes that are not exchanged by recombination. These regions can be used to map genes by association (see figure 18.8).

### 18.4 Genomics and Proteomics

#### **Comparative genomics reveals conserved regions in genomes.**

More than half of the genes of *Drosophila* have human counterparts. The biggest difference between our genome and the chimpanzee genome is in transposable elements.

#### **Synteny allows comparison of unsequenced genomes.**

Synteny refers to the conserved arrangements of segments of DNA in related genomes (see figure 18.9). Many separate species have been found to have large regions of synteny.

#### **Organelle genomes have exchanged genes with the nuclear genome.**

Both chloroplasts and mitochondria contain components that indicate exchange of genetic material with the nuclear genome.

#### **Functional genomics reveals gene function at the genome level.**

Functional genomics uses high-end computer technology to analyze gene function and gene products. DNA microarrays allow the expression of all of the genes in a cell to be monitored at once (see figure 18.10).

#### **Proteomics moves from genes to proteins.**

Proteomics characterizes all of the proteins produced by a cell. The transcriptome is all the mRNAs present in a cell at a specific time. Protein microarrays can identify and characterize large numbers of proteins.

#### **Large-scale screens reveal protein–protein interactions.**

The yeast two-hybrid system is used to generate large-scale maps of interacting proteins; however, the scope of this task is daunting in humans, mice, and other vertebrates. Selective applications in specific areas, such as signal transduction, have been undertaken.

### 18.5 Applications of Genomics

#### **Genomics can help to identify infectious diseases.**

Genomics can help identify naturally occurring and intentional outbreaks of infectious diseases and tracing of disease strains.

#### **Genomics can help improve agricultural crops.**

Genomics can potentially increase the nutritional value of crops and alter their responses to environmental stresses, potentially helping to feed a growing population.

#### **Genomics raises ethical issues over ownership of genomic information.**

Questions regarding profit and ownership of genomic data provide ongoing challenges for the ethical use of scientific knowledge.

## Review Questions

### UNDERSTAND

- A genetic map is based on the
  - sequence of the DNA.
  - relative position of genes on chromosomes.
  - location of sites of restriction enzyme cleavage.
  - banding pattern on a chromosome.
- What is an STS?
  - A unique sequence within the DNA that can be used for mapping
  - A repeated sequence within the DNA that can be used for mapping
  - An upstream element that allows for mapping of the 3' region of a gene
  - Both b and c
- Which number represents the total number of genes in the human genome?
  - 2500
  - 10,000
  - 25,000
  - 100,000
- An open reading frame (ORF) is distinguished by the presence of
  - a stop codon.
  - a start codon.
  - a sequence of DNA long enough to encode a protein.
  - All of the above
- What is a BLAST search?
  - A mechanism for aligning consensus regions during whole-genome sequencing
  - A search for similar gene sequences from other species
  - A method of screening a DNA library
  - A method for identifying ORFs
- Which of the following is *not* an example of a protein-encoding gene?
  - Single-copy gene
  - Tandem clusters
  - Pseudogene
  - Multigene family
- What is a proteome?
  - The collection of all genes encoding proteins
  - The collection of all proteins encoded by the genome
  - The collection of all proteins present in a cell
  - The amino acid sequence of a protein
- Which of the following is *not* an example of noncoding DNA?
  - Promoter
  - Intron
  - Pseudogene
  - Exon
- Which of the following techniques relies on prior knowledge of overlapping sequences?
  - Yeast two-hybrid system
  - Shotgun method of genome sequencing
  - FISH
  - Clone-by-clone method of genome sequencing
- The duplication of a gene due to uneven meiotic crossing over is thought to lead to the production of a
  - segmental duplication.
  - tandem duplication.
  - simple sequence repeat.
  - multigene family.
- What information can be obtained from a DNA microarray?
  - The sequence of a particular gene.
  - The presence of genes within a specific tissue.
  - The pattern of gene expression.
  - Differences between genomes.
- Which of the following is true regarding microarray technology and cancer?
  - A DNA microarray can determine the type of cancer.
  - A DNA microarray can measure the response of a cancer to therapy.
  - A DNA microarray can be used to predict whether the cancer will metastasize.
  - All of the above
- Which of the following techniques could be used to examine protein–protein interactions in a cell?
  - Two-hybrid screens
  - Protein structure databases
  - Protein microarrays
  - Both a and c

### SYNTHESIZE

- You are in the early stages of a genome-sequencing project. You have isolated a number of clones from a BAC library and mapped the inserts in these clones using STSs. Use the STSs to align the clones into a contiguous sequence of the genome (a contig).

- Genomic research can be used to determine if an outbreak of an infectious disease is natural or “intentional.” Explain what a genomic researcher would be looking for in a suspected intentional outbreak of a disease like anthrax.

### APPLY

- An artificial chromosome is useful because it
  - produces more consistent results than a natural chromosome.
  - allows for the isolation of larger DNA sequences.
  - provides a high copy number of a DNA sequence.
  - is linear.
- Comparisons between genomes is made easier because of
  - synteny.
  - haplotypes.
  - transposons.
  - expressed sequence tags.

# Chapter 19

## Cellular Mechanisms of Development

### Chapter Outline

- 19.1 The Process of Development
- 19.2 Cell Division
- 19.3 Cell Differentiation
- 19.4 Nuclear Reprogramming
- 19.5 Pattern Formation
- 19.6 Morphogenesis

### Introduction

Recent work with different kinds of stem cells, like those pictured, have captured the hopes and imagination of the public. For thousands of years, humans have wondered how organisms arise, grow, change, and mature. We are now in an era when long-standing questions may be answered, and new possibilities for regenerative medicine seem on the horizon.

We have explored gene expression from the perspective of individual cells, examining the diverse mechanisms cells employ to control the transcription of particular genes. Now we broaden our perspective and look at the unique challenge posed by the development of a single cell, the fertilized egg, into a multicellular organism. In the course of this developmental journey, a pattern of decisions about gene expression takes place that causes particular lines of cells to proceed along different paths, spinning an incredibly complex web of cause and effect. Yet, for all its complexity, this developmental program works with impressive precision. In this chapter, we explore the mechanisms of development at the cellular and molecular level.

### 19.1 The Process of Development

Development can be defined as the process of systematic, gene-directed changes through which an organism forms the successive stages of its life cycle. Development is a continuum, and explorations of development can be focused on any point along this continuum. The study of development plays a central role in unifying the understanding of both the similarities and diversity of life on Earth.

We can divide the overall process of development into four subprocesses:

- **Cell Division.** A developing plant or animal begins as a fertilized egg, or zygote, that must undergo cell division to produce the new individual. In all cases early development involves extensive cell division, but in many cases it does not include much growth as the egg cell itself is quite large.
- **Differentiation.** As cells divide, orchestrated changes in gene expression result in differences between cells that ultimately result in cell specialization. In differentiated

cells, certain genes are expressed at particular times, but other genes may not be expressed at all.

- **Pattern Formation.** Cells in a developing embryo must become oriented to the body plan of the organism the embryo will become. Pattern formation involves cells' abilities to detect positional information that guides their ultimate fate.
- **Morphogenesis.** As development proceeds, the form of the body—its organs and anatomical features—is generated. Morphogenesis may involve cell death as well as cell division and differentiation.

Despite the overt differences between groups of plants and animals, most multicellular organisms develop according to molecular mechanisms that are fundamentally very similar. This observation suggests that these mechanisms evolved very early in the history of multicellular life.

## 19.2 Cell Division

### Learning Outcomes

1. Explain the importance of cell division to early development.
2. Describe the use of *C. elegans* to track cell lineages.
3. Distinguish differences in cell division between animals and plants.

When a frog tadpole hatches out of its protective coats, it is roughly the same overall mass as the fertilized egg from which it came. Instead of being made up of just one cell, however, the tadpole consists of about a million cells, which are organized into tissues and organs with different functions. Thus, the very first process that must occur during embryogenesis is cell division.

Immediately following fertilization, the diploid zygote undergoes a period of rapid mitotic divisions that ultimately result in an early embryo comprised of dozens to thousands of diploid cells. In animal embryos, the timing and number of these divisions are species-specific and are controlled by a set of molecules that we examined in chapter 10: the *cyclins* and *cyclin-dependent kinases* (*Cdks*). These molecules exert control over checkpoints in the cycle of mitosis.

### Development begins with cell division

In animal embryos, the period of rapid cell division following fertilization is called **cleavage**. During cleavage, the enormous mass of the zygote is subdivided into a larger and larger number of smaller and smaller cells, called **blastomeres** (figure 19.1). Hence, cleavage is not accompanied by any increase in the overall size of the embryo. The  $G_1$  and  $G_2$  phases of the cell cycle, during which a cell increases its mass and size, are extremely shortened or eliminated during cleavage (figure 19.2).

Because of the absence of the two gap/growth phases, the rapid rate of mitotic divisions during cleavage is never again approached in the lifetime of any animal. For example, zebrafish blastomeres divide once every several minutes during cleavage, to create an embryo with a thousand cells in just under 3 hr! In contrast, cycling adult human intestinal epithelial cells divide on average only once every 19 hr. A comparison of the different patterns of cleavage can be found in chapter 54.

When external sources of nutrients become available—for example, during larval feeding stages or after implantation of mammalian embryos—daughter cells can increase in size following cytokinesis, and an overall increase in the size of the organism occurs as more cells are produced.

### Every cell division is known in the development of *C. elegans*

One of the most completely described models of development is the tiny nematode *Caenorhabditis elegans*. Only about 1 mm long, the adult worm consists of 959 somatic cells.

Because *C. elegans* is transparent, individual cells can be followed as they divide. By observing them, researchers have learned how each of the cells that make up the adult worm is derived from the fertilized egg. As shown on the lineage map in figure 19.3a, the egg divides into two cells, and these daughter cells continue to divide. Each horizontal line on the map represents one round of cell division. The length of each vertical line represents the time between cell divisions, and the end of each vertical line represents one fully differentiated cell. In figure 19.3b, the major organs of the worm are color-coded to match the colors of the corresponding groups of cells on the lineage map.

Some of these differentiated cells, such as some cells that generate the worm's external cuticle, are "born" after only 8 rounds of cell division; other cuticle cells require as many as 14 rounds. The cells that make up the worm's pharynx, or feeding organ, are born after 9 to 11 rounds of division, whereas cells in the gonads require up to 17 divisions.

Exactly 302 nerve cells are destined for the worm's nervous system. Exactly 131 cells are programmed to die, mostly within minutes of their "birth." The fate of each cell is the same in every *C. elegans* individual, except for the cells that will become eggs and sperm.

**Figure 19.1** Cleavage divisions in a frog embryo. *a.* The first cleavage division divides the egg into two large blastomeres. *b.* After two more divisions, four small blastomeres sit on top of four large blastomeres, each of which continues to divide to produce *(c)* a compact mass of cells.

**Figure 19.2 Cell cycle of adult cell and embryonic cell.** In contrast to the cell cycle of adult somatic cells (*a*), the dividing cells of early frog embryos lack  $G_1$  and  $G_2$  stages (*b*), enabling the cleavage stage nuclei to rapidly cycle between DNA synthesis and mitosis. Large stores of cyclin mRNA are present in the unfertilized egg. Periodic degradation of cyclin proteins correlates with exiting from mitosis. Cyclin degradation and Cdk inactivation allow the cell to complete mitosis and initiate the next round of DNA synthesis.

### Plant growth occurs in specific areas called meristems

A major difference between animals and plants is that most animals are mobile, at least in some phase of their life cycles, and therefore they can move away from unfavorable circumstances. Plants, in contrast, are anchored in position and must simply endure whatever environment they experience. Plants compen-

sate for this restriction by allowing development to accommodate local circumstances.

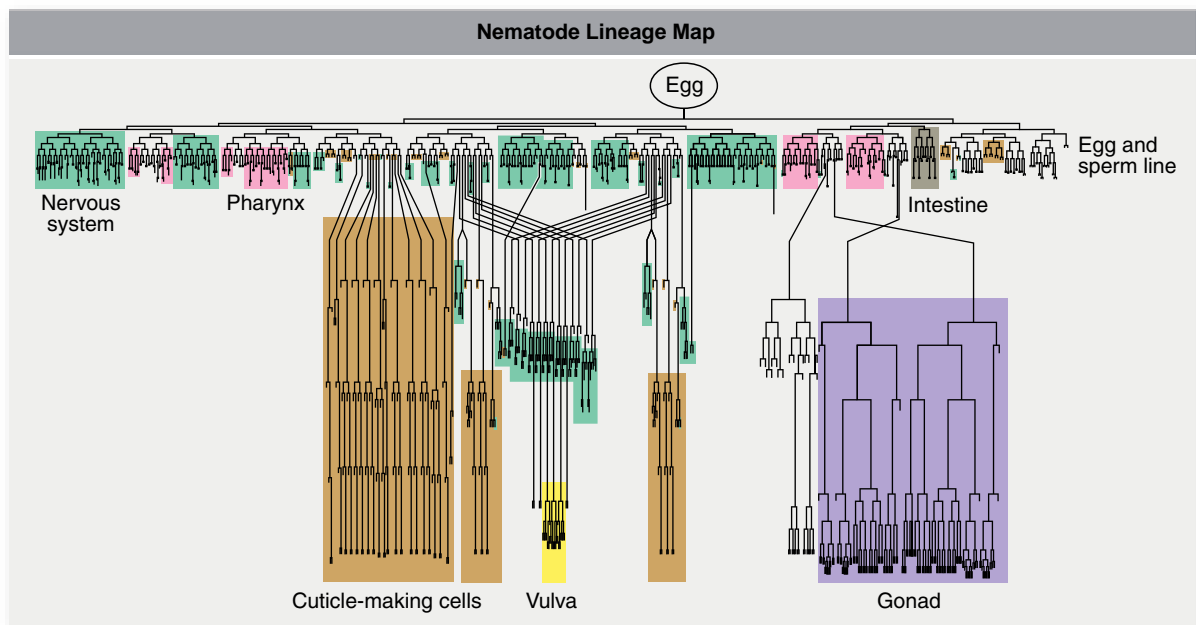

Instead of creating a body in which every part is specified to have a fixed size and location, a plant assembles its body throughout its life span from a few types of modules, such as leaves, roots, branch nodes, and flowers. Each module has a rigidly controlled structure and organization, but how the modules are utilized is quite flexible—they can be adjusted to environmental conditions.

### Figure 19.3 Studying embryonic cell division and development in the nematode.

Development in *C. elegans* has been mapped out such that the fate of each cell from the single egg cell has been determined.

*a.* The lineage map shows the number of cell divisions from the egg, and the color coding links their placement in (*b*) the adult organism.

M. E. Challinor illustration. From Howard Hughes Medical Institute © as published in *From Egg to Adult*, 1992. Reprinted by permission.

*b.*

Plants develop by building their bodies outward, creating new parts from groups of stem cells that are contained in structures called **meristems**. As meristematic stem cells continually divide, they produce cells that can differentiate into the tissues of the plant.

This simple scheme indicates a need to control the process of cell division. We know that cell-cycle control genes are present in both yeast (fungi) and animal cells, implying that these are a eukaryotic innovation—and in fact, the plant cell cycle is regulated by the same mechanisms, namely through cyclins and cyclin-dependent kinases. In one experiment, over-expression of a Cdk inhibitor in transgenic *Arabidopsis thaliana* plants resulted in strong inhibition of cell division in leaf meristems, leading to significant changes in leaf size and shape.

### Learning Outcomes Review 19.2

In animal embryos, a series of rapid cell divisions that skip the G<sub>1</sub> and G<sub>2</sub> phases convert the fertilized egg into many cells with no change in size. In the nematode *C. elegans*, every cell division leading to the adult form is known, and this pattern is invariant, allowing biologists to trace development in a cell-by-cell fashion. In plants, growth is restricted to specific areas called meristems, where undifferentiated stem cells are retained.

- How are early cell divisions in an embryo different from in an adult organism?

## 19.3 Cell Differentiation

### Learning Outcomes

1. Describe the progressive nature of determination.
2. List the ways in which cells become committed to developmental pathways on the molecular level.
3. Differentiate between the different types of stem cells.

### Figure 19.4 The standard test for determination.

The gray ovals represent embryos at early stages of development. The cells to the right normally develop into head structures, whereas the cells to the left usually form tail structures. If prospective tail cells from an early embryo are transplanted to the opposite end of a host embryo, they develop according to their new position into head structures. These cells are not determined. At later stages of development, the tail cells are determined since they now develop into tail structures after transplantation into the opposite end of a host embryo!

In chapter 16, we examined the mechanisms that control eukaryotic gene expression. These processes are critical for the development of multicellular organisms, in which life functions are carried out by different tissues and organs. In the course of development, cells become different from one another because of the differential expression of subsets of genes—not only at different times, but in different locations of the growing embryo. We now explore some of the mechanisms that lead to differential gene expression during development.

### Cells become determined prior to differentiation

A human body contains more than 210 major types of differentiated cells. These differentiated cells are distinguishable from one another by the particular proteins that they synthesize, their morphologies, and their specific functions. A molecular decision to become a particular type of differentiated cell occurs prior to any overt changes in the cell. This molecular decision-making process is called **cell determination**, and it commits a cell to a particular developmental pathway.

#### Tracking determination

Determination is often not visible in the cell and can only be “seen” by experiment. The standard experiment to test whether a cell or group of cells is determined is to move the donor cell(s) to a different location in a host (recipient) embryo. If the cells of the transplant develop into the same type of cell as they would have if left undisturbed, then they are judged to be already determined (figure 19.4).

Determination has a time course; it depends on a series of intrinsic or extrinsic events, or both. For example, a cell in the prospective brain region of an amphibian embryo at the early gastrula stage (see chapter 54) has not yet been determined; if transplanted elsewhere in the embryo, it will develop according to the site of transplant. By the late gastrula stage, however,

additional cell interactions have occurred, determination has taken place, and the cell will develop as neural tissue no matter where it is transplanted.

Determination often takes place in stages, with a cell first becoming partially committed, acquiring positional labels that reflect its location in the embryo. These labels can have a great influence on how the pattern of the body subsequently develops. In a chicken embryo, tissue at the base of the leg bud normally gives rise to the thigh. If this tissue is transplanted to the tip of the identical-looking wing bud, which would normally give rise to the wing tip, the transplanted tissue will develop into a toe rather than a thigh. The tissue has already been determined as leg, but it is not yet committed to being a particular part of the leg. Therefore, it can be influenced by the positional signaling at the tip of the wing bud to form a tip (but in this case, a tip of leg).

### The molecular basis of determination

Cells initiate developmental changes by using transcription factors to change patterns of gene expression. When genes encoding these transcription factors are activated, one of their effects is to reinforce their own activation. This rein-

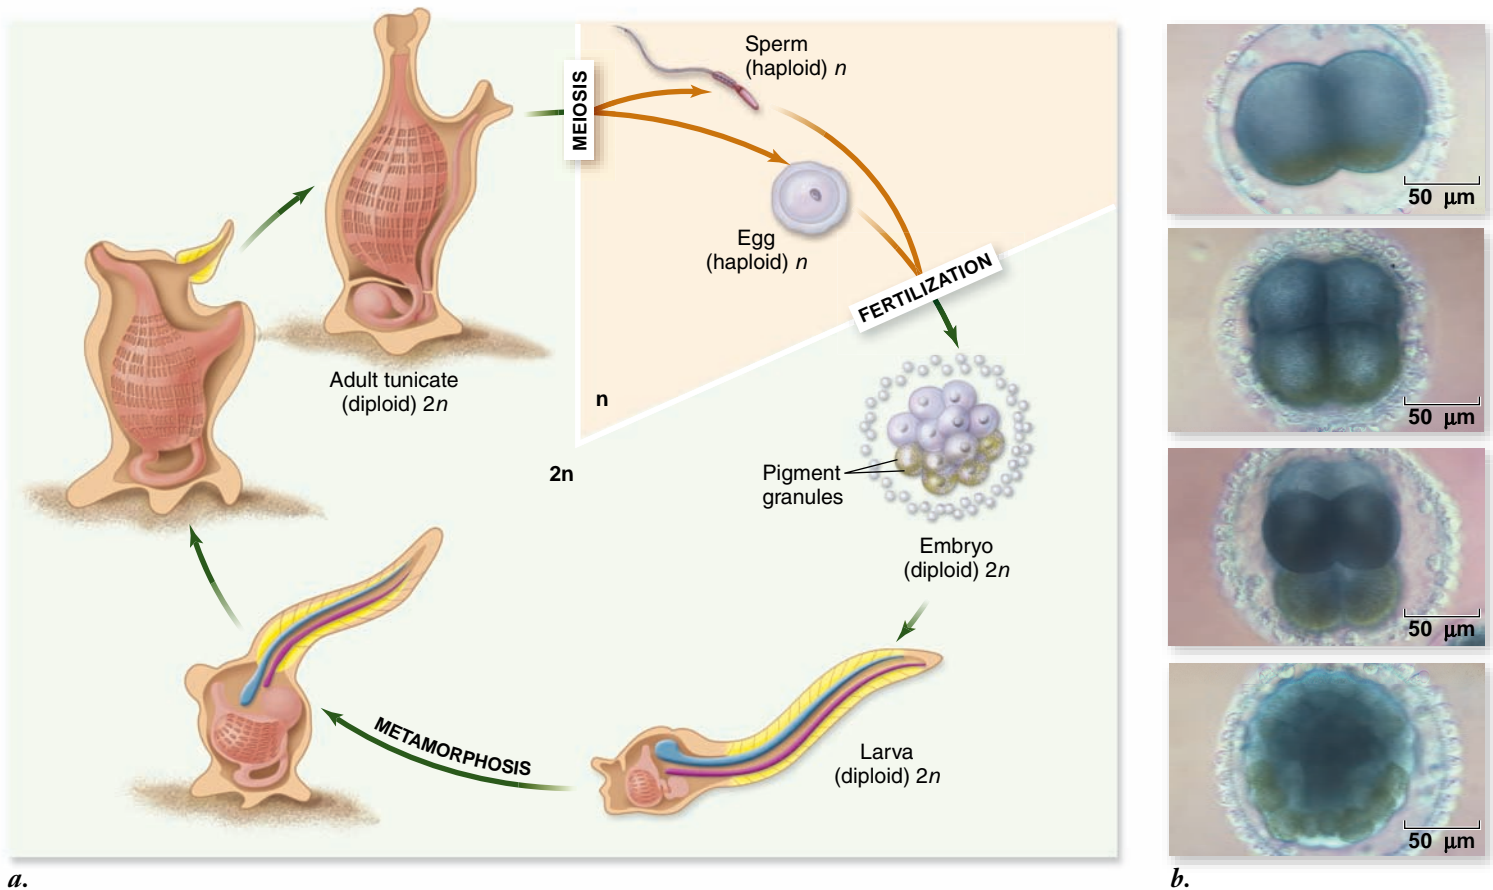

forcement makes the developmental switch deterministic, initiating a chain of events that leads down a particular developmental pathway.

Cells in which a set of regulatory genes have been activated may not actually undergo differentiation until some time later, when other factors interact with the regulatory protein and cause it to activate still other genes. Nevertheless, once the initial “switch” is thrown, the cell is fully committed to its future developmental path.

Cells become committed to follow a particular developmental pathway in one of two ways:

1. via the differential inheritance of cytoplasmic determinants, which are maternally produced and deposited into the egg during oogenesis; or
2. via cell–cell interactions.

The first situation can be likened to a person’s social status being determined by who his or her parents are and what he or she has inherited. In the second situation, the person’s social standing is determined by interactions with his or her neighbors. Clearly both can be powerful factors in the development and maturation of that individual.

**Figure 19.5 Muscle determinants in tunicates.** *a.* The life cycle of a solitary tunicate. Muscle cells that move the tail of the swimming tadpole are arranged on either side of the notochord and nerve cord. The tail is lost during metamorphosis into the sedentary adult. *b.* The egg of the tunicate *Styela* contains bright yellow pigment granules. These become asymmetrically localized in the egg following fertilization, and cells that inherit the yellow granules during cleavage will become the larval muscle cells. Embryos at the 2-cell, 4-cell, 8-cell, and 64-cell stages are shown. The tadpole tail will grow out from the lower region of the embryo in the bottom panel.

## Determination can be due to cytoplasmic determinants

Many invertebrate embryos provide good visual examples of cell determination through the differential inheritance of cytoplasmic determinants. Tunicates are marine invertebrates (see chapter 35), and most adults have simple, saclike bodies that are attached to the underlying substratum. Tunicates are placed in the phylum Chordata, however, due to the characteristics of their swimming, tadpolelike larval stage, which has a dorsal nerve cord and notochord (figure 19.5*a*). The muscles that move the tail develop on either side of the notochord.

In many tunicate species, colored pigment granules become asymmetrically localized in the egg following fertilization and subsequently segregate to the tail muscle cell progenitors during cleavage (figure 19.5*b*). When these pigment granules are shifted experimentally into other cells that normally do not develop into muscle, their fate is changed and they become muscle cells. Thus, the molecules that flip the switch for muscle development appear to be associated with the pigment granules.

The next step is to determine the identity of the molecules involved. Experiments indicate that the female parent provides the egg with mRNA encoded by the *macho-1* gene. The elimination of *macho-1* function leads to a loss of tail muscle in the tadpole, and the misexpression of *macho-1* mRNA leads to the formation of additional (ectopic) muscle cells from nonmuscle lineage cells. The *macho-1* gene product has been shown to be a transcription factor that can activate the expression of several muscle-specific genes.

## Induction can lead to cell differentiation

In chapter 9, we examined a variety of ways by which cells communicate with one another. We can demonstrate the importance of cell–cell interactions in development by separating the cells of an early frog embryo and allowing them to develop independently.

Under these conditions, blastomeres from one pole of the embryo (the “animal pole”) develop features of ectoderm, and blastomeres from the opposite pole of the embryo (the “vegetal pole”) develop features of endoderm. None of the two separated groups of cells ever develop features characteristic of mesoderm, the third main cell type. If animal-pole cells and vegetal-pole cells are placed next to each other, however, some of the animal-pole cells develop as mesoderm. The interaction between the two cell types triggers a switch in the developmental path of these cells. This change in cell fate due to interaction with an adjacent cell is called **induction**. Signaling molecules act to alter gene expression in the target cells, in this case, some of the animal-pole cells.

Another example of inductive cell interactions is the formation of the notochord and mesenchyme, a specific tissue, in tunicate embryos. Muscle, notochord, and mesenchyme all arise from mesodermal cells that form at the vegetal margin of the 32-cell stage embryo. These prospective mesodermal cells receive signals from the underlying endodermal precursor cells that lead to the formation of notochord and mesenchyme (figure 19.6).

*a.*

*b.*

*c.*

**Figure 19.6 Inductive interactions contribute to cell fate specification in tunicate embryos.** *a.* Internal structures of a tunicate larva. To the left is a sagittal section through the larva with dotted lines indicating two longitudinal sections. Section 1, through the midline of a tadpole, shows the dorsal nerve cord (NC), the underlying notochord (Not) and the ventral endoderm cells (En). Section 2, a more lateral section, shows the mesenchymal cells (Mes) and the tail muscle cells (Mus). *b.* View of the 32-cell stage looking up at the endoderm precursor cells. FGF secreted by these cells is indicated with light-green arrows. Only the surfaces of the marginal cells that directly border the endoderm precursor cells bind FGF signal molecules. Note that the posterior vegetal blastomeres also contain the *macho-1* determinants (red and white stripes). *c.* Cell fates have been fixed by the 64-cell stage. Colors are as in (*a*). Cells on the anterior margin of the endoderm precursor cells become notochord and nerve cord, respectively, whereas cells that border the posterior margin of the endoderm cells become mesenchyme and muscle cells, respectively.

The chemical signal is a member of the *fibroblast growth factor (FGF)* family of signaling molecules. It induces the overlying marginal zone cells to differentiate into either notochord (anterior) or mesenchyme (posterior). The FGF receptor on the marginal zone cells is a receptor tyrosine kinase that signals through a MAP kinase cascade to activate a transcription factor that turns on gene expression resulting in differentiation (figure 19.7).

This example is also a case of two cells responding differently to the same signal. The presence or absence of the *macho-1* muscle determinant discussed earlier controls this difference in cell fate. In the presence of *macho-1*, cells differentiate into mesenchyme; in its absence, cells differentiate into notochord.

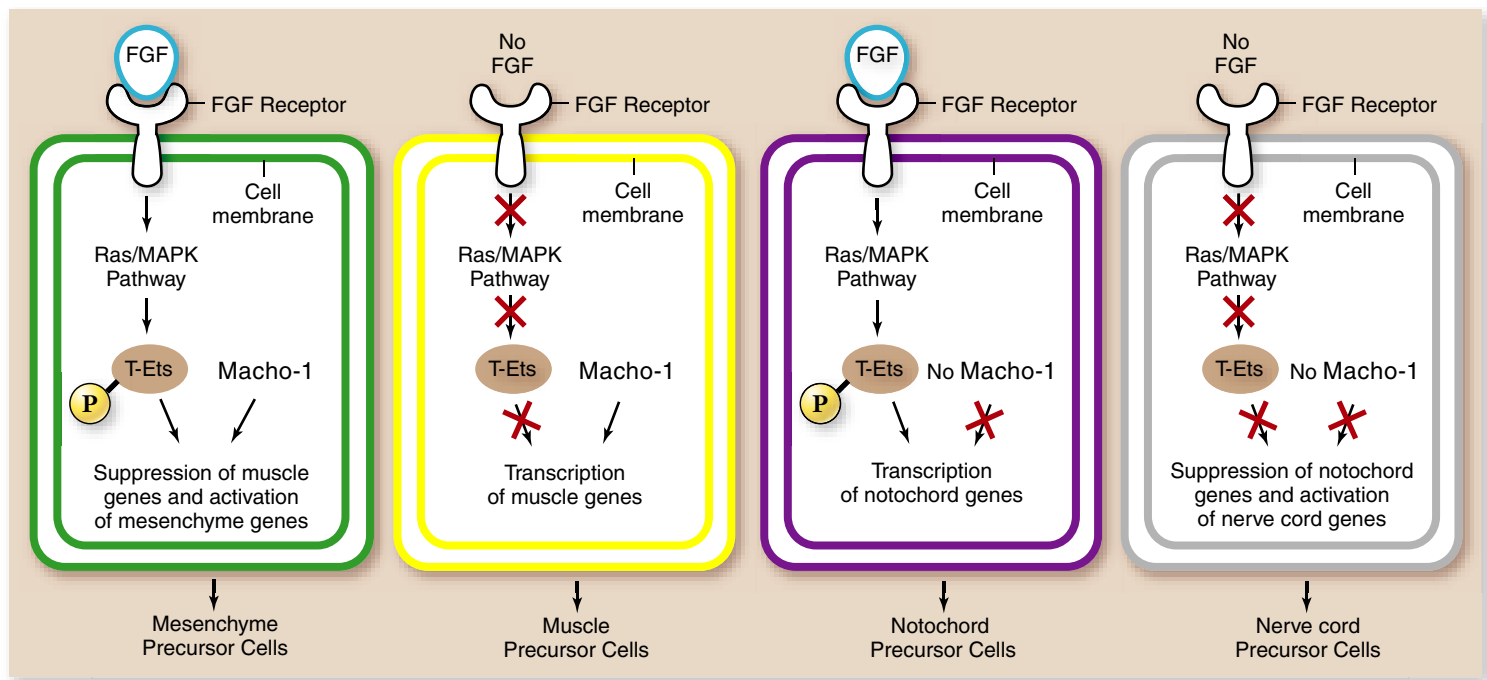

Thus, the combination of *macho-1* and FGF signaling leads to four different cell types (see figure 19.7)

### Stem cells can divide and produce cells that differentiate

It is important, both during development, and even in the adult animal, to have cells set aside that can divide but are not determined for only a single cell fate. We call cells that are capable of continued division but that can also give rise to differentiated cells, **stem cells**. These cells can be characterized based on the degree to which they have become determined.

a.

b.

**Figure 19.7 Model for cell fate specification by Macho-1 muscle determinant and FGF signaling.** *a.* Two-step model of cell fate specification in vegetal marginal cells of the tunicate embryo. The first step is inheritance (or not) of muscle *macho-1* mRNA. The second step is FGF signaling from the underlying endoderm precursor cells. *b.* Posterior vegetal margin cells inherit *macho-1* mRNA. Signaling by FGF activates a Ras/MAP kinase pathway that produces the transcription factor T-Ets. Macho-1 protein and T-Ets suppress muscle-specific genes and turn on mesenchyme specific genes (*green cells*). In cells with Macho-1 that do not receive the FGF signal, Macho-1 alone turns on muscle-specific cells (*yellow cells*). Anterior vegetal margin cells do not inherit *macho-1* mRNA. If these cells receive the FGF signal, T-Ets turns on notochord-specific genes (*purple cells*). In cells that lack Macho-1 and FGF, notochord-specific genes are suppressed and nerve cord-specific genes are activated (*gray cells*).

#### Inquiry question

What dictates whether Macho-1 acts as a transcriptional repressor or a transcriptional activator?

At one extreme, we call a cell that can give rise to any tissue in an organism **totipotent**. In mammals, the only cells that can give rise to both the embryo and the extraembryonic membranes are the zygote and early blastomeres from the first few cell divisions. Cells that can give rise to all of the cells in the organism's body are called **pluripotent**. A stem cell that can give rise to a limited number of cell types, such as the cells that give rise to the different blood cell types, are called **multipotent**. Then at the other extreme, **unipotent** stem cells give rise to only a single cell type, such as the cells that give rise to sperm cells in males.

## Embryonic stem cells are pluripotent cells derived from embryos

A form of pluripotent stem cells that has been derived in the laboratory are called embryonic stem cells (ES cells). These cells are made from mammalian embryos that have undergone the cleavage stage of development to produce a ball of cells called a blastocyst. The blastocyst consists of an outer ball of cells, the trophoblast, which will become the placenta, and the inner cell mass that will go on to form the embryo (see chapter 54 for details). Embryonic stem cells can be isolated from the inner cell mass and grown in culture (figure 19.8). In mice, these cells have been studied extensively and have been shown to be able to develop into any type of cell in the tissues of the adult. However, these cells cannot give rise to the extraembryonic tissues that arise during development, so they are pluripotent, but not totipotent.

Once these cells were found in mice, it was only a matter of time before human ES cells were derived as well. In 1998, the first human ES cells (hES cells) were isolated and grown in culture. While there are differences between human and mouse ES cells, there are also substantial similarities. These

embryonic stem cells hold great promise for regenerative medicine based on their potential to produce any cell type as described below. These cells have also been the source of much controversy and ethical discussion due to their embryonic origin.

### Differentiation in culture

In addition to their possible therapeutic uses, ES cells offer a way to study the differentiation process in culture. The manipulation of these cells by additions to the culture media will allow us to tease out the factors involved in differentiation at the level of the actual cell undergoing the process. Early attempts at assessing differentiation in culture was plagued by the culture conditions. The medium in early experiments contained fetal calf serum (common in tissue culture), which is ill-defined, and varies lot-to-lot. More recently, more defined culture conditions have been found that allow greater reproducibility in controlling differentiation in culture.

Using more defined media, ES cells have been used to recapitulate in culture the early events in mouse development. Thus mouse ES cells can be used to first give rise to ectoderm, endoderm, and mesoderm, then these three cell types will give rise to the different cells each germ layer is determined to become. This work is in early stages but is tremendously exciting as it offers the promise of understanding the molecular cues that are involved in the stepwise determination of different cell types.

In humans, ES cells have been used to give rise to a variety of cell types in culture. For example, human ES cells have been shown to give rise to different kinds of blood cells in culture. Work is underway to produce hematopoietic stem cells in culture, which could be used to replace such cells in patients with diseases that affect blood cells. Human ES cells have also been used to produce cardiomyocytes in culture. These cells could be used to replace damaged heart tissue after heart attacks.

**Figure 19.8 Isolation of embryonic stem cells.** *a.* Early cell divisions lead to the blastocyst stage that consists of an outer layer and an inner cell mass, which will go on to form the embryo. Embryonic stem cells (ES cells) can be isolated from this stage by disrupting the embryo and plating the cells. Stem cells removed from a six-day blastocyst can be established in culture and maintained indefinitely in an undifferentiated state. *b.* Human embryonic stem cells. This mass in the photograph is a colony of undifferentiated human embryonic stem cells being studied in the developmental biologist James Thomson's research lab at the University of Wisconsin–Madison.

### Learning Outcomes Review 19.3

Cell differentiation is preceded by determination, where the cell becomes committed to a developmental pathway, but has not yet differentiated. Differential inheritance of cytoplasmic factors can cause determination and differentiation, as can interactions between neighboring cells (induction). Inductive changes are mediated by signaling molecules that trigger transduction pathways. Stem cells are able to divide indefinitely, and they can give rise to differentiated cells. Embryonic stem cells are pluripotent cells that can give rise to all adult structures.

- How could you distinguish whether a cell becomes determined by induction or because of cytoplasmic factors?

## 19.4 Nuclear Reprogramming

### Learning Outcomes

1. Define nuclear reprogramming and describe ways in which it has been accomplished.
2. Differentiate between reproductive and therapeutic cloning.

The study of the process of determination and differentiation leads quite naturally to questions about whether this process can be reversed. This is of interest both in terms of the experimental possibilities to understand the basic process, and the prospect of creating patient-specific populations of specific cell types to replace cells lost to disease or trauma. This has led to a fascinating path with many twists and turns that has accelerated in the recent past. We will briefly consider the history of this topic, then look at the most recent results available.

### Reversal of determination has allowed cloning

Experiments carried out in the 1950s showed that single cells from fully differentiated tissue of an adult plant could develop

into entire, mature plants. The cells of an early cleavage stage mammalian embryo are also totipotent. When mammalian embryos naturally split in two, identical twins result. If individual blastomeres are separated from one another, any one of them can produce a completely normal individual. In fact, this type of procedure has been used to produce sets of four or eight identical offspring in the commercial breeding of particularly valuable lines of cattle.

### Early research in amphibians

An early question in developmental biology was whether the production of differentiated cells during development involved irreversible changes to cells. Experiments carried out in the 1950s by Briggs and King, and by John Gurdon in the 1960s and 1970s showed nuclei could be transplanted between cells. Using very fine pipettes (hollow glass tubes), these researchers sucked the nucleus out of a frog or toad egg and replaced the egg nucleus with a nucleus sucked out of a body cell taken from another individual.

The conclusions from these experiments are somewhat contradictory. On the one hand, cells do not appear to undergo any truly irreversible changes, such as loss of genes. On the other hand, the more differentiated the cell type, the less successful the nucleus in directing development when transplanted. This led to the concept of *nuclear reprogramming*, that is, a nucleus from a differentiated cell undergoes **epigenetic** changes that must be reversed to allow the nucleus to direct development. Epigenetic changes do not change a cell's DNA but are stable through cell divisions. The early work on amphibians showed that tadpoles' intestinal cell nuclei could be reprogrammed to produce viable adult frogs. These animals not only can be considered clones, but they show that tadpole nuclei can be completely reprogrammed. However, nuclei from adult differentiated cells could only be reprogrammed to produce tadpoles, but not viable, fertile adults. Thus this work showed that adult nuclei have remarkable developmental potential, but cannot be reprogrammed to be totipotent.

### Early research in mammals

Given the work done in amphibians, much effort was put into nuclear transfer in mammals, primarily mice and cattle. Not only did this not result in reproducible production of cloned

animals, but this work led to the discovery of imprinting through the production of embryos with only maternal or paternal input (see chapter 13 for more information on imprinting). These embryos never developed, and showed different kinds of defects depending on whether the maternal or paternal genome was the sole contributor.

### Successful nuclear transplant in mammals

These results stood until a sheep was cloned using the nucleus from a cell of an early embryo in 1984. The key to this success was in picking a donor cell very early in development. This exciting result was soon replicated by others in a host of other organisms, including pigs and monkeys. Only early embryo cells seemed to work, however.

Geneticists at the Roslin Institute in Scotland reasoned that the egg and donated nucleus would need to be at the same stage of the cell cycle for successful development. To test this idea, they performed the following procedure (figure 19.9):

1. They removed differentiated mammary cells from the udder of a six-year-old sheep. The cells were grown in tissue culture, and then the concentration of serum nutrients was substantially reduced for five days, causing them to pause at the beginning of the cell cycle.
2. In parallel preparation, eggs obtained from a ewe were enucleated.
3. Mammary cells and egg cells were surgically combined in a process called **somatic cell nuclear transfer (SCNT)** in January of 1996. Mammary cells and eggs were fused to introduce the mammary nucleus into egg.
4. Twenty-nine of 277 fused couplets developed into embryos, which were then placed into the reproductive tracts of surrogate mothers.
5. A little over five months later, on July 5, 1996, one sheep gave birth to a lamb named Dolly, the first clone generated from a fully differentiated animal cell.

Dolly matured into an adult ewe, and she was able to reproduce the old-fashioned way, producing six lambs. Thus, Dolly established beyond all dispute that determination in animals is reversible—that with the right techniques, the nucleus of a fully differentiated cell *can* be reprogrammed to be totipotent.

## Reproductive cloning has inherent problems

The term **reproductive cloning** refers to the process just described, in which scientists use SCNT to create an animal that is genetically identical to another animal. Since Dolly's birth in 1997, scientists have successfully cloned one or more cats, rabbits, rats, mice, cattle, goats, pigs, and mules. All of these procedures used some form of adult cell.

### Low success rate and age-associated diseases

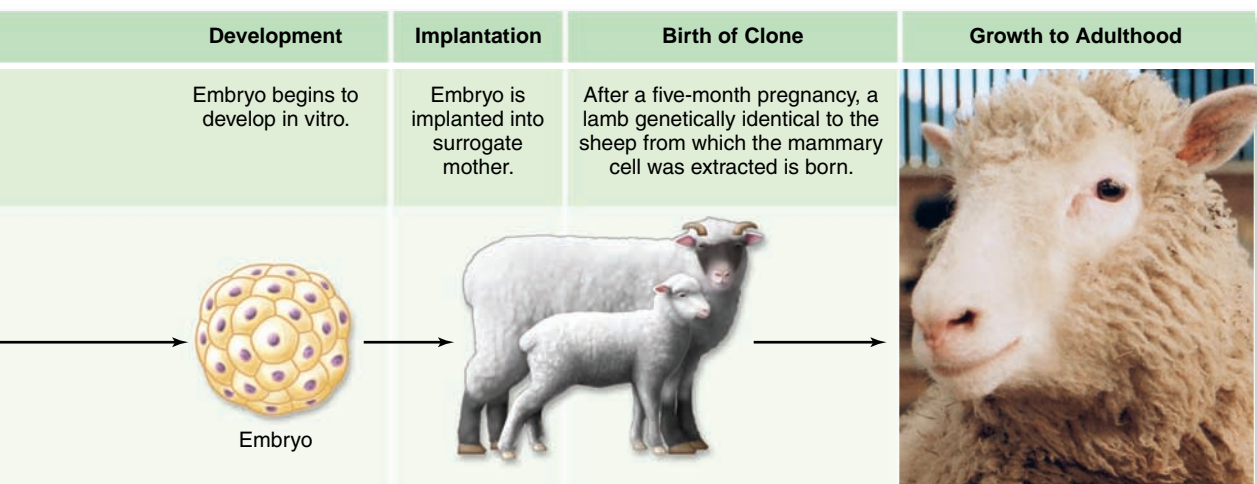

The efficiency in all reproductive cloning is quite low—only 3–5% of adult nuclei transferred to donor eggs result in live births. In addition, many clones that are born usually die soon thereafter of liver failure or infections. Many become oversized, a condition known as *large offspring syndrome (LOS)*. In 2003, three of four cloned piglets developed to adulthood, but all three suddenly died of heart failure at less than 6 months of age.

Dolly herself was euthanized at the relatively young age of six. Although she was put down because of virally induced lung cancer, she had been diagnosed with advanced-stage arthritis a year earlier. Thus, one difficulty in using genetic engineering and cloning to improve livestock is production of enough healthy animals.

### Lack of imprinting

The reason for these problems lies in a phenomenon discussed in chapter 13: *genomic imprinting*. Imprinted genes are expressed differently depending on parental origin—that is, they are turned off in either egg or sperm, and this “setting” continues through development into the adult. Normal mammalian development depends on precise genomic imprinting.

The chemical reprogramming of the DNA, which occurs in adult reproductive tissue, takes months for sperm and years for eggs. During cloning, by contrast, the reprogramming of the donor DNA must occur within a few hours. The organization of the chromatin in a somatic cell is also quite different from that in a newly fertilized egg. Significant chromatin remodeling of the transferred donor nucleus must also occur if the cloned embryo is to survive. Cloning fails because there is likely not enough time in these few hours to get the remodeling and reprogramming jobs done properly.

### Figure 19.9 Proof that determination in animals is reversible.

Scientists combined a nucleus from an adult mammary cell with an enucleated egg cell to successfully clone a sheep, named Dolly, who grew to be a normal adult and bore healthy offspring. This experiment, the first successful cloning of an adult animal, shows that a differentiated adult cell can be used to drive all of development.

**Figure 19.10 Methods to reprogram adult cell nuclei.**

Cells taken from adult organisms can be reprogrammed to pluripotent cells in a number of different ways. Nuclei from somatic cells can be transplanted into oocytes as during cloning. Somatic cells can be fused to ES cells created by some other means. Germ cells, and some adult stem cells, after prolonged culture appear to be reprogrammed. Recent work has shown that somatic cells in culture can be reprogrammed by introduction of specific factors.

### Nuclear reprogramming has been accomplished by use of defined factors

Stimulated by the discovery of ES cells and success in the reproductive cloning of mammals, much work has been put into trying to find ways to reprogram adult cells to become pluripotent cells without the use of embryos (figure 19.10). One approach was to fuse an ES cell to a differentiated cell.

These fusion experiments showed that the nucleus of the differentiated cell could be reprogrammed by exposure to ES cell cytoplasm. Of course, the resulting cells are tetraploid (4 copies of the genome), which limits their experimental and practical utility. Another line of research showed that primordial germ cells explanted into culture can give rise to cells that act similar to ES cells after extended time in culture. There are also reports that some adult stem cells become pluripotent cells with prolonged culture, but this is still controversial.

All of these different lines of inquiry showed that reprogramming of somatic nuclei was possible. The next obvious step was to reprogram nuclei using defined factors. While it was assumed that this was possible, it was not accomplished until 2006 when the genes for four different transcription factors, Oct4, Sox2, c-Myc, and Klf4 were introduced into fibroblast cells in culture. These cells were then selected for expression of a gene that is a target for Oct4 and Sox2, and these cells appear to be pluripotent. These were named induced pluripotent stem cells, or iPS cells. This protocol has been improved by selection for a different target gene, Nanog. These Nanog expressing iPS cells appear to be similar to ES cells in terms of developmental potential, as well as gene expression pattern.

This technology has now been used to construct ES cells from patients with the inherited neurological disorder spinal muscular atrophy. These ES cells will differentiate in culture into motor neurons that show the phenotype expected for the disease. The ability to derive disease specific stem cells will be an incredible advance for researchers studying such diseases. This will allow the creation of in vitro systems to study directly the cells affected by genetic diseases, and to screen for possible therapeutics.

Pluripotent cell types have potential for therapeutic applications. One way to solve the problem of graft rejection, such as in skin grafts in severe burn cases, is to produce patient-specific lines of embryonic stem cells. Early in 2001, a research team at Rockefeller University devised a way to accomplish this feat.

First, skin cells are isolated; then, using the same SCNT procedure that created Dolly, an embryo is assembled. After removing the nucleus from the skin cell, they insert it into an egg whose nucleus has already been removed. The egg with

3. Explain the importance of homeobox-containing genes in development.

its skin cell nucleus is allowed to form a blastocyst stage embryo. This artificial embryo is then destroyed, and its cells are used as embryonic stem cells for transfer to injured tissue (figure 19.11).

Using this procedure, termed **therapeutic cloning**, the researchers succeeded in converting cells from the tail of a mouse into the dopamine-producing cells of the brain that are lost in Parkinson disease. Therapeutic cloning successfully addresses the key problem that must be solved before stem cells can be used to repair human tissues damaged by heart attack, nerve injury, diabetes, or Parkinson disease—the problem of immune acceptance. Since stem cells are cloned from a person's own tissues in therapeutic cloning, they pass the immune system's "self" identity check, and the body readily accepts them.

These early attempts at therapeutic cloning may become obsolete before they are even refined with the work described above on iPS cells. The potential to produce pluripotent cells from adult skin cells removes the ethical problems of embryo destruction, and the practical problem of the requirement for oocytes for therapeutic cloning. However, these cell types are not without problems of their own. Two of the genes introduced to reprogram the nuclei of cells are oncogenes, and although these experiments have been reproduced without c-Myc, the efficiency is greatly reduced. These also require the introduction of new DNA, which can induce mutations by integration into the genome.

### Learning Outcomes Review 19.4

Cloning has long been practiced in plants. In animals, cells from early-stage embryos are also totipotent, but attempts to use adult nuclei for cloning led to mixed results. The nucleus of a differentiated cell requires reprogramming to be totipotent. This appears to be necessary at least in part because of genomic imprinting. Nuclei may be reprogrammed by fusion with an embryonic stem cell, which produces a tetraploid cell, or through the introduction of four important transcription factors. That reprogramming is possible was shown by reproductive cloning via somatic cell nuclear transfer (SCNT). In therapeutic cloning, the goal is to produce replacement tissue using a patient's own cells.

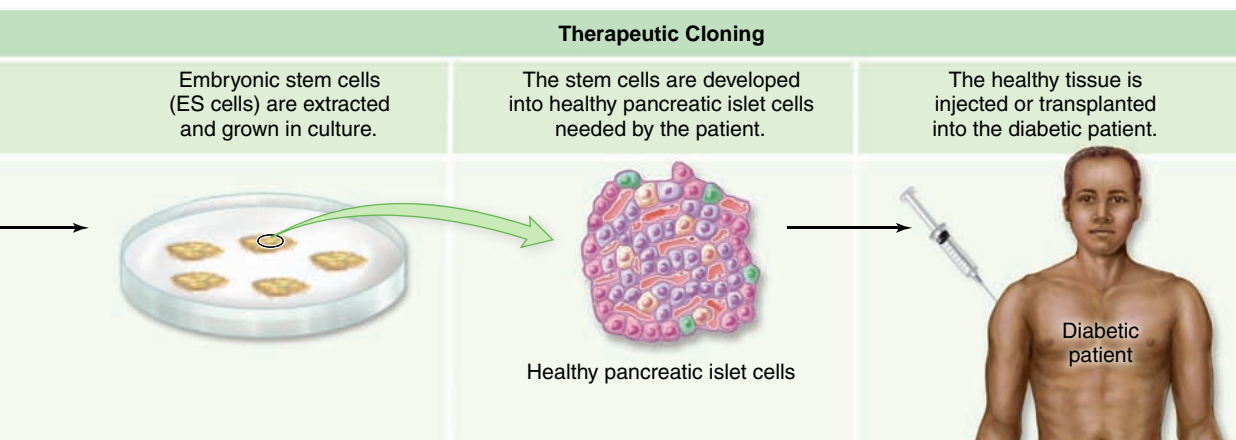

- What changes must occur to produce a totipotent cell from a differentiated nucleus?

For cells in multicellular organisms to differentiate into appropriate cell types, they must gain information about their relative locations in the body. All multicellular organisms seem to use positional information to determine the basic pattern of body compartments and, thus, the overall architecture of the adult body. This positional information then leads to intrinsic changes in gene activity, so that cells ultimately adopt a fate appropriate for their location.

Pattern formation is an unfolding process. In the later stages, it may involve morphogenesis of organs (to be discussed later), but during the earliest events of development, the basic body plan is laid down, along with the establishment of the anterior–posterior (A/P, head-to-tail) axis and the dorsal–ventral (D/V, back-to-front) axis. Thus, pattern formation can be considered the process of taking a radially symmetrical cell and imposing two perpendicular axes to define the basic body plan, which in this way becomes bilaterally symmetrical. Developmental biologists use the term **polarity** to refer to the acquisition of axial differences in developing structures.

The fruit fly *Drosophila melanogaster* is the best understood animal in terms of the genetic control of early patterning. We will concentrate on the *Drosophila* system here, and later in chapter 54 we will examine axis formation in vertebrates in the context of their overall development.

A hierarchy of gene expression that begins with maternally expressed genes controls the development of *Drosophila*. To understand the details of these gene interactions, we first need to briefly review the stages of *Drosophila* development.

**Figure 19.11** How human embryos might be used for therapeutic cloning. In therapeutic cloning, after initial stages to reproductive cloning, the embryo is broken apart and its embryonic stem cells are extracted. These are grown in culture and used to replace the diseased tissue of the individual who provided the DNA. This is useful only if the disease in question is not genetic as the stem cells are genetically identical to the patient.

## *Drosophila* embryogenesis produces a segmented larva

*Drosophila* and many other insects produce two different kinds of bodies during their development: the first, a tubular eating machine called a **larva**, and the second, an adult flying sex machine with legs and wings. The passage from one body form to the other, called **metamorphosis**, involves a radical shift in development (figure 19.12). In this chapter, we concentrate on the process of going from a fertilized egg to a larva, which is termed *embryogenesis*.

### Prefertilization maternal contribution

The development of an insect like *Drosophila* begins before fertilization, with the construction of the egg. Specialized *nurse cells* that help the egg grow move some of their own maternally encoded mRNAs into the maturing oocyte (figure 19.12a).

Following fertilization, the maternal mRNAs are transcribed into proteins, which initiate a cascade of sequential gene activations. Embryonic nuclei do not begin to function (that is, to direct new transcription of genes) until approximately 10 nuclear divisions have occurred. Therefore, the action of maternal, rather than zygotic, genes determines the initial course of *Drosophila* development.

### Postfertilization events

After fertilization, 12 rounds of nuclear division without cytokinesis produce about 4000 nuclei, all within a single cytoplasm. All of the nuclei within this **syncytial blastoderm** (figure 19.12b) can freely communicate with one another, but nuclei located in different sectors of the egg encounter different maternal products.

Once the nuclei have spaced themselves evenly along the surface of the blastoderm, membranes grow between them to form the **cellular blastoderm**. Embryonic folding and primary tissue development soon follow, in a process fundamentally similar to that seen in vertebrate development. Within a day of fertilization, embryogenesis creates a segmented, tubular body—which is destined to hatch out of the protective coats of the egg as a larva.

## Morphogen gradients form the basic body axes in *Drosophila*

Pattern formation in the early *Drosophila* embryo requires positional information encoded in labels that can be read by cells. The unraveling of this puzzle, work that earned the 1995 Nobel Prize for researchers Christiane Nüsslein-Volhard and Eric Wieschaus, is summarized in figure 19.13. We now know that two different genetic pathways control the establishment of A/P and D/V polarity in *Drosophila*.

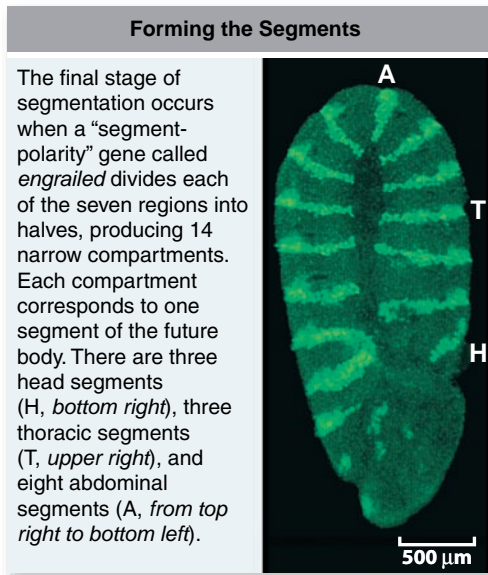

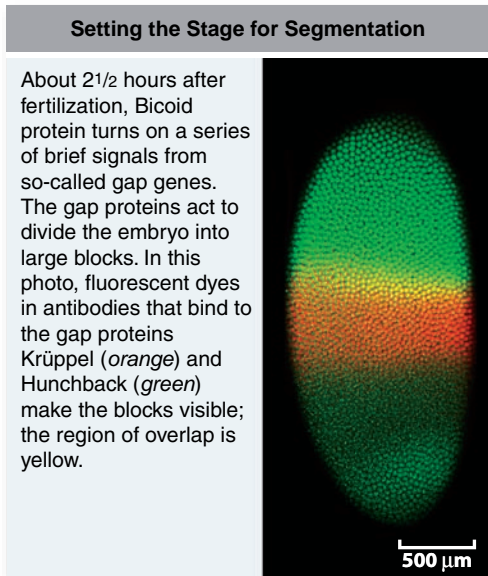

### Anterior–posterior axis

Formation of the A/P axis begins during maturation of the oocyte and is based on opposing gradients of two different proteins: **Bicoid** and **Nanos**. These protein gradients are established by an interesting mechanism.

Nurse cells in the ovary secrete maternally produced *bicoid* and *nanos* mRNAs into the maturing oocyte where they are differentially transported along microtubules to opposite poles of the oocyte (figure 19.14a). This differential transport comes

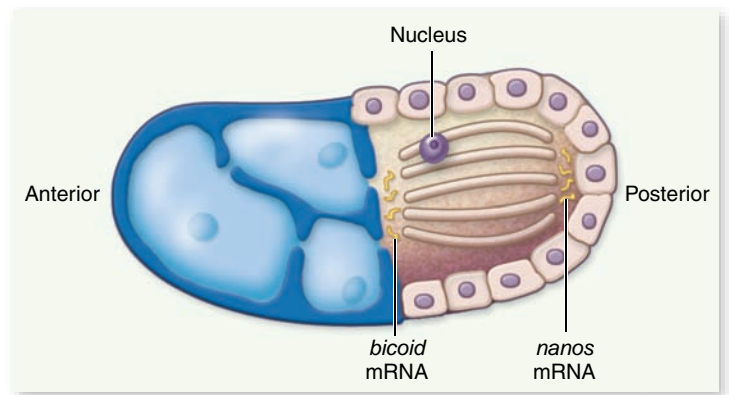

**Figure 19.12** The path of fruit fly development. Major stages in the development of *Drosophila melanogaster* include formation of the (a) egg, (b) syncytial and cellular blastoderm, (c) larval instars, (d) pupa and metamorphosis into a (e) sexually mature adult.

**Figure 19.13 Body organization in an early *Drosophila* embryo.** In these fluorescent microscope images by 1995 Nobel laureate Christiane Nüsslein-Volhard and Sean Carroll, we watch a *Drosophila* egg pass through the early stages of development, in which the basic segmentation pattern of the embryo is established. The proteins in the photographs were made visible by binding fluorescent antibodies to each specific protein.

*a.*

*b.*

**Figure 19.14 Specifying the A/P axis in *Drosophila* embryos I.** *a.* In the ovary, nurse cells secrete maternal mRNAs into the cytoplasm of the oocyte. Clusters of microtubules direct oocyte growth and maturation. Motor proteins travel along the microtubules transporting molecules in two directions. *Bicoid* mRNAs are transported toward the anterior pole of the oocyte, *nanos* mRNA is transported toward the posterior pole of the oocyte. *b.* A mature oocyte, showing localization of *bicoid* mRNAs to the anterior pole and *nanos* mRNAs to the posterior pole.

about due to the use of different motor proteins to move the two mRNAs. The *bicoid* mRNA then becomes anchored in the cytoplasm at the end of the oocyte closest to the nurse cells, and this end will develop into the anterior end of the embryo. *Nanos* mRNA becomes anchored to the opposite end of the oocyte, which will become the posterior end of the embryo. Thus, by the end of oogenesis, the *bicoid* and *nanos* mRNAs are already set to function as cytoplasmic determinants in the fertilized egg (figure 19.14b).

Following fertilization, translation of the anchored mRNA and diffusion of the proteins away from their respective sites of synthesis create opposing gradients of each protein: Highest levels of Bicoid protein are at the anterior pole of the embryo (figure 19.15a), and highest levels of the Nanos protein are at the posterior pole. Concentration gradients of soluble molecules can specify different cell fates along an axis, and proteins that act in this way, like Bicoid and Nanos, are called **morphogens**.

The Bicoid and Nanos proteins control the translation of two other maternal messages, *hunchback* and *caudal*, that encode transcription factors. **Hunchback** activates genes required for the formation of anterior structures, and **Caudal** activates genes required for the development of posterior (abdominal) structures. The *hunchback* and *caudal* mRNAs are evenly distributed across the egg (figure 19.15b), so how is it that proteins translated from these mRNAs become localized?

The answer is that Bicoid protein binds to and inhibits translation of *caudal* mRNA. Therefore, *caudal* is only translated in the posterior regions of the egg where Bicoid is absent. Similarly, Nanos protein binds to and prevents translation of the *hunchback* mRNA. As a result, *hunchback* is only translated in the anterior regions of the egg (figure 19.15c). Thus, shortly after fertilization, four protein gradients exist in the embryo: anterior–posterior gradients of Bicoid and Hunchback proteins, and posterior–anterior gradients of Nanos and Caudal proteins (figure 19.15c).

### Dorsal–ventral axis

The dorsal–ventral axis in *Drosophila* is established by actions of the *dorsal* gene product. Once again the process begins in the ovary, when maternal transcripts of the *dorsal* gene are put into the oocyte. However, unlike *bicoid* or *nanos*, the *dorsal* mRNA does not become asymmetrically localized. Instead, a series of steps are required for Dorsal to carry out its function.

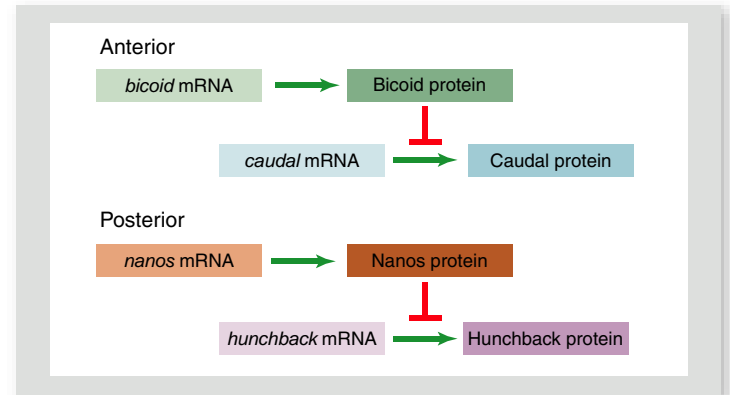

First, the oocyte nucleus, which is located to one side of the oocyte, synthesizes *gurken* mRNA. The *gurken* mRNA then accumulates in a crescent between the nucleus and the membrane on that side of the oocyte (figure 19.16a). This will be the future dorsal side of the embryo.

The Gurken protein is a soluble cell-signaling molecule, and when it is translated and released from the oocyte, it binds to receptors in the membranes of the overlying follicle cells (figure 19.16b). These cells then differentiate into a dorsal morphology. Meanwhile, no Gurken signal is released from the other side of the oocyte, and the follicle cells on that side of the oocyte adopt a ventral fate.

Following fertilization, a signaling molecule is differentially activated on the ventral surface of the embryo in a complex sequence of steps. This signaling molecule then binds to a membrane receptor in the ventral cells of the embryo and acti-

c. Early cleavage embryo proteins

### Figure 19.15 Specifying the A/P axis in *Drosophila* embryos II.

**a.** Unlike *bicoid* and *nanos*, *hunchback* and *caudal* mRNAs are evenly distributed throughout the cytoplasm of the oocyte. **b.** Following fertilization, *bicoid* and *nanos* mRNAs are translated into protein, making opposing gradients of each protein. Bicoid binds to and represses translation of *caudal* mRNAs (in anterior regions of the egg). Nanos binds to and represses translation of *hunchback* mRNAs (in posterior regions of the egg). **c.** Translation of *hunchback* mRNAs in anterior regions of the egg will create a Hunchback gradient that mirrors the Bicoid gradient. Translation of *caudal* mRNAs in posterior regions of the embryo will create a Caudal gradient that mirrors the Nanos gradient.

vates a signal transduction pathway in those cells. Activation of this pathway results in the selected transport of the Dorsal protein (which is everywhere) into ventral nuclei, forming a gradient along the D/V axis. The Dorsal protein levels are highest in the nuclei of ventral cells (figure 19.16c).

**Figure 19.16 Specifying the D/V axis in *Drosophila* embryos.** *a.* The *gurken* mRNA (dark stain) is concentrated between the oocyte nucleus (not visible) and the dorsal, anterior surface of the oocyte. *b.* In a more mature oocyte, Gurken protein (yellow stain) is secreted from the dorsal anterior surface of the oocyte, forming a gradient along the dorsal surface of the egg. Gurken then binds to membrane receptors in the overlying follicle cells. Double staining for actin (red) shows the cell boundaries of the oocyte, nurse cells, and follicle cells. *c.* For these images, cellular blastoderm stage embryos were cut in cross section to visualize the nuclei of cells around the perimeter of the embryos. Dorsal protein (dark stain) is localized in nuclei on the ventral surface of the blastoderm in a wild-type embryo (left). The *dorsal* mutant on the right will not form ventral structures, and Dorsal is not present in ventral nuclei of this embryo.

The Dorsal protein is a transcription factor, and once it is transported into nuclei, it activates genes required for the proper development of ventral structures, simultaneously repressing genes that specify dorsal structures. Hence, the prod-

uct of the *dorsal* gene ultimately directs the development of ventral structures.

(Note that many *Drosophila* genes are named for the mutant phenotype that results from a loss of function in that gene. A lack of *dorsal* function produces dorsalized embryos with no ventral structures.)

Although profoundly different mechanisms are involved, the unifying factor controlling the establishment of both A/P and D/V polarity in *Drosophila* is that *bicoid*, *nanos*, *gurken*, and *dorsal* are all maternally expressed genes. The polarity of the future embryo in both instances is therefore laid down in the oocyte using information coming from the maternal genome.

The preceding discussion simplifies events, but the outline is clear: Polarity is established by the creation of morphogen gradients in the embryo based on maternal information in the egg. These gradients then drive the expression of the zygotic genes that will actually pattern the embryo. This reliance on a hierarchy of regulatory genes is a unifying theme for all of development.

## The body plan is produced by sequential activation of genes

Let us now return to the process of pattern formation in *Drosophila* along the A/P axis. Determination of structures is accomplished by the sequential activation of three classes of **segmentation genes**. These genes create the hallmark segmented body plan of a fly, which consists of three fused head segments, three thoracic segments, and eight abdominal segments (see figure 19.12*e*).

To begin, Bicoid protein exerts its profound effect on the organization of the embryo by activating the translation and transcription of *hunchback* mRNA (which is the first mRNA to be transcribed after fertilization). *Hunchback* is a member of a group of nine genes called the **gap genes**. These genes map out the initial subdivision of the embryo along the A/P axis (see figure 19.13).

All of the gap genes encode transcription factors, which, in turn, activate the expression of eight or more **pair-rule genes**. Each of the pair-rule genes, such as *hairy*, produces seven distinct bands of protein, which appear as stripes when visualized with fluorescent reagents (see figure 19.13). These bands subdivide the broad gap regions and establish boundaries that divide the embryo into seven zones. When mutated, each of the pair-rule genes alters every other body segment.

All of the pair-rule genes also encode transcription factors, and they, in turn, regulate the expression of each other and of a group of nine or more **segment polarity genes**. The segment polarity genes are each expressed in 14 distinct bands of cells, which subdivide each of the seven zones specified by the pair-rule genes (see figure 19.13). The *engrailed* gene, for example, divides each of the seven zones established by *hairy* into anterior and posterior compartments. The segment polarity genes encode proteins that function in cell–cell signaling pathways. Thus, they function in inductive events—which occur *after* the syncytial blastoderm is divided into cells—to fix the anterior and posterior fates of cells within each segment.

In summary, within 3 hr after fertilization, a highly orchestrated cascade of segmentation gene activity transforms the broad gradients of the early embryo into a periodic, segmented

**Figure 19.17 Mutations in homeotic genes.** Three separate mutations in the bithorax complex caused this fruit fly to develop an additional second thoracic segment, with accompanying wings.

racic segments, but only the second thoracic segment has wings. Mutations in the *Ultrabithorax* gene cause a fly to grow an extra pair of wings, as though it has two second thoracic segments (figure 19.17). Even more bizarre are mutations in *Antennapedia*, which cause legs to grow out of the head in place of antennae!

structure with A/P and D/V polarity. The activation of the segmentation genes depends on the free diffusion of maternally encoded morphogens, which is only possible within the syncytial blastoderm of the early *Drosophila* embryo.

Thus, mutations in these genes lead to the appearance of perfectly normal body parts in inappropriate places. Such mutants are termed *homeotic mutants* because the transformed body

part looks similar (homeotic) to another. The genes in which such mutants occur are therefore called **homeotic genes**.

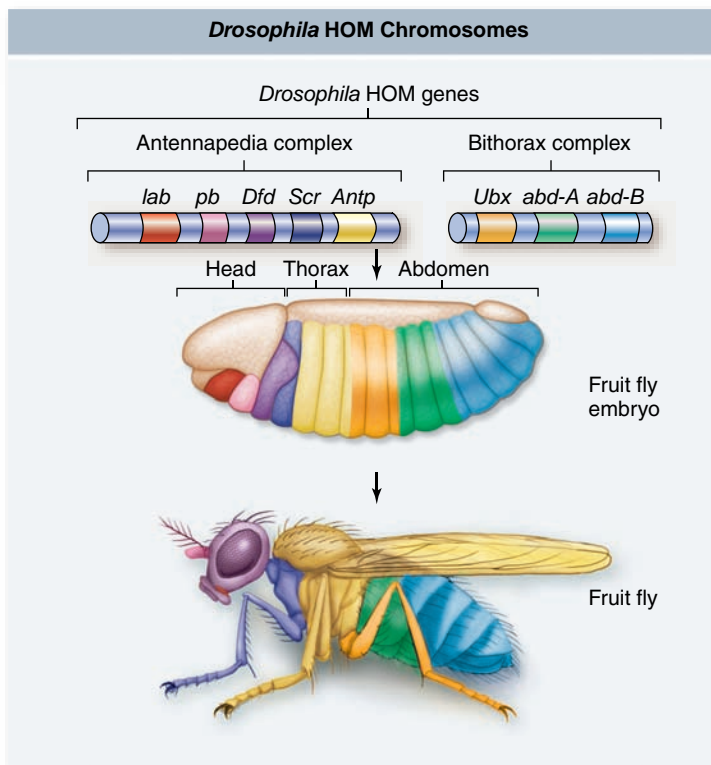

### Segment identity arises from the action of homeotic genes

With the basic body plan laid down, the next step is to give identity to the segments of the embryo. A highly interesting class of *Drosophila* mutants has provided the starting point for understanding the creation of segment identity.

In these mutants, a particular segment seems to have changed its identity—that is, it has characteristics of a different segment. In wild-type flies, a pair of legs emerges from each of the three tho-

### Homeotic gene complexes

In the early 1950s, geneticist and Nobel laureate Edward Lewis discovered that several homeotic genes, including *Ultrabithorax*, map together on the third chromosome of *Drosophila* in a tight cluster called the **bithorax complex**. Mutations in these genes all affect body parts of the thoracic and abdominal segments, and Lewis concluded that the genes of the bithorax complex control the development of body parts in the rear half of the thorax and all of the abdomen.

a.

b.

**Figure 19.18 A comparison of homeotic gene clusters in the fruit fly *Drosophila melanogaster* and the mouse *Mus musculus*.**

a. *Drosophila* homeotic genes. Called the homeotic gene complex, or HOM complex, the genes are grouped into two clusters: the Antennapedia complex (anterior) and the bithorax complex (posterior). b. The *Drosophila* HOM genes and the mouse *Hox* genes are related genes that control the regional differentiation of body parts in both animals. These genes are located on a single chromosome in the fly and on four separate chromosomes in mammals. In this illustration, the genes are color-coded to match the parts of the body along the A/P axis in which they are expressed. Note that the order of the genes along the chromosome(s) is mirrored by their pattern of expression in the embryo and in structures in the adult fly.

Interestingly, the order of the genes in the bithorax complex mirrors the order of the body parts they control, as though the genes are activated serially. Genes at the beginning of the cluster switch on development of the thorax; those in the middle control the anterior part of the abdomen; and those at the end affect the posterior tip of the abdomen.

A second cluster of homeotic genes, the **Antennapedia complex**, was discovered in 1980 by Thomas Kaufmann. The Antennapedia complex governs the anterior end of the fly, and the order of genes in this complex also corresponds to the order of segments they control (figure 19.18a).

### The homeobox

An interesting relationship was discovered after the genes of the bithorax and Antennapedia complexes were cloned and sequenced. These genes all contain a conserved sequence of 180 nucleotides that codes for a 60-amino-acid, DNA-binding domain. Because this domain was found in all of the homeotic genes, it was named the *homeodomain*, and the DNA that encodes it is called the homeobox. Thus, the term **Hox gene** now refers to a homeobox-containing gene that specifies the identity of a body part. These genes function as transcription factors that bind DNA using their homeobox domain.

Clearly, the homeobox distinguishes portions of the genome that are devoted to pattern formation. How the *Hox* genes do this is the subject of much current research. Scientists believe that the ultimate targets of *Hox* gene function must be genes that control cell behaviors associated with organ morphogenesis.

### Evolution of homeobox-containing genes

A large amount of research has been devoted to analyzing the clustered complexes of *Hox* genes in other organisms. These investigations have led to a fairly coherent view of homeotic gene evolution.

It is now clear that the *Drosophila* bithorax and Antennapedia complexes represent two parts of a single cluster of genes. In vertebrates, there are four copies of *Hox* gene clusters. As in *Drosophila*, the spatial domains of *Hox* gene expression correlate with the order of the genes on the chromosome (figure 19.18b). The existence of four *Hox* clusters in vertebrates is viewed by many as evidence that two duplication events of the entire genome have occurred in the vertebrate lineage.

This idea raises the issue of when the original cluster arose. To answer this question, researchers have turned to more primitive organisms, such as *Amphioxus* (now called *Branchiostoma*), a lancelet chordate (see chapter 35). The finding of only one cluster of *Hox* genes in *Amphioxus* implies that indeed there have been two duplications in the vertebrate lineage, at least of the *Hox* cluster. Given the single cluster in arthropods, this finding implies that the common ancestor to all animals with bilateral symmetry had a single *Hox* cluster as well.

The next logical step is to look at even more-primitive animals: the radially symmetrical cnidarians such as *Hydra* (see chapter 33). Thus far, *Hox* genes have been found in a number of cnidarian species, and recent sequence analyses suggest that cnidarian *Hox* genes are also arranged into clusters. Thus, the appearance of the ancestral *Hox* cluster likely preceded the divergence between radial and bilateral symmetries in animal evolution.

## Pattern formation in plants is also under genetic control

The evolutionary split between plant and animal cell lineages occurred about 1.6 BYA, before the appearance of multicellular organisms with defined body plans. The implication is that multicellularity evolved independently in plants and animals. Because of the activity of meristems, additional modules can be added to plant bodies throughout their lifetimes. In addition, plant flowers and roots have a radial organization, in contrast to the bilateral symmetry of most animals. We may therefore expect that the genetic control of pattern formation in plants is fundamentally different from that of animals.

Although plants have homeobox-containing genes, they do not possess complexes of *Hox* genes similar to the ones that determine regional identity of developing structures in animals. Instead, the predominant homeotic gene family in plants appears to be the **MADS-box** genes.

**MADS-box** genes are a family of transcriptional regulators found in most eukaryotic organisms, including plants, animals, and fungi. The MADS-box is a conserved DNA-binding and dimerization domain, named after the first five genes to be discovered with this domain. Only a small number of **MADS-box** genes are found in animals, where their functions include the control of cell proliferation and tissue-specific gene expression in postmitotic muscle cells. They do not appear to play a role in the patterning of animal embryos.

In contrast, the number and functional diversity of **MADS-box** genes increased considerably during the evolution of land plants, and there are more than 100 **MADS-box** genes in the *Arabidopsis* genome. In flowering plants, the **MADS-box** genes dominate the control of development, regulating such processes as the transition from vegetative to reproductive growth, root development, and floral organ identity.

Although distinct from genes in the *Hox* clusters of animals, homeodomain-containing transcription factors in plants do have important developmental functions. One such example is the family of *knottedlike homeobox (knox)* genes, which are important regulators of shoot apical meristem development in both seed-bearing and nonseed-bearing plants. Mutations that affect expression of *knox* genes produce changes in leaf and petal shape, suggesting that these genes play an important role in generating leaf form.

### Learning Outcomes Review 19.5

Pattern formation in animals involves the coordinated expression of a hierarchy of genes. Gradients of morphogens in *Drosophila* specify A/P and D/V axes, then lead to sequential activation of segmentation genes. Bicoid and Nanos protein gradients determine the A/P axis. The protein Dorsal determines the D/V axis, but activation requires a series of steps beginning with the oocyte's Gurken protein. The action of homeotic genes provide segment identity. These genes, which include a DNA-binding homeodomain sequence, are called *Hox* genes (for *homeobox* genes), and they are organized into clusters. Plants use a different set of developmental control genes called **MADS-box** genes.

- Why would you expect homeotic genes to be conserved across species evolution?

## 19.6 Morphogenesis

### Learning Outcomes

1. Discuss the importance of cell shape changes and cell migration in development.
2. Explain how cell death can contribute to morphogenesis.
3. Describe the role of the extracellular matrix in cell migration.

At the end of cleavage, the *Drosophila* embryo still has a relatively simple structure: It comprises several thousand identical-looking cells, which are present in a single layer surrounding a central yolky region. The next step in embryonic development is **morphogenesis**—the generation of ordered form and structure.

Morphogenesis is the product of changes in cell structure and cell behavior. Animals regulate the following processes to achieve morphogenesis:

- The number, timing, and orientation of cell divisions;
- Cell growth and expansion;
- Changes in cell shape;
- Cell migration; and
- Cell death.

Plant and animal cells are fundamentally different in that animal cells have flexible surfaces and can move, but plant cells are immotile and encased within stiff cellulose walls. Each cell in a plant is fixed into position when it is created. Thus, animal cells use cell migration extensively during development while plants use the other four mechanisms but lack cell migration. We consider the morphogenetic changes in animals first, and then those that occur in plants.

### Cell division during development may result in unequal cytokinesis

The orientation of the mitotic spindle determines the plane of cell division in eukaryotic cells. The coordinated function of microtubules and their motor proteins determines the respective position of the mitotic spindle within a cell (see chapter 10). If the spindle is centrally located in the dividing cell, two equal-sized daughter cells will result. If the spindle is off to one side, one large daughter cell and one small daughter cell will result.

The great diversity of cleavage patterns in animal embryos is determined by differences in spindle placement. In many cases, the fate of a cell is determined by its relative placement in the embryo during cleavage. For example, in preimplantation mammalian embryos, cells on the outside of the embryo usually differentiate into trophectoderm cells, which form only extra-embryonic structures later in development (for example, a part of the placenta). In contrast, the embryo proper is derived from the inner cell mass, cells which, as the name implies, are in the interior of the embryo.

### Cells change shape and size as morphogenesis proceeds

In animals, cell differentiation is often accompanied by profound changes in cell size and shape. For example, the large nerve cells that connect your spinal cord to the muscles in your big toe develop long processes called *axons* that span this entire distance. The cytoplasm of an axon contains microtubules, which are used for motor-driven transport of materials along the length of the axon.

As another example, muscle cells begin as *myoblasts*, undifferentiated muscle precursor cells. They eventually undergo conversion into the large, multinucleated *muscle fibers* that make up mammalian skeletal muscles. These changes begin with the expression of the *MyoD1* gene, which encodes a transcription factor that binds to the promoters of muscle-determining genes to initiate these changes.

### Programmed cell death is a necessary part of development

Not every cell produced during development is destined to survive. For example, human embryos have webbed fingers and toes at an early stage of development. The cells that make up the webbing die in the normal course of morphogenesis. As another example, vertebrate embryos produce a very large number of neurons, ensuring that enough neurons are available to make the necessary synaptic connections, but over half of these neurons never make connections and die in an orderly way as the nervous system develops.

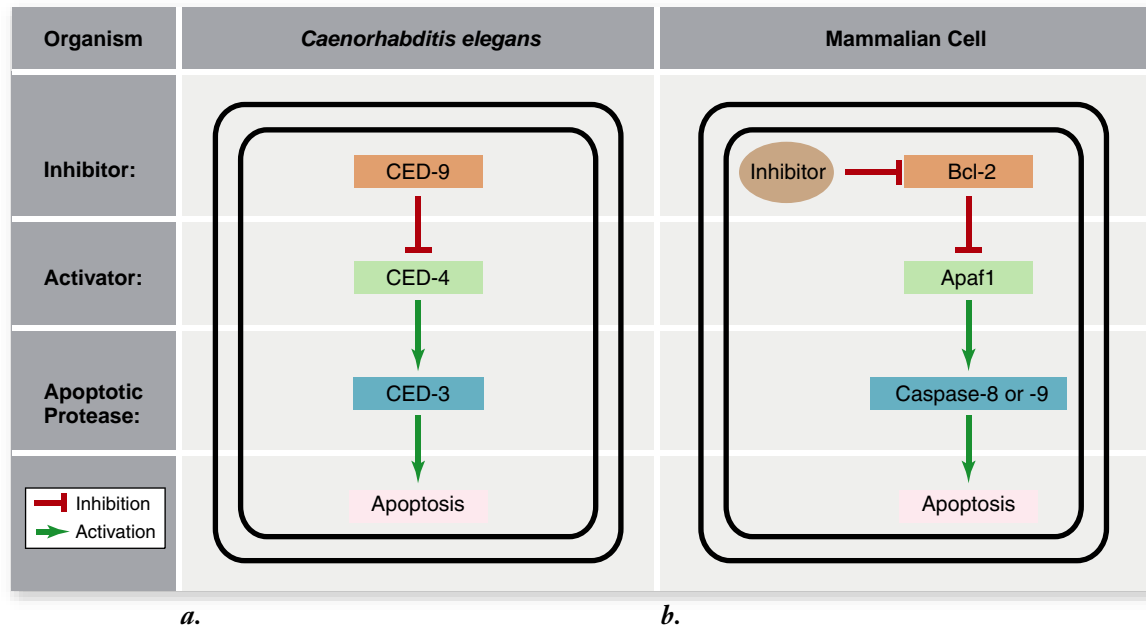

Unlike accidental cell deaths due to injury, these cell deaths are planned—and indeed required—for proper development and morphogenesis. Cells that die due to injury typically swell and burst, releasing their contents into the extracellular fluid. This form of cell death is called necrosis. In contrast, cells programmed to die shrivel and shrink in a process called apoptosis, which means “falling away,” and their remains are taken up by surrounding cells.

### Genetic control of apoptosis

Apoptosis occurs when a “death program” is activated. All animal cells appear to possess such programs. In *C. elegans*, the same 131 cells always die during development in a predictable and reproducible pattern.

Work on *C. elegans* showed that three genes are central to this process. Two (*ced-3* and *ced-4*) activate the death program itself; if either is mutant, those 131 cells do not die, and go on instead to form nervous tissue and other tissue. The third gene (*ced-9*) represses the death program encoded by the other two: All 1090 cells of the *C. elegans* embryo die in *ced-9* mutants. In *ced-9/ced-3* double mutants, all 1090 cells live, which suggests that *ced-9* inhibits cell death by functioning prior to *ced-3* in the apoptotic pathway (figure 19.19a).

The mechanism of apoptosis appears to have been highly conserved during the course of animal evolution. In human nerve cells, the *Apaf1* gene is similar to *ced-4* of *C. elegans* and activates the cell death program, and the human *bcl-2* gene acts

**Figure 19.19 Programmed cell death pathway.** Apoptosis, or programmed cell death, is necessary for the normal development of all animals. *a.* In the developing nematode, for example, two genes, *ced-3* and *ced-4*, code for proteins that cause the programmed cell death of 131 specific cells. In the other (surviving) cells of the developing nematode, the product of a third gene, *ced-9*, represses the death program encoded by *ced-3* and *ced-4*. *b.* The mammalian homologues of the apoptotic genes in *C. elegans* are *bcl-2* (*ced-9* homologue), *Apaf1* (*ced-4* homologue), and *caspase-8* or *-9* (*ced-3* homologues). In the absence of any cell survival factor, Bcl-2 is inhibited and apoptosis occurs. In the presence of nerve growth factor (NGF) and NGF receptor binding, Bcl-2 is activated, thereby inhibiting apoptosis.

similarly to *ced-9* to repress apoptosis. If a copy of the human *bcl-2* gene is transferred into a nematode with a defective *ced-9* gene, *bcl-2* suppresses the cell death program of *ced-3* and *ced-4*.

### The mechanism of apoptosis

The product of the *C. elegans ced-4* gene is a protease that activates the product of the *ced-3* gene, which is also a protease. The human *Apaf1* gene is actually named for its role: *Apoptotic protease activating factor*. It activates two proteases called caspases that have a role similar to the Ced-3 protease in *C. elegans* (figure 19.19*b*). When the final proteases are activated, they chew up proteins in important cellular structures such as the cytoskeleton and the nuclear lamina, leading to cell fragmentation.

The role of Ced-9/Bcl-2 is to inhibit this program. Specifically, it inhibits the activating protease, preventing the activation of the destructive proteases. The entire process is thus controlled by an inhibitor of the death program.

Both internal and external signals control the state of the Ced-9/Bcl-2 inhibitor. For example, in the human nervous system, neurons have a cytoplasmic inhibitor of Bcl-2 that allows the death program to proceed (see figure 19.19*b*). In the presence of nerve growth factor, a signal transduction pathway leads to the cytoplasmic inhibitor being inactivated, allowing Bcl-2 to inhibit apoptosis and the nerve cell to survive.

### Cell migration gets the right cells to the right places

The migration of cells is important during many stages of animal development. The movement of cells involves both adhe-

sion and the loss of adhesion. Adhesion is necessary for cells to get “traction,” but cells that are initially attached to others must lose this adhesion to be able to leave a site.

Cell movement also involves cell-to-substrate interactions, and the extracellular matrix may control the extent or route of cell migration. The central paradigm of morphogenetic cell movements in animals is a change in cell adhesiveness, which is mediated by changes in the composition of macromolecules in the plasma membranes of cells or in the extracellular matrix. Cell-to-cell interactions are often mediated through cadherins, but cell-to-substrate interactions often involve integrin-to-extracellular-matrix (ECM) interactions.

### Cadherins

Cadherins are a large gene family, with over 80 members identified in humans. In the genomes of *Drosophila*, *C. elegans*, and humans, the cadherins can be sorted into several subfamilies that exist in all three genomes.

The cadherin proteins are all transmembrane proteins that share a common motif, the *cadherin domain*, a 110-amino-acid domain in the extracellular portion of the protein that mediates  $\text{Ca}^{2+}$ -dependent binding between like cadherins (homophilic binding).

Experiments in which cells are allowed to sort in vitro illustrate the function of cadherins. Cells with the same cadherins adhere specifically to one another, while not adhering to other cells with different cadherins. If cell populations with different cadherins are dispersed and then allowed to reaggregate, they sort into two populations of cells based on the nature of the cadherins on their surface.

An example of the action of cadherins can be seen in the development of the vertebrate nervous system. All surface ectoderm cells of the embryo express E-cadherin. The formation of the nervous system begins when a central strip of cells on the dorsal surface of the embryo turns off E-cadherin expression and turns on N-cadherin expression. In the process of **neurulation**, the formation of the neural tube (see chapter 54), the central strip of N-cadherin-expressing cells folds up to form the tube. The neural tube pinches off from the overlying cells, which continue to express E-cadherin. The surface cells outside the tube differentiate into the epidermis of the skin, whereas the neural tube develops into the brain and spinal cord of the embryo.

### Integrins

In some tissues, such as connective tissue, much of the volume of the tissue is taken up by the spaces *between* cells. These spaces are filled with a network of molecules secreted by surrounding cells, termed a *matrix*. In connective tissue such as cartilage, long polysaccharide chains are covalently linked to proteins (proteoglycans), within which are embedded strands of fibrous protein (collagen, elastin, and fibronectin). Migrating cells traverse this matrix by binding to it with cell surface proteins called integrins.

Integrins are attached to actin filaments of the cytoskeleton and protrude out from the cell surface in pairs, like two hands. The “hands” grasp a specific component of the matrix, such as collagen or fibronectin, thus linking the cytoskeleton to the fibers of the matrix. In addition to providing an anchor, this binding can initiate changes within the cell, alter the growth of the cytoskeleton, and activate gene expression and the production of new proteins.

The process of **gastrulation** (described in detail in chapter 54), during which the hollow ball of animal embryonic cells folds in on itself to form a multilayered structure, depends on fibronectin–integrin interactions. For example, injection of antibodies against either fibronectin or integrins into salamander embryos blocks binding of cells to fibronectin in the ECM and inhibits gastrulation. The result is like a huge traffic jam following a major accident on a freeway: Cells (cars) keep coming, but they get backed up since they cannot get beyond the area of inhibition (accident site) (figure 19.20). Similarly, a targeted knockout of the fibronectin gene in mice resulted in gross defects in the migration, proliferation, and differentiation of embryonic mesoderm cells.

Thus, cell migration is largely a matter of changing patterns of cell adhesion. As a migrating cell travels, it continually extends projections that probe the nature of its environment. Tugged this way and that by different tentative attachments, the cell literally feels its way toward its ultimate target site.

### In seed plants, the plane of cell division determines morphogenesis

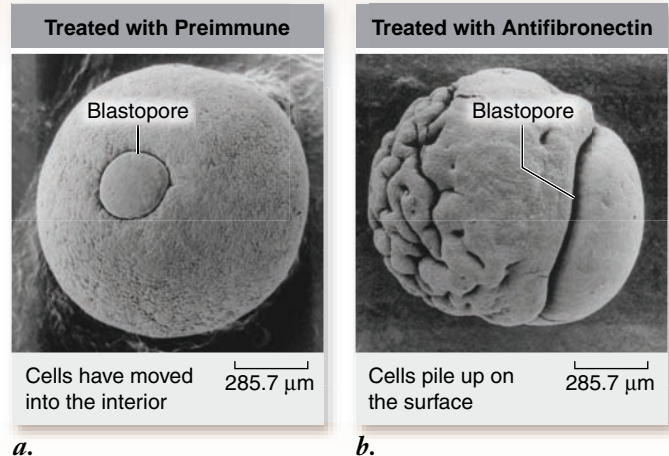

The form of a plant body is largely determined by the plane in which cells divide. The first division of the fertilized egg in a flowering plant is off-center, so that one of the daughter

### SCIENTIFIC THINKING

**Hypothesis:** *Fibronectin is required for cell migration during gastrulation.*

**Prediction:** *Blocking fibronectin with antifibronectin antibodies before gastrulation should prevent cell movement.*

**Test:** *Staged salamander embryos were injected either with antifibronectin antibody, or with preimmune serum as a control, prior to gastrulation. Cell movements were then monitored photographically.*

a.

b.

**Result:** *The experimental embryos injected with antifibronectin antibody show extremely aberrant gastrulation where cells pile up and do not enter the interior of the embryo. Control embryos gastrulate normally.*

**Conclusion:** *Fibronectin is required for cells to migrate into the interior of the embryo during gastrulation.*

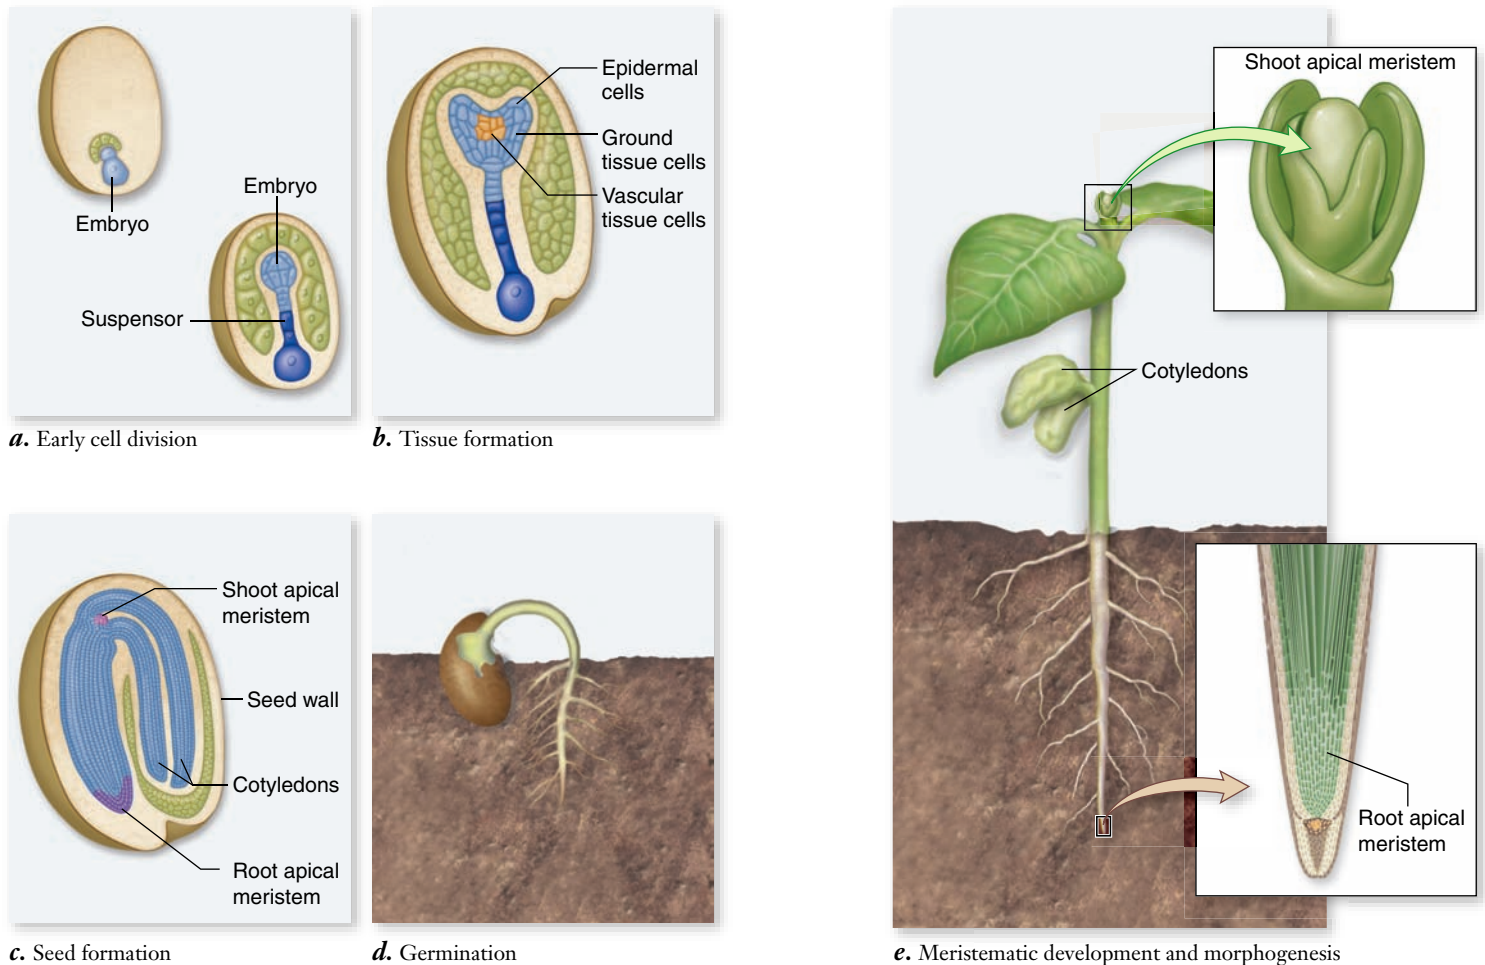

**Further Experiments:** *How can this same system be used to analyze the role of fibronectin in other early morphogenetic events?*

**Figure 19.20** Fibronectin is necessary for cell migration during gastrulation.

cells is small, with dense cytoplasm (figure 19.21a). That cell, the future embryo, begins to divide repeatedly, forming a ball of cells. The other daughter cell also divides repeatedly, forming an elongated structure called a *suspensor*, which links the embryo to the nutrient tissue of the seed. The suspensor also provides a route for nutrients to reach the developing embryo.

Just as many animal embryos acquire their initial axis as a cell mass formed during cleavage divisions, so the plant embryo forms its root–shoot axis at this time. Cells near the suspensor are destined to form a root, whereas those at the other end of the axis ultimately become a shoot, the aboveground portion of the plant.

The relative position of cells within the plant embryo is also a primary determinant of cell differentiation. The outermost cells in a plant embryo become epidermal cells. The bulk of the embryonic interior consists of ground tissue cells that eventually function in food and water storage. Finally, cells at the core of the embryo are destined to form the future vascular tissue (figure 19.21b). (Plant tissues and development are described in detail in chapters 36 and 37.)

**Figure 19.21 The path of plant development.** The developmental stages of *Arabidopsis thaliana* are (a) early embryonic cell division, (b) embryonic tissue formation, (c) seed formation, (d) germination, and (e) meristematic development and morphogenesis.

Soon after the three basic tissues form, a flowering plant embryo develops one or two seed leaves called *cotyledons*. At this point, development is arrested, and the embryo is either surrounded by nutritive tissue or has amassed stored food in its cotyledons (figure 19.21c). The resulting package, known as a *seed*, is resistant to drought and other unfavorable conditions.

A seed germinates in response to favorable changes in its environment. The embryo within the seed resumes development and grows rapidly, its roots extending downward and its leaf-bearing shoots extending upward (figure 19.21d). Plant development exhibits its great flexibility during the assembly of the modules that make up a plant body. Apical meristems at the root and shoot tips generate the large numbers of cells needed to form leaves, flowers, and all other components of the mature plant (figure 19.21e).

Growth within the developing flower is controlled by a cascade of transcription factors. A key member of this cascade is the *AINTEGUMENTA (ANT)* gene. Loss of ANT function reduces the number and size of floral organs, and inappropriate expression leads to larger floral organs.

Plant body form is also established by controlled changes in cell shape as cells expand osmotically after they form. Plant growth-regulating hormones and other factors influence the orientation of bundles of microtubules on the interior of the plasma membrane. These microtubules seem to guide cellulose deposition as the cell wall forms around the outside of a new cell. The orientation of the cellulose fibers, in turn, determines how the cell will elongate as it increases in volume due to osmosis, and so determines the cell's final shape.

### Learning Outcomes Review 19.6

Morphogenesis is the generation of ordered form and structure. This process proceeds along with cell differentiation. The primary mechanisms of morphogenesis are cell shape change and cell migration. Apoptosis is programmed cell death that is a necessary part of morphogenesis. Cell migration in animals involves alternating changes in adhesion brought about by cadherins and integrins. In plants, which cannot move, cell division and cell expansion are the primary morphogenetic processes.

#### ■ Why is cell death important to morphogenesis?

## 19.1 The Process of Development

Development is the sequence of systematic, gene-directed changes throughout a life cycle. The four subprocesses of development are growth, cell differentiation, pattern formation, and morphogenesis.

## 19.2 Cell Division

**Development begins with cell division.**

In animals, cleavage stage divisions divide the fertilized egg into numerous smaller cells called blastomeres. During cleavage the G<sub>1</sub> and G<sub>2</sub> phases of the cell cycle are shortened or eliminated (figure 19.2).

**Every cell division is known in the development of *C. elegans*.**

The lineage of 959 adult somatic *Caenorhabditis elegans* cells is invariant. Knowledge of the differentiation sequence and outcome allows study of developmental mechanisms.

**Plant growth occurs in specific areas called meristems.**

Plant growth continues throughout the life span from meristematic stem cells that can divide and differentiate into any plant tissue.

## 19.3 Cell Differentiation

**Cells become determined prior to differentiation.**

The process of determination commits a cell to a particular developmental pathway prior to its differentiation. This is not visible but can be tracked experimentally. Determination is due to differential inheritance of cytoplasmic factors or cell-to-cell interactions.

**Determination can be due to cytoplasmic determinants.**

In tunicates, determination of tail muscle cells depends on the presence of mRNA for the Macho-1 transcription factor, which is deposited in the egg cytoplasm during gamete formation.

**Induction can lead to cell differentiation.**

Induction occurs when one cell type produces signal molecules that induce gene expression in neighboring target cells.

In frogs, cells from animal and vegetal poles do not develop into mesoderm when isolated. In tunicates, signaling by the growth factor FGF induces mesoderm development.

**Stem cells can divide and produce cells that differentiate.**

Stem cells replace themselves by division and produce cells that differentiate. Totipotent stem cells can give rise to any cell type including extraembryonic tissues; pluripotent cells can give rise to all cells of an organism; and multipotent stem cells can give rise to many kinds of cells.

**Embryonic stem cells are pluripotent cells derived from embryos.**

Embryonic stem cells are derived from the inner cell mass of the blastocyst (figure 19.8). They can differentiate into any adult tissue in a mouse.

## 19.4 Nuclear Reprogramming

**Reversal of determination has allowed cloning.**

Cells undergo no irreversible changes during development. However, transplanted nuclei from older donors are less able to direct complete development. The cloning of the sheep Dolly showed that the nucleus of an adult cell can be reprogrammed to be totipotent (figure 19.9).

**Reproductive cloning has inherent problems.**

Reproductive cloning has a low success rate, and clones often develop age-associated diseases.

**Nuclear reprogramming has been accomplished by use of defined factors.**

Adult cells can be converted into pluripotent cells by introduction of four genes for transcription factors. These induced pluripotent cells appear to be similar to ES cells.

The use of cells cloned from a patient's cells to replace damaged tissue could avoid the problem of transplant rejection.

## 19.5 Pattern Formation

***Drosophila* embryogenesis produces a segmented larva.**

The maternal contribution of mRNA along with the postfertilization events of cellular blastoderm formation produce a segmented embryo.

**Morphogen gradients form the basic body axes in *Drosophila*.**

Pattern formation produces two perpendicular axes in a bilaterally symmetrical organism. Positional information leads to changes in gene activity so cells adopt a fate appropriate for their location.

Formation of the anterior/posterior (A/P) axis is based on opposing gradients of morphogens, Bicoid and Nanos, synthesized from maternal mRNA (figures 19.14, 19.15).

The dorsal/ventral (D/V) axis is established by a gradient of the Dorsal transcription factor. Successive action of transcription factors divides the embryo into segments.

**The body plan is produced by sequential activation of genes.**

**Segment identity arises from the action of homeotic genes.**

Homeotic genes, called *Hox* genes because they contain a DNA sequence called the homeobox, give identity to embryo segments.

*Hox* genes are found in four clusters in vertebrates.

**Pattern formation in plants is also under genetic control.**

Plants have *MADS*-box genes that control the transition from vegetative to reproductive growth, root development, and floral organ identity.

## 19.6 Morphogenesis

**Cell division during development may result in unequal cytokinesis.**

**Cells change shape and size as morphogenesis proceeds.**

Depending on the orientation of the mitotic spindle, cells of equal or different sizes can arise. Morphogenesis involves changes in cell shape and size and cell migration.

**Programmed cell death is a necessary part of development.**

Apoptosis, the programmed death of cells, removes structures once they are no longer needed (figure 19.19).

**Cell migration gets the right cells to the right places.**

The migration of cells requires both adhesion and loss of adhesion between cells and their substrate.

Cell-to-cell interactions are often mediated by cadherin proteins, whereas cell-to-substrate interactions may involve integrin-to-extracellular-matrix interactions.

Integrins bind to fibers found in the extracellular matrix. This action can alter the cytoskeleton and activate gene expression.

**In seed plants, the plane of cell division determines morphogenesis.**

In plants, the primary morphogenetic processes are cell division, relative position of cells within the embryo, and changes in cell shape. Plant development stages begin with cell division and end with meristematic development and morphogenesis (figure 19.21).

Relative position of cells in the plant embryo is the main determinant of cell differentiation.

## Review Questions

### UNDERSTAND

- During development, cells become
  - differentiated before they become determined.
  - determined before they become differentiated.
  - determined by the loss of genetic material.
  - differentiated by the loss of genetic material.
- Determination can occur by
  - the action of cytoplasmic determinants.
  - induction by other cells.
  - the loss of chromosomes during cell division.
  - both a and b.
- The rapid divisions that occur early in development are made possible by shortening
  - M phase.
  - S phase.
  - G<sub>1</sub> and G<sub>2</sub> phases.
  - all of the above.
- A pluripotent cell is one that can
  - become any cell type in an organism.
  - produce an indefinite supply of a single cell type.
  - produce a limited amount of a specific cell type.
  - produce multiple cell types.
- Plant meristems
  - are only present during development.
  - contain stem cells.
  - undergo meiosis.
  - all of the above
- Pattern formation involves cells determining their position in the embryo. One mechanism that can accomplish this is
  - the loss of genetic material.
  - alterations of chromosome structure.
  - gradients of morphogens.
  - changes in the cell cycle.
- The process of nuclear reprogramming
  - is a normal part of pattern formation.
  - reverses the changes that occur during differentiation.
  - requires the introduction of new DNA.
  - is not possible with mammalian cells.

### APPLY

- What is the common theme in cell determination by induction or cytoplasmic determinants?
    - The activation of transcription factors
    - The activation cell division
    - A change in gene expression
    - Both a and c
  - The process of reproductive cloning
    - shows that nuclear reprogramming is possible.
    - is very efficient in mammals.
    - always produces adult animals that are identical to the donor.
    - is both a and b.
  - Production of anterior–posterior and dorsal–ventral axes in the fruit fly *Drosophila*
    - both use gradients of mRNA.
    - are conceptually similar but mechanistically different.
    - use the exact same mechanisms.
    - both use gradients of protein.
- For pattern formation to occur, the cells in the developing embryo must
    - “know” their position in the embryo.
    - be determined during the earliest divisions.
    - differentiate as they are “born.”
    - must all be reprogrammed after each cell division.
  - The genes that encode the morphogen gradients in *Drosophila* were all identified in mutant screens. A mutation that removes the gradient necessary for the A/P morphogen gradient would be expected to
    - affect the larvae but not the adult.
    - affect the adult but not the larvae.
    - be lethal and lead to an abnormal embryo.
    - produce replacement of one adult structure with another.
  - What would be the likely result of a mutation of the *bcl-2* gene on the level of apoptosis?
    - No change
    - A decrease in apoptosis
    - An increase in apoptosis
    - An initial decrease, followed by an increase in apoptosis
  - MADS*-box, and *Hox* genes are
    - found only in plants and animals, respectively.
    - found only in animals and plants, respectively.
    - have similar roles in development in plants and animals, respectively.
    - have similar roles in development in animals and plants, respectively.

### SYNTHESIZE

- The fate map for *C. elegans* (refer to figure 19.3) diagrams development of a multicellular organism from a single cell. Use this fate map to determine the number of cell divisions required to establish the population of cells that will become (a) the nervous system and (b) the gonads.
- Carefully examine the *C. elegans* fate map in figure 19.3. Notice that some of the branchpoints (daughter cells) do *not* go on to produce more cells. What is the cellular mechanism underlying this pattern?
- You have generated a set of mutant embryonic mouse cells. Predict the developmental consequences for each of the following mutations.
  - Knockout mutation for N-cadherin
  - Knockout mutation for integrin
  - Deletion of the cytoplasmic domain of integrin
- Assume you have the factors in hand necessary to reprogram an adult cell, and the factors necessary to induce differentiation to any cell type. How could these be used to replace a specific damaged tissue in a human patient?

## Chapter 20

## Genes Within Populations

### Chapter Outline

- 20.1 Genetic Variation and Evolution
- 20.2 Changes in Allele Frequency
- 20.3 Five Agents of Evolutionary Change
- 20.4 Fitness and Its Measurement
- 20.5 Interactions Among Evolutionary Forces
- 20.6 Maintenance of Variation
- 20.7 Selection Acting on Traits Affected by Multiple Genes
- 20.8 Experimental Studies of Natural Selection
- 20.9 The Limits of Selection

### Introduction

*No other human being is exactly like you (unless you have an identical twin). Often the particular characteristics of an individual have an important bearing on its survival, on its chances to reproduce, and on the success of its offspring. Evolution is driven by such factors, as different alleles rise and fall in populations. These deceptively simple matters lie at the core of evolutionary biology, which is the topic of this chapter and chapters 21 through 25.*

### 20.1 Genetic Variation and Evolution

#### Learning Outcomes

1. Define evolution and population genetics.
2. Explain the difference between evolution by natural selection and the inheritance of acquired characteristics.

Genetic variation, that is, differences in alleles of genes found within individuals of a population, provides the raw material for natural selection, which will be described shortly. Natural populations contain a wealth of such variation. In plants, insects, and vertebrates, many genes exhibit some level of variation. In this chapter, we explore genetic variation in natural populations and consider the evolutionary forces that cause allele frequencies in natural populations to change.

The word *evolution* is widely used in the natural and social sciences. It refers to how an entity—be it a social system, a gas,

or a planet—changes through time. Although development of the modern concept of evolution in biology can be traced to Darwin’s landmark work, *On the Origin of Species*, the first five editions of his book never actually used the term. Rather, Darwin used the phrase “descent with modification.”

Although many more complicated definitions have been proposed, Darwin’s words probably best capture the essence of biological evolution: Through time, species accumulate differences; as a result, descendants differ from their ancestors. In this way, new species arise from existing ones.

## Many processes can lead to evolutionary change

You have already learned about the development of Darwin’s ideas in chapter 1. Darwin was not the first to propose a theory of evolution. Rather, he followed a long line of earlier philosophers and naturalists who deduced that the many kinds of organisms around us were produced by a process of evolution.

Unlike his predecessors, however, Darwin proposed natural selection as the mechanism of evolution. Natural selection produces evolutionary change when some individuals in a population possess certain inherited characteristics and then produce more surviving offspring than individuals lacking these characteristics. As a result, the population gradually comes to include more and more individuals with the advantageous characteristics. In this way, the population evolves and becomes better adapted to its local circumstances.

A rival theory, championed by the prominent biologist Jean-Baptiste Lamarck, was that evolution occurred by the **inheritance of acquired characteristics**. According to Lamarck, changes that individuals acquired during their lives were passed on to their offspring. For example, Lamarck proposed that ancestral giraffes with short necks tended to stretch their necks to feed on tree leaves, and this extension of the neck was passed on to subsequent generations, leading to the long-necked giraffe (figure 20.1a). In Darwin’s theory, by contrast, the variation is not created by experience, but is the result of preexisting genetic differences among individuals (figure 20.1b).

One way to monitor how populations change through time is to look at changes in the frequencies of alleles of a gene from one generation to the next. Natural selection, by favoring individuals with certain alleles, can lead to change in such *allele frequencies*, but it is not the only process that can do so. Allele frequencies can also change when mutations occur repeatedly, changing one allele to another, and when migrants bring alleles into a population. In addition, when populations are small, the frequencies of alleles can change randomly as the result of chance events. Often, natural selection overwhelms the effects of these other processes, but as you will see later in this chapter, this is not always the case.

Evolution can result from any process that causes a change in the genetic composition of a population. We cannot talk about evolution, therefore, without also considering **population genetics**, the study of the properties of genes in populations.

Proposed ancestor of giraffes has characteristics of modern-day okapi.

The giraffe ancestor lengthened its neck by stretching to reach tree leaves, then passed the change to offspring.

a. Lamarck’s theory: acquired variation is passed on to descendants.

Some individuals born happen to have longer necks due to genetic differences.

Individuals pass on their traits to next generation.

Over many generations, longer-necked individuals are more successful, perhaps because they can feed on taller trees, and pass the long-neck trait on to their offspring.

b. Darwin’s theory: natural selection or genetically-based variation leads to evolutionary change.

## Figure 20.1 Two ideas of how giraffes might have evolved long necks.

### Populations contain ample genetic variation

It is best to start by looking at the genetic variation present among individuals within a species. This is the raw material available for the selective process.

As you saw in chapter 12, a natural population can contain a great deal of genetic variation. How much variation usually occurs? Humans are representative of most—but not all—species in that human populations contain substantial amounts of genetic variation. For example:

1. **Genes that influence blood groups.** Chemical analysis has revealed the existence of more than 30 blood group genes in humans, in addition to the ABO locus. At least

one third of these genes are routinely found in several alternative allelic forms in human populations. In addition to these, more than 45 variable genes encode other proteins in human blood cells and plasma that are not considered blood groups. In short, many genetically variable genes are present in this one system alone.

2. **Genes that influence enzymes.** Alternative alleles of genes specifying particular enzymes are easy to distinguish by measuring how fast the alternative proteins migrate in an electrical field (a process called *electrophoresis*—see chapter 17). A great deal of variation exists at enzyme-specifying loci. About 5% of the enzyme loci of a typical human are heterozygous: If you picked an individual at random, and in turn selected one of the enzyme-encoding genes of that individual at random, the chances are 1 in 20 (5%) that the gene you selected would be heterozygous in that individual.

Considering the entire genome, it is fair to say that all humans are different from one another except for identical twins. This is also true of other organisms, except for those that reproduce asexually. In nature, genetic variation is the rule.

### Enzyme polymorphism

Many loci in a particular population have more than one allele at frequencies significantly greater than would occur due to mutation alone. Researchers refer to such a locus as **polymorphic** (figure 20.2). The extent of such variation within natural popula-

**Figure 20.2 Polymorphic variation.** This natural population of loosestrife, *Lythrum salicaria*, exhibits considerable variation in flower color. Individual differences are inherited and passed on to offspring.

tions was not even suspected a few decades ago, when modern techniques such as protein electrophoresis made it possible to examine enzymes and other proteins directly.

We now know that most populations of insects and plants are polymorphic at more than half of their enzyme-encoding loci, that is, the loci have more than one allele occurring at a frequency greater than 5%. Vertebrates are somewhat less polymorphic. Heterozygosity, the probability that a randomly selected gene will be heterozygous in a randomly selected individual, is about 15% in *Drosophila* and other invertebrates, between 5% and 8% in vertebrates, and around 8% in outcrossing plants (values of heterozygosity tend to be lower than the proportion of loci that are polymorphic because for loci that are polymorphic, many individuals within the population will be homozygous). These high levels of genetic variability provide ample supplies of raw material for evolution.

### DNA sequence polymorphism

The advent of gene technology has made it possible to assess genetic variation even more directly by sequencing the DNA itself. For example, when the *ADH* genes (which encode for alcohol dehydrogenase) of 11 *Drosophila melanogaster* individuals were sequenced, scientists found 43 variable sites, only 1 of which had been detected by protein electrophoresis.

Numerous other studies of variation at the DNA level have confirmed these findings: Abundant variation exists in both the coding regions of genes and in their nontranslated introns—considerably more variation than we can detect by examining enzymes with electrophoresis.

### Learning Outcomes Review 20.1

Evolution can be described as descent with modification. Natural selection occurs when individuals carrying certain alleles leave more offspring than those without the alleles. Natural populations contain more genetic variation than can be accounted for by mutation alone. Population genetics studies this variability through statistical analyses.

- Why is genetic variation in a population necessary for evolution to occur?

## 20.2 Changes in Allele Frequency

### Learning Outcomes

1. Explain the Hardy–Weinberg principle.
2. Describe the characteristics of a population that is in Hardy–Weinberg equilibrium.
3. Demonstrate how the operation of evolutionary processes can be detected.

Genetic variation within natural populations was a puzzle to Darwin and his contemporaries in the mid-1800s. The way in which meiosis produces genetic segregation among the progeny of a hybrid had not yet been discovered. And, although Mendel performed his experiments during this same time period, his work was largely unknown. Selection, scientists then thought, should always favor an optimal form, and so tend to eliminate variation. Moreover, the theory of *blending inheritance*—in which offspring were expected to be phenotypically intermediate relative to their parents—was widely accepted. If blending inheritance were correct, then the effect of any new genetic variant would quickly be diluted to the point of disappearance in subsequent generations.

## The Hardy–Weinberg principle allows prediction of genotype frequencies

Following the rediscovery of Mendel’s research, two people in 1908 solved the puzzle of why genetic variation persists—Godfrey H. Hardy, an English mathematician, and Wilhelm Weinberg, a German physician. These workers were initially confused about why, after many generations, a population didn’t come to be composed solely of individuals with the dominant phenotype. The conclusion they independently came to was that the original proportions of the genotypes in a population will remain constant from generation to generation, as long as the following assumptions are met:

1. No mutation takes place.
2. No genes are transferred to or from other sources (no immigration or emigration takes place).
3. Random mating is occurring.
4. The population size is very large.
5. No selection occurs.

Because the genotypes’ proportions do not change, they are said to be in **Hardy–Weinberg equilibrium**.

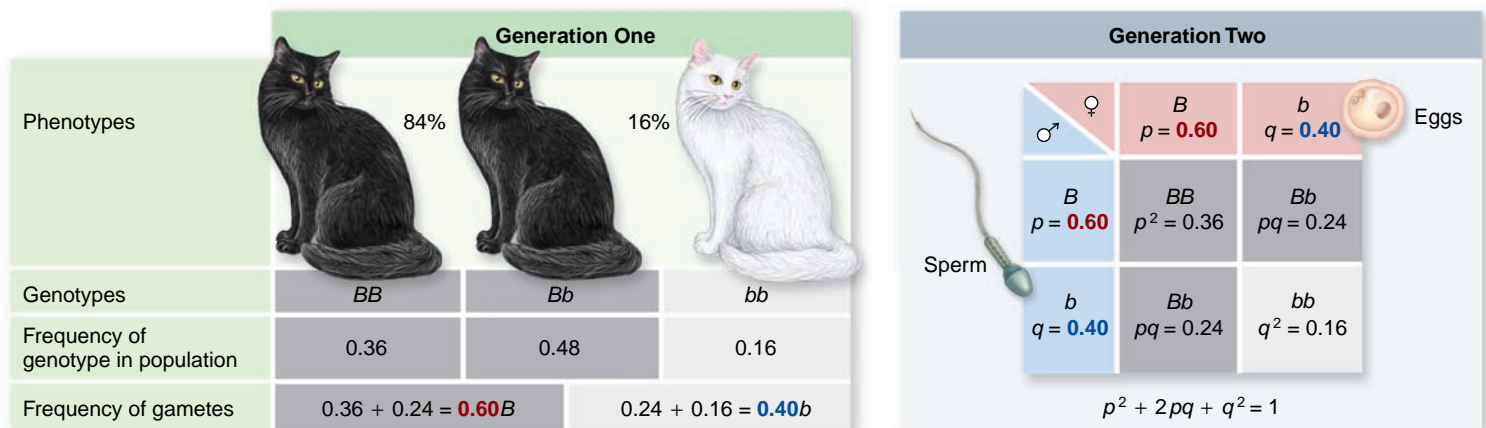

## The Hardy–Weinberg equation with two alleles: A binomial expansion

In algebraic terms, the Hardy–Weinberg principle is written as an equation. Consider a population of 100 cats in which 84 are black and 16 are white. The frequencies of the two phenotypes would be 0.84 (or 84%) black and 0.16 (or 16%) white. Based on these phenotypic frequencies, can we deduce the underlying frequency of genotypes?

If we assume that the white cats are homozygous recessive for an allele we designate as  $b$ , and the black cats are either homozygous dominant  $BB$  or heterozygous  $Bb$ , we can calculate the **allele frequencies** of the two alleles in the population from the proportion of black and white individuals, assuming that the population is in Hardy–Weinberg equilibrium.

Let the letter  $p$  designate the frequency of the  $B$  allele and the letter  $q$  the frequency of the alternative allele. Because there are only two alleles,  $p$  plus  $q$  must always equal 1 (that is, the total population). In addition, we know that the sum of the three genotype frequencies must also equal 1. If the frequency of the  $B$  allele is  $p$ , then the probability that an individual will have two  $B$  alleles is simply the probability that each of its alleles is a  $B$ . The probability of two events happening independently is the product of the probability of each event; in this case, the probability that the individual received a  $B$  allele from its father is  $p$ , and the probability the individual received a  $B$  allele from its mother is also  $p$ , so the probability that both happened is  $p * p = p^2$  (figure 20.3). By the same reasoning, the probability that an individual will have two  $b$  alleles is  $q^2$ .

What about the probability that an individual will be a heterozygote? There are two ways this could happen: The individual could receive a  $B$  from its father and a  $b$  from its mother, or vice versa. The probability of the first case is  $p * q$  and the probability of the second case is  $q * p$ . Because the result in either case is that the individual is a heterozygote, the probability of that outcome is the sum of the two probabilities, or  $2pq$ .

**Figure 20.3 The Hardy–Weinberg equilibrium.** In the absence of factors that alter them, the frequencies of gametes, genotypes, and phenotypes remain constant generation after generation.

### Inquiry question

If all white cats died, what proportion of the kittens in the next generation would be white?

So, to summarize, if a population is in Hardy–Weinberg equilibrium with allele frequencies of  $p$  and  $q$ , then the probability that an individual will have each of the three possible genotypes is  $p^2 + 2pq + q^2$ . You may recognize this as the *binomial expansion*:

$$(p + q)^2 = p^2 + 2pq + q^2$$

Finally, we may use these probabilities to predict the distribution of genotypes in the population, again assuming that the population is in Hardy–Weinberg equilibrium. If the probability that any individual is a heterozygote is  $2pq$ , then we would expect the proportion of heterozygous individuals in the population to be  $2pq$ ; similarly, the frequency of  $BB$  and  $bb$  homozygotes would be expected to be  $p^2$  and  $q^2$ .

Let us return to our example. Remember that 16% of the cats are white. If white is a recessive trait, then this means that such individuals must have the genotype  $bb$ . If the frequency of this genotype is  $q^2 = 0.16$  (the frequency of white cats), then  $q$  (the frequency of the  $b$  allele) = 0.4. Because  $p + q = 1$ , therefore,  $p$ , the frequency of allele  $B$ , would be  $1.0 - 0.4 = 0.6$  (remember, the frequencies must add up to 1). We can now easily calculate the expected **genotype frequencies**: homozygous dominant  $BB$  cats would make up the  $p^2$  group, and the value of  $p^2 = (0.6)^2 = 0.36$ , or 36 homozygous dominant  $BB$  individuals in a population of 100 cats. The heterozygous cats have the  $Bb$  genotype and would have the frequency corresponding to  $2pq$ , or  $(2 * 0.6 * 0.4) = 0.48$ , or 48 heterozygous  $Bb$  individuals.

### Using the Hardy–Weinberg equation to predict frequencies in subsequent generations

The Hardy–Weinberg equation is another way of expressing the Punnett square described in chapter 12, with two alleles assigned frequencies,  $p$  and  $q$ . Figure 20.3 allows you to trace genetic re-assortment during sexual reproduction and see how it affects the frequencies of the  $B$  and  $b$  alleles during the next generation.

In constructing this diagram, we have assumed that the union of sperm and egg in these cats is random, so that all combinations of  $b$  and  $B$  alleles occur. The alleles are therefore mixed randomly and are represented in the next generation in proportion to their original occurrence. Each individual egg or sperm in each generation has a 0.6 chance of receiving a  $B$  allele ( $p = 0.6$ ) and a 0.4 chance of receiving a  $b$  allele ( $q = 0.4$ ).

In the next generation, therefore, the chance of combining two  $B$  alleles is  $p^2$ , or 0.36 (that is,  $0.6 * 0.6$ ), and approximately 36% of the individuals in the population will continue to have the  $BB$  genotype. The frequency of  $bb$  individuals is  $q^2$  ( $0.4 * 0.4$ ) and so will continue to be about 16%, and the frequency of  $Bb$  individuals will be  $2pq$  ( $2 * 0.6 * 0.4$ ), or on average, 48%.

Phenotypically, if the population size remains at 100 cats, we would still see approximately 84 black individuals (with either  $BB$  or  $Bb$  genotypes) and 16 white individuals (with the  $bb$  genotype). Allele, genotype, and phenotype frequencies have remained unchanged from one generation to the next, despite the reshuffling of genes that occurs during meiosis and sexual reproduction. Dominance and recessiveness of alleles can therefore be seen only to affect how an allele is expressed in an individual and not how allele frequencies will change through time.

## Hardy–Weinberg predictions can be applied to data to find evidence of evolutionary processes

The lesson from the example of black and white cats is that if all five of the assumptions listed earlier hold true, the allele and genotype frequencies will not change from one generation to the next. But in reality, most populations in nature will not fit all five assumptions. The primary utility of this method is to determine whether some evolutionary process or processes are operating in a population and, if so, to suggest hypotheses about what they may be.

Suppose, for example, that the observed frequencies of the  $BB$ ,  $bb$ , and  $Bb$  genotypes in a different population of cats were 0.6, 0.2, and 0.2, respectively. We can calculate the allele frequencies for  $B$  as follows: 60% (0.6) of the cats have two  $B$  alleles, 20% have one, and 20% have none. This means that the average number of  $B$  alleles per cat is 1.4 [ $(0.6 * 2) + (0.2 * 1) + (0.2 * 0) = 1.4$ ]. Because each cat has two alleles for this gene, the frequency is  $1.4/2.0 = 0.7$ . Similarly, you should be able to calculate that the frequency of the  $b$  allele = 0.3.

If the population were in Hardy–Weinberg equilibrium, then, according to the equation earlier in this section, the frequency of the  $BB$  genotype would be  $0.7^2 = 0.49$ , lower than it really is. Similarly, you can calculate that there are fewer heterozygotes and more  $bb$  homozygotes than expected; then clearly, the population is not in Hardy–Weinberg equilibrium.

What could cause such an excess of homozygotes and deficit of heterozygotes? A number of possibilities exist, including (1) natural selection favoring homozygotes over heterozygotes, (2) individuals choosing to mate with genetically similar individuals (because  $BB * BB$  and  $bb * bb$  matings always produce homozygous offspring, but only half of  $Bb * Bb$  produce heterozygous offspring, such mating patterns would lead to an excess of homozygotes), or (3) an influx of homozygous individuals from outside populations (or conversely, emigration of heterozygotes to other populations). By detecting a lack of Hardy–Weinberg equilibrium, we can generate potential hypotheses that we can then investigate directly.

The operation of evolutionary processes can be detected in a second way. As discussed previously, if all of the Hardy–Weinberg assumptions are met, then allele frequencies will stay the same from one generation to the next. Changes in allele frequencies between generations would indicate that one of the assumptions is not met.

Suppose, for example, that the frequency of  $b$  was 0.53 in one generation and 0.61 in the next. Again, there are a number of possible explanations: For example, (1) selection favoring individuals with  $b$  over  $B$ , (2) immigration of  $b$  into the population or emigration of  $B$  out of the population, or (3) high rates of mutation that more commonly occur from  $B$  to  $b$  than vice versa. Another possibility is that the population is a small one, and that the change represents the random fluctuations that result because, simply by chance, some individuals pass on more of their genes than others. We will discuss how each of these processes is studied in the rest of the chapter.

### Learning Outcomes Review 20.2

The Hardy–Weinberg principle states that in a large population with no selection and random mating, the proportion of alleles does not change through the generations. Finding that a population is not in Hardy–Weinberg equilibrium indicates that one or more evolutionary agents are operating.

- *If you know the genotype frequencies in a population, how can you determine whether the population is in Hardy–Weinberg equilibrium?*

## 20.3 Five Agents of Evolutionary Change

### Learning Outcomes

1. Define the five processes that can cause evolutionary change.
2. Explain how these processes can cause populations to deviate from Hardy–Weinberg Equilibrium

The five assumptions of the Hardy–Weinberg principle also indicate the five agents that can lead to evolutionary change in populations. They are mutation, gene flow, nonrandom mating, genetic drift in small populations, and the pressures of natural selection. Any one of these may bring about changes in allele or genotype proportions.

### Mutation changes alleles

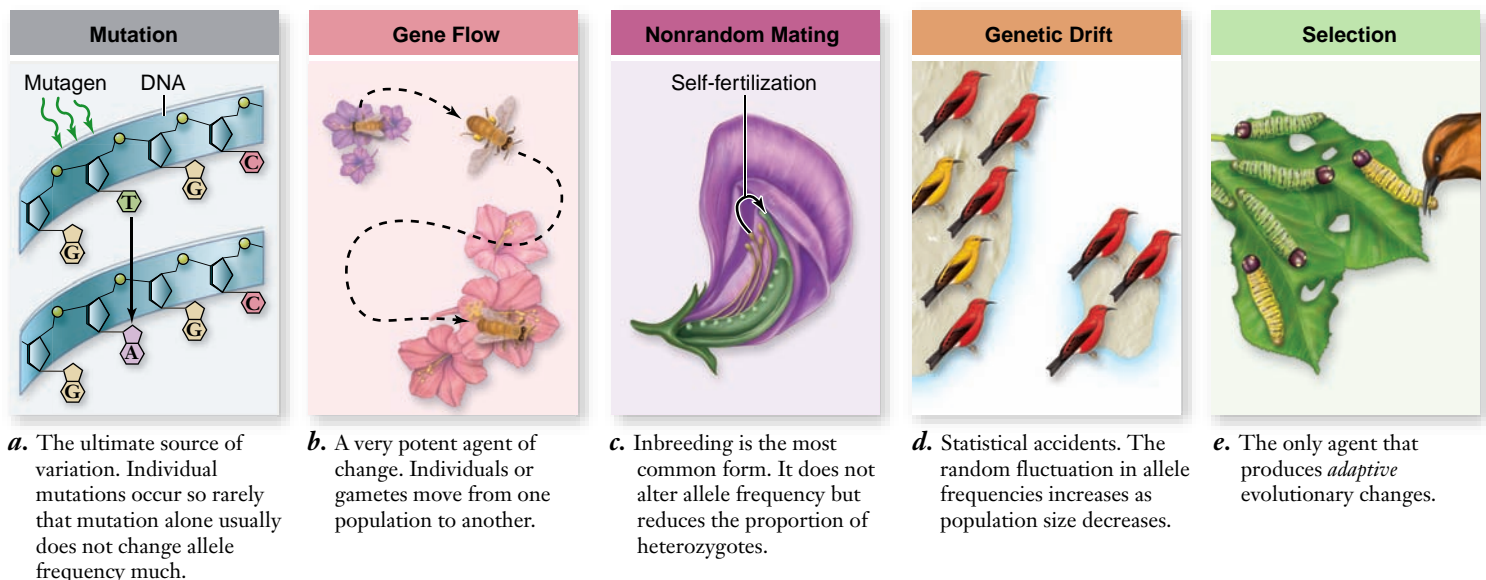

Mutation from one allele to another can obviously change the proportions of particular alleles in a population. Mutation rates are generally so low that they have little effect on the Hardy–Weinberg proportions of common alleles. A typical gene mutates about once per 100,000 cell divisions. Because this rate is so low, other evolutionary processes are usually more important in determining how allele frequencies change.

Nonetheless, mutation is the ultimate source of genetic variation and thus makes evolution possible (figure 20.4*a*). It is important to remember, however, that the likelihood of a particular mutation occurring is not affected by natural selection; that is, mutations do not occur more frequently in situations in which they would be favored by natural selection.

### Gene flow occurs when alleles move between populations

Gene flow is the movement of alleles from one population to another. It can be a powerful agent of change. Sometimes gene flow is obvious, as when an animal physically moves from one place to another. If the characteristics of the newly arrived individual differ from those of the animals already there, and if the newcomer is adapted well enough to the new area to survive and mate successfully, the genetic composition of the receiving population may be altered.

Other important kinds of gene flow are not as obvious. These subtler movements include the drifting of gametes or the immature stages of plants or marine animals from one place to another (figure 20.4*b*). Pollen, the male gamete of flowering plants, is often carried great distances by insects and other animals that visit flowers. Seeds may also blow in the wind or be carried by animals to new populations far from their place of

**Figure 20.4** Five agents of evolutionary change. *a.* Mutation, *(b)* gene flow, *(c)* nonrandom mating, *(d)* genetic drift, and *(e)* selection.

origin. In addition, gene flow may also result from the mating of individuals belonging to adjacent populations.

Consider two populations initially different in allele frequencies: In population 1,  $p = 0.2$  and  $q = 0.8$ ; in population 2,  $p = 0.8$  and  $q = 0.2$ . Gene flow will tend to bring the rarer allele into each population. Thus, allele frequencies will change from generation to generation, and the populations will not be in Hardy–Weinberg equilibrium. Only when allele frequencies reach 0.5 for both alleles in both populations will equilibrium be attained. This example also indicates that gene flow tends to homogenize allele frequencies among populations.

## Nonrandom mating shifts genotype frequencies

Individuals with certain genotypes sometimes mate with one another more commonly than would be expected on a random basis, a phenomenon known as *nonrandom mating* (figure 20.4c). **Assortative mating**, in which phenotypically similar individuals mate, is a type of nonrandom mating that causes the frequencies of particular genotypes to differ greatly from those predicted by the Hardy–Weinberg principle.

Assortative mating does not change the frequency of the individual alleles, but rather increases the proportion of homozygous individuals because phenotypically similar individuals are likely to be genetically similar and thus are also more likely to produce offspring with two copies of the same allele. This is why populations of self-fertilizing plants consist primarily of homozygous individuals.

By contrast, **disassortative mating**, in which phenotypically different individuals mate, produces an excess of heterozygotes.

## Genetic drift may alter allele frequencies in small populations

In small populations, frequencies of particular alleles may change drastically by chance alone. Such changes in allele frequencies occur randomly, as if the frequencies were drifting from their values. These changes are thus known as **genetic drift** (figure 20.4d). For this reason, a population must be large to be in Hardy–Weinberg equilibrium.

If the gametes of only a few individuals form the next generation, the alleles they carry may by chance not be representative of the parent population from which they were drawn, as illustrated in figure 20.5. In this example, a small number of individuals are removed from a bottle containing many. By chance, most of the individuals removed are green, so the new population has a much higher population of green individuals than the parent generation had.

A set of small populations that are isolated from one another may come to differ strongly as a result of genetic drift, even if the forces of natural selection are the same for both. Because of genetic drift, sometimes harmful alleles may increase in frequency in small populations, despite selective disadvantage, and favorable alleles may be lost even though they are selectively advantageous. It is interesting to realize that humans have lived in small groups for much of the course of their

**Figure 20.5 Genetic drift: a bottleneck effect.** The parent population contains roughly equal numbers of green and yellow individuals and a small number of red individuals. By chance, the few remaining individuals that contribute to the next generation are mostly green. The bottleneck occurs because so few individuals form the next generation, as might happen after an epidemic or a catastrophic storm.

evolution; consequently, genetic drift may have been a particularly important factor in the evolution of our species.

Larger populations also experience the effect of genetic drift, but to a lesser extent than smaller populations—the magnitude of genetic drift is inversely related to population size. However, large populations may have been much smaller in the past, and genetic drift may have greatly altered allele frequencies at that time. Imagine a population containing only two alleles of a gene,  $B$  and  $b$ , in equal frequency (that is,  $p = q = 0.50$ ). In a large Hardy–Weinberg population, the genotype frequencies are expected to be 0.25  $BB$ , 0.50  $Bb$ , and 0.25  $bb$ . If only a small sample of individuals produces the next generation, large deviations in these genotype frequencies can occur simply by chance.

Suppose, for example, that four individuals form the next generation, and that by chance they are two  $Bb$  heterozygotes and two  $BB$  homozygotes—that is, the allele frequencies in the next generation would be  $p = 0.75$  and  $q = 0.25$ . In fact, if you were to replicate this experiment 1000 times, each time randomly drawing four individuals from the parental population, then in about 8 of the 1000 experiments, one of the two alleles would be missing entirely.

This result leads to an important conclusion: Genetic drift can lead to the loss of alleles in isolated populations. Alleles that initially are uncommon are particularly vulnerable (see figure 20.5).

Although genetic drift occurs in any population, it is particularly likely in populations that were founded by a few individuals or in which the population was reduced to a very small number at some time in the past.

### The founder effect

Sometimes one or a few individuals disperse and become the founders of a new, isolated population at some distance from their place of origin. These pioneers are not likely to carry all the alleles present in the source population. Thus, some alleles may be lost from the new population, and others may change

drastically in frequency. In some cases, previously rare alleles in the source population may be a significant fraction of the new population's genetic endowment. This phenomenon is called the **founder effect**.

Founder effects are not rare in nature. Many self-pollinating plants start new populations from a single seed. Founder effects have been particularly important in the evolution of organisms on distant oceanic islands, such as the Hawaiian and Galápagos Islands. Most of the organisms in such areas probably derive from one or a few initial founders. Although rare, such events are occasionally observed, such as when a mass of vegetation carrying several iguanas washed up on the shore of the Caribbean island of Anguilla in 1996, leading to the establishment of a population that still occurs there to this day.

In a similar way, isolated human populations begun by relatively few individuals are often dominated by genetic features characteristic of their founders. Amish populations in the United States, for example, have unusually high frequencies of a number of conditions, such as polydactylism (the presence of a sixth finger).

### The bottleneck effect

Even if organisms do not move from place to place, occasionally their populations may be drastically reduced in size. This may result from flooding, drought, epidemic disease, and other natural forces, or from changes in the environment. The few surviving individuals may constitute a random genetic sample of the original population (unless some individuals survive specifically because of their genetic makeup). The resulting alterations and loss of genetic variability have been termed the **bottleneck effect**.

The genetic variation of some living species appears to be severely depleted, probably as the result of a bottleneck effect in the past. For example, the northern elephant seal, which breeds on the western coast of North America and nearby islands, was nearly hunted to extinction in the nineteenth century and was reduced to a single population containing perhaps

no more than 20 individuals on the island of Guadalupe off the coast of Baja, California (figure 20.6). As a result of this bottleneck, the species has lost almost all of its genetic variation, even though the seal populations have rebounded and now number in the tens of thousands and breed in locations as far north as near San Francisco.

Any time a population becomes drastically reduced in numbers, such as in endangered species, the bottleneck effect is a potential problem. Even if population size rebounds, the lack of variability may mean that the species remains vulnerable to extinction—a topic we will return to in chapter 59.

## Selection favors some genotypes over others

As Darwin pointed out, some individuals leave behind more progeny than others, and the rate at which they do so is affected by phenotype and behavior. We describe the results of this process as **selection** (see figure 20.4e). In *artificial selection*, a breeder selects for the desired characteristics. In *natural selection*, environmental conditions determine which individuals in a population produce the most offspring.

For natural selection to occur and to result in evolutionary change, three conditions must be met:

1. **Variation must exist among individuals in a population.** Natural selection works by favoring individuals with some traits over individuals with alternative traits. If no variation exists, natural selection cannot operate.
2. **Variation among individuals must result in differences in the number of offspring surviving in the next generation.** This is the essence of natural selection. Because of their phenotype or behavior, some individuals are more successful than others in producing offspring. Although many traits are phenotypically variable, individuals exhibiting variation do not always differ in survival and reproductive success.
3. **Variation must be genetically inherited.** For natural selection to result in evolutionary change, the selected differences must have a genetic basis. Not all variation has a genetic basis—even genetically identical individuals may be phenotypically quite distinctive if they grow up in different environments. Such environmental effects are

**Figure 20.6 Bottleneck effect: case study.** Because the Northern Elephant Seal (*Mirounga angustirostris*) lives in very cold waters, these, the world's largest seals, have thick layers of fat, for which they were hunted nearly to extinction late in the nineteenth century. At the low point, only one population remained on Guadalupe Island, with perhaps as few as 20 individuals; during this time, genetic variation was lost through the process of random genetic drift. Since being protected, the species has reclaimed most of its original range and now numbers in the tens of thousands, but genetic variation will only recover slowly over time as mutations accumulate.

common in nature. In many turtles, for example, individuals that hatch from eggs laid in moist soil are heavier, with longer and wider shells, than individuals from nests in drier areas.

When phenotypically different individuals do not differ genetically, then differences in the number of their offspring will not alter the genetic composition of the population in the next generation, and thus, no evolutionary change will have occurred.

It is important to remember that natural selection and evolution are not the same—the two concepts often are incorrectly equated. Natural selection is a process, whereas evolution is the historical record, or outcome, of change through time. Natural selection (the process) can lead to evolution (the outcome), but natural selection is only one of several processes that can result in evolutionary change. Moreover, natural selection can occur without producing evolutionary change; only if variation is genetically based will natural selection lead to evolution.

### Selection to avoid predators

The result of evolution driven by natural selection is that populations become better adapted to their environment. Many of the most dramatic documented instances of adaptation involve genetic changes that decrease the probability of capture by a predator. The caterpillar larvae of the common sulphur butterfly *Colias eurytheme* usually exhibit a pale green color, providing excellent camouflage against the alfalfa plants on which they feed. An alternative bright yellow color morph is kept at very low frequency because this color renders the larvae highly visible on the food plant, making it easier for bird predators to see them (see figure 20.4e).

One of the most dramatic examples of background matching involves ancient lava flows in the deserts of the American Southwest. In these areas, the black rock formations produced when the lava cooled contrast starkly with the surrounding bright glare of the desert sand. Populations of many species of animals occurring on these rocks—including lizards, rodents, and a variety of insects—are dark in color, whereas sand-dwelling populations in surrounding areas are much lighter (figure 20.7).

Predation is the likely cause for these differences in color. Laboratory studies have confirmed that predatory birds such as owls are adept at picking out individuals occurring on backgrounds to which they are not adapted.

### Selection to match climatic conditions

Many studies of selection have focused on genes encoding enzymes, because in such cases the investigator can directly assess the consequences to the organism of changes in the frequency of alternative enzyme alleles.

Often investigators find that enzyme allele frequencies vary with latitude, so that one allele is more common in northern populations, but is progressively less common at more southern locations. A superb example is seen in studies of a fish, the mummichog (*Fundulus heteroclitus*), which ranges along the eastern coast of North America. In this fish, geographic variation occurs in allele frequencies for the gene that produces the enzyme lactate dehydrogenase, which catalyzes the conversion of pyruvate to lactate (see section 7.8).

**Figure 20.7** Pocket mice from the Tularosa Basin of New Mexico whose color matches their background.

Black lava formations are surrounded by desert, and selection favors coat color in pocket mice that matches their surroundings. Genetic studies indicate that the differences in coat color are the result of small differences in the DNA of alleles of a single gene.

Biochemical studies show that the enzymes formed by these alleles function differently at different temperatures, thus explaining their geographic distributions. The form of the enzyme more frequent in the north is a better catalyst at low temperatures than is the enzyme from the south. Moreover, studies indicate that at low temperatures, individuals with the northern allele swim faster, and presumably survive better, than individuals with the alternative allele.

### Selection for pesticide and microbial resistance

A particularly clear example of selection in natural populations is provided by studies of pesticide resistance in insects. The widespread use of insecticides has led to the rapid evolution of resistance in more than 500 pest species. The cost of this evolution, in terms of crop losses and increased pesticide use, has been estimated at \$3-8 billion per year.

In the housefly, the resistance allele at the *pen* gene decreases the uptake of insecticide, whereas alleles at the *kdr* and *dld-r* genes decrease the number of target sites, thus decreasing the binding ability of the insecticide (figure 20.8). Other alleles enhance the ability of the insects' enzymes to identify and detoxify insecticide molecules.

Single genes are also responsible for resistance in other organisms. For example, Norway rats are normally susceptible to the pesticide warfarin, which diminishes the clotting ability of the rat's blood and leads to fatal hemorrhaging. However, a resistance allele at a single gene reduces the ability of warfarin to bind to its target enzyme and thus renders it ineffective.

Selection imposed by humans has also led to the evolution of resistance to antibiotics in many disease-causing pathogens. For example, *Staphylococcus aureus*, which causes staph infections, was initially treated by penicillin. However, within four years of mass-production of the drug, evolutionary change

**a.** Insect cells with resistance allele at *pen* gene: decreased uptake of the pesticide.

**b.** Insect cells with resistance allele at *kdr* gene: decreased number of target sites for the pesticide.

**Figure 20.8 Selection for pesticide resistance.** Resistance alleles at genes such as *pen* and *kdr* allow insects to be more resistant to pesticides. Insects that possess these resistance alleles have become more common through selection.

in *S. aureus* modified an enzyme so that it would attack penicillin and render it inactive. Since that time, several other drugs have been developed to attack the microbe, and each time resistance has evolved. As a result, staph infections have re-emerged as a major health threat.

### Learning Outcomes Review 20.3

Five factors can bring about deviation from the predicted Hardy–Weinberg genotype frequencies. Of these, only selection regularly produces adaptive evolutionary change, but the genetic constitution of populations, and thus the course of evolution, can also be affected by mutation, gene flow, nonrandom mating, and genetic drift.

- How do each of these processes cause populations to vary from Hardy–Weinberg equilibrium?

## 20.4 Fitness and Its Measurement

### Learning Outcomes

1. Define evolutionary fitness.
2. Explain the different components of fitness.
3. Demonstrate how the success of different phenotypes can be compared by calculating their relative fitness.

Selection occurs when individuals with one phenotype leave more surviving offspring in the next generation than individuals with an alternative phenotype. Evolutionary biologists quantify reproductive success as **fitness**, the number of surviving offspring left in the next generation.

Fitness is a relative concept; the most fit phenotype is simply the one that produces, on average, the greatest number of offspring.

### A phenotype with greater fitness usually increases in frequency

Suppose, for example, that in a population of toads, two phenotypes exist: green and brown. Suppose, further, that green toads leave, on average, 4.0 offspring in the next generation, but brown toads leave only 2.5. By custom, the most fit phenotype is assigned a fitness value of 1.0, and other phenotypes are expressed as relative proportions. In this case, the fitness of the green phenotype would be  $4.0/4.0 = 1.000$ , and the fitness of the brown phenotype would be  $2.5/4.0 = 0.625$ . The difference in fitness would therefore be  $1.000 - 0.625 = 0.375$ . A difference in fitness of 0.375 is quite large; natural selection in this case strongly favors the green phenotype.

If differences in color have a genetic basis, then we would expect evolutionary change to occur; the frequency of green toads should be substantially greater in the next generation. Further, if the fitness of two phenotypes remained unchanged, we would expect alleles for the brown phenotype eventually to disappear from the population.

### Inquiry question

? Why might the frequency of green toads not increase in the next generation, even if color differences have a genetic basis?

### Fitness may consist of many components

Although selection is often characterized as “survival of the fittest,” differences in survival are only one component of fitness.

Even if no differences in survival occur, selection may operate if some individuals are more successful than others in attracting mates. In many territorial animal species, for example, large males mate with many females, and small males rarely get to mate. Selection with respect to mating success is termed *sexual selection*; we describe this topic more fully in the discussion of behavioral biology in chapter 54.

In addition, the number of offspring produced per mating is also important. Large female frogs and fish lay more eggs than do smaller females, and thus they may leave more offspring in the next generation.

Fitness is therefore a combination of survival, mating success, and number of offspring per mating. Selection favors phenotypes with the greatest fitness, but predicting fitness from a single component can be tricky because traits favored for one component of fitness may be at a disadvantage for others. As an example, in water striders, larger females lay more eggs per day

**Figure 20.9 Body size and egg-laying in water striders.** Larger female water striders lay more eggs per day (left panel), but also survive for a shorter period of time (center panel). As a result, intermediate-sized females produce the most offspring over the course of their entire lives and thus have the highest fitness (right panel).

### Inquiry question

? What evolutionary change in body size might you expect? If the number of eggs laid per day was not affected by body size, would your prediction change?

(figure 20.9). Thus, natural selection at this stage favors large size. However, larger females also die at a younger age and thus have fewer opportunities to reproduce than smaller females. Overall, the two opposing directions of selection cancel each other out, and the intermediate-sized females leave the most offspring in the next generation.

### Learning Outcomes Review 20.4

Fitness is defined by an organism's reproductive success relative to other members of its population. This success is determined by how long it survives, how often it mates, and how many offspring it produces per mating. Relative fitness assigns numerical values to different phenotypes relative to the most fit phenotype.

- Is one of these factors always the most important in determining reproductive success? Explain.

## 20.5 Interactions Among Evolutionary Forces

### Learning Outcomes

1. Discuss how evolutionary processes can work simultaneously, but in opposing ways.
2. Evaluate what determines the evolutionary outcome when multiple processes are operating simultaneously.

The amount of genetic variation in a population may be determined by the relative strength of different evolutionary processes. Sometimes these processes act together, and in other cases they work in opposition.

### Mutation and genetic drift may counter selection

In theory, if allele  $B$  mutates to allele  $b$  at a high enough rate, allele  $b$  could be maintained in the population, even if natural selection strongly favored allele  $B$ . In nature, however, mutation rates are rarely high enough to counter the effects of natural selection.

The effect of natural selection also may be countered by genetic drift. Both of these processes may act to remove variation from a population. But selection is a nonrandom process that operates to increase the representation of alleles that enhance survival and reproductive success, whereas genetic drift is a random process in which any allele may increase. Thus, in some cases, drift may lead to a decrease in the frequency of an allele that is favored by selection. In some extreme cases, drift may even lead to the loss of a favored allele from a population.

Remember, however, that the magnitude of drift is inversely related to population size; consequently, natural selection is expected to overwhelm drift, except when populations are very small.

### Gene flow may promote or constrain evolutionary change

Gene flow can be either a constructive or a constraining force. On one hand, gene flow can spread a beneficial mutation that arises in one population to other populations. On the other hand, gene flow can impede adaptation within a population by the continual flow of inferior alleles from other populations.

Consider two populations of a species that live in different environments. In this situation, natural selection might favor different alleles— $B$  and  $b$ —in the two populations. In the absence of other evolutionary processes such as gene flow, the frequency of  $B$  would be expected to reach 100% in one population and 0% in the other. However, if gene flow occurred

between the two populations, then the less favored allele would continually be reintroduced into each population. As a result, the frequency of the alleles in the populations would reflect a balance between the rate at which gene flow brings the inferior allele into a population, and the rate at which natural selection removes it.

A classic example of gene flow opposing natural selection occurs on abandoned mine sites in Great Britain. Although mining activities ceased hundreds of years ago, the concentration of metal ions in the soil is still much greater than in surrounding areas. Large concentrations of heavy metals are generally toxic to plants, but alleles at certain genes confer the ability to grow on soils high in heavy metals. The ability to tolerate heavy metals comes at a price, however; individuals with the resistance allele exhibit lower growth rates on nonpolluted soil. Consequently, we would expect the resistance allele to occur with a frequency of 100% on mine sites and 0% elsewhere.

Heavy-metal tolerance has been studied intensively in the slender bent grass *Agrostis tenuis*, in which the resistance allele occurs at intermediate levels in many areas (figure 20.10). The explanation relates to the reproductive system of this grass, in which pollen, the floral equivalent of sperm, is dispersed by the wind. As a result, pollen grains—and the alleles they carry—can move great distances, leading to levels of gene flow between mine sites and unpolluted areas high enough to counteract the effects of natural selection.

In general, the extent to which gene flow can hinder the effects of natural selection should depend on the relative

strengths of the two processes. In species in which gene flow is generally strong, such as in birds and wind-pollinated plants, the frequency of the allele less favored by natural selection may be relatively high. In more sedentary species that exhibit low levels of gene flow, such as salamanders, the favored allele should occur at a frequency near 100%.

### Learning Outcomes Review 20.5

Allele frequencies sometimes reflect a balance between opposing processes. Gene flow, for example, may increase some alleles while natural selection decreases them. Where several processes are involved, observed frequencies depend on the relative strength of the processes.

- Under what circumstances might evolutionary processes operate in the same direction, and what would be the outcome?

## 20.6 Maintenance of Variation

### Learning Outcomes

1. Define frequency-dependent selection, oscillating selection, and heterozygote advantage.
2. Explain how these processes affect the amount of genetic variation in a population.

**Figure 20.10** Degree of copper tolerance in grass plants on and near ancient mine sites.

Individuals with tolerant alleles have decreased growth rates on unpolluted soil. Thus, we would expect copper tolerance to be 100% on mine sites and 0% on non-mine sites. However, prevailing winds blow pollen containing nontolerant alleles onto the mine site and tolerant alleles beyond the site's borders. The amount of pollen received decreases with distance, which explains the changes in levels of tolerance. The index of copper tolerance is calculated as the growth rate of a plant on soil with high concentrations of copper relative to growth rate on soils with low levels of copper; the higher the index, the more tolerant the plant is of heavy metal pollution.

### Inquiry question

Would you expect the frequency of copper tolerance to be affected by distance from the mine site?

In the previous pages, natural selection has been discussed as a process that removes variation from a population by favoring one allele over others at a gene locus. However, in some circumstances, selection can do exactly the opposite and actually maintain population variation.

### Frequency-dependent selection may favor either rare or common phenotypes

In some circumstances, the fitness of a phenotype depends on its frequency within the population, a phenomenon termed **frequency-dependent selection**. This type of selection favors certain phenotypes depending on how commonly or uncommonly they occur.

#### Negative frequency-dependent selection

In negative frequency-dependent selection, rare phenotypes are favored by selection. Assuming a genetic basis for phenotypic variation, such selection will have the effect of making rare alleles more common, thus maintaining variation.

Negative frequency-dependent selection can occur for many reasons. For example, it is well known that animals or people searching for something form a “search image.” That is, they become particularly adept at picking out certain objects. Consequently, predators may form a search image for common prey phenotypes. Rare forms may thus be preyed upon less frequently.

An example is fish predation on an insect, the water boatman, which occurs in three different colors. Experiments indicate that each of the color types is preyed upon disproportionately when it is the most common one; fish eat more of the common-colored insects than would occur by chance alone (figure 20.11).

Another cause of negative frequency dependence is resource competition. If genotypes differ in their resource requirements, as occurs in many plants, then the rarer genotype will have fewer competitors. When the different resource types are equally abundant, the rarer genotype will be at an advantage relative to the more common genotype.

### Positive frequency-dependent selection

Positive frequency-dependent selection has the opposite effect; by favoring common forms, it tends to eliminate variation from a population. For example, predators don't always select common individuals. In some cases, "oddballs" stand out from the rest and attract attention (figure 20.12).

The strength of selection should change through time as a result of frequency-dependent selection. In negative frequency-dependent selection, rare genotypes should become increasingly common, and their selective advantage will decrease correspondingly. Conversely, in positive frequency dependence, the rarer a genotype becomes, the greater the chance it will be selected against.

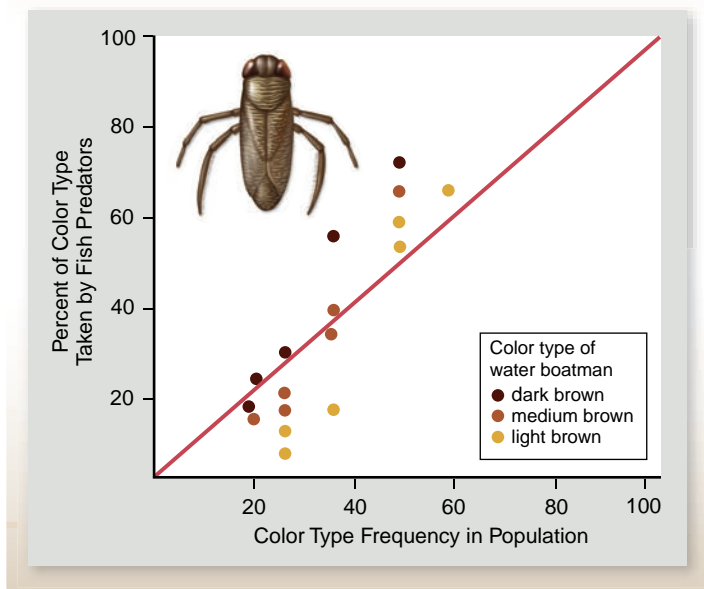

### SCIENTIFIC THINKING

**Question:** Does negative frequency-dependent selection maintain variation in a population?

**Hypothesis:** Fish may disproportionately capture water boatmen (a type of aquatic insect) with the most common color.

**Experiment:** Place predatory fish in different aquaria with the different frequencies of the color types in each aquarium.

**Result:** Fish prey disproportionately on the common color in each aquarium. The rare color in each aquarium generally survives best.

**Figure 20.11** Frequency-dependent selection.

**Figure 20.12** Positive frequency-dependent selection.

In some cases, rare individuals stand out from the rest and draw the attention of predators; thus, in these cases, common phenotypes have the advantage (positive frequency-dependent selection).

### In oscillating selection, the favored phenotype changes as the environment changes

In some cases, selection favors one phenotype at one time and another phenotype at another time, a phenomenon called **oscillating selection**. If selection repeatedly oscillates in this fashion, the effect will be to maintain genetic variation in the population.

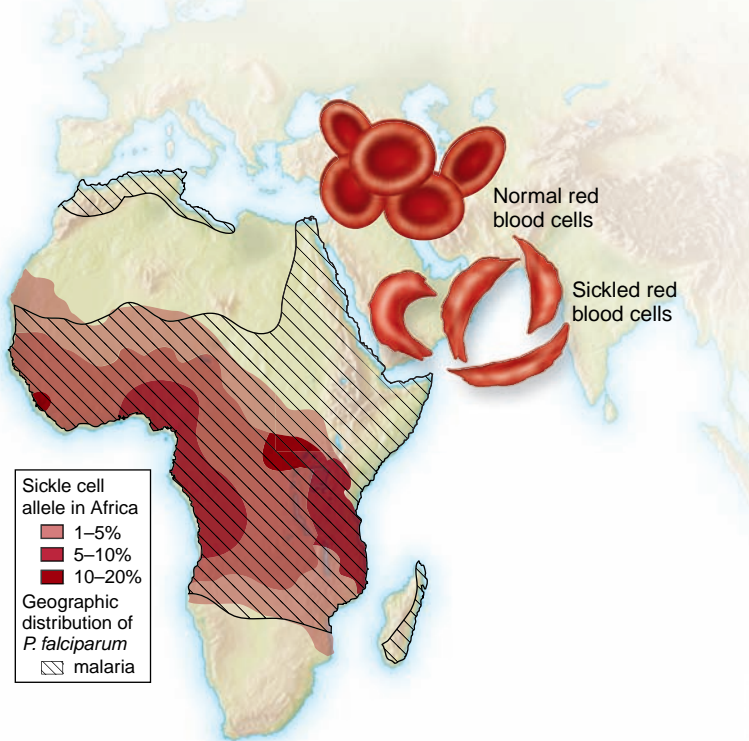

One example, discussed in chapter 21, concerns the medium ground finch of the Galápagos Islands. In times of drought, the supply of small, soft seeds is depleted, but there are still enough large seeds around. Consequently, birds with big bills are favored. However, when wet conditions return, the ensuing abundance of small seeds favors birds with smaller bills.

Oscillating selection and frequency-dependent selection are similar because in both cases the form of selection changes through time. But it is important to recognize that they are not the same: In oscillating selection, the fitness of a phenotype does not depend on its frequency; rather, environmental changes lead to the oscillation in selection. In contrast, in frequency-dependent selection, it is the change in frequencies themselves that leads to the changes in fitness of the different phenotypes.

### In some cases, heterozygotes may exhibit greater fitness than homozygotes

If heterozygotes are favored over homozygotes, then natural selection actually tends to maintain variation in the population. This **heterozygote advantage** favors individuals with copies of both alleles, and thus works to maintain both alleles in the population. Some evolutionary biologists believe that heterozygote advantage is pervasive and can explain the high levels of polymorphism observed in natural populations. Others, however, believe that it is relatively rare.

The best documented example of heterozygote advantage is sickle cell anemia, a hereditary disease affecting hemoglobin in humans. Individuals with sickle cell anemia exhibit symptoms of severe anemia and abnormal red blood cells that are irregular

**Figure 20.13** Frequency of sickle cell allele and distribution of *Plasmodium falciparum* malaria. The red blood cells of people homozygous for the sickle cell allele collapse into sickled shapes when the oxygen level in the blood is low. The distribution of the sickle cell allele in Africa coincides closely with that of *P. falciparum* malaria.

in shape, with a great number of long, sickle-shaped cells (figure 20.13). Chapter 13 discusses why the sickle cell mutation (*S*) causes red blood cells to sickle.

The average incidence of the *S* allele in central African populations is about 0.12, far higher than that found among African Americans. From the Hardy–Weinberg principle, you can calculate that 1 in 5 central African individuals is heterozygous at the *S* allele, and 1 in 100 is homozygous and develops the fatal form of the disorder. People who are homozygous for the sickle cell allele almost never reproduce because they usually die before they reach reproductive age.

Why, then, is the *S* allele not eliminated from the central African population by selection rather than being maintained at such high levels? As it turns out, one of the leading causes of illness and death in central Africa, especially among young children, is malaria. People who are heterozygous for the sickle cell allele (and thus do not suffer from sickle cell anemia) are much less susceptible to malaria. The reason is that when the parasite that causes malaria, *Plasmodium falciparum*, enters a red blood cell, it causes extremely low oxygen tension in the cell, which leads to sickling in cells of individuals either homozygous or heterozygous for the sickle cell allele (but not in individuals that do not have the sickle cell allele). Such cells are quickly filtered out of the bloodstream by the spleen, thus eliminating the parasite. (The spleen’s filtering effect is what leads to anemia in persons homozygous for the sickle cell allele because large numbers of red blood cells become sickle-shaped and are removed; in the case of heterozygotes, only those cells containing the *Plasmodium* parasite sickle, whereas the remaining cells are not affected, and thus anemia does not occur.)

Consequently, even though most homozygous recessive individuals die at a young age, the sickle cell allele is maintained at high levels in these populations because it is associated with resistance to malaria in heterozygotes and also, for reasons not yet fully understood, with increased fertility in female heterozygotes. Figure 20.13 shows the overlap between regions where sickle cell anemia is found and where malaria is prevalent.

For people living in areas where malaria is common, having the sickle cell allele in the heterozygous condition has adaptive value (see figure 20.13). Among African Americans, however, many of whose ancestors have lived for many generations in a country where malaria is now essentially absent, the environment does not place a premium on resistance to malaria. Consequently, no adaptive value counterbalances the ill effects of the disease; in this nonmalarial environment, selection is acting to eliminate the *S* allele. Only 1 in 375 African Americans develops sickle cell anemia, far fewer than in central Africa.

### Learning Outcomes Review 20.6

Selection can maintain variation within populations in a number of ways. Negative frequency-dependent selection tends to favor rare phenotypes. Oscillating selection favors different phenotypes at different times. In some cases, heterozygotes have a selective advantage that may act to retain deleterious alleles.

- How would genetic variation in a population change if heterozygotes had the lowest fitness?

## 20.7 Selection Acting on Traits Affected by Multiple Genes

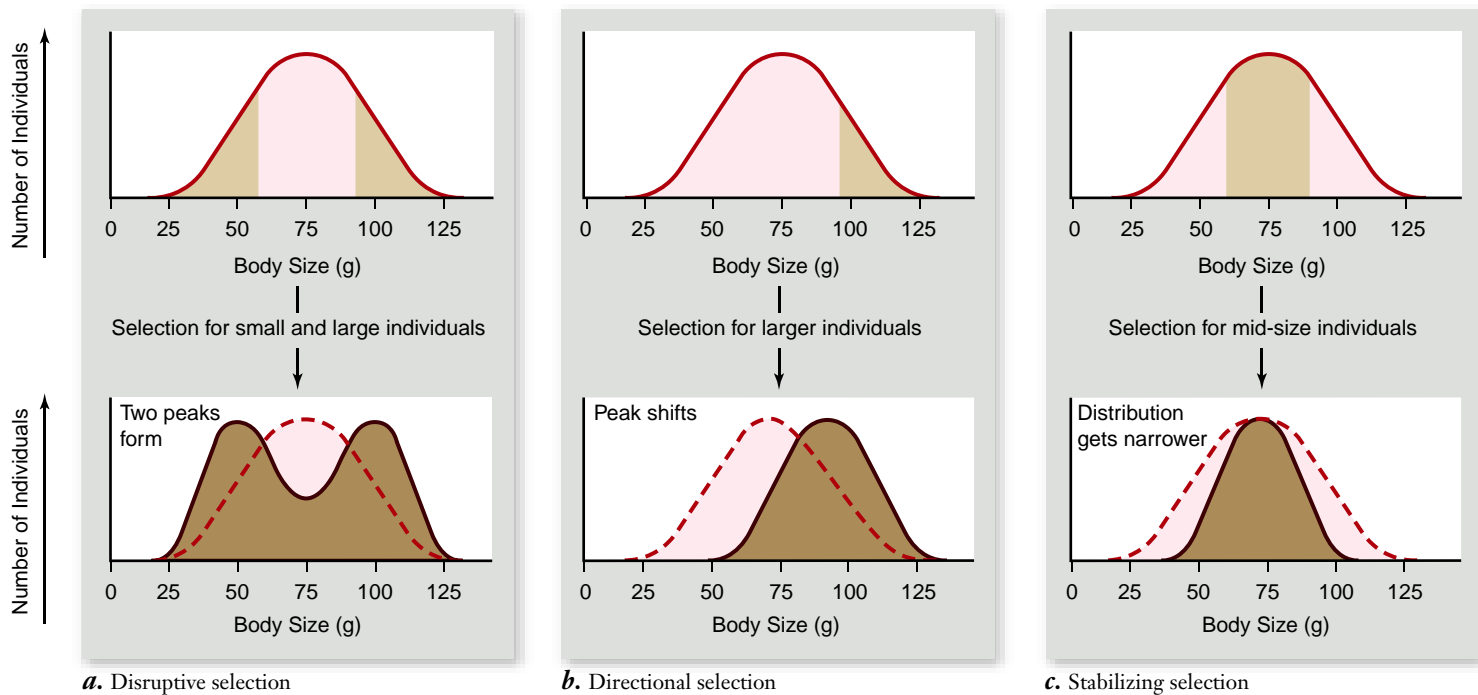

### Learning Outcomes

1. Define and contrast disruptive, stabilizing, and directional selection.
2. Explain the evolutionary outcome of each of these types of selection.

In nature, many traits—perhaps most—are affected by more than one gene. The interactions between genes are typically complex, as you saw in chapter 12. For example, alleles of many different genes play a role in determining human height (see figure 12.11). In such cases, selection operates on all the genes, influencing most strongly those that make the greatest contribution to the phenotype. How selection changes the population depends on which genotypes are favored.

### Disruptive selection removes intermediates

In some situations, selection acts to eliminate intermediate types, a phenomenon called **disruptive selection** (figure 20.14*a*). A clear example is the different beak sizes of the African black-bellied

**Figure 20.14 Three kinds of selection.** The top panels show the populations before selection has occurred (under the solid red line). Within the population, those favored by selection are shown in light brown. The bottom panels indicate what the populations would look like in the next generation. The dashed red lines are the distribution of the original population and the solid, dark brown lines are the true distribution of the population in the next generation. *a.* In disruptive selection, individuals in the middle of the range of phenotypes of a certain trait are selected against, and the extreme forms of the trait are favored. *b.* In directional selection, individuals concentrated toward one extreme of the array of phenotypes are favored. *c.* In stabilizing selection, individuals with midrange phenotypes are favored, with selection acting against both ends of the range of phenotypes.

seedcracker finch *Pyrenestes ostrinus* (figure 20.15). Populations of these birds contain individuals with large and small beaks, but very few individuals with intermediate-sized beaks.

As their name implies, these birds feed on seeds, and the available seeds fall into two size categories: large and small. Only large-beaked birds can open the tough shells of large seeds, whereas birds with the smaller beaks are more adept at handling small seeds. Birds with intermediate-sized beaks are at a disadvantage with both seed types—they are unable to open large seeds and too clumsy to efficiently process small seeds. Consequently, selection acts to eliminate the intermediate phenotypes, in effect partitioning (or “disrupting”) the population into two phenotypically distinct groups.

### Directional selection eliminates phenotypes on one end of a range

When selection acts to eliminate one extreme from an array of phenotypes, the genes promoting this extreme become less frequent in the population and may eventually disappear. This form of selection is called **directional selection** (see figure 20.14*b*). Thus, in the *Drosophila* population illustrated in figure 20.16, eliminating flies that move toward light causes the population over time to contain fewer individuals with alleles promoting such behavior. If you were to pick an individual at random from a later generation of flies, there is a smaller chance that the fly

### SCIENTIFIC THINKING

**Question:** Does disruptive selection promote differences in beak size in the African Black-bellied Seedcracker Finches (*Pyrenestes ostrinus*)?

**Field Study:** Capture, measure, and release birds in a population. Follow the birds through time to determine how long each lives.

**Result:** Large- and small-beaked birds have higher survival rates than birds with intermediate-sized beaks.

**Interpretation:** What would happen if the distribution of seed size and hardness in the environment changed?

**Figure 20.15 Disruptive selection for large and small beaks.** Differences in beak size in the black-bellied seedcracker finch of west Africa are the result of disruptive selection.

would spontaneously move toward light than if you had selected a fly from the original population. Artificial selection has changed the population in the direction of being less attracted to light. Directional selection often occurs in nature when the environment changes; one example is the widespread evolution of pesticide resistance discussed earlier in this chapter.

### Stabilizing selection favors individuals with intermediate phenotypes

When selection acts to eliminate both extremes from an array of phenotypes, the result is to increase the frequency of the already common intermediate type. This form of selection is called **stabilizing selection** (see figure 20.14c). In effect, selection is operating to prevent change away from this middle range of values. Selection does not change the most common phenotype of the population, but rather makes it even more common by eliminating extremes. Many examples are known. In humans, infants with intermediate weight at birth have the highest survival rate (figure 20.17). In ducks and chickens, eggs of intermediate weight have the highest hatching success.

#### Learning Outcomes Review 20.7

In disruptive selection, intermediate forms of a trait diminish; in stabilizing selection, intermediates increase, whereas in disruptive selection they decrease. Directional selection shifts frequencies toward one end or the other and may eventually eliminate alleles entirely.

- How does directional selection differ from frequency-dependent selection?

**Figure 20.16** Directional selection for negative phototropism in *Drosophila*. Flies that moved toward light were discarded, and only flies that moved away from light were used as parents for the next generation. This procedure was repeated for 20 generations, producing substantial evolutionary change.

#### Inquiry question

- ? What would happen if after 20 generations, experimenters started keeping flies that moved toward the light and discarded the others?

**Figure 20.17** Stabilizing selection for birth weight in humans. The death rate among babies (red curve; right y-axis) is lowest at an intermediate birth weight; both smaller and larger babies have a greater tendency to die than those around the most frequent weight (tan area; left y-axis) of between 7 and 8 pounds. Recent medical advances have reduced mortality rates for small and large babies.

#### Inquiry question

- ? As improved medical technology leads to decreased infant mortality rates, how would you expect the distribution of birth weights in the population to change?

## 20.8 Experimental Studies of Natural Selection

#### Learning Outcome

1. Explain how experiments can be used to test evolutionary hypotheses.

To study evolution, biologists have traditionally investigated what has happened in the past, sometimes many millions of years ago. To learn about dinosaurs, a paleontologist looks at dinosaur fossils. To study human evolution, an anthropologist looks at human fossils and, increasingly, examines the “family tree” of mutations that have accumulated in human DNA over millions of years. In this traditional approach, evolutionary biology is similar to astronomy and history, relying on observation rather than experimentation to examine ideas about past events.

Nonetheless, evolutionary biology is not entirely an observational science. Darwin was right about many things, but one area in which he was mistaken concerns the pace at which evolution occurs. Darwin thought that evolution occurred at a very slow, almost imperceptible pace. But in recent years many case studies have demonstrated that in some circumstances, evolutionary change can occur rapidly. Consequently, experimental studies can be devised to test evolutionary hypotheses.

Although laboratory studies on fruit flies and other organisms have been common for more than 50 years, scientists have only recently started conducting experimental studies of evolution in nature. One excellent example of how observations of the natural world can be combined with rigorous experiments in the lab and in the field concerns research on the guppy, *Poecilia reticulata*.

## Guppy color variation in different environments suggests natural selection at work

The guppy is a popular aquarium fish because of its bright coloration and prolific reproduction. In nature, guppies are found in small streams in northeastern South America and in many mountain streams on the nearby island of Trinidad. One interesting feature of several of the streams is that they have waterfalls. Amazingly, guppies and some other fish are capable of colonizing portions of the stream above the waterfall.

The killifish is a particularly good colonizer; apparently on rainy nights, it will wriggle out of the stream and move through the damp leaf litter. Guppies are not so proficient, but they are good at swimming upstream. During flood seasons, rivers sometimes overflow their banks, creating secondary channels that move through the forest. On these occasions, guppies may be able to swim upstream in the secondary channels and invade the pools above waterfalls.

By contrast, some species are not capable of such dispersal and thus are only found in streams below the first waterfall. One species whose distribution is restricted by waterfalls is the pike cichlid a voracious predator that feeds on other fish, including guppies.

Because of these barriers to dispersal, guppies can be found in two very different environments. In pools just below the waterfalls, predation by the pike cichlid is a substantial risk, and rates of survival are relatively low. But in similar pools just above the waterfall, the only predator present is the killifish, which rarely preys on guppies.

Guppy populations above and below waterfalls exhibit many differences. In the high-predation pools, guppies exhibit drab coloration. Moreover, they tend to reproduce at a younger age and attain relatively smaller adult sizes. Male fish above the waterfall, in contrast, are colorful (figure 20.18), mature later, and grow to larger sizes.

These differences suggest the operation of natural selection. In the low-predation environment, males display gaudy colors and spots that they use to court females. Moreover, larger males are most successful at holding territories and mating with females, and larger females lay more eggs. Thus, in the absence of predators, larger and more colorful fish may have produced more offspring, leading to the evolution of those traits.

In pools below the waterfall, natural selection would favor different traits. Colorful males are likely to attract the attention of the pike cichlid, and high predation rates mean that most fish live short lives. Individuals that are more drab and shunt energy into early reproduction, rather than growth to a larger size, are therefore likely to be favored by natural selection.

## Experimentation reveals the agent of selection

Although the differences between guppies living above and below the waterfalls suggest evolutionary responses to differences in the strength of predation, alternative explanations are possible. Perhaps, for example, only very large fish are capable of crawling past the waterfall to colonize pools. If this were the case, then a founder effect would occur in which the new population was established solely by individuals with genes for large size. The only way to rule out such alternative possibilities is to conduct a controlled experiment.

### The laboratory experiment

The first experiments were conducted in large pools in laboratory greenhouses. At the start of the experiment, a group of

**Figure 20.18** The evolution of protective coloration in guppies. In pools below waterfalls where predation is high, male guppies are drab in color. In the absence of the highly predatory pike cichlid (*Crenicichla alta*) in pools above waterfalls, male guppies are much more colorful and attractive to females. The killifish is also a predator, but it only rarely eats guppies. The evolution of these differences in guppies can be experimentally tested.

2000 guppies was divided equally among 10 large pools. Six months later, pike cichlids were added to four of the pools and killifish to another four, with the remaining two pools left to serve as “no-predation” controls.

Fourteen months later (which corresponds to 10 guppy generations), the scientists compared the populations. The guppies in the killifish and control pools were indistinguishable—brightly colored and large. In contrast, the guppies in the pike cichlid pools were smaller and drab in coloration (figure 20.19).

These results established that predation can lead to rapid evolutionary change, but do these laboratory experiments reflect what occurs in nature?

### SCIENTIFIC THINKING

**Question:** Does the presence of predators affect the evolution of guppy color?

**Hypothesis:** Predation on the most colorful individuals will cause a population to become increasingly dull through time. Conversely, in populations with few or no predators, increased color will evolve.

**Experiment:** Establish laboratory populations of guppies in large pools with or without predators.

**Result:** The populations with predators evolved to have fewer spots, while the populations in pools without predators evolved more spots.

**Interpretation:** Why does color increase in the absence of predators? How would you test your hypothesis?

### Figure 20.19 Evolutionary change in spot number.

Guppy populations raised for 10 generations in low-predation or no-predation environments in laboratory greenhouses evolved a greater number of spots, whereas selection in more dangerous environments, such as the pools with the highly predatory pike cichlid, led to less conspicuous fish. The same results are seen in field experiments conducted in pools above and below waterfalls.

### Inquiry question

? How do these results depend on the manner by which the guppy predators locate their prey?

### The field experiment

To find out whether the laboratory results were an accurate reflection of natural processes, the scientists located two streams that had guppies in pools below a waterfall, but not above it. As in other Trinidadian streams, the pike cichlid was present in the lower pools, but only the killifish was found above the waterfalls.

The scientists then transplanted guppies to the upper pools and returned at several-year intervals to monitor the populations. Despite originating from populations in which predation levels were high, the transplanted populations rapidly evolved the traits characteristic of low-predation guppies: they matured late, attained greater size, and had brighter colors. The control populations in the lower pools, by contrast, continued to be drab and to mature early and at a smaller size. Laboratory analysis confirmed that the variations between the populations were the result of genetic differences.

These results demonstrate that substantial evolutionary change can occur in less than 12 years. More generally, these studies indicate how scientists can formulate hypotheses about how evolution occurs and then test these hypotheses in natural conditions. The results give strong support to the theory of evolution by natural selection.

### Learning Outcome Review 20.8

Although much of evolutionary theory is derived from observation, experiments are sometimes possible in natural settings. Studies have revealed that traits can shift in populations in a relatively short time. The data obtained from evolutionary experiments can be used to refine theoretical assumptions.

- What experiments could you design to test other examples of natural selection, such as the evolution of pesticide resistance or background color matching?

## 20.9 The Limits of Selection

### Learning Outcomes

1. Define pleiotropy and epistasis.
2. Explain how these phenomena may affect the evolutionary response to selective pressure.

Although selection is the most powerful of the principal agents of genetic change, there are limits to what it can accomplish. These limits result from multiple phenotypic effects of alleles, lack of genetic variation upon which selection can act, and interactions between genes.

### Genes have multiple effects

Alleles often affect multiple aspects of a phenotype (the phenomenon of *pleiotropy*; see chapter 12). These multiple effects tend to set limits on how much a phenotype can be altered.

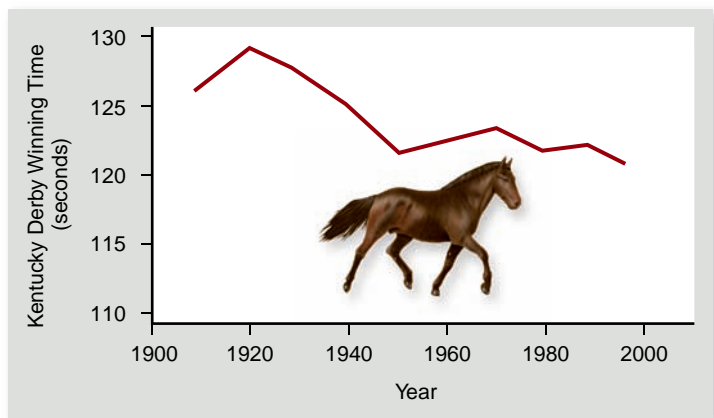

For example, selecting for large clutch size in chickens eventually leads to eggs with thinner shells that break more easily. For this reason, we could never produce chickens that lay eggs twice as large as the best layers do now. Likewise, we cannot produce gigantic cattle that yield twice as much meat as our leading breeds, or corn with an ear at the base of every leaf, instead of just at the bases of a few leaves.

## Evolution requires genetic variation

Over 80% of the gene pool of the thoroughbred horses racing today goes back to 31 ancestors from the late eighteenth century. Despite intense directional selection on thoroughbreds, their performance times have not improved for more than 50 years (figure 20.20). Decades of intense selection presumably have removed variation from the population at a rate greater than mutation can replenish it, such that little genetic variation now remains, and evolutionary change is not possible.

In some cases, phenotypic variation for a trait may never have had a genetic basis. The compound eyes of insects are made up of hundreds of visual units, termed ommatidia (described in chapter 34). In some individuals, the left eye contains more ommatidia than the right. In other individuals, the right eye contains more than the left (figure 20.21). However, despite intense selection experiments in the laboratory, scientists have never been able to produce a line of fruit flies that consistently has more ommatidia in the left eye than in the right.

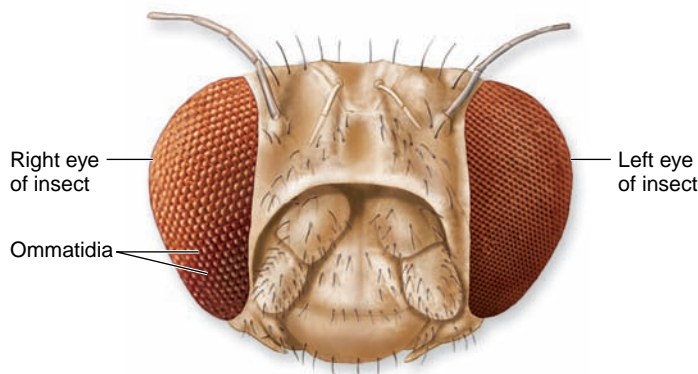

The reason is that separate genes do not exist for the left and right eyes. Rather, the same genes affect both eyes, and differences in the number of ommatidia result from differences

**Figure 20.20** Selection for increased speed in racehorses is no longer effective. Kentucky Derby winning speeds have not improved significantly since 1950.

### Inquiry question

? What might explain the lack of change in winning speeds?

**Figure 20.21** Phenotypic variation in insect ommatidia.

In some individuals, the number of ommatidia in the left eye is greater than the number in the right.

that occur as the eyes are formed in the development process. Thus, despite the existence of phenotypic variation, no underlying genetic variation is available for selection to favor.

## Gene interactions affect fitness of alleles

As discussed in chapter 12, *epistasis* is the phenomenon in which an allele for one gene may have different effects, depending on alleles present at other genes. Because of epistasis, the selective advantage of an allele at one gene may vary from one genotype to another. If a population is polymorphic for a second gene, then selection on the first gene may be constrained because different alleles are favored in different individuals of the same population.

Studies on bacteria illustrate how selection on alleles for one gene can depend on which alleles are present at other genes. In *E. coli*, two biochemical pathways exist to break down gluconate, each using enzymes produced by different genes. One gene produces the enzyme 6-PGD, for which there are several alleles. When the common allele for the second gene, which codes for the other biochemical pathway, is present, selection does not favor one allele over another at the 6-PGD gene. In some *E. coli*, however, an alternative allele at the second gene occurs that is not functional. The bacteria with this alternative allele are forced to rely only on the 6-PGD pathway, and in this case, selection favors one 6-PGD allele over another. Thus, epistatic interactions exist between the two genes, and the outcome of natural selection on the 6-PGD gene depends on which alleles are present at the second gene.

### Learning Outcomes Review 20.9

In pleiotropy, a single gene affects multiple traits; in epistasis, interaction between alleles of different genes affects a single trait. Both these conditions can constrain the effects of natural selection.

- How can epistasis and pleiotropy constrain the evolutionary response to natural selection?

## Chapter Review

### 20.1 Genetic Variation and Evolution

*Many processes can lead to evolutionary change.*

Darwin proposed that evolution of species occurs by the process of natural selection. Other processes can also lead to evolutionary change.

*Populations contain ample genetic variation.*

For a population to be able to evolve, it must contain genetic variation. DNA testing shows that natural populations generally have substantial variation.

### 20.2 Changes in Allele Frequency (figure 20.3)

*The Hardy–Weinberg principle allows prediction of genotype frequencies.*

Hardy–Weinberg equilibrium exists when observed genotype frequencies match the prediction from calculated frequencies. It occurs only when evolutionary processes are not acting to shift the distribution of alleles or genotypes in the population.

*Hardy–Weinberg predictions can be applied to data to find evidence of evolutionary processes.*

If genotype frequencies are not in Hardy–Weinberg equilibrium, then evolutionary processes must be at work.

### 20.3 Five Agents of Evolutionary Change (figure 20.4)

*Mutation changes alleles.*

Mutations are the ultimate source of genetic variation. Because mutation rates are low, mutation usually is not responsible for deviations from Hardy–Weinberg equilibrium.

*Gene flow occurs when alleles move between populations.*

Gene flow is the migration of new alleles into a population. It can introduce genetic variation and can homogenize allele frequencies between populations.

*Nonrandom mating shifts genotype frequencies.*

Assortative mating, in which similar individuals tend to mate, increases homozygosity; disassortative mating increases the frequency of heterozygotes.

*Genetic drift may alter allele frequencies in small populations.*

Genetic drift refers to random shifts in allele frequency. Its effects may be severe in small populations.

*Selection favors some genotypes over others.*

For natural selection to occur, genetic variation must exist, it must result in differential reproductive success, and it must be inheritable.

### 20.4 Fitness and Its Measurement

*A phenotype with greater fitness usually increases in frequency.*

Fitness is defined as the reproductive success of an individual. Relative fitness refers to the success of one genotype relative to others in a population. Usually, the genotype with highest relative fitness increases in frequency in the next generation.

*Fitness may consist of many components.*

Reproductive success is determined by how long an individual survives, how often it mates, and how many offspring it has per reproductive event.

### 20.5 Interactions Among Evolutionary Forces

*Mutation and genetic drift may counter selection.*

In theory, a high rate of mutation could oppose natural selection, but this rarely happens. Genetic drift also can work counter to natural selection.

*Gene flow may promote or constrain evolutionary change.*

Gene flow can spread a beneficial mutation to other populations, but it can also impede adaptation due to influx of alleles with low fitness in a population's environment.

### 20.6 Maintenance of Variation

*Frequency-dependent selection may favor either rare or common phenotypes.*

Negative frequency-dependent selection favors rare phenotypes and maintains variation within a population. Positive frequency-dependent selection favors the common phenotype and leads to decreased variation.

*In oscillating selection, the favored phenotype changes as the environment changes.*

If environmental change is cyclical, selection would favor first one phenotype, then another, maintaining variation.

*In some cases, heterozygotes may exhibit greater fitness than homozygotes.*

Heterozygote advantage favors individuals with both alleles.

### 20.7 Selection Acting on Traits Affected by Multiple Genes (figure 20.13)

*Disruptive selection removes intermediates.*

When intermediate phenotypes are at a disadvantage, a population may exhibit a bimodal trait distribution.

*Directional selection eliminates phenotypes at one end of a range.*

Directional selection tends to shift the mean value of the population toward the favored end of the distribution.

*Stabilizing selection favors individuals with intermediate phenotypes.*

Stabilizing selection eliminates both extremes and increases the frequency of an intermediate type. The population may have the same mean value, but with decreased variation.

### 20.8 Experimental Studies of Natural Selection

*The hypothesis that natural selection leads to evolutionary change can be tested experimentally.*

*Guppy color variation in different environments suggests natural selection at work.*

*Experimentation reveals the agent of selection.*

Guppies in natural populations subject to different predators were shown to undergo color change over generations.

### 20.9 The Limits of Selection

*Genes have multiple effects.*

Pleiotropic genes, which have multiple effects, set limits on how much a phenotype can be altered. Even if one affected trait is favored, other affected traits may not be.

*Evolution requires genetic variation.*

Intense selection pressure may remove genetic variation.

*Gene interactions affect fitness of alleles.*

In epistasis, fitness of one allele may vary depending on the genotype of a second gene.

## Review Questions

### UNDERSTAND

- Assortative mating
  - affects genotype frequencies expected under Hardy–Weinberg equilibrium.
  - affects allele frequencies expected under Hardy–Weinberg equilibrium.
  - has no effect on the genotypic frequencies expected under Hardy–Weinberg equilibrium because it does not affect the relative proportion of alleles in a population.
  - increases the frequency of heterozygous individuals above Hardy–Weinberg expectations.
- When the environment changes from year to year and different phenotypes have different fitness in different environments
  - natural selection will operate in a frequency-dependent manner.
  - the effect of natural selection may oscillate from year to year, favoring alternative phenotypes in different years.
  - genetic variation is not required to get evolutionary change by natural selection.
  - none of the above.
- Many factors can limit the ability of natural selection to cause evolutionary change, including
  - a conflict between reproduction and survival as seen in Trinidadian guppies.
  - lack of genetic variation.
  - pleiotropy.
  - all of the above.
- Stabilizing selection differs from directional selection because
  - in the former, phenotypic variation is reduced but the average phenotype stays the same, whereas in the latter both the variation and the mean phenotype change.
  - the former requires genetic variation, but the latter does not.
  - intermediate phenotypes are favored in directional selection.
  - none of the above.
- Founder effects and bottlenecks are
  - expected only in large populations.
  - mechanisms that increase genetic variation in a population.
  - two different modes of natural selection.
  - forms of genetic drift.
- Relative fitness*
  - refers to the survival rate of one phenotype compared to that of another.
  - is the physical condition of an individual's siblings and cousins.
  - refers to the reproductive success of a phenotype.
  - is none of the above.
- For natural selection to result in evolutionary change
  - variation must exist in a population.
  - reproductive success of different phenotypes must differ.
  - variation must be inherited from one generation to the next.
  - all of the above.

### APPLY

- In a population of red (dominant allele) or white flowers in Hardy–Weinberg equilibrium, the frequency of red flowers is 91%. What is the frequency of the red allele?
 

a. 9%	c. 91%
b. 30%	d. 70%

- Genetic drift and natural selection can both lead to rapid rates of evolution. However,
  - genetic drift works fastest in large populations.
  - only drift leads to adaptation.
  - natural selection requires genetic drift to produce new variation in populations.
  - both processes of evolution can be slowed by gene flow.
- What would happen to average birth weight if over the next several years advances in medical technology reduced infant mortality rates of large babies to equal that for intermediate-sized babies (see the following figure, red line). Assume that differences in birth weight have a genetic basis.
  - Over time, average birth weight would only increase.
  - Over time, average birth weight would only decrease.
  - Both a and b.
  - None of the above.

### SYNTHESIZE

- In Trinidadian guppies a combination of elegant laboratory and field experiments builds a very compelling case for predator-induced evolutionary changes in color and life history traits. It is still possible, though not likely, that there are other differences between the sites above and below the falls aside from whether predators are present. What additional studies could strengthen the interpretation of the results?
- On large, black lava flows in the deserts of the southwestern United States, populations of many types of animals are composed primarily of black individuals. By contrast, on small lava flows, populations often have a relatively high proportion of light-colored individuals. How can you explain this difference?
- Based on a consideration of how strong artificial selection has helped eliminate genetic variation for speed in thoroughbred horses, we are left with the question of why, for many traits like speed (continuous traits), there is usually abundant genetic variation. This is true even for traits we know are under strong selection. Where does genetic variation ultimately come from, and how does the rate of production compare with the strength of natural selection? What other mechanisms can maintain and increase genetic variation in natural populations?

- 21.6** Convergent Evolution and the Biogeographical Record
- 21.7** Darwin's Critics

## Introduction

As we discussed in chapter 1, when Darwin proposed his revolutionary theory of evolution by natural selection, little actual evidence existed to bolster his case. Instead, Darwin relied on observations of the natural world, logic, and results obtained by breeders working with domestic animals. Since his day, however, the evidence for Darwin's theory has become overwhelming.

The case is built upon two pillars: first, evidence that natural selection can produce evolutionary change, and second, evidence from the fossil record that evolution has occurred. In addition, information from many different areas of biology—fields as different as anatomy, molecular biology, and biogeography—is only interpretable scientifically as being the outcome of evolution.

## The Beaks of Darwin's Finches: Evidence of Natural Selection

### Learning Outcomes

1. Describe how the species of Darwin's finches have adapted to feed in different ways.
2. Explain how climatic variation drives evolutionary change in the medium ground finch.

As you learned in the preceding chapter, a variety of processes can produce evolutionary change. Most evolutionary biologists, however, agree with Darwin's thinking that natural selection is the primary process responsible for evolution. Although we cannot travel back through time, modern-day evidence allows us to test hypotheses about how evolution proceeds and confirms the power of natural selection as an agent of evolutionary change. This evidence comes from both the field and the laboratory and from both natural and human-altered situations.

Darwin's finches are a classic example of evolution by natural selection. When he visited the Galápagos Islands off the coast of Ecuador in 1835, Darwin collected 31 specimens of finches from three islands. Darwin, not an expert on birds, had trouble identifying the specimens, believing by examining their bills that his collection contained wrens, "gross-beaks," and blackbirds.

Upon Darwin's return to England, ornithologist John Gould informed Darwin that his collection was in fact a closely related group of distinct species, all similar to one another except for their bills. In all, 14 species are now recognized.

### Galápagos finches exhibit variation related to food gathering

The diversity of Darwin's finches is illustrated in figure 21.1. The ground finches feed on seeds that they crush in their powerful beaks; species with smaller and narrower bills such as the warbler finch eat insects. Other species include fruit and bud eaters, and species that feed on cactus fruits and the insects they attract; some populations of the sharp-beaked ground finch even include "vampires" that sometimes creep up on seabirds and use their sharp beaks to pierce the seabirds' skin and drink their blood. Perhaps most remarkable are the tool users, woodpecker finches that pick up a twig, cactus spine, or leaf stalk, trim it into shape with their bills, and then poke it into dead branches to pry out grubs.

The correspondence between the beaks of the finch species and their food source suggested to Darwin that natural selection had shaped them. In *The Voyage of the Beagle*, Darwin wrote, "Seeing this gradation and diversity of structure in one small, intimately related group of birds, one might really fancy that from an original paucity of birds in this archipelago, one species has been taken and modified for different ends."

Woodpecker finch (*Cactospiza pallida*)

Large ground finch (*Geospiza magnirostris*)

Cactus finch (*Geospiza scandens*)

Warbler finch (*Certhidea olivacea*)

Vegetarian tree finch (*Platyspiza crassirostris*)

**Figure 21.1 Darwin's finches.** These species show differences in bills and feeding habits among Darwin's finches. This diversity arose when an ancestral finch colonized the islands and diversified into habitats lacking other types of small birds. The bills of several species resemble those of different families of birds on the mainland. For example, the warbler finch has a beak very similar to warblers, to which it is not closely related.

## Modern research has verified Darwin's selection hypothesis

Darwin's observations suggest that differences among species in beak size and shape have evolved as the species adapted to use different food resources, but can this hypothesis be tested? In chapter 20, you read that the theory of evolution by natural selection requires that three conditions be met:

1. Variation must exist in the population.
2. This variation must lead to differences among individuals in lifetime reproductive success.
3. Variation among individuals must be genetically transmissible to the next generation.

The key to successfully testing Darwin's proposal proved to be patience. For more than 30 years, starting in 1973, Peter and Rosemary Grant of Princeton University and their students have studied the medium ground finch, *Geospiza fortis*, on a tiny island in the center of the Galápagos called Daphne Major. These finches feed preferentially on small, tender seeds, produced in abundance by plants in wet years. The birds resort to larger, drier seeds, which are harder to crush, only when small seeds become depleted during long periods of dry weather, when plants produce few seeds.

The Grants quantified beak shape among the medium ground finches of Daphne Major by carefully measuring beak depth (height of beak, from top to bottom, at its base) on individual birds. Measuring many birds every year, they were able to assemble for the first time a detailed portrait of evolution in action. The Grants found that not only did a great deal of

variation in beak depth exist among members of the population, but the average beak depth changed from one year to the next in a predictable fashion.

During droughts, plants produced few seeds, and all available small seeds were quickly eaten, leaving large seeds as the major remaining source of food. As a result, birds with deeper, more powerful beaks survived better, because they were better able to break open these large seeds. Consequently, the average beak depth of birds in the population increased the next year. Then, when normal rains returned, average beak depth of the population decreased to its original size (figure 21.2a).

Conversely, in particularly wet years, plants flourished, producing an abundance of small seeds; as a result, small-beaked birds were favored, and beak depth decreased greatly.

Could these changes in beak dimension reflect the action of natural selection? An alternative possibility might be that the changes in beak depth do not reflect changes in gene frequencies, but rather are simply a response to diet—for example, perhaps crushing large seeds causes a growing bird to develop a larger beak.

To rule out this possibility, the Grants measured the relation of parent beak size to offspring beak size, examining many broods over several years. The depth of the beak was very similar between parents and offspring regardless of environmental conditions (figure 21.2b), suggesting that the differences among individuals in beak size reflect genetic differences, and therefore that the year-to-year changes in average beak depth represent evolutionary change resulting from natural selection.

a.

b.

**Figure 21.2** Evidence that natural selection alters beak shape in the medium ground finch (*Geospiza fortis*). *a.* In dry years, when only large, tough seeds are available, the mean beak depth increases. In wet years, when many small seeds are available, mean beak depth decreases. *b.* Beak depth is inherited from parents to offspring.

### Inquiry question

? Suppose a bird with a large bill mates with a bird with a small bill. Would the bills of the pair's offspring tend to be larger or smaller than the bills of offspring from a pair of birds with medium-sized bills?

## Learning Outcomes Review 21.1

Among Darwin's finches, natural selection has been responsible for changes in the shape of the beak corresponding to characteristics of the available food supply. Because beak morphology is a transmissible trait, a beak better suited to the distribution of available seed types would become more common in subsequent generations.

- Suppose that the act of eating hard seeds caused birds to develop bigger beaks. Would this lead to an evolutionary increase in beak size after a drought?

## 21.2 Peppered Moths and Industrial Melanism: More Evidence of Selection

### Learning Outcomes

1. Explain the relationship between pollution and color evolution in peppered moths.
2. Distinguish between demonstrating that evolution has occurred and understanding the mechanism that caused it.

When the environment changes, natural selection often may favor different traits in a species. One classic example concerns the peppered moth, *Biston betularia*. Adults come in a range of shades, from light gray with black speckling (hence the name “peppered” moth) to jet black (melanic).

Extensive genetic analysis has shown that the moth's body color is a genetic trait that reflects different alleles of a single gene. Black individuals have a dominant allele, one that was present but very rare in populations before 1850. From that time on, dark individuals increased in frequency in moth populations near industrialized centers until they made up almost 100% of these populations.

**Figure 21.3** Tutt's hypothesis explaining industrial melanism. These photographs show preserved specimens of the peppered moth (*Biston betularia*) placed on trees. Tutt proposed that the dark melanic variant of the moth is more visible to predators on unpolluted trees (left), while the light “peppered” moth is more visible to predators on bark blackened by industrial pollution (right).

Biologists soon noticed that in industrialized regions where the dark moths were common, the tree trunks were darkened almost black by the soot of pollution, which also killed many of the light-colored lichens on tree trunks.

### Light-colored moths decreased in polluted areas

Why did dark moths gain a survival advantage around 1850? In 1896, an amateur moth collector named J. W. Tutt proposed what became the most commonly accepted hypothesis explaining the decline of the light-colored moths. He suggested that peppered forms were more visible to predators on sooty trees that have lost their lichens. Consequently, birds ate the peppered moths resting on the trunks of trees during the day. The black forms, in contrast, had an advantage because they were camouflaged (figure 21.3).

Although Tutt initially had no evidence, British ecologist Bernard Kettlewell tested the hypothesis in the 1950s by releasing equal numbers of dark and light individuals into two sets of woods: one near heavily polluted Birmingham, and the other in unpolluted Dorset. Kettlewell then set up lights in the woods to attract moths to traps to see how many of both kinds of moths survived. To evaluate his results, he had marked the released moths with a dot of paint on the underside of their wings, where birds could not see it.

In the polluted area near Birmingham, Kettlewell recaptured only 19% of the light moths, but 40% of the dark ones. This indicated that dark moths had a far better chance of surviving in these polluted woods, where tree trunks were dark. In the relatively unpolluted Dorset woods, Kettlewell recovered 12.5% of the light moths but only 6% of the dark ones. This result indicated that where the tree trunks were still light-colored, light moths had a much better chance of survival.

Kettlewell later solidified his argument by placing moths on trees and filming birds looking for food. Sometimes the birds actually passed right over a moth that was the same color as its background.

Kettlewell's finding that birds more frequently detect moths whose color does not match their background has subsequently been confirmed in eight separate field studies, with a variety of experimental designs and corrections for deficiencies

in Kettlewell's initial design. These results, combined with the recapture studies, provide strong evidence for the action of natural selection and implicate birds as the agent of selection in the case of the peppered moth.

### When environmental conditions reverse, so does selection pressure

In industrialized areas throughout Eurasia and North America, dozens of other species of moths have evolved in the same way as the peppered moth. The term **industrial melanism** refers to the phenomenon in which darker individuals come to predominate over lighter ones. In the second half of the 20th century, with the widespread implementation of pollution controls, the trend toward melanism began reversing for many species of moths throughout the northern continents.

In England, the air pollution that promoted industrial melanism began to reverse following enactment of the Clean Air Act in 1956. Beginning in 1959, the *Biston* population at Caldy Common outside Liverpool has been sampled each year. The frequency of the melanic (dark) form has dropped from a high of 93% in 1959 to a low of 15% in 1995 (figure 21.4).

The drop correlates well with a significant drop in air pollution, particularly with a lowering of the levels of sulfur dioxide and suspended particulates, both of which act to darken trees. The drop is consistent with a 15% selective disadvantage acting against moths with the dominant melanic allele.

Interestingly, the same reversal of melanism occurred in the United States. Of 576 peppered moths collected at a field station near Detroit from 1959 to 1961, 515 were melanic, a frequency of 89%. The American Clean Air Act, passed in 1963, led to significant reductions in air pollution. Resampled in 1994, the Detroit field station peppered moth population had only 15% melanic moths (see figure 21.4). The moth populations in Liverpool and Detroit, both part of the same natural experiment, exhibit strong evidence for natural selection.

### The agent of selection may be difficult to pin down

Although the evidence for natural selection in the case of the peppered moth is strong, Tutt's hypothesis about the agent of selection is currently being reevaluated. Researchers have noted that the recent selection against melanism does not appear to correlate with changes in tree lichens.

At Caldy Common, the light form of the peppered moth began to increase in frequency long before lichens began to reappear on the trees. At the Detroit field station, the lichens never changed significantly as the dark moths first became dominant and then declined over a 30-year period. In fact, investigators have not been able to find peppered moths on Detroit trees at all, whether covered with lichens or not. Some evidence suggests the moths rest on leaves in the treetops during the day, but no one is sure. Could poisoning by pollution rather than predation by birds be the agent of natural selection on the moths? Perhaps—but to date, only predation by birds is backed by experimental evidence.

Researchers supporting the bird predation hypothesis point out that a bird's ability to detect moths may depend less on

**Figure 21.4 Selection against melanism.** The red circles indicate the frequency of melanic *Biston betularia* moths at Caldy Common in England, sampled continuously from 1959 to 1995. Green diamonds indicate frequencies of melanic *B. betularia* in Michigan from 1959 to 1962 and from 1994 to 1995.

### Inquiry question

? What can you conclude from the fact that the frequency of melanic moths decreased to the same degree in the two locations?

the presence or absence of lichens, and more on other ways in which the environment is darkened by industrial pollution. Pollution tends to cover all objects in the environment with a fine layer of particulate dust, which tends to decrease how much light surfaces reflect. In addition, pollution has a particularly severe effect on birch trees, which are light in color. Both effects would tend to make the environment darker, and thus would favor darker moths by protecting them from predation by birds.

Despite this uncertainty over the agent of selection, the overall pattern is clear. Kettlewell's experiments established indisputably that selection favors dark moths in polluted habitats and light moths in pristine areas. The increase and subsequent decrease in the frequency of melanic moths, correlated with levels of pollution independently on two continents, demonstrates clearly that this selection drives evolutionary change.

The current reconsideration of the agent of natural selection illustrates well the way in which scientific progress is achieved: Hypotheses, such as Tutt's, are put forth and then tested. If rejected, new hypotheses are formulated, and the process begins anew.

### Learning Outcomes Review 21.2

Natural selection has favored the dark form of the peppered moth in areas subject to severe air pollution, perhaps because on darkened trees they are less easily seen by moth-eating birds. As pollution has abated, selection has in turn shifted to favor the light form. Although selection is clearly occurring, further research is required to understand whether predation by birds is the agent of selection.

- How would you test the idea that predation by birds is the agent of selection on moth coloration?

## 21.3 Artificial Selection: Human-Initiated Change

### Learning Outcomes

1. Contrast the processes of artificial and natural selection.
2. Explain what artificial selection demonstrates about the power of natural selection.

Humans have imposed selection upon plants and animals since the dawn of civilization. Just as in natural selection, artificial selection operates by favoring individuals with certain phenotypic traits, allowing them to reproduce and pass their genes on to the next generation. Assuming that phenotypic differences are genetically determined, this directional selection should lead to evolutionary change, and indeed it has.

Artificial selection, imposed in laboratory experiments, agriculture, and the domestication process, has produced substantial change in almost every case in which it has been applied. This success is strong proof that selection is an effective evolutionary process.

### Experimental selection produces changes in populations

With the rise of genetics as a field of science in the 1920s and 1930s, researchers began conducting experiments to test the hypothesis that selection can produce evolutionary change. A favorite subject was the laboratory fruit fly, *Drosophila melanogaster*. Geneticists have imposed selection on just about every conceivable aspect of the fruit fly—including body size, eye color, growth rate, life span, and exploratory behavior—with a consistent result: Selection for a trait leads to strong and predictable evolutionary response.

In one classic experiment, scientists selected for fruit flies with many bristles (stiff, hairlike structures) on their abdomens. At the start of the experiment, the average number of bristles was 9.5. Each generation, scientists picked out the 20% of the population with the greatest number of bristles and allowed them to reproduce, thus establishing the next generation. After 86 generations of this directional selection, the average number of bristles had quadrupled, to nearly 40! In another experiment, fruit flies in one population were selected for high numbers of bristles, while fruit flies in the other cage were selected for low numbers of bristles. Within 35 generations, the populations did not overlap at all in range of variation (figure 21.5).

Similar experiments have been conducted on a wide variety of other laboratory organisms. For example, by selecting for rats that were resistant to tooth decay, in less than 20 generations scientists were able to increase the average time for onset of decay from barely over 100 days to greater than 500 days.

### Agricultural selection has led to extensive modification of crops and livestock

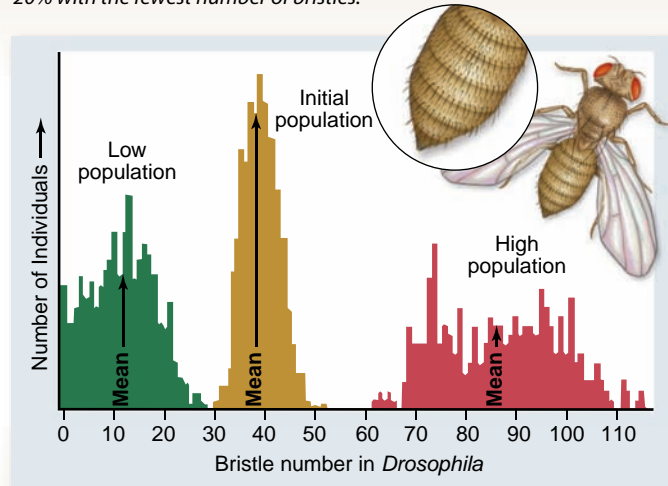

Familiar livestock, such as cattle and pigs, and crops, such as corn and strawberries, are greatly different from their wild an-

### SCIENTIFIC THINKING

**Question:** Can artificial selection lead to substantial evolutionary change?

**Hypothesis:** Strong directional selection will quickly lead to a large shift in the mean value of the population.

**Experiment:** In one population, every generation pick out the 20% of the population with the most bristles and allow them to reproduce to form the next generation. In the other population, do the same with the 20% with the fewest number of bristles.

**Result:** After 35 generations, mean number of bristles has changed substantially in both populations.

**Interpretation:** Note that at the end of the experiment, the range of variation lies outside the range seen in the initial population. Selection can move a population beyond its original range because mutation and recombination continuously introduce new variation into populations.

**Figure 21.5** Artificial selection can lead to rapid and substantial evolutionary change.

### Inquiry question

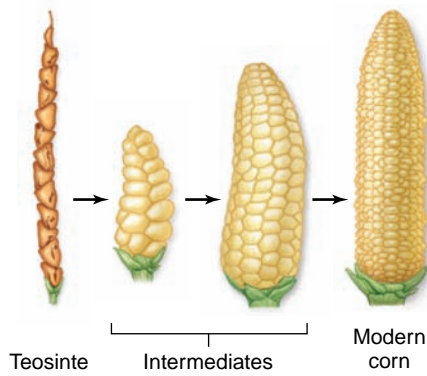

? What would happen if, within a population, both small and large individuals were allowed to breed, but middle-sized ones were not?

cestors (figure 21.6). These differences have resulted from generations of human selection for desirable traits, such as greater milk production and larger corn ear size.

An experiment with corn demonstrates the ability of artificial selection to rapidly produce major change in crop plants. In 1896, agricultural scientists began selecting for the oil content of corn kernels, which initially was 4.5%. Just as in the fruit fly experiments, the top 20% of all individuals were allowed to reproduce. By 1986, at which time 90 generations had passed, average oil content of the corn kernels had increased approximately 450%.

### Domesticated breeds have arisen from artificial selection

Human-imposed selection has produced a great variety of breeds of cats, dogs (figure 21.7), pigeons, and other domestic animals. In some cases, breeds have been developed for particular purposes. Greyhound dogs, for example, resulted from

**Figure 21.6** Corn looks very different from its ancestor.

Teosinte, which can be found today in a remote part of Mexico, is very similar to the ancestor of modern corn. Artificial selection has transformed it into the form we know today.

selection for maximal running ability, resulting in an animal with long legs, a long tail for balance, an arched back to increase stride length, and great muscle mass. By contrast, the odd proportions of the ungainly dachshund resulted from selection for dogs that could enter narrow holes in pursuit of badgers. In other cases, varieties have been selected primarily for their appearance, such as the many colorful breeds of pigeons or cats.

Domestication also has led to unintentional selection for some traits. In recent years, as part of an attempt to domesticate the silver fox, Russian scientists have chosen the most docile animals in each generation and allowed them to reproduce. Within 40 years, most foxes were exceptionally tame, not only allowing themselves to be petted, but also whimpering to get attention and sniffing and licking their caretakers (figure 21.8). In many respects, they had become no different from domestic dogs.

It was not only their behavior that changed, however. These foxes also began to exhibit other traits seen in some dog breeds, such as different color patterns, floppy ears, curled tails, and shorter legs and tails. Presumably, the genes responsible for docile behavior either affect these traits as well or are closely linked to the genes for these other traits (the phenomena of pleiotropy and linkage, which are discussed in chapters 12 and 13).

**Figure 21.7** Breeds of dogs. The differences among dog breeds are greater than the differences displayed among wild species of canids.

**Figure 21.8** Domesticated foxes. After 40 years of selectively breeding the tamest individuals, artificial selection has produced silver foxes that are not only as friendly as domestic dogs, but also exhibit many physical traits seen in dog breeds.

### Can selection produce major evolutionary changes?

Given that we can observe the results of selection operating over a relatively short time, most scientists think that natural selection is the process responsible for the evolutionary changes documented in the fossil record. Some critics of evolution accept that selection can lead to changes within a species, but contend that such changes are relatively minor in scope and not equivalent to the substantial changes documented in the fossil record. In other words, it is one thing to change the number of bristles on a fruit fly or the size of an ear of corn, and quite another to produce an entirely new species.

This argument does not fully appreciate the extent of change produced by artificial selection. Consider, for example, the existing breeds of dogs, all of which have been produced since wolves were first domesticated, perhaps 10,000 years ago. If the various dog breeds did not exist and a paleontologist found fossils of animals similar to dachshunds, greyhounds, mastiffs, and chihuahuas, there is no question that they would be considered different species. Indeed, the differences in size and shape exhibited by these breeds are greater than those between members of different genera in the family Canidae—such as coyotes, jackals, foxes, and wolves—which have been evolving separately for 5 to 10 million years. Consequently, the claim that artificial selection produces only minor changes is clearly incorrect. If selection operating over a period of only 10,000 years can produce such substantial differences, it should be powerful enough, over the course of many millions of years, to produce the diversity of life we see around us today.

### Learning Outcomes Review 21.3

In artificial selection, humans choose which plants or animals to mate in an attempt to conserve desirable traits. Rapid and substantial results can be obtained over a very short time, often in a few generations. From this we can see that natural selection is capable of producing major evolutionary change.

- In what circumstances might artificial selection fail to produce a desired change?

## 21.4 Fossil Evidence of Evolution

### Learning Outcomes

1. Describe how fossils are formed.
2. Explain the importance of the discovery of transitional fossils.
3. Name the evolutionary trends revealed by study of horse evolution.

**Figure 21.9 Radioactive decay.** Radioactive elements decay at a known rate, called their half-life. After one half-life, one half of the original amount of parent isotope has transformed into a nonradioactive daughter isotope. After each successive half-life, one half of the remaining amount of parent isotope is transformed.

The most direct evidence that evolution has occurred is found in the fossil record. Today we have a far more complete understanding of this record than was available in Darwin's time.

Fossils are the preserved remains of once-living organisms. They include specimens preserved in amber, Siberian permafrost, and dry caves, as well as the more common fossils preserved as rocks.

Rock fossils are created when three events occur. First, the organism must become buried in sediment; then, the calcium in bone or other hard tissue must mineralize; and finally, the surrounding sediment must eventually harden to form rock.

The process of fossilization occurs only rarely. Usually, animal or plant remains decay or are scavenged before the process can begin. In addition, many fossils occur in rocks that are inaccessible to scientists. When they do become available, they are often destroyed by erosion and other natural processes before they can be collected. As a result, only a very small fraction of the species that have ever existed (estimated by some to be as many as 500 million) are known from fossils. Nonetheless, the fossils that have been discovered are sufficient to provide detailed information on the course of evolution through time.

### The age of fossils is estimated by rates of radioactive decay

By dating the rocks in which fossils occur, we can get an accurate idea of how old the fossils are. In Darwin's day, rocks were dated by their position with respect to one another (*relative dating*); rocks in deeper strata are generally older. Knowing the relative positions of sedimentary rocks and the rates of erosion of different kinds of sedimentary rocks in different environments, geologists of the 19th century derived a fairly accurate idea of the relative ages of rocks.

Today, geologists take advantage of radioactive decay to establish the age of rocks (*absolute dating*). Many types of rock, such as the igneous rocks formed when lava cools, contain radioactive elements such as uranium-238. These isotopes transform at a precisely known rate into nonradioactive forms. For example, for  $U^{238}$  the *half-life* (that is, the amount of time needed for one-half of the original amount to be transformed) is 4.5 billion years. Once a rock is formed, no additional radioactive isotopes are added. Therefore, by measuring the ratio of the radioactive isotope to its derivative, "daughter" isotope (figure 21.9), geologists

**Figure 21.10 History of evolutionary change as revealed by the fossil record.**

can determine the age of the rock. If a fossil is found between two layers of rock, each of which can be dated, then the age at which the fossil formed can be determined.

## Fossils present a history of evolutionary change

When fossils are arrayed according to their age (figure 21.10), from oldest to youngest, they often provide evidence of successive evolutionary change. At the largest scale, the fossil record documents the course of life through time, from the origin of first prokaryotic and then eukaryotic organisms, through the evolution of fishes, the rise of land-dwelling organisms, the reign of the dinosaurs, and on to the origin of humans. In addition, the fossil record shows the waxing and waning of biological diversity through time, such as the periodic mass extinctions that have reduced the number of living species.

## Fossils document evolutionary transition

Given the low likelihood of fossil preservation and recovery, it is not surprising that there are gaps in the fossil record. Nonetheless, intermediate forms are often available to illustrate how the major transitions in life occurred.

Undoubtedly the most famous of these is the oldest known bird, *Archaeopteryx* (meaning “ancient feather”) which lived around 165 million years ago (figure 21.11). This specimen is clearly intermediate between birds and dinosaurs. Its feathers, similar in many respects to those of birds today, clearly reveal that it is a bird. Nonetheless, in many other respects—for example, possession of teeth, a bony tail, and other anatomical characteristics—it is indistinguishable from some carnivorous dinosaurs. Indeed, it is so similar to these dinosaurs that several specimens lacking preserved feathers were misidentified as dinosaurs and lay in the wrong natural history museum cabinet for several decades before the mistake was discovered!

*Archaeopteryx* reveals a pattern commonly seen in intermediate fossils—rather than being intermediate in every trait, such fossils usually exhibit some traits like their ancestors and

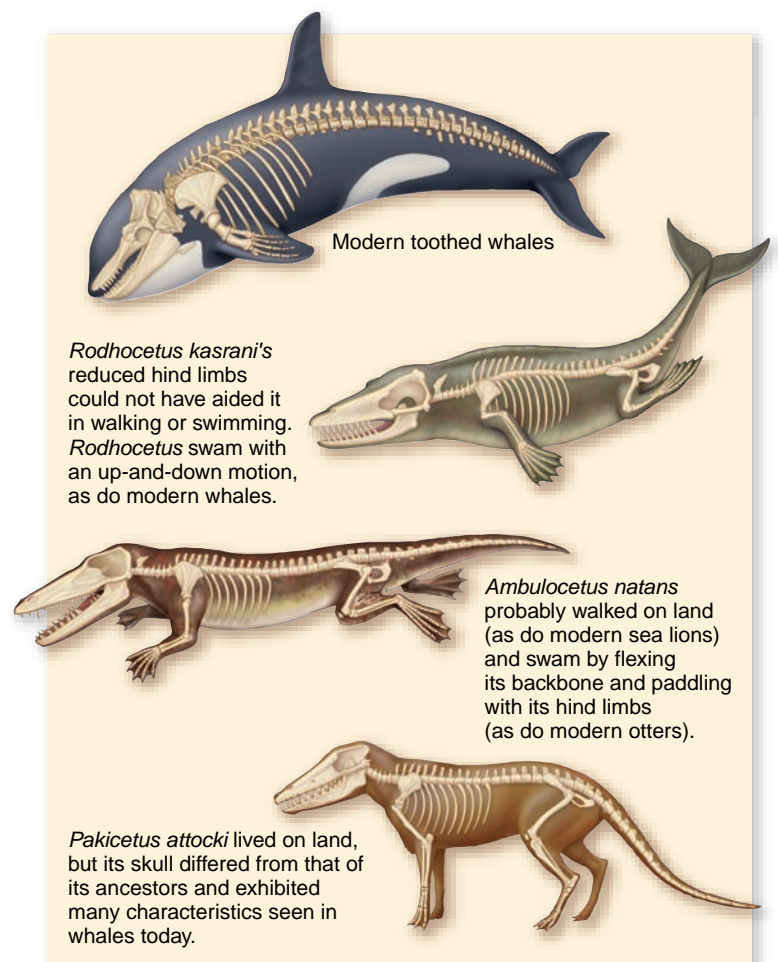

**Figure 21.11** Fossil of *Archaeopteryx*, the first bird.

The remarkable preservation of this specimen reveals soft parts usually not preserved in fossils; the presence of feathers makes clear that *Archaeopteryx* was a bird, despite the presence of many dinosaurian traits.

others like their descendants. In other words, traits evolve at different rates and different times; expecting an intermediate form to be intermediate in every trait would not be correct.

The first *Archaeopteryx* fossil was discovered in 1859, the year Darwin published *On the Origin of Species*. Since then, paleontologists have continued to fill in the gaps in the fossil record. Today, the fossil record is far more complete, particularly among the vertebrates; fossils have been found linking all the major groups.

Recent years have seen spectacular discoveries, closing some of the major remaining gaps in our understanding of vertebrate evolution. For example, a four-legged aquatic mammal was discovered only recently that provides important insights concerning the evolution of whales and dolphins from land-dwelling, hoofed ancestors (figure 21.12). Similarly, a fossil snake with legs has shed light on the evolution of snakes, which are descended from lizards that gradually

**Figure 21.12** Whale “missing links.” The recent discoveries of *Ambulocetus*, *Rodhocetus*, and *Pakicetus* have filled in the gaps between whales and their hoofed mammal ancestors. The features of *Pakicetus* illustrate that intermediate forms are not intermediate in all characteristics; rather, some traits evolve before others. In the case of the evolution of whales, changes occurred in the skull prior to evolutionary modification of the limbs. All three fossil forms occurred in the Eocene period, 45–55 MYA.

became more and more elongated with the simultaneous reduction and eventual disappearance of the limbs. In chapter 35, we discuss the most recent such discovery, *Tiktaalik*, a species that bridged the gap between fish and the first amphibians.

On a finer scale, evolutionary change within some types of animals is known in exceptional detail. For example, about 200 million years ago (MYA), oysters underwent a change from small, curved shells to larger, flatter ones, with progressively flatter fossils seen in the fossil record over a period of 12 million years. A host of other examples illustrate similar records of successive change. The demonstration of this successive change is one of the strongest lines of evidence that evolution has occurred.

## The evolution of horses is a prime example of evidence from fossils

One of the most studied cases in the fossil record concerns the evolution of horses. Modern-day members of the family Equidae include horses, zebras, donkeys, and asses, all of which are large, long-legged, fast-running animals adapted to living on open grasslands. These species, all classified in the genus *Equus*, are the last living descendants of a long lineage that has produced 34 genera since its origin in the Eocene period, approximately 55 MYA. Examination of these fossils has provided a particularly well-documented case of how evolution has proceeded through adaptation to changing environments.

### The first horse

The earliest known members of the horse family, species in the genus *Hyracotherium*, didn't look much like modern-day horses at all. Small, with short legs and broad feet, these species occurred in wooded habitats, where they probably browsed on leaves and herbs and escaped predators by dodging through openings in the forest vegetation. The evolutionary path from these diminutive creatures to the workhorses of today has involved changes in a variety of traits, including size, toe reduction, and tooth size and shape (figure 21.13).

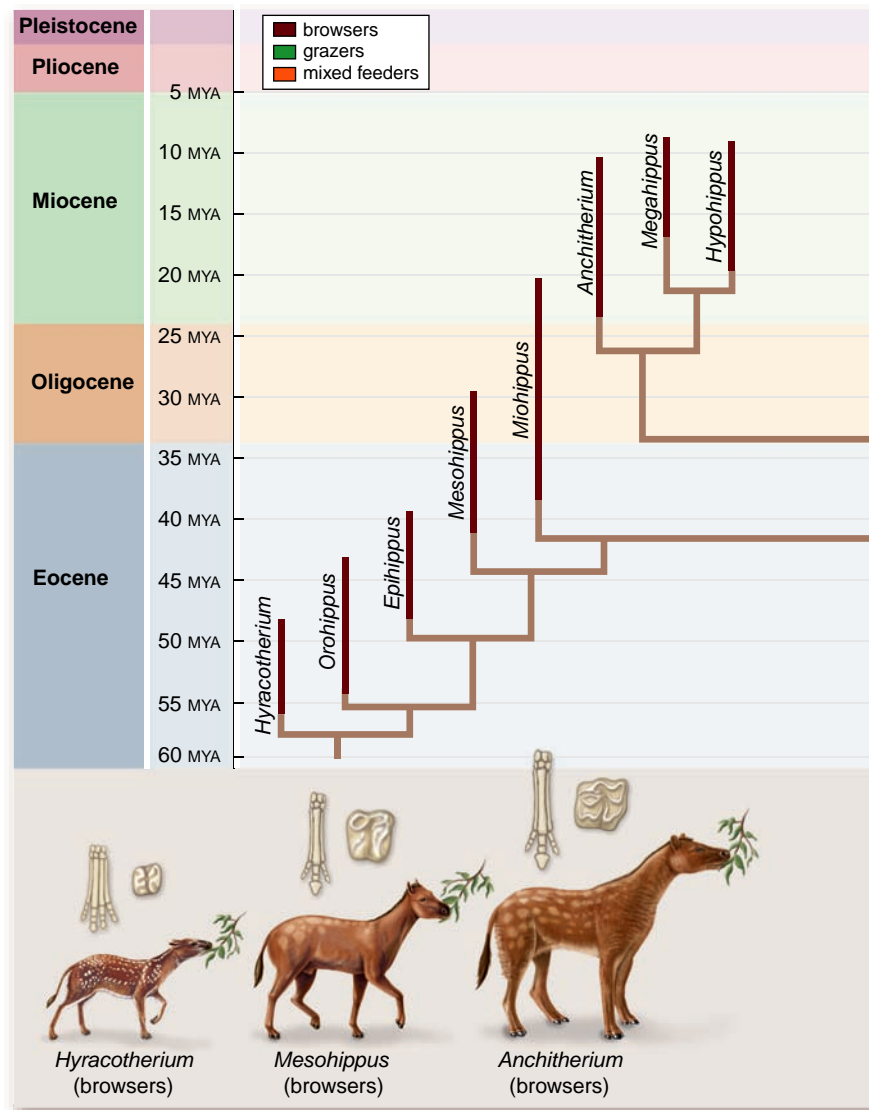

### Changes in size

The first species of horses were as big as a large house cat or a medium-sized dog. By contrast, modern equids can weigh more than 500 kg. Examination of the fossil record reveals that horses changed little in size for their first 30 million years, but since then, a number of different lineages have exhibited rapid and substantial increases. However, trends toward decreased size were also exhibited in some branches of the equid evolutionary tree.

### Toe reduction

The feet of modern horses have a single toe enclosed in a tough, bony hoof. By contrast, *Hyracotherium* had four toes on its front feet and three on its hind feet. Rather than hooves, these toes were encased in fleshy pads like those of dogs and cats.

Examination of fossils clearly shows the transition through time: a general increase in length of the central toe, develop-

**Figure 21.13 Evolutionary change in body size of horses.** Lines indicate evolutionary relationships of the horse family. Horse evolution is more like a bush than a single-trunk tree; diversity was much greater in the past than it is today. In general, there has been a trend toward larger size, more complex molar teeth, and fewer toes, but this trend has exceptions. For example, a relatively recent form, *Nannippus*, evolved in the opposite direction, toward decreased size.

### Inquiry question

? Why might the evolutionary line leading to *Nannippus* have experienced an evolutionary decrease in body size?

ment of the bony hoof, and reduction and loss of the other toes (see figure 21.13). As with body size, these trends occurred concurrently on several different branches of the horse evolutionary tree and were not exhibited by all lineages.

At the same time as toe reduction was occurring, these horse lineages were evolving changes in the length and skeletal structure of their limbs, leading to animals capable of running long distances at high speeds.

### Tooth size and shape

The teeth of *Hyracotherium* were small and relatively simple in shape. Through time, horse teeth have increased greatly in length and have developed a complex pattern of ridges on their molars and premolars. The effect of these changes is to produce teeth better capable of chewing tough and gritty vegetation, such as grass, which tends to wear teeth down.

Accompanying these changes have been alterations in the shape of the skull that strengthened the skull to withstand the stresses imposed by continual chewing. As with body size, evolutionary change has not been constant through time. Rather, much of the change in tooth shape has occurred within the past 20 million years, and changes have not been constant among all horse lineages.

All of these changes may be understood as adaptations to changing global climates. In particular, during the late Miocene and early Oligocene epochs (approximately 20 to 25 MYA), grasslands became widespread in North America, where much of horse evolution occurred. As horses adapted to these habitats, high-speed locomotion probably became more important to escape predators. By contrast, the greater flexibility provided

by multiple toes and shorter limbs, which was advantageous for ducking through complex forest vegetation, was no longer beneficial. At the same time, horses were eating grasses and other vegetation that contained more grit and other hard substances, thus favoring teeth and skulls better suited for withstanding such materials.

### Evolutionary trends

For many years, horse evolution was held up as an example of constant evolutionary change through time. Some even saw in the record of horse evolution evidence for a progressive, guiding force, consistently pushing evolution in a single direction. We now know that such views are misguided, and that the course of evolutionary change over millions of years is rarely so simple.

Rather, the fossils demonstrate that even though overall trends have been evident in a variety of characteristics, evolutionary change has been far from constant and uniform through time. Instead, rates of evolution have varied widely, with long periods of little observable change and some periods of great change. Moreover, when changes happen, they often occur simultaneously in different lineages of the horse evolutionary tree.

Finally, even when a trend exists, exceptions, such as the evolutionary decrease in body size exhibited by some lineages, are not uncommon. These patterns are usually discovered for any group of plants and animals for which we have an extensive fossil record, as you will see when we discuss human evolution in chapter 35.

### Horse diversity

One reason that horse evolution was originally conceived of as linear through time may be that modern horse diversity is relatively limited. For this reason it is easy to mentally picture a straight line from *Hyracotherium* to modern-day *Equus*. But today's limited horse diversity—only one surviving genus—is unusual. In fact, at the peak of horse diversity in the Miocene epoch, 13 genera of horses could be found in North America alone. These species differed in body size and in a wide variety of other characteristics. Presumably, they lived in different habitats and exhibited different dietary preferences. Had this diversity existed to modern times, early evolutionary biologists would likely have had a different outlook on horse evolution.

#### Learning Outcomes Review 21.4

Fossils form when an organism is preserved in a matrix such as amber, permafrost, or rock. They can be used to construct a record of major evolutionary transitions over long periods of time. The extensive fossil record for horses provides a detailed view of evolutionary diversification of this group, although trends are not constant and uniform and may include exceptions.

- Why might rates and direction of evolutionary change vary through time?

## 21.5 Anatomical Evidence for Evolution

### Learning Outcomes

1. Explain the evolutionary significance of homologous and vestigial structures.
2. Describe how patterns of early development provide evidence for evolution.

Much of the power of the theory of evolution is its ability to provide a sensible framework for understanding the diversity of life. Many observations from throughout biology simply cannot be understood in any meaningful way except as a result of evolution.

### Homologous structures suggest common derivation

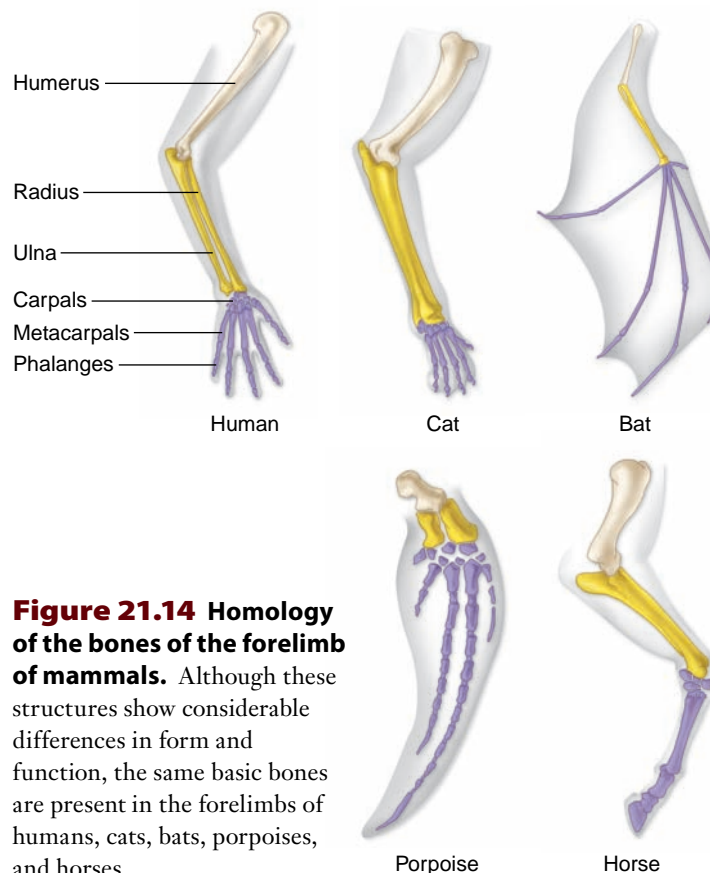

As vertebrates have evolved, the same bones have sometimes been put to different uses. Yet the bones are still recognizable,

their presence betraying their evolutionary past. For example, the forelimbs of vertebrates are all **homologous structures**—structures with different appearances and functions that all derived from the same body part in a common ancestor.

You can see in figure 21.14 how the bones of the forelimb have been modified in different ways for different mammals. Why should these very different structures be composed of the same bones—a single upper forearm bone, a pair of lower forearm bones, several small carpals, and one or more digits? If evolution had not occurred, this would indeed be a riddle. But when we consider that all of these animals are descended from a common ancestor, it is easy to understand that natural selection has modified the same initial starting blocks to serve very different purposes.

### Early embryonic development shows similarities in some groups

Some of the strongest anatomical evidence supporting evolution comes from comparisons of how organisms develop. Embryos of different types of vertebrates, for example, often are similar early on, but become more different as they develop. Early in their development vertebrate embryos possess pharyngeal pouches, which develop into different structures. In humans, for example, they become various glands and ducts; in fish, they turn into gill slits. At a later stage, every human embryo has a long tail, the vestige of which we carry to adulthood as the coccyx at the end of our spine. Human fetuses

**Figure 21.14 Homology of the bones of the forelimb of mammals.** Although these structures show considerable differences in form and function, the same basic bones are present in the forelimbs of humans, cats, bats, porpoises, and horses.

**Figure 21.15** Developmental features reflect evolutionary ancestry. Some species of frogs have lost the tadpole stage. Nonetheless, tadpole features first appear and then disappear during development in the egg.

even possess a fine fur (called *lanugo*) during the fifth month of development.

Similarly, although most frogs go through a tadpole stage, some species develop directly and hatch out as little, fully-formed frogs. However, the embryos of these species still ex-

hibit tadpole features, such as the presence of a tail, which disappear before the froglet hatches (figure 21.15).

These relict developmental forms suggest strongly that our development has evolved, with new instructions modifying ancestral developmental patterns. We will return to the topic of embryonic development and evolution in chapter 25.

### Some structures are imperfectly suited to their use

Because natural selection can only work on the variation present in a population, it should not be surprising that some organisms do not appear perfectly adapted to their environments. For example, most animals with long necks have many neck vertebrae for enhanced flexibility: Geese have up to 25, and plesiosaurs, the long-necked reptiles that patrolled the seas during the age of dinosaurs, had as many as 76. By contrast, almost all mammals have only 7 neck vertebrae, even the giraffe. In the absence of variation in vertebrae number, selection led to an evolutionary increase in vertebra size to produce the long neck of the giraffe.

An excellent example of an imperfect design is the eye of vertebrate animals, in which the photoreceptors face backward, toward the wall of the eye (figure 21.16*a*). As a result, the nerve fibers extend not backward, toward the brain, but forward into the eye chamber, where they slightly obstruct light. Moreover, these fibers bundle together to form the optic nerve, which exits through a hole at the back of the eye, creating a blind spot.

By contrast, the eye of mollusks—such as squid and octopuses—are more optimally designed: The photoreceptors face forward, and the nerve fibers exit at the back, neither obstructing light nor creating a blind spot (figure 21.16*b*).

Such examples illustrate that natural selection is like a tinkerer, working with whatever material is available to craft a workable solution, rather than like an engineer, who can design

**Figure 21.16** The eyes of vertebrates and mollusks. *a*. Photoreceptors of vertebrates point backward, whereas (*b*) those of mollusks face forward. As a result, vertebrate nerve fibers pass in front of the photoreceptor; and where they bundle together and exit the eye, a blind spot is created. Mollusks' eyes have neither of these problems.

and build the best possible structure for a given task. Workable, but imperfect, structures such as the vertebrate eye are an expected outcome of evolution by natural selection.

## Vestigial structures can be explained as holdovers from the past

Many organisms possess **vestigial structures** that have no apparent function, but resemble structures their ancestors possessed. Humans, for example, possess a complete set of muscles for wiggling their ears, just like many other mammals do. Although these muscles allow other mammals to move their ears to pinpoint sounds such as the movements or growl of a predator, they have little purpose in humans other than amusement.

As other examples, boa constrictors have hip bones and rudimentary hind legs. Manatees (a type of aquatic mammal often referred to as “sea cows”) have fingernails on their fins, which evolved from legs. Blind cave fish, which never see the light of day, have small, nonfunctional eyes. Figure 21.17 illustrates the skeleton of a baleen whale, which contains pelvic bones, as other mammal skeletons do, even though such bones serve no known function in the whale.

The human vermiform appendix is apparently vestigial; it represents the degenerate terminal part of the cecum, the blind pouch or sac in which the large intestine begins. In other mammals, such as mice, the cecum is the largest part of the large intestine and functions in storage—usually of bulk cellulose in herbivores. Although some functions have been suggested, it is difficult to assign any current function to the human vermiform appendix. In many respects, it can be a dangerous organ: appendicitis, which results from infection of the appendix, can be fatal.

It is difficult to understand vestigial structures such as these as anything other than evolutionary relicts, holdovers from the past. However, the existence of vestigial structures argues strongly for the common ancestry of the members of the groups that share them, regardless of how different those groups have subsequently become.

All of these anatomical lines of evidence—homology, development, and imperfect and vestigial structures—are readily understandable as a result of descent with modification, that is, evolution.

### Learning Outcomes Review 21.5

Comparisons of the anatomy of different living animals often reveal evidence of shared ancestry. In cases of homology, the same organ has evolved to carry out different functions. In other cases, an organ is still present, usually in diminished form, even though it has lost its function altogether; such an organ or structure is termed vestigial.

- *How might homologous and vestigial structures be explained other than as a result of evolutionary descent with modification?*

**Figure 21.17 Vestigial structures.** The skeleton of a whale reveals the presence of pelvic bones. These bones resemble those of other mammals, but are only weakly developed in the whale and have no apparent function.

## 21.6 Convergent Evolution and the Biogeographical Record

### Learning Outcomes

1. *Explain the principle of convergent evolution.*
2. *Demonstrate how the biogeographical distribution of plant and animal species on islands provides evidence of evolutionary diversification.*

**Biogeography**, the study of the geographic distribution of species, reveals that different geographical areas sometimes exhibit groups of plants and animals of strikingly similar appearance, even though the organisms may be only distantly related.

It is difficult to explain so many similarities as the result of coincidence. Instead, natural selection appears to have favored parallel evolutionary adaptations in similar environments. Because selection in these instances has tended to favor changes that made the two groups more alike, their phenotypes have converged. This form of evolutionary change is referred to as **convergent evolution**.

### Marsupials and placentals demonstrate convergence

In the best known case of convergent evolution, two major groups of mammals—marsupials and placentals—have evolved in very similar ways in different parts of the world. Marsupials

Niche	Burrower	Anteater	Nocturnal Insectivore	Climber	Glider	Stalking Predator	Chasing Predator
Placental Mammals	Mole	Lesser anteater	Grasshopper mouse	Ring-tailed lemur	Flying squirrel	Ocelot	Wolf
	Marsupial mole	Numbat	Marsupial mouse	Spotted cuscus	Flying phalanger	Tasmanian quoll	Thylacine

**Figure 21.18 Convergent evolution.** Many marsupial species in Australia resemble placental mammals occupying similar ecological niches elsewhere in the rest of the world. Marsupials evolved in isolation after Australia separated from other continents.

are a group in which the young are born in a very immature condition and held in a pouch until they are ready to emerge into the outside world. In placentals, by contrast, offspring are not born until they can safely survive in the external environment (with varying degrees of parental care).

Australia separated from the other continents more than 70 million years ago; at that time, both marsupials and placental mammals had evolved, but in different places. In particular, only marsupials occurred in Australia. As a result of this continental separation, the only placental mammals in Australia today are bats and a few colonizing rodents (which arrived relatively recently), and Australia is dominated by marsupials.

What are the Australian marsupials like? To an astonishing degree, they resemble the placental mammals living today on the other continents (figure 21.18). The similarity between some individual members of these two sets of mammals argues strongly that they are the result of convergent evolution, similar forms having evolved in different, isolated areas because of similar selective pressures in similar environments.

### Convergent evolution is a widespread phenomenon

When species interact with the environment in similar ways, they often are exposed to similar selective pressures, and they therefore frequently develop the same evolutionary adaptations. Consider, for example, fast-moving marine predators (figure 21.19). The hydrodynamics of moving through water require a streamlined body shape to minimize friction. It is no coincidence that dolphins, sharks, and tuna—among the fastest of marine species—have all evolved to have the same basic shape. We can infer as well that ichthyosaurs—marine reptiles that lived during the Age of the Dinosaurs—exhibited a similar lifestyle.

Island trees exhibit a similar phenomenon. Most islands are covered by trees (or were until the arrival of humans). Careful inspection of these trees, however, reveals that they are not closely related to the trees with which we are familiar. Although they have all the characteristics of trees, such as being tall and having a tough outer covering, in many cases island trees are members of plant families that elsewhere exist only as flowers,

**Figure 21.19 Convergence among fast-swimming predators.** Fast movement through water requires a streamlined body form, which has evolved numerous times.

shrubs, or other small bushes. For example, on many islands, the native trees are members of the sunflower family.

Why do these plants evolve into trees on islands? Probably because seeds from trees rarely make it to isolated islands. As a result, those species that do manage to colonize distant islands face an empty ecological landscape upon arrival. In the absence of other tree-like plants, natural selection often would favor individual plants that could capture the most sunlight for photosynthesis, and the result is the evolution of similar tree-like forms on islands throughout the world.

Convergent evolution is even seen in humans. People in most populations stop producing lactase, the enzyme that digests milk, some time in childhood. However, individuals in African and European populations that raise cattle produce lactase throughout their lives. DNA analysis indicates that this has been accomplished by the incorporation of different mutations in Africa and Europe, which indicates that the populations have independently acquired this adaptation.

## Biogeographical studies provide further evidence of evolution

Darwin made several important observations during his voyage around the world. He noted that islands often are missing plants and animals common on continents, such as frogs and land mammals. Accidental human introductions have proved that these species can survive if they are released on islands, so lack of suitable habitat is not the cause. In addition, those species that are present on islands often have diverged from their continental relatives and sometimes—as with Darwin’s finches and the island trees just discussed—occupy ecological niches used by other species on continents. Lastly, island species usually are more closely related to species on nearby continents, even though the environment there is often not very similar to that on island.

Darwin deduced the explanation for these phenomena. Many islands have never been connected to continental areas. The species that occur there arrived by dispersing across the water; dispersal from nearby areas is more likely than from more distant sources, though long-distance colonization does occur occasionally. Some species, those that can fly, float, or swim are more likely to get to the island than others. Some, like frogs, are particularly vulnerable to dehydration in saltwater and have almost no chance of island colonization.

The absence of some types of plants and animals provides opportunity to those that do arrive; as a result, colonizers often evolve into many species exhibiting great ecological and morphological diversity.

Geographic proximity is not always a good predictor of evolutionary relationships, however. Earth’s continents have not always been where they are today; rather, continents are constantly moving because of the process known as *continental drift*. Although the pace is slow, on the order of several centimeters per year, the configuration of the continents can, and has, changed considerably over geologic time. As a result, closely related species that at one time occurred near each other may now be separated by thousands of miles. Many examples occur on the southern continents, which were last united as the supercontinent Gondwana more than 100 million years ago.

One such example is the southern beech tree, which is found in Chile, and also in Australia and New Zealand. In cases such as this, Earth’s history and evolutionary history must be considered jointly to make sense of geographical distributions.

### Learning Outcomes Review 21.6

Convergence is the evolution of similar forms in different lineages when exposed to similar selective pressures. The biogeographical distribution of species often reflects the outcome of evolutionary diversification with closely related species in nearby areas.

- **Why does convergent evolution occur and why might species occupying similar environments in different localities sometimes not exhibit it?**

## 21.7 Darwin’s Critics

### Learning Outcomes

1. **Characterize the criticisms of evolutionary theory and list counterarguments that can be made.**
2. **Distinguish between hypothesis and theory in scientific usage.**

In the century and a half since he proposed it, Darwin’s theory of evolution by natural selection has become nearly universally accepted by biologists, but has been a source of controversy among some members of the general public. Here we discuss seven principle objections that critics raise to the teaching of evolution as biological fact, along with some answers that scientists present in response.

1. **Evolution is not solidly demonstrated.** “Evolution is just a theory,” Darwin’s critics point out, as though *theory* meant a lack of knowledge, or some kind of guess.  
Scientists, however, use the word *theory* in a very different sense than the general public does. Theories are the solid ground of science—that about which we are most certain. Few of us doubt the theory of gravity because it is “just a theory.”
2. **There are no fossil intermediates.** “No one ever saw a fin on the way to becoming a leg,” critics claim, pointing to the many gaps in the fossil record in Darwin’s day.  
Since that time, however, many fossil intermediates in vertebrate evolution have indeed been found. A clear line of fossils now traces the transition between hoofed mammals and whales, between reptiles and mammals, between dinosaurs and birds, and between apes and humans. The fossil evidence of evolution between major forms is compelling.
3. **The intelligent design argument.** “The organs of living creatures are too complex for a random process to have produced—the existence of a clock is evidence of the existence of a clockmaker.”

Evolution by natural selection is not a random process. Quite the contrary, by favoring those variations that lead to the highest reproductive fitness, natural selection is a nonrandom process that can construct highly complex organs by incrementally improving them from one generation to the next.

For example, the intermediates in the evolution of the mammalian ear can be seen in fossils, and many intermediate “eyes” are known in various invertebrates. These intermediate forms arose because they have value—being able to detect light slightly is better than not being able to detect it at all. Complex structures such as eyes evolved as a progression of slight improvements. Moreover, inefficiencies of certain designs, such as the vertebrate eye and the existence of vestigial structures, do not support the idea of an intelligent designer.

4. **Evolution violates the Second Law of Thermodynamics.** “A jumble of soda cans doesn’t by itself jump neatly into a stack—things become more disorganized due to random events, not more organized.”

Biologists point out that this argument ignores what the second law really says: Disorder increases in a closed system, which the Earth most certainly is not. Energy continually enters the biosphere from the Sun, fueling life and all the processes that organize it.

5. **Proteins are too improbable.** “Hemoglobin has 141 amino acids. The probability that the first one would be leucine is 1/20, and that all 141 would be the ones they are by chance is  $(1/20)^{141}$ , an impossibly rare event.”

This argument illustrates a lack of understanding of probability and statistics—probability cannot be used to argue backwards. The probability that a student in a classroom has a particular birthdate is 1/365; arguing this way, the probability that everyone in a class of 50 would have the birthdates that they do is  $(1/365)^{50}$ , and yet there the class sits, all with their actual birthdates.

6. **Natural selection does not imply evolution.** “No scientist has come up with an experiment in which fish evolve into frogs and leap away from predators.”

Can we extrapolate from our understanding that natural selection produces relatively small changes that are observable in populations *within* species to explain the major differences observed *between* species? Most biologists who have studied the problem think so. The differences between breeds produced by artificial selection—such as chihuahuas, mastiffs, and greyhounds—are more distinctive than the differences between some wild species, and laboratory selection experiments sometimes create forms that cannot interbreed and thus would in nature be considered different species. Thus, production of radically different forms has indeed been observed, repeatedly. To object that evolution still does not explain really major differences, such as those between fish and amphibians, simply takes us back to point number 2. These changes take millions of years, and they are seen clearly in the fossil record.

7. **The irreducible complexity argument.** Because each part of a complex cellular mechanism such as blood

clotting is essential to the overall process, the intricate machinery of the cell cannot be explained by evolution from simpler stages.

What’s wrong with this argument is that each part of a complex molecular machine evolves as part of the whole system. Natural selection can act on a complex system because at every stage of its evolution, the system functions. Parts that improved function are added. Subsequently, other parts may be modified or even lost, so that parts that were not essential when they first evolved become essential. In this way, an “irreducible complex” structure can evolve by natural selection. The same process works at the molecular level.

For example, snake venom initially evolved as enzymes to increase the ability of snakes to digest large prey items, which were captured by biting the prey and then constricting them with coils. Subsequently, the digestive enzymes evolved to become increasingly lethal. Rattlesnakes kill large prey by injecting them with venom, letting them go, and then tracking them down and eating them after they die. To do so, they have evolved extremely toxic venom, highly modified syringelike front teeth, and many other characteristics. Take away the fangs or the venom and the rattlesnakes can’t feed—what initially evolved as nonessential parts are now indispensable; irreducible complexity has evolved by natural selection.

The mammalian blood clotting system similarly has evolved from much simpler systems. The core clotting system evolved at the dawn of the vertebrates more than 500 million years ago, and it is found today in primitive fishes such as lampreys. One hundred million years later, as vertebrates continued to evolve, proteins were added to the clotting system, making it sensitive to substances released from damaged tissues. Fifty million years later, a third component was added, triggering clotting by contact with the jagged surfaces produced by injury. At each stage, as the clotting system evolved to become more complex, its overall performance came to depend on the added elements. Thus, blood clotting has become “irreducibly complex” as the result of Darwinian evolution.

Statements that various structures could not have been built by natural selection have repeatedly been made over the past 150 years. In many cases, after detailed scientific study, the likely path by which such structures have evolved has been discovered.

### Learning Outcomes Review 21.7

Darwin’s theory of evolution is controversial to some in the general public. Objections are often based on a misunderstanding of the theory. In scientific usage, a hypothesis is an educated guess, whereas a theory is an explanation that fits available evidence and has withstood rigorous testing.

- Suppose someone suggests that humans originally came from Mars. Would this be a hypothesis or a theory, and how could it be tested?

## 21.1 The Beaks of Darwin's Finches: Evidence of Natural Selection

### *Galápagos finches exhibit variation related to food gathering.*

The correspondence between beak shape and its use in obtaining food suggested to Darwin that finch species had diversified and adapted to eat different foods.

### *Modern research has verified Darwin's selection hypothesis.*

Natural selection acts on variation in beak morphology, favoring larger-beaked birds during extended droughts and smaller-beaked birds during long periods of heavy rains.

Because this variation is heritable, evolutionary change occurs in the frequencies of beak sizes in subsequent generations.

## 21.2 Peppered Moths and Industrial Melanism: More Evidence of Selection

### *Light-colored moths decreased in polluted areas.*

In polluted areas where soot built up on tree trunks, the dark-colored form of the peppered moth became more common. In unpolluted areas, light-colored forms remained predominant.

Experiments suggested that predation by birds was the cause; light-colored moths stand out on dark trunks, and vice-versa.

### *When environmental conditions reverse, so does selection pressure.*

In the last 40 years, pollution has decreased in many areas and the frequency of light-colored moths has rebounded.

### *The agent of selection may be difficult to pin down.*

Recent research has questioned whether bird predation is the agent of selection. Regardless, the observation that the dark-colored form has increased during times of pollution and then declined as pollution abates indicates that natural selection has acted on moth coloration.

## 21.3 Artificial Selection: Human-Initiated Change (see figure 21.5)

### *Experimental selection produces changes in populations.*

Laboratory experiments in directional selection have shown that substantial evolutionary change can occur in these controlled populations.

### *Agricultural selection has led to extensive modification of crops and livestock.*

### *Domesticated breeds have arisen from artificial selection.*

Crop plants and domesticated animal breeds are often substantially different from their wild ancestors.

If artificial selection can rapidly create substantial change, then it is reasonable to assume that natural selection could have created the Earth's diversity of life over millions of years.

## 21.4 Fossil Evidence of Evolution

### *The age of fossils is estimated by rates of radioactive decay.*

Specimens become fossilized in different ways. Fossils in rock can be dated by calculating the extent of radioactive decay based on half-lives of known isotopes.

### *Fossils present a history of evolutionary change.*

### *Fossils document evolutionary transition.*

The history of life on Earth can be traced through the fossil record. In recent years, new fossil discoveries have provided more detailed understanding of major evolutionary transitions.

### *The evolution of horses is a prime example of evidence from fossils.*

The fossil record indicates that horses have evolved from small, forest-dwelling animals to the large and fast plains-dwelling species alive today. Over the course of 50 million years, evolution has not been constant and uniform. Rather, change has been rapid at some times, slow at others. Although a general trend toward increase in size is evident, some species evolved to smaller sizes.

## 21.5 Anatomical Evidence for Evolution

### *Homologous structures suggest common derivation.*

Homologous structures may have different appearances and functions even though derived from the same common ancestral body part.

### *Early embryonic development shows similarities in some groups.*

Embryonic development shows similarity in developmental patterns among species whose adult phenotypes are very different.

Species that have lost a feature that was present in an ancestral form often develop and then lose that feature during embryological development.

### *Some structures are imperfectly suited to their use.*

Natural selection can influence only the variation present in a population; because of this, evolution often results in workable, but imperfect structures, such as the vertebrate eye.

### *Vestigial structures can be explained as holdovers from the past.*

The existence of vestigial structures supports the concept of common ancestry among organisms that share them.

## 21.6 Convergent Evolution and the Biogeographical Record

### *Marsupials and placentals demonstrate convergence.*

Convergent evolution may occur in species or populations exposed to similar selective pressures. Marsupial mammals in Australia have converged upon features of their placental counterparts elsewhere.

### *Convergent evolution is a widespread phenomenon.*

Examples include hydrodynamic streamlining in marine species and the evolution of tree species on islands from ancestral forms that were not treelike.

### *Biogeographical studies provide further evidence of evolution.*

Island species usually are closely related to species on nearby continents even if the environments are different. Early island colonizers often evolve into diverse species because other, competing species are scarce.

## 21.7 Darwin's Critics

Darwin's theory of evolution by natural selection is almost universally accepted by biologists. Many criticisms have been made both historically and recently, but most stem from a lack of understanding of scientific principles, the theory's actual content, or the time spans involved in evolution.

## Review Questions

### UNDERSTAND

- Artificial selection is different from natural selection because
    - artificial selection is not capable of producing large changes.
    - artificial selection does not require genetic variation.
    - natural selection cannot produce new species.
    - breeders (people) choose which individuals reproduce based on desirability of traits.
  - Gaps in the fossil record
    - demonstrate our inability to date geological sediments.
    - are expected since the probability that any organism will fossilize is extremely low.
    - have not been filled in as new fossils have been discovered.
    - weaken the theory of evolution.
  - The evolution of modern horses (*Equus*) is best described as
    - the constant change and replacement of one species by another over time.
    - a complex history of lineages that changed over time, with many going extinct.
    - a simple history of lineages that have always resembled extant horses.
    - none of these.
  - Homologous structures
    - are structures in two or more species that originate as the same structure in a common ancestor.
    - are structures that look the same in different species.
    - cannot serve different functions in different species.
    - must serve different functions in different species.
  - Convergent evolution
    - is an example of stabilizing selection.
    - depends on natural selection to independently produce similar phenotypic responses in different species or populations.
    - occurs only on islands.
    - is expected when different lineages are exposed to vastly different selective environments.
  - Darwin's finches are a noteworthy case study of evolution by natural selection because evidence suggests
    - they are descendants of many different species that colonized the Galápagos.
    - they radiated from a single species that colonized the Galápagos.
    - they are more closely related to mainland species than to one another.
    - none of the above.
  - The possession of fine fur in 5-month human embryos indicates
    - that the womb is cold at that point in pregnancy.
    - humans evolved from a hairy ancestor.
    - hair is a defining feature of mammals.
    - some parts of the embryo grow faster than others.
- large beak size is always favored.
  - all of the above.
- Artificial selection experiments in the laboratory such as in figure 21.5 are an example of
    - stabilizing selection.
    - negative frequency-dependent selection.
    - directional selection.
    - disruptive selection.
  - Convergent evolution is often seen among species on different islands because
    - island populations are usually smaller and more affected by genetic drift.
    - disruptive selection occurs commonly on islands.
    - island species are usually most closely related to species in similar habitats elsewhere.
    - when islands are first colonized, many ecological resources are unused, allowing descendants of a colonizing species to diversify and adapt to many different parts of the environment.

### SYNTHESIZE

- What conditions are necessary for evolution by natural selection?

Refer to figure 21.2 for the following two questions.

- Explain how data shown in figure 21.2*a* and *b* relate to the conditions identified by you in question 1.
- On figure 21.2*b*, draw the relationship between offspring beak depth and parent beak depth, assuming that there is no genetic basis to beak depth in the medium ground finch.
- Refer to figure 21.5, artificial selection in the laboratory. In this experiment, one population of *Drosophila* was selected for low numbers of bristles and the other for high numbers. Note that not only did the means of the populations change greatly in 35 generations, but also all individuals in both experimental populations lie outside the range of the initial population. What would the result of this experiment have been if only flies with high numbers of bristles were allowed to breed?
- The ancestor of horses was a small, many-toed animal that lived in forests, whereas today's horses are large animals with a single hoof that live on open plains. A series of intermediate fossils illustrate how this transition has occurred, and for this reason, many old treatments of horse evolution portrayed it as a steady increase through time in body size accompanied by a steady decrease in toe number. Why is this interpretation incorrect?

### APPLY

- In Darwin's finches,
  - occurrence of wet and dry years preserves genetic variation for beak size.
  - increasing beak size over time proves that beak size is inherited.

# The Origin of Species

## Chapter Outline

---

- 22.1** The Nature of Species and the Biological Species Concept
- 22.2** Natural Selection and Reproductive Isolation
- 22.3** The Role of Genetic Drift and Natural Selection in Speciation
- 22.4** The Geography of Speciation
- 22.5** Adaptive Radiation and Biological Diversity
- 22.6** The Pace of Evolution
- 22.7** Speciation and Extinction Through Time

## Introduction

Although Darwin titled his book *On the Origin of Species*, he never actually discussed what he referred to as that “mystery of mysteries”—how one species gives rise to another. Rather, his argument concerned evolution by natural selection; that is, how one species evolves through time to adapt to its changing environment. Although an important mechanism of evolutionary change, the process of adaptation does not explain how one species becomes another, a process we call speciation. As we shall see, adaptation may be involved in the speciation process, but it does not have to be.

Before we can discuss how one species gives rise to another, we need to understand exactly what a species is. Even though the definition of a species is of fundamental importance to evolutionary biology, this issue has still not been completely settled and is currently the subject of considerable research and debate.

## 22.1 The Nature of Species and the Biological Species Concept

### Learning Outcomes

1. Distinguish between the biological species concept and the ecological species concept.
2. Define the two kinds of reproductive isolating mechanisms.
3. Describe the relationship of reproductive isolating mechanisms to the biological species concept.

Any concept of a species must account for two phenomena: the distinctiveness of species that occur together at a single locality, and the connection that exists among different populations belonging to the same species.

### Sympatric species inhabit the same locale but remain distinct

Put out birdfeeders on your balcony or in your back yard, and you will attract a wide variety of birds (especially if you include different kinds of foods). In the midwestern United States, for example, you might routinely see cardinals, blue jays, downy woodpeckers, house finches—even hummingbirds in the summer.

Although it might take a few days of careful observation, you would soon be able to readily distinguish the many different species. The reason is that species that occur together (termed **sympatric**) are distinctive entities that are phenotypically different, utilize different parts of the habitat, and behave differently. This observation is generally true not only for birds, but also for most other types of organisms.

Occasionally, two species occur together that appear to be nearly identical. In such cases, we need to go beyond visual similarities. When other aspects of the phenotype are examined, such as the mating calls or the chemicals exuded by each species, they usually reveal great differences. In other words, even though we might have trouble distinguishing them, the organisms themselves have no such difficulties.

### Populations of a species exhibit geographic variation

Within a single species, individuals in populations that occur in different areas may be distinct from one another. Such groups of distinctive individuals may be classified as **subspecies** (the vague term *race* has a similar connotation, but is no longer commonly used). In areas where these populations occur close to one another, individuals often exhibit combinations of features characteristic of both populations (figure 22.1). In other words, even though geographically distant populations may appear distinct, they are usually connected by intervening populations that are intermediate in their characteristics.

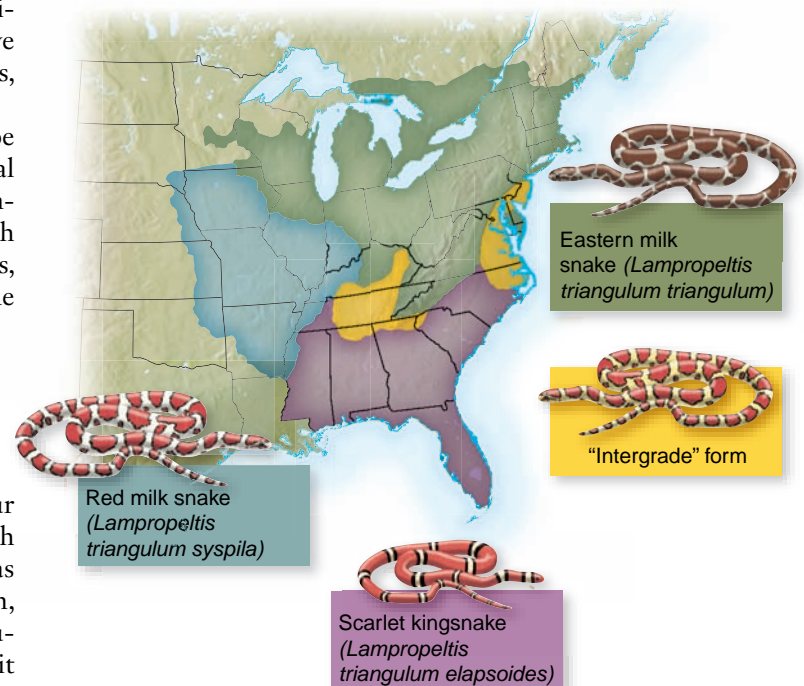

### The biological species concept focuses on the ability to exchange genes

What can account for both the distinctiveness of sympatric species and the connectedness of geographically separate populations of the same species? One obvious possibility is that each species exchanges genetic material only with other members of its species. If sympatric species commonly exchanged genes, which they generally do not, we might expect such species to rapidly lose their distinctions, as the gene pools (that is, all of the alleles present in a species) of the different species became homogenized. Conversely, the ability of geographically distant populations of a single species to share genes through the process of gene flow may keep these populations integrated as members of the same species.

Based on these ideas, in 1942 the evolutionary biologist Ernst Mayr set forth the **biological species concept**, which defines *species* as “. . . groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.”

In other words, the biological species concept says that a species is composed of populations whose members mate with each other and produce fertile offspring—or would do so if they came into contact. Conversely, populations whose members do not mate with each other or who cannot produce fertile offspring are said to be **reproductively isolated** and, therefore, are members of different species.

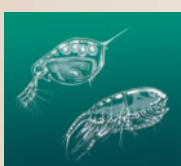

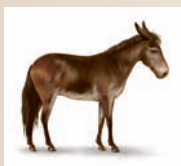

What causes reproductive isolation? If organisms cannot interbreed or cannot produce fertile offspring, they clearly belong to different species. However, some populations that are considered separate species can interbreed and produce fertile offspring,

**Figure 22.1** Geographic variation in the milk snake, *Lampropeltis triangulum*. Although subspecies appear phenotypically quite distinctive from one another, they are connected by populations that are phenotypically intermediate.

but they ordinarily do not do so under natural conditions. They are still considered reproductively isolated in that genes from one species generally will not enter the gene pool of the other.

Table 22.1 summarizes the steps at which barriers to successful reproduction may occur. Such barriers are termed

TABLE 22.1 Reproductive Isolating Mechanisms		
Mechanism		Description
<b>P R E Z Y G O T I C I S O L A T I N G M E C H A N I S M S</b>		
Geographic isolation		Species occur in different areas, which are often separated by a physical barrier, such as a river or mountain range.
Ecological isolation		Species occur in the same area, but they occupy different habitats and rarely encounter each other.
Behavioral isolation		Species differ in their mating rituals.
Temporal isolation		Species reproduce in different seasons or at different times of the day.
Mechanical isolation		Structural differences between species prevent mating.
Prevention of gamete fusion		Gametes of one species function poorly with the gametes of another species or within the reproductive tract of another species.
<b>P O S T Z Y G O T I C I S O L A T I N G M E C H A N I S M S</b>		
Hybrid inviability or infertility		Hybrid embryos do not develop properly, hybrid adults do not survive in nature, or hybrid adults are sterile or have reduced fertility.

**reproductive isolating mechanisms** because they prevent genetic exchange between species. We will discuss examples of these next, beginning with those that prevent the formation of zygotes, which are called **prezygotic isolating mechanisms**. Mechanisms that prevent the proper functioning of zygotes after they form are called **postzygotic isolating mechanisms**.

### Prezygotic isolating mechanisms prevent the formation of a zygote

Mechanisms that prevent formation of a zygote include ecological or environmental isolation, behavioral isolation, temporal isolation, mechanical isolation, and prevention of gamete fusion.

#### Ecological isolation

Even if two species occur in the same area, they may utilize different portions of the environment and thus not hybridize because they do not encounter each other. For example, in India, the ranges of lions and tigers overlapped until about 150 years ago. Even so, there were no records of natural hybrids. Lions stayed mainly in the open grassland and hunted in groups called prides; tigers tended to be solitary creatures of the forest (figure 22.2). Because of their ecological and behavioral differences, lions and tigers rarely came into direct contact with each other, even though their ranges overlapped over thousands of square kilometers.

In another example, the ranges of two toads, *Bufo woodhousei* and *B. americanus*, overlap in some areas. Although these two species can produce viable hybrids, they usually do not interbreed because they utilize different portions of the habitat for breeding. *B. woodhousei* prefers to breed in streams, and *B. americanus* breeds in rainwater puddles.

Similar situations occur among plants. Two species of oaks occur widely in California: the valley oak, *Quercus lobata*, and the scrub oak, *Q. dumosa*. The valley oak, a graceful deciduous tree that can be as tall as 35 m, occurs in the fertile soils of open grassland on gentle slopes and valley floors. In contrast, the scrub oak is an evergreen shrub, usually only 1 to 3 m tall, which often forms the kind of dense scrub known as chaparral. The scrub oak is found on steep slopes in less fertile soils. Hybrids between these different oaks do occur and are fully fertile, but they are rare. The sharply distinct habitats of their parents limit their occurrence together, and there is little intermediate habitat where the hybrids might flourish.

#### Figure 22.2 Lions and tigers are ecologically isolated.

The ranges of lions and tigers overlap in India. However, lions and tigers do not hybridize in the wild because they utilize different portions of the habitat. Lions live in open grassland, whereas tigers are solitary animals that live in the forest. Hybrids, such as this tiglon, have been successfully produced in captivity, but hybridization does not occur in the wild.

**Figure 22.3 Differences in courtship rituals can isolate related bird species.** These Galápagos blue-footed boobies select their mates only after an elaborate courtship display. This male is lifting his feet in a ritualized high-step that shows off his bright blue feet. The display behavior of the two other species of boobies that occur in the Galápagos is very different, as is the color of their feet.

### Behavioral isolation

Chapter 54 describes the often elaborate courtship and mating rituals of some groups of animals. Related species of organisms such as birds often differ in their courtship rituals, which tends to keep these species distinct in nature even if they inhabit the same places (figure 22.3). For example, mallard and pintail ducks are perhaps the two most common freshwater ducks in North America. In captivity, they produce completely fertile hybrid offspring, but in nature they nest side by side and only rarely hybridize.

Sympatric species avoid mating with members of the wrong species in a variety of ways; every mode of communication imaginable appears to be used by some species. Differences in visual signals, as just discussed, are common; however, other types of animals rely more on other sensory modes for communication. Many species, such as frogs, birds, and a variety of insects, use sound to attract mates. Predictably, sympatric species of these animals produce different calls. Similarly, the “songs” of lacewings are produced when they vibrate their abdomens against the surface on which they are sitting, and sympatric species produce different vibration patterns (figure 22.4).

Other species rely on the detection of chemical signals, called **pheromones**. The use of pheromones in moths has been particularly well studied. When female moths are ready to mate, they emit a pheromone that males can detect at great distances. Sympatric species differ in the pheromone they produce: Either they use different chemical compounds, or, if using the same compounds the proportions used are different. Laboratory studies indicate that males are remarkably adept at distinguishing the pheromones of their own species from those of other species or even from synthetic compounds similar, but not identical, to that of their own species.

Some species even use electroreception. African and South Asian electric fish independently have evolved specialized organs in their tails that produce electrical discharges and electroreceptors on their skins to detect them. These discharges are used to communicate in social interactions; field

experiments indicate that males can distinguish between signals produced by their own and other species, probably on the basis of differences in the timing of the electrical pulses.

### Temporal isolation

*Lactuca graminifolia* and *L. canadensis*, two species of wild lettuce, grow together along roadsides throughout the southeastern United States. Hybrids between these two species are easily made experimentally and are completely fertile. But these hybrids are rare in nature because *L. graminifolia* flowers in early spring and *L. canadensis* flowers in summer. When their blooming periods overlap, as happens occasionally, the two species do form hybrids, which may become locally abundant.

Many species of closely related amphibians have different breeding seasons that prevent hybridization. For example, five species of frogs of the genus *Rana* occur together in most of the eastern United States, but hybrids are rare because the peak breeding time is different for each of them.

### Mechanical isolation

Structural differences prevent mating between some related species of animals. Aside from such obvious features as size, the structure of the male and female copulatory organs may be incompatible. In many insect and other arthropod groups, the sexual organs, particularly those of the male, are so diverse that they are used as a primary basis for distinguishing species.

Similarly, flowers of related species of plants often differ significantly in their proportions and structures. Some of these differences limit the transfer of pollen from one plant species to another. For example, bees may carry the pollen of one species on a certain place on their bodies; if this area does not come into

**Figure 22.4 Differences in courtship song of sympatric species of lacewings.** Lacewings are small insects that rely on auditory signals produced by moving their abdomens to vibrate the surface on which they are sitting to attract mates. As these recordings indicate, the vibration patterns produced by sympatric species differ greatly. Females, which detect the calls as they are transmitted through solid surfaces such as branches, are able to distinguish calls of different species and only respond to individuals producing their own species’ call.

### Figure 22.5 Postzygotic isolation in leopard frogs.

These four species resemble one another closely in their external features. Their status as separate species first was suspected when hybrids between some pairs of these species were found to produce defective embryos in the laboratory. Subsequent research revealed that the mating calls of the four species differ substantially, indicating that the species have both pre- and postzygotic isolating mechanisms.

contact with the receptive structures of the flowers of another plant species, the pollen is not transferred.

#### Prevention of gamete fusion

In animals that shed gametes directly into water, the eggs and sperm derived from different species may not attract or fuse with one another. Many land animals may not hybridize successfully because the sperm of one species functions so poorly within the reproductive tract of another that fertilization never takes place. In plants, the growth of pollen tubes may be impeded in hybrids between different species. In both plants and animals, isolating mechanisms such as these prevent the union of gametes, even following successful mating.

#### Postzygotic isolating mechanisms prevent normal development into reproducing adults

All of the factors we have discussed so far tend to prevent hybridization. If hybrid matings do occur and zygotes are produced, many factors may still prevent those zygotes from developing into normally functioning, fertile individuals.

As you saw in chapter 19, development is a complex process. In hybrids, the genetic complements of two species may be so different that they cannot function together normally in embryonic development. For example, hybridization between sheep and goats usually produces embryos that die in the earliest developmental stages.

The leopard frogs (*Rana pipiens* complex) of the eastern United States are a group of similar species, assumed for a long time to constitute a single species (figure 22.5). Careful examination, however, revealed that although the frogs appear similar, successful mating between them is rare because of problems that occur as the fertilized eggs develop. Many of the hybrid combinations cannot be produced even in the laboratory.

Examples of this kind, in which similar species have been recognized only as a result of hybridization experiments, are common in plants. Sometimes the hybrid plant embryos can be removed at an early stage and grown in an artificial medium. When these hybrids are supplied with extra nutrients or other supplements that compensate for their weakness or inviability, they may complete their development normally.

Even when hybrids survive the embryo stage, they may still not develop normally. If the hybrids are less physically fit than their parents, they will almost certainly be eliminated in nature. Even if a hybrid is vigorous and strong, as in the case of the mule, which is a hybrid between a female horse and a male donkey, it may still be sterile and thus incapable of contributing to succeeding generations.

Hybrids may be sterile because the development of sex organs is abnormal, because the chromosomes derived from the respective parents cannot pair properly during meiosis, or due to a variety of other causes.

### The biological species concept does not explain all observations

The biological species concept has proved to be an effective way of understanding the existence of species in nature. Nonetheless, it fails to take into account all observations, leading some biologists to propose alternative species concepts.

One criticism of the biological species concept concerns the extent to which all species truly are reproductively isolated. By definition, under the biological species concept, species should not interbreed and produce fertile offspring. But in recent years, biologists have detected much greater amounts of interspecies hybridization than was previously thought to occur between populations that seem to coexist as distinct biological entities.

Botanists have always been aware that plant species often undergo substantial amounts of hybridization. More than 50% of California plant species included in one study, for example, were not well defined by genetic isolation. This coexistence without genetic isolation can be long-lasting: Fossil data show that balsam poplars and cottonwoods have been phenotypically distinct for 12 million years, but they also have routinely produced hybrids throughout this time. Consequently, many botanists have long felt that the biological species concept applies only to animals.

New evidence, however, increasingly indicates that hybridization is not all that uncommon in animals, either. In recent years, many cases of substantial hybridization between animal species have been documented. One recent survey indicated that almost 10% of the world's 9500 bird species are known to have hybridized in nature.

The Galápagos finches provide a particularly well-studied example. Three species on the island of Daphne Major—the

medium ground finch, the cactus finch, and the small ground finch—are clearly distinct morphologically, and they occupy different ecological niches. Studies over the past 20 years by Peter and Rosemary Grant found that, on average, 2% of the medium ground finches and 1% of the cactus ground finches mated with other species every year. Furthermore, hybrid offspring appeared to be at no disadvantage in terms of survival or subsequent reproduction. This is not a trivial amount of genetic exchange, and one might expect to see the species coalesce into one genetically variable population—but the species are maintaining their distinctiveness.

Hybridization is not rampant throughout the animal world, however. Most bird species do not hybridize, and probably even fewer experience significant amounts of hybridization. Still, hybridization is common enough to cast doubt on whether reproductive isolation is the only force maintaining the integrity of species.

### **Natural selection and the ecological species concept**

An alternative hypothesis proposes that the distinctions among species are maintained by natural selection. The idea is that each species has adapted to its own specific part of the environment. Stabilizing selection, described in chapter 20, then maintains the species' adaptations. Hybridization has little effect because alleles introduced into one species' gene pool from other species are quickly eliminated by natural selection.

You probably recall from chapter 20 that the interaction between gene flow and natural selection can have many outcomes. In some cases, strong selection can overwhelm any effects of gene flow—but in other situations, gene flow can prevent populations from eliminating less successful alleles from a population.

As a general explanation, then, an ecological species concept is not likely to have any fewer exceptions than does the biological species concept, although it might prove to be a more successful description for certain types of organisms or habitats.

### **Other weaknesses of the biological species concept**

The biological species concept has been criticized for other reasons as well. For example, it can be difficult to apply the concept to populations that are geographically separated in nature. Because individuals of these populations do not encounter each other, it is not possible to observe whether they would interbreed naturally.

Although experiments can determine whether fertile hybrids can be produced, this information is not enough. Many species that coexist without interbreeding in nature will readily hybridize in the artificial settings of the laboratory or zoo. Consequently, evaluating whether such populations constitute different species is ultimately a judgment call. In addition, the concept is more limited than its name would imply. Many organisms are asexual and reproduce without mating. Reproductive isolation therefore has no meaning for such organisms.

For these reasons, a variety of other ideas have been put forward to establish criteria for defining species. Many of these are specific to a particular type of organism, and none has universal applicability. In reality, there may be no single explanation for what maintains the identity of species. Given the incredible variation evident in plants, animals, and microorganisms in all

aspects of their biology, it would not be surprising to find that different processes are operating in different organisms.

In addition, some scientists have turned from emphasizing the processes that maintain species distinctions to examining the evolutionary history of populations. These genealogical species concepts are currently a topic of great debate and are discussed further in chapter 23.

### **Learning Outcomes Review 22.1**

Species are populations of organisms that are distinct from other, co-occurring species, and are interconnected geographically. The biological species concept therefore defines species based on their ability to interbreed. Reproductive isolating mechanisms prevent successful interbreeding between species. The ecological species concept relies on adaptation and natural selection as a force for maintaining separation of species.

- How does the ability to exchange genes explain why sympatric species remain distinct and geographic populations of one species remain connected?

## **22.2** Natural Selection and Reproductive Isolation

### **Learning Outcomes**

1. Define reinforcement in the context of reproductive isolation.
2. Explain the possible outcomes when two populations that are partially reproductively isolated become sympatric.

One of the oldest questions in the field of evolution is: How does one ancestral species become divided into two descendant species (a process termed cladogenesis)? If species are defined by the existence of reproductive isolation, then the process of speciation is identical to the evolution of reproductive isolating mechanisms.

### **Selection may reinforce isolating mechanisms**

The formation of species is a continuous process, and as a result, two populations may only be partially reproductively isolated. For example, because of behavioral or ecological differences, individuals of two populations may be more likely to mate with members of their own population, and yet between-population matings may still occur. If mating occurs and fertilization produces a zygote, postzygotic barriers may also be incomplete: developmental problems may result in lower embryo survival or reduced fertility, but some individuals may survive and reproduce.

What happens when two populations come into contact thus depends on the extent to which isolating mechanisms have already evolved. If isolating mechanisms have not evolved at all,

### Figure 22.6 Reinforcement in

**European flycatchers.** The pied flycatcher (*Ficedula hypoleuca*) and the collared flycatcher (*F. albicollis*) appear very similar when they occur alone. However, in places where the two species occur sympatrically (indicated by the yellow color on the map), they have evolved differences in color and pattern, which allow individuals to choose mates from their own species and thus avoid hybridizing.

then the two populations will interbreed freely, and whatever other differences have evolved between them should disappear over the course of time, as genetic exchange homogenizes the populations. Conversely, if the populations are completely reproductively isolated, then no genetic exchange will occur, and the two populations will remain different species.

#### How reinforcement can complete the speciation process

The intermediate state, in which reproductive isolation has partially evolved but is not complete, is perhaps the most interesting situation. If the hybrids are partly sterile, or not as well adapted to the existing habitats as their parents, they will be at a disadvantage. Selection would favor any alleles in the parental populations that prevented hybridization, because individuals that did not engage in hybridization would produce more successful offspring.

The result would be the continual improvement of prezygotic isolating mechanisms until the two populations were completely reproductively isolated. This process is termed **reinforcement** because initially incomplete isolating mechanisms are reinforced by natural selection until they are completely effective.

An example of reinforcement is provided by pied and collared flycatchers. Throughout much of eastern and central Europe, these two bird species are geographically separated (**allopatric**) and are very similar in color (figure 22.6). However, in the Czech Republic and Slovakia, the two species occur together and occasionally hybridize, producing offspring that usually have very low fertility. At those sites, the species have evolved to look very different from each other, and birds prefer to mate with individuals with their own species' coloration. In contrast, birds from the allopatric populations prefer the allopatric color pattern. As a consequence of the color differences

where the species are sympatric the rate of hybridization is extremely low. These results indicate that when populations of the two species came into contact, natural selection led to the evolution of differences in color patterns, resulting in the evolution of behavioral, prezygotic isolation.

#### How gene flow may counter speciation

Reinforcement is not inevitable, however. When incompletely isolated populations come together, gene flow immediately begins to occur between them. Although hybrids may be inferior, they are not completely inviable or infertile—if they were, the species would already be completely reproductively isolated. When these surviving hybrids reproduce with members of either population, they will serve as a conduit of genetic exchange from one population to the other, and the two populations will tend to lose their genetic distinctiveness. Thus, a race ensues: Can complete reproductive isolation evolve before gene flow erases the differences between the populations? Experts disagree on the likely outcome, but many consider reinforcement to be the much less common outcome.

#### Learning Outcomes Review 22.2

Natural selection may favor the evolution of increased prezygotic reproductive isolation between sympatric populations. This phenomenon is termed reinforcement, and it may lead to populations becoming completely reproductively isolated. In contrast, however, genetic exchange between populations may decrease genetic differences among populations, thus preventing speciation from occurring.

- How might the initial degree of reproductive isolation affect the probability that reinforcement will occur when two populations come into sympatry?

## 22.3 The Role of Genetic Drift and Natural Selection in Speciation

### Learning Outcomes

1. Describe the effects of genetic drift on a population.
2. Explain how genetic drift and natural selection can lead to speciation.

What role does natural selection play in the speciation process? Certainly, the process of reinforcement is driven by natural selection, favoring the evolution of complete reproductive isolation. But reinforcement may not be common. In situations other than reinforcement, does natural selection play a role in the evolution of reproductive isolating mechanisms?

### Random changes may cause reproductive isolation

As mentioned in chapter 20, populations may diverge for purely random reasons. Genetic drift in small populations, founder effects, and population bottlenecks all may lead to changes in traits that cause reproductive isolation.

For example, in the Hawaiian Islands, closely related species of *Drosophila* often differ greatly in their courtship behavior. Colonization of new islands by these fruit flies probably involved a founder effect, in which one or a few flies—perhaps only a single pregnant female—was blown by strong winds to the new island. Changes in courtship behavior between ancestor and descendant populations may be the result of such founder events.

Given enough time, any two isolated populations will diverge because of genetic drift (remember that even large populations experience drift, but at a lower rate than in small populations). In some cases, this random divergence may affect traits responsible for reproductive isolation, and speciation may occur.

### Adaptation can lead to speciation

Although random processes may sometimes be responsible, in many cases natural selection probably plays a role in the speciation process. As populations of a species adapt to different circumstances, they likely accumulate many differences that may lead to reproductive isolation. For example, if one population of flies adapts to wet conditions and another to dry ones, then natural

selection will favor a variety of corresponding differences in physiological and sensory traits. These differences may promote ecological and behavioral isolation and may cause any hybrids the two populations produce to be poorly adapted to either habitat.

Selection might also act directly on mating behavior. Male *Anolis* lizards, for example, court females by extending a colorful flap of skin, called a *dewlap*, located under their throats (figure 22.7). The ability of one lizard to see the dewlap of another lizard depends not only on the color of the dewlap, but on the environment in which the lizards occur. A light-colored dewlap, for example, is most effective in reflecting light in a dim forest, whereas dark colors are more apparent in the bright glare of open habitats. As a result, when these lizards occupy new habitats, natural selection favors evolutionary change in dewlap color because males whose dewlaps cannot be seen will attract few mates. But the lizards also distinguish members of their own species from other species by the color of the dewlap. Adaptive change in mating signals in new environments could therefore have the incidental consequence of producing reproductive isolation from populations in the ancestral environment.

Laboratory scientists have conducted experiments on fruit flies and other fast-reproducing organisms in which they isolate populations in different laboratory chambers and measure how much reproductive isolation evolves. These experiments indicate that genetic drift by itself can lead to some degree of reproductive isolation, but in general, reproductive isolation evolves more rapidly when the populations are forced to adapt to different laboratory environments (such as temperature or food type). Although natural selection in the experiment does not directly favor traits because they lead to reproductive isolation, the incidental effect of adaptive divergence is that populations in different environments become reproductively isolated. For this reason, some biologists believe that the term *isolating mechanisms* is misguided, because it implies that the traits evolved specifically for the purpose of genetically isolating a species, which in most cases—except reinforcement—is probably incorrect.

### Learning Outcomes Review 22.3

Genetic drift refers to randomly generated changes in a population's genetic makeup. Isolated populations will eventually diverge because of genetic drift. Adaptation to different environments may also lead to populations becoming reproductively isolated from each other.

- How is the evolution of reproductive isolation in populations adapting to different environments different from the process of reinforcement?

**Figure 22.7 Dewlaps of different species of Caribbean *Anolis* lizards.** Males use their dewlaps in both territorial and courtship displays. Coexisting species almost always differ in their dewlaps, which are used in species recognition. Darker-colored dewlaps, such as those of the two species on the left, are easier to see in open habitats, whereas lighter-colored dewlaps, like those of the two species on the right, are more visible in shaded environments.

a.

b.

c.

**Figure 22.8** Populations can become geographically isolated for a variety of reasons. *a.* Colonization of remote areas by one or a few individuals can establish populations in a distant place. *b.* Barriers to movement can split an ancestral population into two isolated populations. *c.* Extinction of intermediate populations can leave the remaining populations isolated from one another.

## 22.4 The Geography of Speciation

### Learning Outcomes

1. Compare and contrast sympatric and allopatric speciation.
2. Explain the conditions required for sympatric speciation to occur.

Speciation is a two-part process. First, initially identical populations must diverge, and second, reproductive isolation must evolve to maintain these differences. The difficulty with this process, as we have seen, is that the homogenizing effect of gene flow between populations is constantly acting to erase any differences that may arise, either by genetic drift or natural selection. Gene flow only occurs between populations that are in contact, however, and populations can become geographically isolated for a variety of reasons (figure 22.8). Consequently, evolutionary biologists have long recognized that speciation is much more likely in geographically isolated populations.

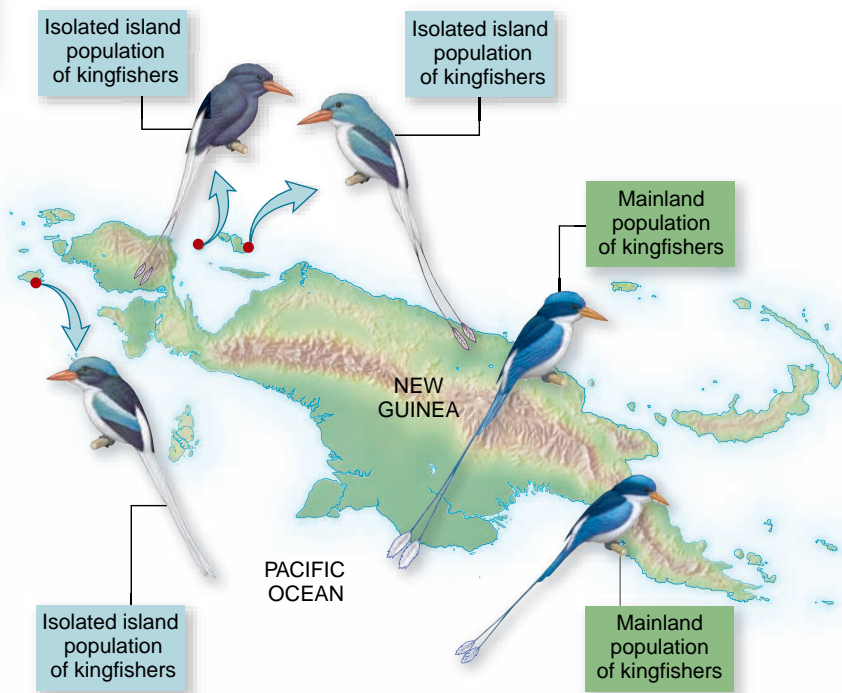

### Allopatric speciation takes place when populations are geographically isolated

Ernst Mayr was the first biologist to demonstrate that geographically separated, or *allopatric*, populations appear much more likely to have evolved substantial differences leading to speciation. Marshalling data from a wide variety of organisms and localities, Mayr made a strong case for allopatric speciation as the primary means of speciation.

For example, the little paradise kingfisher varies little throughout its wide range in New Guinea, despite the great variation in the island's topography and climate. By contrast, isolated populations on nearby islands are strikingly differ-

ent from one another and from the mainland population (figure 22.9). Thus, geographic isolation seems to have been an important prerequisite for the evolution of differences between populations.

Many other examples indicate that speciation can occur under allopatric conditions. Because we would expect isolated populations to diverge over time, by either drift or selection,

**Figure 22.9** Phenotypic differentiation in the little paradise kingfisher *Tanysiptera hydrocharis* in New Guinea.

Isolated island populations (*left*) are quite distinctive, showing variation in tail feather structure and length, plumage coloration, and bill size, whereas kingfishers on the mainland (*right*) show little variation.

this result is not surprising. Rather, the more intriguing question becomes: Is geographic isolation *required* for speciation to occur?

## Sympatric speciation occurs without geographic separation

For decades, biologists have debated whether one species can split into two at a single locality, without the two new species ever having been geographically separated. Investigators have suggested that this sympatric speciation could occur either instantaneously or over the course of multiple generations. Although most of the hypotheses suggested so far are highly controversial, one type of instantaneous sympatric speciation is known to occur commonly, as the result of polyploidy.

### Instantaneous speciation through polyploidy

Instantaneous sympatric speciation occurs when an individual is born that is reproductively isolated from all other members of its species. In most cases, a mutation that would cause an individual to be greatly different from others of its species would have many adverse pleiotropic side effects, and the individual would not survive. One exception often seen in plants, however, occurs through the process of **polyploidy**, which produces individuals that have more than two sets of chromosomes.

Polyploid individuals can arise in two ways. In **autopolyploidy**, all of the chromosomes may arise from a single species. This might happen, for example, due to an error in cell division that causes a doubling of chromosomes. Such individuals, termed *tetraploids* because they have four sets of chromosomes, can self fertilize or mate with other tetraploids, but cannot mate and produce fertile offspring with normal diploids. The reason is that the tetraploid species produce “diploid” gametes that produce triploid offspring (having three sets of chromosomes) when combined with haploid gametes from normal diploids. Triploids are sterile because the odd number of chromosomes prevent proper pairing during meiosis.

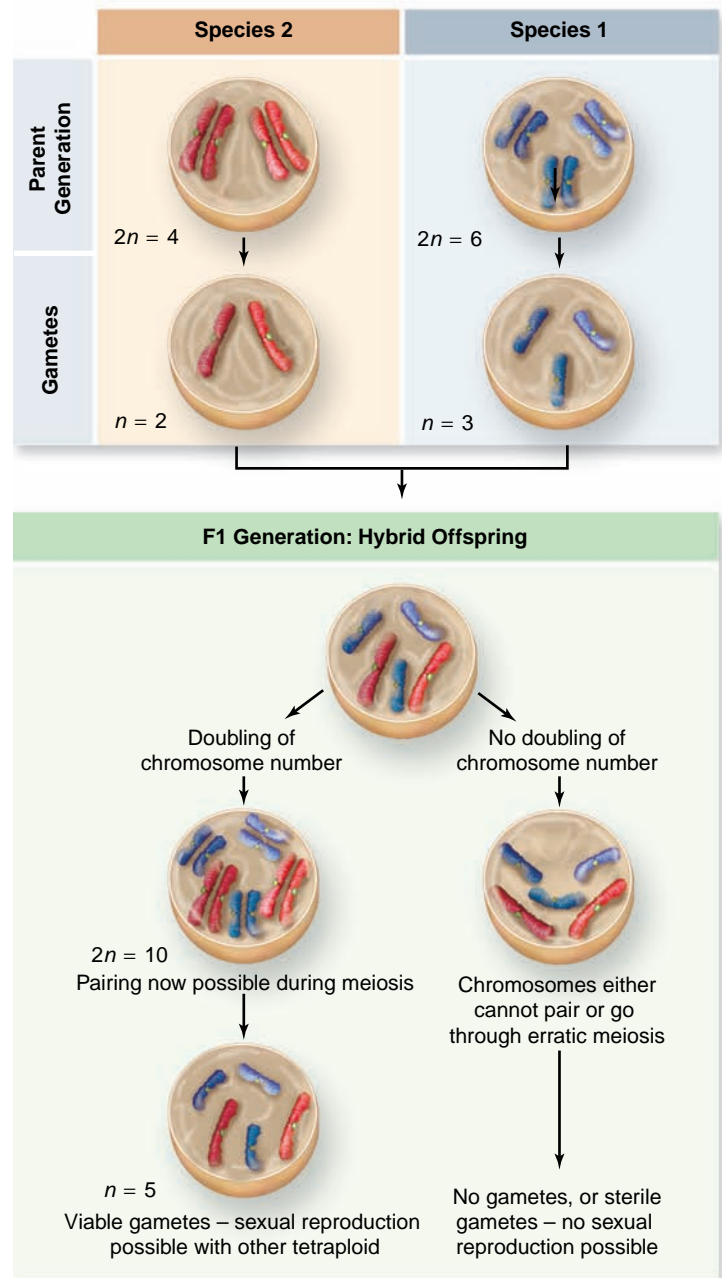

A more common type of polyploid speciation is **allopolyploidy**, which may happen when two species hybridize (figure 22.10). The resulting offspring, having one copy of the chromosomes of each species, is usually infertile because the chromosomes do not pair correctly in meiosis. However, such individuals are often otherwise healthy, can reproduce asexually, and can even become fertile through a variety of events. For example, if the chromosomes of such an individual were to spontaneously double, as just described, the resulting tetraploid would have two copies of each set of chromosomes. Consequently, pairing would no longer be a problem in meiosis. As a result, such tetraploids would be able to interbreed, and a new species would have been created.

It is estimated that about half of the approximately 260,000 species of plants have a polyploid episode in their history, including many of great commercial importance, such as bread wheat, cotton, tobacco, sugarcane, bananas, and potatoes. Speciation by polyploidy is also known to occur in a variety of animals, including insects, fish, and salamanders, although much more rarely than in plants.

### Sympatric speciation by disruptive selection

Some investigators believe that sympatric speciation can occur over the course of multiple generations through the process of disruptive selection. As noted in chapter 20, disruptive selection can cause a population to contain individuals exhibiting two different phenotypes.

One might think that if selection is strong enough, these two phenotypes would evolve over a number of generations into different species. But before the two phenotypes could become different species, they would have to evolve reproductive isolating mechanisms. Initially, the two phenotypes would not

**Figure 22.10 Allopolyploid speciation.** Hybrid offspring from parents with different numbers of chromosomes often cannot reproduce sexually. Sometimes, the number of chromosomes in such hybrids doubles to produce a tetraploid individual that can undergo meiosis and reproduce with similar tetraploid individuals.

be reproductively isolated at all, and genetic exchange between individuals of the two phenotypes would tend to prevent genetic divergence in mating preferences or other isolating mechanisms. As a result, the two phenotypes would be retained as polymorphisms within a single population. For this reason, most biologists consider sympatric speciation of this type to be a rare event.

In recent years, however, a number of cases have appeared that are difficult to interpret in any way other than as sympatric speciation. For example, Lake Barombi Mbo in Cameroon is an extremely small and ecologically homogeneous lake, with no opportunity for within-lake isolation. Nonetheless, 11 species of closely related cichlid fish occur in the lake; all of the species are more closely related evolutionarily to one another than to any species outside of the lake. The most reasonable explanation is that an ancestral species colonized the lake and subsequently underwent sympatric speciation multiple times.

### Learning Outcomes Review 22.4

Sympatric speciation occurs without geographic separation, whereas allopatric speciation occurs in geographically isolated populations. Polyploidy and disruptive selection are two ways by which a single species may undergo sympatric speciation.

- How do polyploidy and disruptive selection differ as ways in which sympatric speciation can occur?

## 22.5 Adaptive Radiation and Biological Diversity

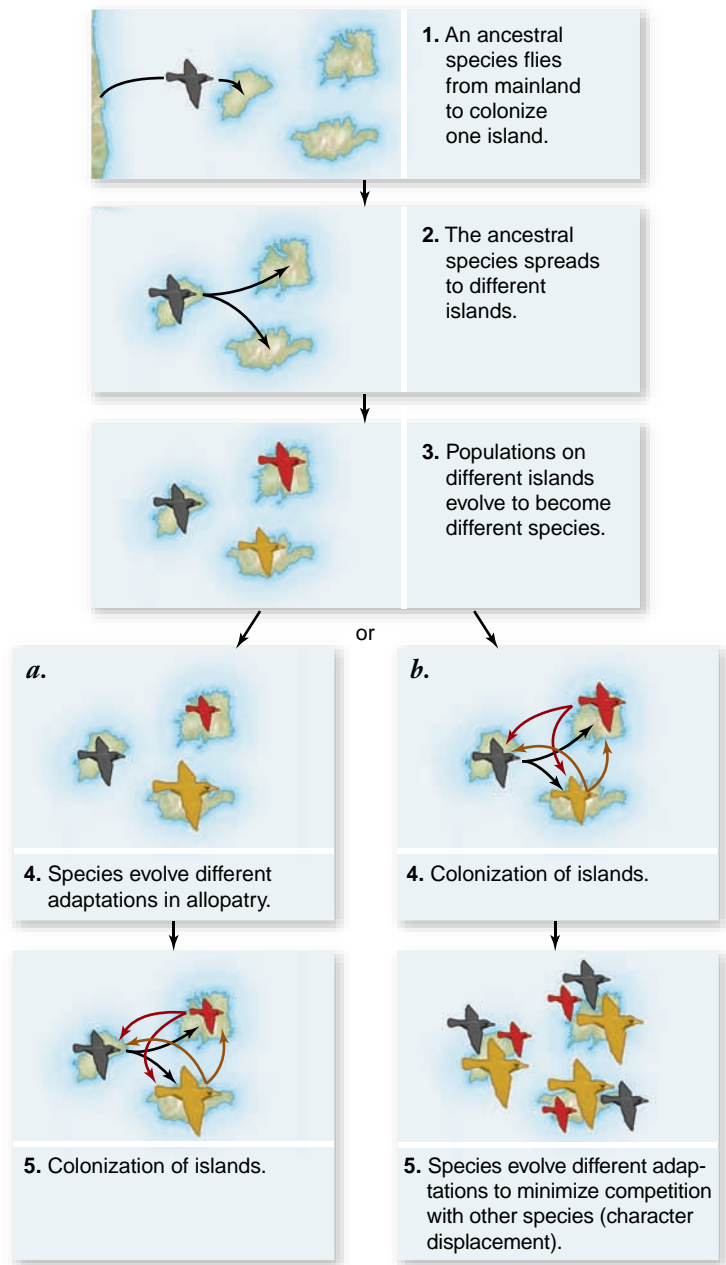

### Learning Outcomes

1. Describe adaptive radiation.
2. List conditions that may lead to adaptive radiation.

One of the most visible manifestations of evolution is the existence of groups of closely related species that have recently evolved from a common ancestor by adapting to different parts of the environment. These **adaptive radiations** are particularly common in situations in which a species occurs in an environment with few other species and many available resources. One example is the creation of new islands through volcanic activity, such as the Hawaiian and Galápagos Islands. Another example is a catastrophic event leading to the extinction of most other species, a situation we will discuss soon in greater detail.

Adaptive radiation can also result when a new trait, called a **key innovation**, evolves within a species allowing it to use resources or other aspects of the environment that were previously inaccessible. Classic examples of key innovation leading to adaptive radiation are the evolution of lungs in fish and of wings in birds and insects, both of which allowed descendant species to diversify and adapt to many newly available parts of the environment.

Adaptive radiation requires both speciation and adaptation to different habitats. A classic model postulates that a species colonizes multiple islands in an archipelago. Speciation subsequently occurs allopatrically, and then the newly arisen species colonize other islands, producing multiple species per island (figure 22.11).

**Figure 22.11 Classic model of adaptive radiation on island archipelagoes.** (1) An ancestral species colonizes an island in an archipelago. Subsequently, the population colonizes other islands (2), after which the populations on the different islands speciate in allopatry (3). Then some of these new species colonize other islands, leading to local communities of two or more species. Adaptive differences can either evolve when species are in allopatry in response to different environmental conditions (a) or as the result of ecological interactions between species (b) by the process of character displacement.

Adaptation to new habitats can occur either during the allopatric phase, as the species respond to different environments on the different islands, or after two species become sympatric. In the latter case, this adaptation may be driven by the need to minimize competition for available resources with other species. Populations on different islands evolve to become different species. In this process, termed **character displacement**, natural selection in each species favors those individuals that use resources not used by the other species. Because those individuals will have greater fitness, whatever traits cause the differences in resource use will increase in frequency (assuming that a genetic basis exists for these differences), and, over time, the species will diverge (figure 22.12).

An alternative possibility is that adaptive radiation occurs through repeated instances of sympatric speciation, producing a suite of species adapted to different habitats. As discussed earlier such scenarios are hotly debated.

In the following sections we discuss four exemplary cases of adaptive radiation.

### SCIENTIFIC THINKING

**Question:** Does competition for resources cause character displacement?

**Hypothesis:** Competition with similar species will cause natural selection to promote evolutionary divergence.

**Experiment:** Place a species of fish in a pond with another, similar fish species and measure the form of selection. As a control, place a population of the same species in a pond without the second species. Note that the size of food that these fish eat is related to the size of the fish.

**Result:** In the pond with two species, directional selection favors those individuals which have phenotypes most dissimilar from the other species, and thus are most different in resource use. Directional selection does not occur in the control population.

**Interpretation:** Would you expect character displacement to occur if resources were unlimited?

**Figure 22.12 Character displacement.** *a.* Two species are initially similar and thus overlap greatly in resource use, as might happen if the two species were similar in size (in many species, body size and food size are closely related). Individuals in each species that are most different from the other species (circled) will be favored by natural selection, because they will not have to compete with the other species. For example, the smallest individuals of one species and the largest of the other would not compete with the other species for food and thus would be favored. *b.* As a result, the species will diverge in resource use and minimize competition between the species.

### Inquiry question

How would the scenario for adaptive radiation differ depending on whether speciation is allopatric? What is the relationship between character displacement and sympatric speciation?

### Hawaiian *Drosophila* exploited a rich, diverse habitat

More than 1000 species in the fly genus *Drosophila* occur on the Hawaiian Islands. New species of *Drosophila* are still being discovered in Hawaii, although the rapid destruction of the native vegetation is making the search more difficult.

Aside from their sheer number, Hawaiian *Drosophila* species are unusual because of their incredible diversity of morphological and behavioral traits (figure 22.13). Evidently, when their ancestors first reached these islands, they encountered many “empty” habitats that other kinds of insects and other animals occupied elsewhere. As a result, the species have adapted to all manners of fruit fly life and include predators, parasites, and herbivores, as well as species specialized for eating the detritus in leaf litter and the nectar of flowers. The larvae of various species live in rotting stems, fruits, bark, leaves, or roots, or feed on sap. No comparable diversity of *Drosophila* species is found anywhere else in the world.

The great diversity of Hawaiian species is a result of the geological history of these islands. New islands have continually arisen from the sea in this region. As they have done so, they appear to have been invaded successively by the various *Drosophila* groups present on the older islands. New species thus have evolved as new islands have been colonized.

In addition, the Hawaiian Islands are among the most volcanically active islands in the world. Periodic lava flows often have created patches of habitat within an island surrounded by a “sea” of barren rock. These land islands are termed *kipukas*. *Drosophila* populations isolated in these *kipukas* often undergo speciation. In these ways, rampant speciation combined with ecological opportunity has led to an unparalleled diversity of insect life.

**Figure 22.13 Hawaiian *Drosophila*.** The hundreds of species that have evolved on the Hawaiian Islands are extremely variable in appearance, although genetically almost identical. *a.* *Drosophila heteroneura*. *b.* *Drosophila digressa*.

## Darwin's finch species adapted to use different food types

The diversity of Darwin's finches on the Galápagos Islands was first mentioned in chapter 21. Presumably, the ancestor of Darwin's finches reached these islands before other land birds, and many of the types of habitats that other types of birds use on the mainland were unoccupied.

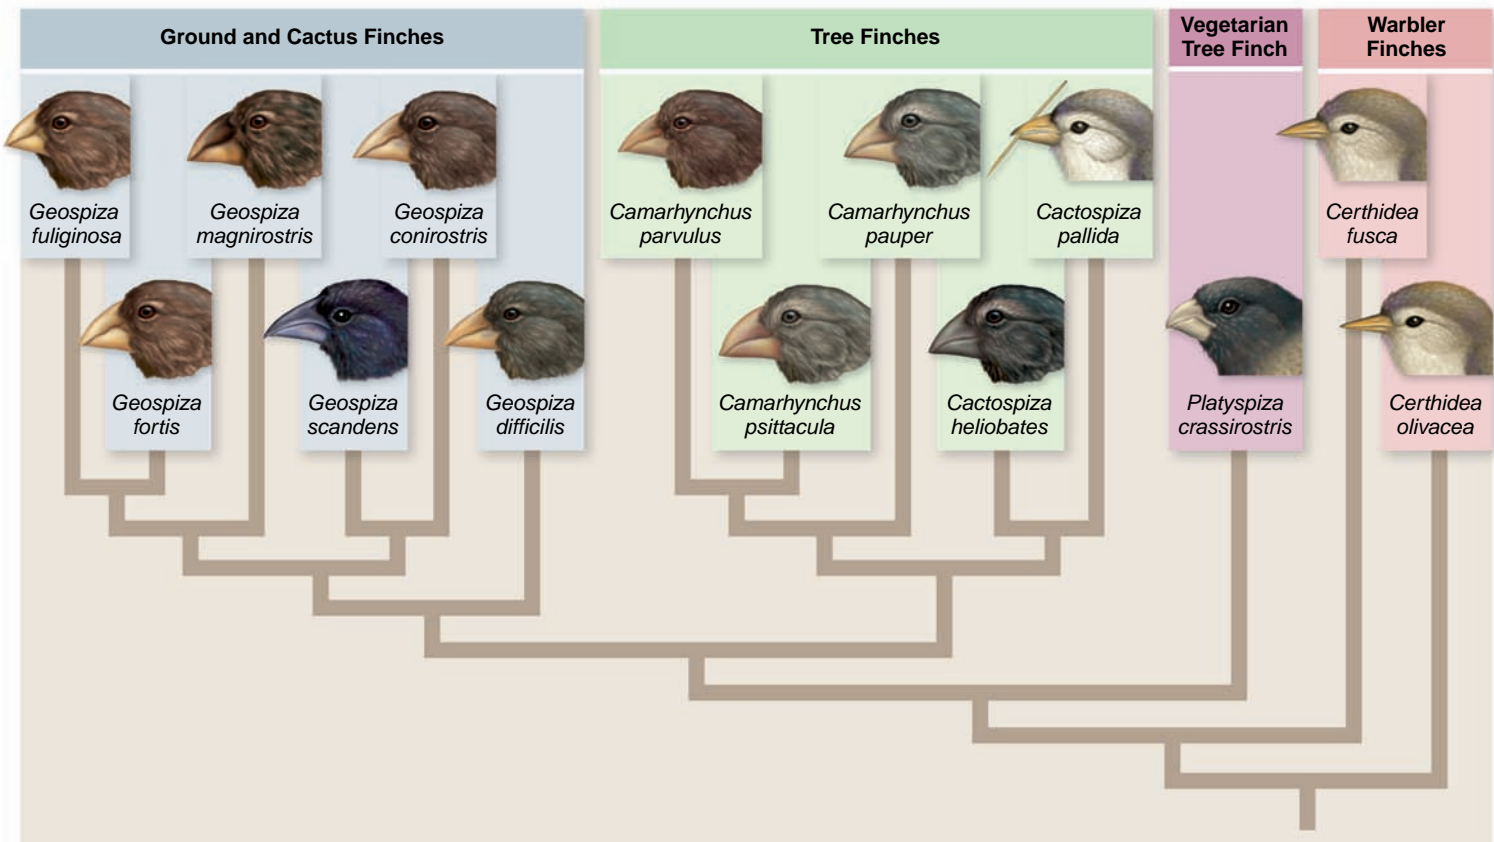

As the new arrivals moved into these vacant ecological niches and adopted new lifestyles, they were subjected to many different sets of selective pressures. Under these circumstances, and aided by the geographic isolation afforded by the many islands of the Galápagos archipelago, the ancestral finches rapidly split into a series of diverse populations, some of which evolved into separate species. These species now occupy many different habitats on the Galápagos Islands, which are comparable to the habitats several distinct groups of birds occupy on the mainland. As illustrated in figure 22.14, the 14 species fall into four groups:

1. **Ground finches.** There are six species of *Geospiza* ground finches. Most of the ground finches feed on seeds. The size of their bills is related to the size of the seeds they eat. Some of the ground finches feed primarily on cactus flowers and fruits, and they have a longer, larger, and more pointed bill than the others.

2. **Tree finches.** There are five species of insect-eating tree finches. Four species have bills suitable for feeding on insects. The woodpecker finch has a chisel-like beak. This unusual bird carries around a twig or a cactus spine, which it uses to probe for insects in deep crevices.
3. **Vegetarian finch.** The very heavy bill of this species is used to wrench buds from branches.
4. **Warbler finches.** These unusual birds play the same ecological role in the Galápagos woods that warblers play on the mainland, searching continuously over the leaves and branches for insects. They have slender, warblerlike beaks.

Recently, scientists have examined the DNA of Darwin's finches to study their evolutionary history. These studies suggest that the deepest branches in the finch evolutionary tree lead to warbler finches, which implies that warbler finches were among the first types to evolve after colonization of the islands. All of the ground species are closely related to one another, as are all of the tree finches. Nonetheless, within each group, species differ in beak size and other attributes, as well as in resource use.

Field studies, conducted in conjunction with those discussed in chapter 21, demonstrate that ground species compete for resources; the differences between species likely resulted from character displacement as initially similar species diverged to minimize competitive pressures.

**Figure 22.14 An evolutionary tree of Darwin's finches.** This evolutionary tree, derived from examination of DNA sequences, suggests that warbler finches are an early offshoot. Ground and tree finches subsequently diverged, and then species within each group specialized to use different resources. Recent studies have shown, surprisingly, that the two warbler finches are not each other's closest relatives. Rather, *Certhidea fusca* is more closely related to the remaining Darwin's finches than it is to *C. olivacea*.

## Lake Victoria cichlid fishes diversified very rapidly

Lake Victoria is an immense, shallow, freshwater sea about the size of Switzerland in the heart of equatorial East Africa. Until recently, the lake was home to an incredibly diverse collection of over 450 species of cichlid fishes.

### Geologically recent radiation

The cluster of cichlid species appears to have evolved recently and quite rapidly. By sequencing the cytochrome *b* gene in many of the lake's fish, scientists have been able to estimate that the first cichlids entered Lake Victoria only 200,000 years ago.

Dramatic changes in water level encouraged species formation. As the lake rose, it flooded new areas and opened up new habitats. Many of the species may have originated after the lake dried down 14,000 years ago, isolating local populations in small lakes until the water level rose again.

### Cichlid diversity

Cichlids are small, perchlike fishes ranging from 5 to 25 centimeters (cm) in length, and the males come in endless varieties of colors. The ecological and morphological diversity of these

fish is remarkable, particularly given the short span of time over which they have evolved.

We can gain some sense of the vast range of types by looking at how different species eat. There are mud biters, algae scrapers, leaf chewers, snail crushers, zooplankton eaters, insect eaters, prawn eaters, and fish eaters. Snail shellers pounce on slow-crawling snails and spear their soft parts with long, curved teeth before the snail can retreat into its shell. Scale scrapers rasp slices of scales off other fish. There are even cichlid species that are "pedophages," eating the young of other cichlids.

Cichlid fish have a remarkable key innovation that may have been instrumental in their evolutionary radiation: They carry a second set of functioning jaws (figure 22.15). This trait occurs in many other fish, but in cichlids it is greatly enlarged. The ability of these second jaws to manipulate and process food has freed the oral jaws to evolve for other purposes, and the result has been the incredible diversity of ecological roles filled by these fish.

### Abrupt extinction in the last several decades

Recently, much of the cichlid diversity has disappeared. In the 1950s, the Nile perch, a large commercial fish with a voracious appetite, was introduced to Lake Victoria. Since

**Figure 22.15 Cichlid fishes of Lake Victoria.** These fishes have evolved adaptations to use a variety of different habitats. The enlarged second set of jaws located in the throat of these fish has provided evolutionary flexibility, allowing oral jaws to be modified in many ways.

then, it has spread through the lake, eating its way through the cichlids.

By 1990, many of the open-water cichlid species had become extinct, as well as others living in rocky shallow regions. Over 70% of all the named Lake Victoria cichlid species had disappeared, as well as untold numbers of species that had yet to be described. We will revisit the story of Lake Victoria when we discuss conservation biology in chapter 59.

## New Zealand alpine buttercups underwent speciation in glacial habitats

Adaptive radiations such as those we have described in Hawaiian *Drosophila*, Galápagos finches, and cichlid fishes seem to have been favored by periodic isolation. A clear example of the role periodic isolation plays in species formation can be seen in the alpine buttercups that grow among the glaciers of New Zealand (figure 22.16).

More species of alpine buttercups grow on the two main islands of New Zealand than in all of North and South America combined. The evolutionary mechanism responsible for this diversity is recurrent isolation associated with the recession of glaciers.

The 14 species of alpine buttercups occupy five distinctive habitats within glacial areas:

- *snowfields*—rocky crevices among outcrops in permanent snowfields at 2130- to 2740-m elevation;
- *snowline fringe*—rocks at lower margin of snowfields between 1220 and 2130 m;
- *stony debris*—slopes of exposed loose rocks at 610 to 1830 m;
- *sheltered situations*—shaded by rock or shrubs at 305 to 1830 m; and
- *boggy habitats*—sheltered slopes and hollows, poorly drained tussocks at elevations between 760 and 1525 m.

Buttercup speciation and diversification have been promoted by repeated cycles of glacial advance and retreat. As the glaciers retreat up the mountains, populations become isolated on mountain peaks, permitting speciation (see figure 22.16). In the next glacial advances, these new species can expand throughout the mountain range, coming into contact with their close relatives. In this way, one initial species could give rise to many descendants. Moreover, on isolated mountaintops during glacial retreats, species have

**Figure 22.16 New Zealand alpine buttercups (genus *Ranunculus*).** Periodic glaciation encouraged species formation among alpine buttercups in New Zealand. **a.** Fourteen species of alpine *Ranunculus* grow among the glaciers and mountains of New Zealand. **b.** The formation of extensive glaciers during the Pleistocene epoch linked the alpine zones (*white*) of many mountains together. When the glaciers receded, these alpine zones were isolated from one another, only to become reconnected with the advent of the next glacial period. During periods of isolation, populations of alpine buttercups diverged in the isolated habitats.

convergently evolved to occupy similar habitats; these distantly related but ecologically similar species have then been brought back into contact in subsequent glacial advances.

### Learning Outcomes Review 22.5

Adaptive radiation occurs when a species diversifies, producing descendant species that are adapted to use many different parts of the environment. Adaptive radiation may occur under conditions of recurrent isolation, which increases the rate at which speciation occurs, and by occupation of areas with few competitors and many types of available resources, such as on volcanic islands. The evolution of a key innovation may also allow adaptation to parts of the environment that previously couldn't be utilized.

- In contrast to the archipelago model, how might an adaptive radiation proceed in a case of sympatric speciation by disruptive selection?

## 22.6 The Pace of Evolution

### Learning Outcomes

1. Define stasis and compare it to gradual evolutionary change.
2. Explain the components of the punctuated equilibrium hypothesis.

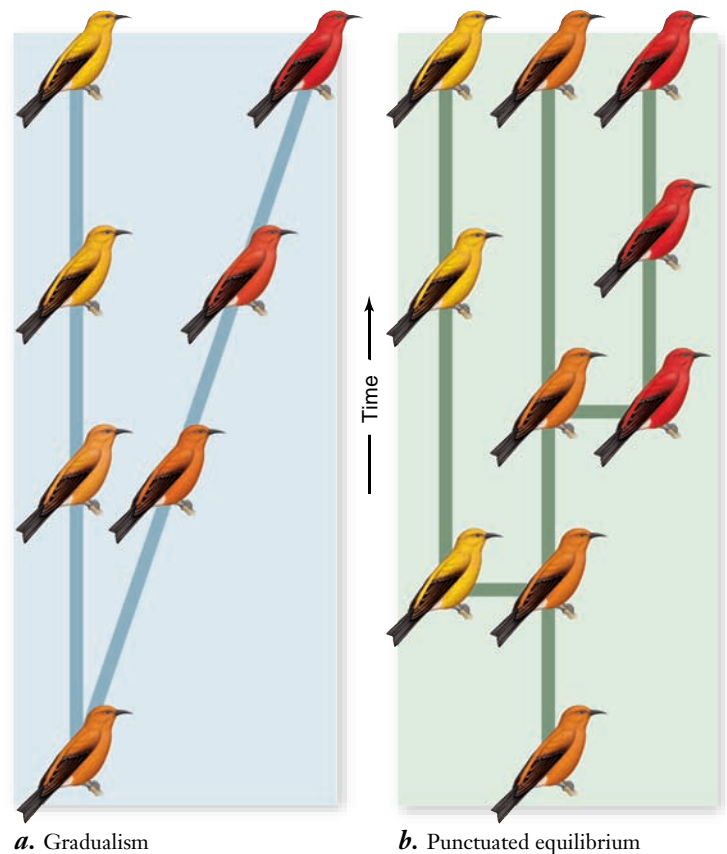

We have discussed the manner in which speciation may occur, but we haven't yet considered the relationship between speciation and the evolutionary change that occurs within a species. Two hypotheses, *gradualism* and *punctuated equilibrium*, have been advanced to explain the relationship.

### Gradualism is the accumulation of small changes

For more than a century after the publication of *On the Origin of Species*, the standard view was that evolution occurred very slowly. Such change would be nearly imperceptible from generation to generation, but would accumulate such that, over the course of thousands and millions of years, major changes could occur. This view is termed **gradualism** (figure 22.17a).

### Punctuated equilibrium is long periods of stasis followed by relatively rapid change

Gradualism was challenged in 1972 by paleontologists Niles Eldredge of the American Museum of Natural History in New York and Stephen Jay Gould of Harvard University, who argued that species experience long periods of little or no evolutionary change (termed **stasis**), punctuated by bursts

**Figure 22.17** Two views of the pace of macroevolution. *a.* Gradualism suggests that evolutionary change occurs slowly through time and is not linked to speciation, whereas *(b)* punctuated equilibrium surmises that phenotypic change occurs in bursts associated with speciation, separated by long periods of little or no change.

of evolutionary change occurring over geologically short time intervals. They called this phenomenon **punctuated equilibrium** (figure 22.17b) and argued that these periods of rapid change occurred only during the speciation process.

Initial criticism of the punctuated equilibrium hypothesis focused on whether rapid change could occur over short periods of time. As we have seen in the last two chapters, however, when natural selection is strong, rapid and substantial evolutionary change can occur. A more difficult question involves the long periods of stasis: Why would species exist for thousands, or even millions, of years without changing?

Although a number of possible reasons have been suggested, most researchers now believe that a combination of stabilizing and oscillating selection is responsible for stasis. If the environment does not change over long periods of time, or if environmental changes oscillate back and forth, then stasis may occur for long periods. One factor that may enhance this stasis is the ability of species to shift their ranges; for example, during the ice ages, when the global climate cooled, the geographic ranges of many species shifted southward, so that the species continued to experience similar environmental conditions.

## Inquiry question

Why would changes in geographic ranges promote evolutionary stasis?

## Evolution may include both types of change

Eldredge and Gould's proposal prompted a great deal of research. Some well-documented groups, such as African mammals, clearly have evolved gradually, not in spurts. Other groups, such as marine bryozoa, seem to show the irregular pattern of evolutionary change predicted by the punctuated equilibrium model. It appears, in fact, that gradualism and punctuated equilibrium are two ends of a continuum. Although some groups appear to have evolved solely in a gradual manner and others only in a punctuated mode, many other groups show evidence of both gradual and punctuated episodes at different times in their evolutionary history.

The idea that speciation is necessarily linked to phenotypic change has not been supported, however. On one hand, it is now clear that speciation can occur without substantial phenotypic change. For example, many closely-related salamander species are nearly indistinguishable. On the other, it is also clear that phenotypic change can occur within species in the absence of speciation.

### Learning Outcomes Review 22.6

Gradualism is the accumulation of almost imperceptible changes that eventually results in major differences. Punctuated equilibrium proposes that long periods of stasis are interrupted (punctuated) by periods of rapid change. Evidence for both gradualism and punctuated equilibrium has been found in different groups. Stasis refers to a period in which little or no evolutionary change occurs. Stasis may result from stabilizing or oscillating selection.

- Could evolutionary change be punctuated in time (that is, rapid and episodic), but not linked to speciation?

## 22.7 Speciation and Extinction Through Time

### Learning Outcomes

1. Describe the pattern of species diversity through time.
2. Define mass extinction and identify when major mass extinctions have occurred.

Biological diversity has increased vastly since the Cambrian period, but the trend has been far from consistent. After a rapid rise, diversity reached a plateau for about 200 million years, but since then has risen steadily. Because changes in the number of species reflect the rate of origin of new species relative to the rate at which existing species disappear, this long-term trend reveals that speciation has, in general, surpassed extinction.

Nonetheless, speciation has not always outpaced extinction. In particular, interspersed in the long-term increase in species diversity have been a number of sharp declines, termed **mass extinctions**.

## Five mass extinctions have occurred in the distant past

Five major mass extinctions have been identified, the most severe one occurring at the end of the Permian period, approximately 250 million years ago (figure 22.18). At that time, more than half of all plant and animal families and as much as 96% of all species may have perished.

**Figure 22.18 Biodiversity through time.** The taxonomic diversity of families of marine animals has increased since the Cambrian period, although occasional dips have occurred. The fossil record is most complete for marine organisms because they are more readily fossilized than terrestrial species. Families are shown, rather than species, because many species are known from only one specimen, thus introducing error into estimates of the time of extinction. Arrows indicate the five major mass extinction events.

The most famous and well-studied extinction, although not as drastic, occurred at the end of the Cretaceous period (65 million years ago), at which time the dinosaurs and a variety of other organisms went extinct. Recent findings have supported the hypothesis that this extinction event was triggered when a large asteroid slammed into Earth, perhaps causing global forest fires and obscuring the Sun for months by throwing particles into the air. The cause of other mass extinction events is less certain. Some scientists suggest that asteroids may have played a role in at least some of the other mass extinction events; other hypotheses implicate global climate change and other causes.

One important result of mass extinctions is that not all groups of organisms are affected equally. For example, in the extinction at the end of the Cretaceous, not only dinosaurs, but also marine and flying reptiles, and ammonites (a type of mollusk) went extinct. Marsupials, flowering plants, birds, and some forms of plankton were greatly reduced in diversity. In contrast, turtles, crocodylians, and amphibians seemed to have been unscathed. Why some groups were harder hit than others is not clear, but one hypothesis suggests that survivors were those animals that could shelter underground or in water, and that could either scavenge or required little food in the cool temperatures that resulted from the blockage of sunlight.

A consequence of mass extinctions is that previously dominant groups may perish, thus changing the course of evolution. This is certainly true of the Cretaceous extinction. During the Cretaceous period, placental mammals were a minor group composed of species that were mostly no larger than a house cat. When the dinosaurs, which had dominated the world for more than 100 million years, disappeared at the end of this period, the placental mammals underwent a significant adaptive radiation. It is humbling to think that humans might never have arisen had that asteroid not struck Earth 65 million years ago.

As the world around us illustrates today, species diversity does rebound after mass extinctions, but this recovery is not

rapid. Examination of the fossil record indicates that rates of speciation do not immediately increase after an extinction pulse, but rather take about 10 million years to reach their maximum. The cause of this delay is not clear, but it may result because it takes time for ecosystems to recover and for the processes of speciation and adaptive diversification to begin. Consequently, species diversity may require 10 million years, or even much longer, to attain its previous level.

## A sixth extinction is underway

The number of species in the world in recent times is greater than it has ever been. Unfortunately, that number is decreasing at an alarming rate due to human activities (see chapter 59).

Some estimate that as much as one-fourth of all species will become extinct in the near future, a rate of extinction not seen on Earth since the Cretaceous mass extinction. Moreover, the rebound in species diversity may be even slower than following previous mass extinction events because, instead of the ecologically impoverished, but energy-rich environment that existed after previous mass extinction events, a large proportion of the world's resources will be taken up already by human activities, leaving few resources available for adaptive radiation.

### Learning Outcomes Review 22.7

The number of species has increased through time, although not at a constant rate. Five major extinction events have substantially, though briefly, reduced the number of species. Diversity rebounds, but the recovery is not rapid, and the groups making up that diversity are not the same as those that existed before the extinction event. Unfortunately, humans are currently causing a sixth mass extinction event.

- *In what ways are the current mass extinction event different from those that have occurred in the past?*

## Chapter Review

### 22.1 The Nature of Species and the Biological Species Concept

***Sympatric species inhabit the same locale but remain distinct.***

Most sympatric species are readily distinguishable phenotypically and ecologically. Others can usually be identified by careful study.

***Populations of a species exhibit geographic variation.***

Populations that differ greatly in phenotype or ecologically are usually connected by geographically intermediate populations.

***The biological species concept focuses on the ability to exchange genes.***

Biological species are generally defined as populations that interbreed, or have the potential to do so, and produce fertile offspring. Reproductive isolating mechanisms prevent genetic exchange between species.

***Prezygotic isolating mechanisms prevent the formation of a zygote.***

Prezygotic isolating mechanisms prevent a viable zygote from being created. These mechanisms include ecological, behavioral, temporal, and mechanical isolation.

***Postzygotic isolating mechanisms prevent normal development into reproducing adults.***

Postzygotic isolating mechanisms prevent a zygote from developing into a viable and fertile individual.

***The biological species concept does not explain all observations.***

The ecological species concept, one alternative explanation, focuses on the role of natural selection and differences among species in their ecological requirements.

In reality, no one species concept can explain all the diversity of life.

## 22.2 Natural Selection and Reproductive Isolation

### *Selection may reinforce isolating mechanisms.*

Populations may evolve complete reproductive isolation in allopatry. If populations that have evolved only partial reproductive isolation come into contact, natural selection can lead to increased reproductive isolation, a process termed “reinforcement.”

Alternatively, genetic exchange between the populations can lead to homogenization and thus prevent speciation from occurring.

## 22.3 The Role of Genetic Drift and Natural Selection in Speciation

### *Random changes may cause reproductive isolation.*

In small populations, genetic drift may cause populations to diverge; the differences that evolve may cause the populations to become reproductively isolated.

### *Adaptation can lead to speciation.*

Adaptation to different situations or environments may incidentally lead to reproductive isolation. In contrast to reinforcement, these differences are not directly favored by natural selection because they prevent hybridization.

Natural selection can directly select for traits that increase reproductive isolation.

## 22.4 The Geography of Speciation (see figure 22.9)

### *Allopatric speciation takes place when populations are geographically isolated.*

Allopatric, or geographically isolated, populations are much more likely to evolve into separate species because no gene flow occurs between them. Most speciation probably occurs in allopatry.

### *Sympatric speciation occurs without geographic separation.*

Sympatric speciation can occur in two ways. One is polyploidy, which instantly creates a new species. Disruptive selection also can cause one species to divide into two, but scientists debate how commonly it occurs.

## 22.5 Adaptive Radiation and Biological Diversity

Adaptive radiation occurs when a species finds itself in a new or suddenly changed environment with many resources and few competing species (see figure 22.11).

The evolution of a new trait that allows individuals to use previously inaccessible parts of the environment, termed a “key innovation,” may also trigger an adaptive radiation.

### *Hawaiian Drosophila exploited a rich, diverse habitat.*

At least 1000 species of Hawaiian *Drosophila* have been identified.

### *Darwin’s finch species adapted to use different food types.*

Fourteen species in four genera have evolved to exploit four different habitats based on type of food.

### *Lake Victoria cichlid fishes diversified very rapidly.*

Cichlids underwent rapid radiation to form 300 species, although today more than 70% of these species are now extinct.

### *New Zealand alpine buttercups underwent speciation in glacial habitats.*

Periodic isolation by glaciers has led to 14 species in distinct habitats.

## 22.6 The Pace of Evolution

### *Gradualism is the accumulation of small changes.*

Historically, scientists took the view that speciation occurred gradually through very small cumulative changes.

### *Punctuated equilibrium is long periods of stasis followed by relatively rapid change.*

The punctuated equilibrium hypothesis contends that not only is change rapid and episodic, but that it is only associated with the speciation process.

### *Evolution may include both types of change.*

Scientists generally agree that evolutionary change occurs on a continuum, with gradualism and punctuated change being the extremes.

## 22.7 Speciation and Extinction Through Time

In general, the number of species have increased through time (see figure 22.18).

### *Five mass extinctions have occurred in the distant past.*

Mass extinctions have led to dramatic decreases in species diversity, which takes millions of years to recover. Five such mass extinctions have occurred in the distant past due to asteroids hitting the Earth and global climate change, among other events.

### *A sixth mass extinction is underway.*

Humans are currently causing a sixth mass extinction.

## Review Questions

### UNDERSTAND

- Prezygotic isolating mechanisms include all of the following except
  - hybrid sterility.
  - courtship rituals.
  - habitat separation.
  - seasonal reproduction.
- Reproductive isolation is
  - a result of individuals not mating with each other.
  - a specific type of postzygotic isolating mechanism.
  - required by the biological species concept.
  - none of the above.
- Problems with the biological species concept include the fact that
  - many species reproduce asexually.
  - postzygotic isolating mechanisms decrease hybrid viability.
  - prezygotic isolating mechanisms are extremely rare.
  - all of these.
- Allopatric speciation
  - is less common than sympatric speciation.
  - involves geographic isolation of some kind.
  - is the only kind of speciation that occurs in plants.
  - requires polyploidy.

5. Gradualism and punctuated equilibrium are
    - a. two ends of the continuum of the rate of evolutionary change over time.
    - b. mutually exclusive views about how all evolutionary change takes place.
    - c. mechanisms of reproductive isolation.
    - d. none of the above.
  6. During the history of life on Earth
    - a. there have been major extinction events.
    - b. species diversity has steadily increased.
    - c. species diversity has stayed relatively constant.
    - d. extinction rates have been completely offset by speciation rates.
  7. Speciation by allopolyploidy
    - a. takes a long time.
    - b. is common in birds.
    - c. leads to reduced numbers of chromosomes.
    - d. occurs after hybridization between two species.
  8. Adaptive radiation
    - a. is the result of enriched uranium used in power plants.
    - b. is the evolution of closely related species adapted to use different parts of the environment.
    - c. results from genetic drift.
    - d. is the outcome of stabilizing selection favoring the maintenance of adaptive traits.
- c. does not promote speciation.
  - d. reduced speciation rates in Galápagos finches.
5. Hybridization between incompletely isolated populations
    - a. always leads to reinforcement due to the inferiority of hybrids.
    - b. can serve as a mechanism for preserving gene flow between populations, thus preventing speciation.
    - c. only occurs in plants.
    - d. never affects rates of speciation.
  6. Natural selection can lead to speciation
    - a. by causing small populations to diverge more than large populations.
    - b. because the evolutionary changes that two populations acquire while adapting to different habitats may have the effect of making them reproductively isolated.
    - c. by favoring the same evolutionary change in multiple populations.
    - d. by favoring intermediate phenotypes.

## SYNTHESIZE

1. Natural selection can lead to the evolution of prezygotic isolating mechanisms, but not postzygotic isolating mechanisms? Explain.
2. If there is no universally accepted definition of a species, what good is the term? Will the idea of and need for a “species concept” be eliminated in the future?
3. Refer to figure 22.6. In Europe, pied and collared flycatchers are dissimilar in sympatry, but very similar in allopatry, consistent with character divergence in coloration. In this case, there is no competition for ecological resources as in other cases of character divergence discussed. How might this example work?
4. Refer to figure 22.14. *Geospiza fuliginosa* and *Geospiza fortis* are found in sympatry on at least one island in the Galápagos and in allopatry on several islands in the same archipelago. Compare your expectations about degree of morphological similarity of the two species in these two contexts, given the hypothesis that competition for food played a large role in the adaptive radiation of this group. Would your expectations be the same for a pair of finch species that are not as closely related? Explain.

## APPLY

1. Leopard frogs from different geographic populations of the *Rana pipiens* complex
  - a. are members of a single species because they look very similar to one another.
  - b. are different species shown to have pre- and postzygotic isolating mechanisms.
  - c. frequently interbreed to produce viable hybrids.
  - d. are genetically identical due to effective reproductive isolation.
2. If reinforcement is weak and hybrids are not completely infertile,
  - a. genetic divergence between populations may be overcome by gene flow.
  - b. speciation will occur 100% of the time.
  - c. gene flow between populations will be impossible.
  - d. the speciation will be more likely than if hybrids were completely infertile.
3. Natural selection can
  - a. enhance the probability of speciation.
  - b. enhance reproductive isolation.
  - c. act against hybrid survival and reproduction.
  - d. do all of these.
4. Character displacement
  - a. arises through competition and natural selection, favoring divergence in resource use.
  - b. arises through competition and natural selection, favoring convergence in resource use.

# Systematics and the Phylogenetic Revolution

## Chapter Outline

- 23.1 Systematics
- 23.2 Cladistics
- 23.3 Systematics and Classification
- 23.4 Phylogenetics and Comparative Biology
- 23.5 Phylogenetics and Disease Evolution

## Introduction

All organisms share many biological characteristics. They are composed of one or more cells, carry out metabolism and transfer energy with ATP, and encode hereditary information in DNA. Yet, there is also a tremendous diversity of life, ranging from bacteria and amoebas to blue whales and sequoia trees. For generations, biologists have tried to group organisms based on shared characteristics. The most meaningful groupings are based on the study of evolutionary relationships among organisms. New methods for constructing evolutionary trees and a sea of molecular sequence data are leading to improved evolutionary hypotheses to explain life's diversification.

### 23.1 Systematics

#### Learning Outcomes

1. Understand what a phylogeny represents.
2. Explain why phenotypic similarity does not necessarily indicate close evolutionary relationship.

One of the great challenges of modern science is to understand the history of ancestor–descendant relationships that unites all forms of life on Earth, from the earliest single-celled organisms to the complex organisms we see around us today. If the fossil record were perfect, we could trace the evolutionary history of species and examine how each arose and proliferated; however, as discussed in chapter 21, the fossil record is far from complete. Although it answers many questions about life's diversification, it leaves many others unsettled.

Consequently, scientists must rely on other types of evidence to establish the best hypothesis of evolutionary relationships. Bear in mind that the outcomes of such studies *are* hypotheses, and as such, they require further testing. All hypotheses may be disproved by new data, leading to the formation of better, more accurate scientific ideas.

The reconstruction and study of evolutionary relationships is called **systematics**. By looking at the similarities and differences between species, systematists can construct an evolutionary tree, or **phylogeny**, which represents a hypothesis about patterns of relationship among species.

## Branching diagrams depict evolutionary relationships

Darwin envisioned that all species were descended from a single common ancestor, and that the history of life could be depicted as a branching tree (figure 23.1). In Darwin's view, the twigs of the tree represent existing species. As one works down the tree, the joining of twigs and branches reflects the pattern of common ancestry back in time to the single common ancestor of all life. The process of descent with modification from common ancestry results in all species being related in this branching, hierarchical fashion, and their evolutionary history can be depicted using branching diagrams or phylogenetic trees. Figure 23.1*b* shows how evolutionary relationships are depicted with a branching diagram. Humans and chimpanzees

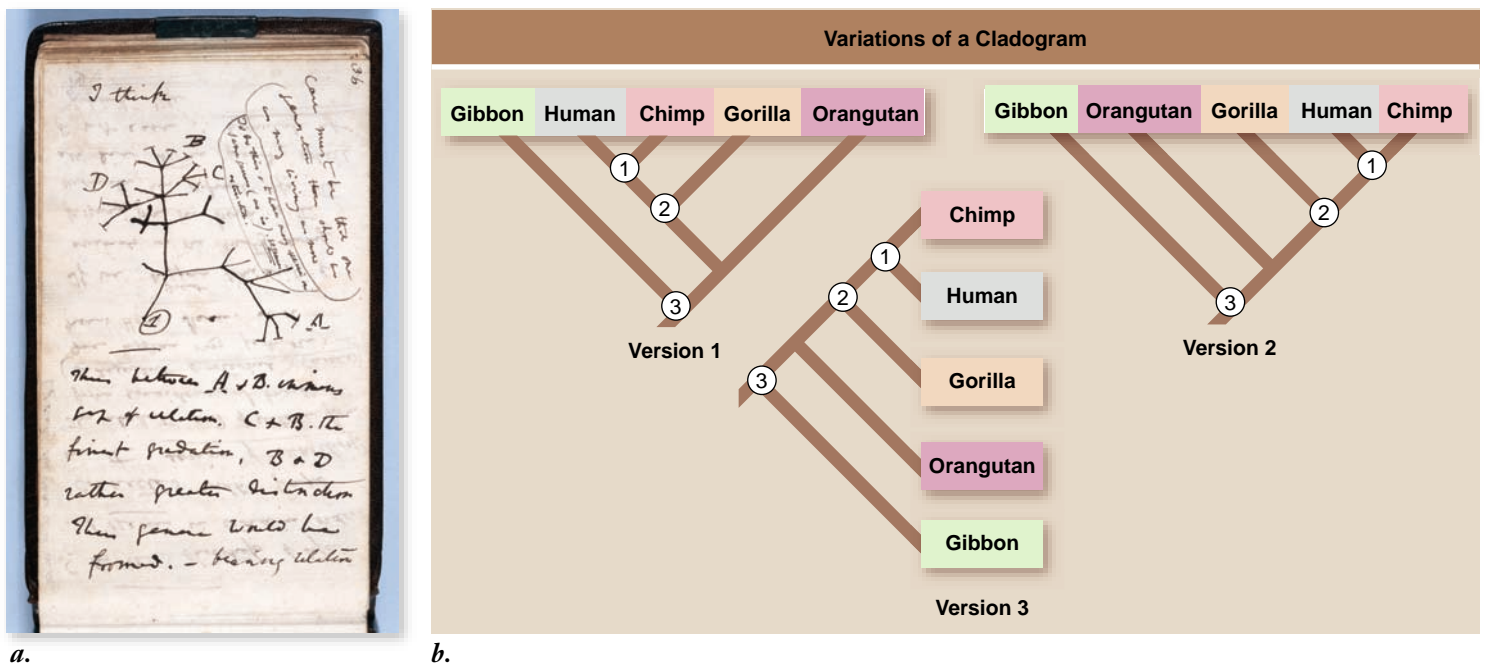

are descended from a common ancestor and are each other's closest living relative (the position of this common ancestor is indicated by the node labeled 1). Humans, chimps, and gorillas share an older common ancestor (node 2), and all great apes share a more distant common ancestor (node 3).

One key to interpreting a phylogeny is to look at how recently species share a common ancestor, rather than looking at the arrangement of species across the top of the tree. If you compare the three versions of the phylogeny of figure 23.1*b*, you can see that the relationships are the same: Regardless of where they are positioned, chimpanzees and humans are still more closely related to each other than to any other species.

Moreover, even though humans are placed next to gibbons in version 1 of figure 23.1*b*, the pattern of relationships still indicates that humans are more closely related (that is, share a more recent common ancestor) with gorillas and orangutans than with gibbons. Phylogenies are also sometimes displayed on their side, rather than upright figure 23.1*b* (version 3), but this arrangement also does not affect its interpretation.

## Similarity may not accurately predict evolutionary relationships

We might expect that the greater the time since two species diverged from a common ancestor, the more different they would be. Early systematists relied on this reasoning and constructed phylogenies based on overall similarity. If, in fact,

**Figure 23.1** Phylogenies depict evolutionary relationships. *a.* A drawing from one of Darwin's notebooks, written in 1837 as he developed his ideas that led to *On the Origin of Species*. Darwin viewed life as a branching process akin to a tree, with species on the twigs, and evolutionary change represented by the branching pattern displayed by a tree as it grows. *b.* An example of a phylogeny. Humans and chimpanzees are more closely related to each other than they are to any other living species. This is apparent because they share a common ancestor (the node labeled 1) that was not an ancestor of other species. Similarly, humans, chimpanzees, and gorillas are more closely related to one another than any of them is to orangutans because they share a common ancestor (node 2) that was not ancestral to orangutans. Node 3 represents the common ancestor of all apes. Note that these three versions convey the same information despite the differences in arrangement of species and orientation.

species evolved at a constant rate, then the amount of divergence between two species would be a function of how long they had been diverging, and thus phylogenies based on degree of similarity would be accurate. As a result, we might think that chimps and gorillas are more closely related to each other than either is to humans.

But as chapter 22 revealed, evolution can occur very rapidly at some times and very slowly at others. In addition, evolution is not unidirectional—sometimes species' traits evolve in one direction, and then back the other way (a result of oscillating selection; see chapter 20). Species invading new habitats are likely to experience new selective pressures and may change greatly; those staying in the same habitats as their ancestors may change only a little. For this reason, similarity is not necessarily a good predictor of how long it has been since two species shared a common ancestor.

A second fundamental problem exists as well: Evolution is not always divergent. In chapter 21, we discussed convergent evolution, in which two species independently evolve the same features. Often, species evolve convergently because they use similar habitats, in which similar adaptations are favored. As a result, two species that are not closely related may end up more similar to each other than they are to their close relatives. Evolutionary reversal, the process in which a species re-evolves the characteristics of an ancestral species, also has this effect.

### Learning Outcomes Review 23.1

Systematics is the study of evolutionary relationships. Phylogenies, or phylogenetic trees, are graphic representations of relationships among species. Similarity of organisms alone does not necessarily correlate with their relatedness because evolutionary change is not constant in rate and direction.

- Why might a species be most phenotypically similar to a species that is not its closest evolutionary relative?

## 23.2 Cladistics

### Learning Outcomes

1. Describe the difference between ancestral and derived similarities.
2. Explain why only shared, derived characters indicate close evolutionary relationship.
3. Demonstrate how a cladogram is constructed.

Because phenotypic similarity may be misleading, most systematists no longer construct their phylogenetic hypotheses solely on this basis. Rather, they distinguish similarity among species that is inherited from the most recent common ancestor of an entire group, which is called **derived**, from similarity that arose prior to the common ancestor of the group, which is termed **ancestral**. In this approach, termed **cladistics**, only **shared**

**derived characters** are considered informative in determining evolutionary relationships.

### The cladistic method requires that character variation be identified as ancestral or derived

To employ the method of cladistics, systematists first gather data on a number of characters for all the species in the analysis. Characters can be any aspect of the phenotype, including morphology, physiology, behavior, and DNA. As chapters 18 and 24 show, the revolution in genomics should soon provide a vast body of data that may revolutionize our ability to identify and study character variation.

To be useful, the characters should exist in recognizable **character states**. For example, consider the character “teeth” in amniote vertebrates (namely birds, reptiles, and mammals; see chapter 35). This character has two states: presence in most mammals and reptiles and absence in birds and a few other groups such as turtles.

### Examples of ancestral versus derived characters

The presence of hair is a shared derived feature of mammals (figure 23.2); in contrast, the presence of lungs in mammals is an ancestral feature because it is also present in amphibians and reptiles (represented by a salamander and a lizard) and therefore presumably evolved prior to the common ancestor of mammals (see figure 23.2). The presence of lungs, therefore, does not tell us that mammal species are all more closely related to one another than to reptiles or amphibians, but the shared, derived feature of hair suggests that all mammal species share a common ancestor that existed more recently than the common ancestor of mammals, amphibians, and reptiles.

To return to the question concerning the relationships of humans, chimps, and gorillas, a number of morphological and DNA characters exist that are derived and shared by chimps and humans, but not by gorillas or other great apes. These characters suggest that chimps and humans diverged from a common ancestor (see figure 23.1*b*, node 1) that existed more recently than the common ancestor of gorillas, chimps, and humans (node 2).

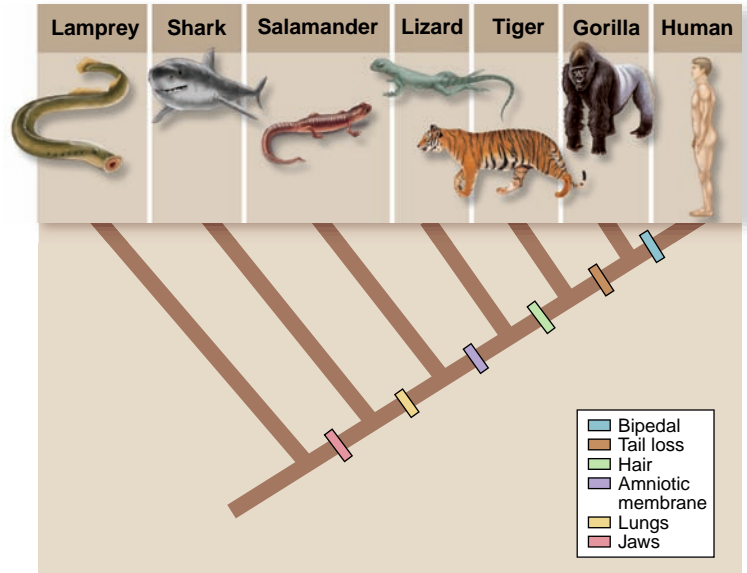

### Determination of ancestral versus derived

Once the data are assembled, the first step in a manual cladistic analysis is to **polarize** the characters—that is, to determine whether particular character states are ancestral or derived. To polarize the character “teeth,” for example, systematists must determine which state—presence or absence—was exhibited by the most recent common ancestor of this group.

Usually, the fossils available do not represent the most recent common ancestor—or we cannot be confident that they do. As a result, the method of *outgroup comparison* is used to assign character polarity. To use this method, a species or group of species that is closely related to, but not a member of, the group under study is designated as the **outgroup**. When the group under study exhibits multiple character states, and one of those states is exhibited by the outgroup, then that state is considered to be ancestral and other states are considered to be derived. However, outgroup species also evolve from their

Traits: Organism	Jaws	Lungs	Amniotic Membrane	Hair	No Tail	Bipedal
Lamprey	0	0	0	0	0	0
Shark	1	0	0	0	0	0
Salamander	1	1	0	0	0	0
Lizard	1	1	1	0	0	0
Tiger	1	1	1	1	0	0
Gorilla	1	1	1	1	1	0
Human	1	1	1	1	1	1

a.

b.

**Figure 23.2 A cladogram.** *a.* Morphological data for a group of seven vertebrates are tabulated. A “1” indicates possession of the derived character state, and a “0” indicates possession of the ancestral character state (note that the derived state for character “no tail” is the absence of a tail; for all other traits, absence of the trait is the ancestral character state). *b.* A tree, or cladogram, diagrams the relationships among the organisms based on the presence of derived characters. The derived characters between the cladogram branch points are shared by all organisms above the branch points and are not present in any below them. The outgroup (in this case, the lamprey) does not possess any of the derived characters.

ancestors, so the outgroup species will not always exhibit the ancestral condition.

Polarity assignments are most reliable when the same character state is exhibited by several different outgroups. In the preceding example, teeth are generally present in the nearest outgroups of amniotes—amphibians and fish—as well as in many species of amniotes themselves. Consequently, the presence of teeth in mammals and reptiles is considered ancestral, and their absence in birds and turtles is considered derived.

### Construction of a cladogram

Once all characters have been polarized, systematists use this information to construct a **cladogram**, which depicts a hypothesis of evolutionary relationships. Species that share a common ancestor, as indicated by the possession of shared derived characters, are said to belong to a **clade**. Clades are thus evolutionary units and refer to a common ancestor and all of its descendants. A derived character shared by clade members is called a **synapomorphy** of that clade. Figure 23.2b illustrates that a simple cladogram is a nested set of clades, each characterized by its own synapomorphies. For example, amniotes are a clade for which the evolution of an amniotic membrane is a synapomorphy. Within that clade, mammals are a clade, with hair as a synapomorphy, and so on.

Ancestral states are also called **plesiomorphies**, and shared ancestral states are called **symplesiomorphies**. In contrast to synapomorphies, symplesiomorphies are not informative about phylogenetic relationships.

Consider, for example, the character state “presence of a tail,” which is exhibited by lampreys, sharks, salamanders, lizards,

and tigers. Does this mean that tigers are more closely related to—and shared a more recent common ancestor with—lizards and sharks than to apes and humans, their fellow mammals? The answer, of course, is no: Because symplesiomorphies reflect character states inherited from a distant ancestor, they do not imply that species exhibiting that state are closely related.

### Homoplasy complicates cladistic analysis

In real-world cases, phylogenetic studies are rarely as simple as the examples we have shown so far. The reason is that in some cases, the same character has evolved independently in several species. These characters would be categorized as shared derived characters, but they would be false signals of a close evolutionary relationship. In addition, derived characters may sometimes be lost as species within a clade re-evolve to the ancestral state.

**Homoplasy** refers to a shared character state that has not been inherited from a common ancestor exhibiting that character state. Homoplasy can result from convergent evolution or from evolutionary reversal. For example, adult frogs do not have a tail. Thus, absence of a tail is a synapomorphy that unites not only gorillas and humans, but also frogs. However, frogs have neither an amniotic membrane nor hair, both of which are synapomorphies for clades that contain gorillas and humans.

In cases such as this, when there are conflicts among the characters, systematists rely on the **principle of parsimony**, which favors the hypothesis that requires the fewest assumptions. As a result, the phylogeny that requires the fewest evolutionary events is considered the best hypothesis of phylogenetic

**Figure 23.3 Parsimony and homoplasy.** *a.* The placement of frogs as closely related to salamanders requires that tail loss evolved twice, an example of homoplasy. *b.* If frogs are closely related to gorillas and humans, then tail loss only had to evolve once. However, this arrangement would require two additional evolutionary changes: Frogs would have had to have lost the amniotic membrane and hair (alternatively, hair could have evolved independently in tigers and the clade of humans and gorillas; this interpretation would require two evolutionary changes in the hair character, just like the interpretation shown in the figure, in which hair evolved only once, but then was lost in frogs). Based on the principle of parsimony, the cladogram that requires the fewest number of evolutionary changes is favored; in this case the cladogram in (*a*) requires four changes, whereas that in (*b*) requires five, so (*a*) is considered the preferred hypothesis of evolutionary relationships.

relationships (figure 23.3). In the example just stated, therefore, grouping frogs with salamanders is favored because it requires only one instance of homoplasy (the multiple origins of taillessness), whereas a phylogeny in which frogs were most closely related to humans and gorillas would require two homoplastic evolutionary events (the loss of both amniotic membranes and hair in frogs).

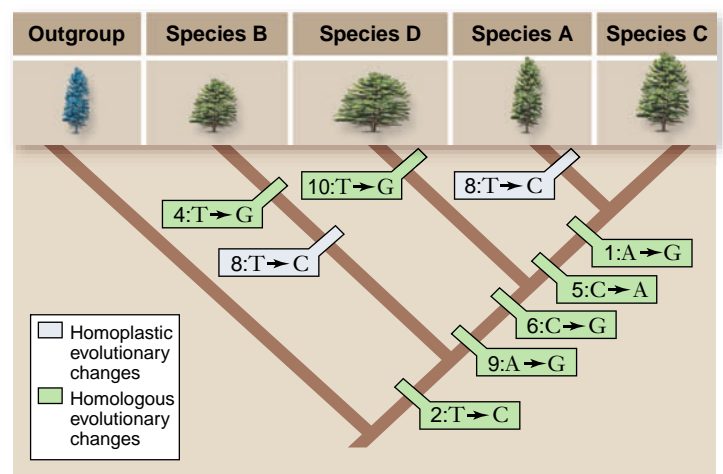

The examples presented so far have all involved morphological characters, but systematists increasingly use DNA sequence data to construct phylogenies because of the large number of characters that can be obtained through sequencing. Cladistics analyzes sequence data in the same manner as any

other type of data: Character states are polarized by reference to the sequence of an outgroup, and a cladogram is constructed that minimizes the amount of character evolution required (figure 23.4).

### Other phylogenetic methods work better than cladistics in some situations

If characters evolve from one state to another at a slow rate compared with the frequency of speciation events, then the principle of parsimony works well in reconstructing

	DNA Sequence									
Site	1	2	3	4	5	6	7	8	9	10
Species A	G	C	A	T	A	G	G	C	G	T
Species B	A	C	A	G	C	C	G	C	A	T
Species C	G	C	A	T	A	G	G	T	G	T
Species D	A	C	A	T	C	G	G	T	G	G
Outgroup	A	T	A	T	C	C	G	T	A	T

**Figure 23.4 Cladistic analysis of DNA sequence data.** Sequence data are analyzed just like any other data. The most parsimonious interpretation of the DNA sequence data requires nine evolutionary changes. Each of these changes is indicated on the phylogeny. Change in site 8 is homoplastic: Species A and B independently evolved from thymine to cytosine at that site.

evolutionary relationships. In this situation, the principle's underlying assumption—that shared derived similarity is indicative of recent common ancestry—is usually correct. In recent years, however, systematists have realized that some characters evolve so rapidly that the principle of parsimony may be misleading.

### **Rapid rates of evolutionary change and homoplasy**

Of particular interest is the rate at which some parts of the genome evolve. As discussed in chapter 18, some stretches of DNA do not appear to have any function. As a result, mutations that occur in these parts of the DNA are not eliminated by natural selection, and thus the rate of evolution of new character states can be quite high in these regions as a result of genetic drift.

Moreover, because only four character states are possible for any nucleotide base (A, C, G, or T), there is a high probability that two species will independently evolve the same derived character state at any particular base position. If such homoplasy dominates the character data set, then the assumptions of the principle of parsimony are violated, and as a result, phylogenies inferred using this method are likely to be inaccurate.

#### **Inquiry question**

**Why do high rates of evolutionary change and a limited number of character states cause problems for parsimony analyses?**

### **Statistical approaches**

Because evolution can sometimes proceed rapidly, systematists in recent years have been exploring other methods based on statistical approaches, such as maximum likelihood, to infer phylogenies. These methods start with an assumption about the rate at which characters evolve and then fit the data to these models to derive the phylogeny that best accords (i.e., “maximally likely”) with these assumptions.

One advantage of these methods is that different assumptions of rate of evolution can be used for different characters. If some DNA characters evolve more slowly than others—for example, because they are constrained by natural selection—then the methods can employ different models of evolution for the different characters. This approach is more effective than parsimony in dealing with homoplasy when rates of evolutionary changes are high.

### **The molecular clock**

In general, cladograms such as the one in figure 23.2 only indicate the order of evolutionary branching events; they do not contain information about the timing of these events. In some cases, however, branching events can be timed, either by reference to fossils, or by making assumptions about the rate at which characters change. One widely used but controversial method is the **molecular clock**, which states that the rate of evolution of a molecule is constant through time. In this model, divergence in DNA can be used to calculate the times at which branching events have occurred. To make such estimates, the timing of one or more divergence events must be confidently estimated. For example, the fossil record may indicate that two clades diverged from a common ancestor at a particular time.

Alternatively, the timing of separation of two clades may be estimated from geological events that likely led to their divergence, such as the rise of a mountain that now separates the two clades. With this information, the amount of DNA divergence separating two clades can be divided by the length of time separating the two clades, which produces an estimate of the rate of DNA divergence per unit of time (usually, per million years). Assuming a molecular clock, this rate can then be used to date other divergence events in a cladogram.

Although the molecular clock appears to hold true in some cases, in many others the data indicate that rates of evolution have not been constant through time across all branches in an evolutionary tree. For this reason, evolutionary dates derived from molecular data must be treated cautiously. Recently, methods have been developed to date evolutionary events without assuming that molecular evolution has been clocklike. These methods hold great promise for providing more reliable estimates of evolutionary timing.

### **Learning Outcomes Review 23.2**

In cladistics, derived character states are distinguished from ancestral character states, species are grouped based on shared derived character states. Derived characters are determined from comparison to a group known to be closely related, termed an outgroup. A clade contains all descendants of a common ancestor. A cladogram is a hypothetical representation of evolutionary relationships based on derived character states. Homoplasies may give a false picture of relationships.

- *Why is cladistics more successful at inferring phylogenetic relationships in some cases than in others?*

## **23.3 Systematics and Classification**

### **Learning Outcomes**

1. *Differentiate among monophyletic, paraphyletic, and polyphyletic groups.*
2. *Explain the meaning of the phylogenetic species concept and why it is controversial.*

Whereas systematics is the reconstruction and study of evolutionary relationships, **classification** refers to how we place species and higher groups—genus, family, class, and so forth—into the taxonomic hierarchy (a topic we discuss in greater detail in chapter 26).

### **Current classification sometimes does not reflect evolutionary relationships**

Systematics and traditional classification are not always congruent; to understand why, we need to consider how species may be grouped based on their phylogenetic relationships. A **monophyletic** group includes the most recent common ancestor of the group and all of

its descendants. By definition, a clade is a monophyletic group. A **paraphyletic** group includes the most recent common ancestor of the group, but not all its descendants, and a **polyphyletic** group does not include the most recent common ancestor of all members of the group (figure 23.5).

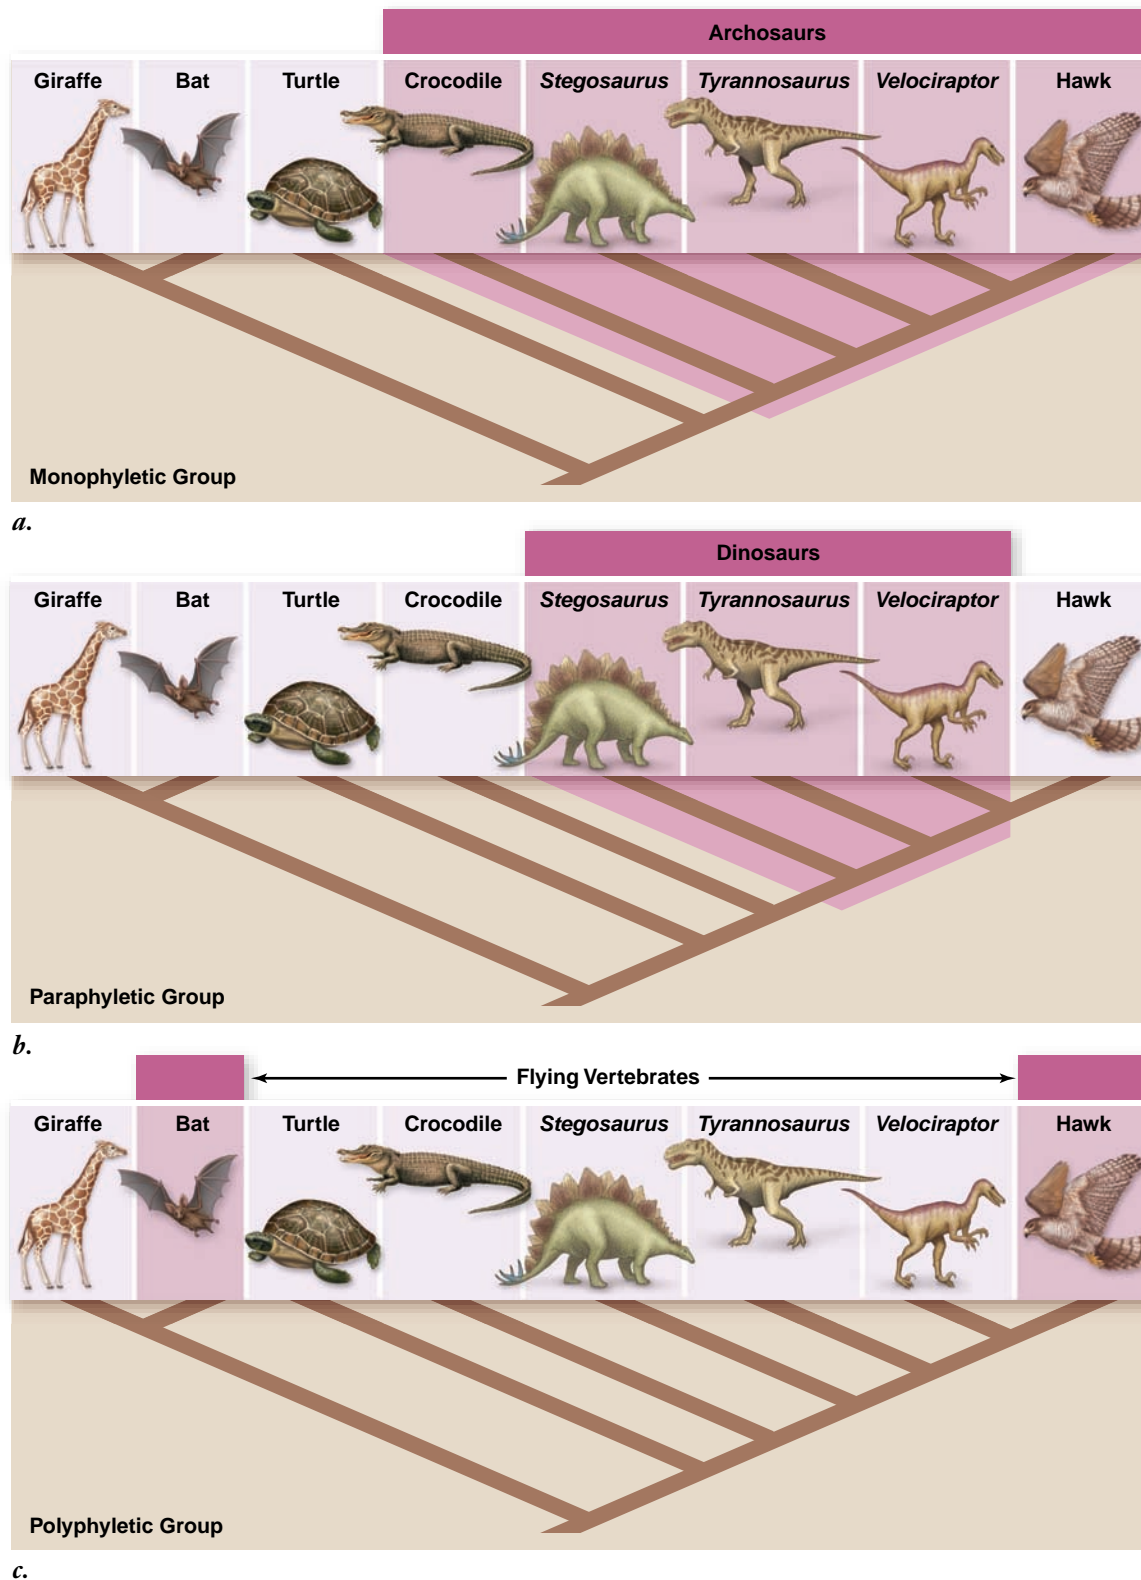

**Figure 23.5**  
**Monophyletic, paraphyletic, and polyphyletic groups.**

**a.** A monophyletic group consists of the most recent common ancestor and all of its descendants. For example, the name “Archosaurs” is given to the monophyletic group that includes a crocodile, *Stegosaurus*, *Tyrannosaurus*, *Velociraptor*, and a hawk.

**b.** A paraphyletic group consists of the most recent common ancestor and some of its descendants. For example, some, but not all, taxonomists traditionally give the name “dinosaurs” to the paraphyletic group that includes *Stegosaurus*, *Tyrannosaurus*, and *Velociraptor*. This group is paraphyletic because one descendant of the most recent ancestor of these species, the bird, is not included in the group. Other taxonomists include birds within the Dinosauria because *Tyrannosaurus* and *Velociraptor* are more closely related to birds than to other dinosaurs.

**c.** A polyphyletic group does not contain the most recent common ancestor of the group. For example, bats and birds could be classified in the same group, which we might call “flying vertebrates,” because they have similar shapes, anatomical features, and habitats. However, their similarities reflect convergent evolution, not common ancestry.

Taxonomic hierarchies are based on shared traits, and ideally they should reflect evolutionary relationships. Traditional taxonomic groups, however, do not always fit well with new understanding of phylogenetic relationships. For example, birds have historically been placed in the class Aves, and

**Inquiry question**  
 ? Based on this phylogeny, are there any alternatives to convergence to explain the presence of wings in birds and bats? What types of data might be used to test these hypotheses?

dinosaurs have been considered part of the class Reptilia. But recent phylogenetic advances make clear that birds evolved from dinosaurs. The last common ancestor of all birds and a dinosaur was a meat-eating dinosaur (see figure 23.5).

Therefore, having two separate monophyletic groups, one for birds and one for reptiles (including dinosaurs and crocodiles, as well as lizards, snakes, and turtles), is not possible based on phylogeny. And yet the terms Aves and Reptilia are so familiar and well established that suddenly referring to birds as a type of dinosaur, and thus a type of reptile, is difficult for some. Nonetheless, biologists increasingly refer to birds as a type of dinosaur and hence a type of reptile.

Situations like this are not uncommon. Another example concerns the classification of plants. Traditionally, three major groups were recognized: green algae, bryophytes, and vascular plants (figure 23.6). However, recent research reveals that neither the green algae nor the bryophytes constitute monophyletic groups. Rather, some bryophyte groups are more closely related to vascular plants than they are to other bryophytes, and some green algae are more closely related to bryophytes and vascular plants than they are to other green algae. As a result, systematists no longer recognize green algae or bryophytes as evolutionary groups, and the classification system has been changed to reflect evolutionary relationships.

### The phylogenetic species concept focuses on shared derived characters

In the preceding chapter, you read about a number of different ideas concerning what determines whether two populations belong to the same species. The biological species concept (BSC) defines species as groups of interbreeding populations that are reproductively isolated from other groups. In recent years, a phylogenetic perspective has emerged and has been applied to the question of species concepts. Advocates of the **phylogenetic species concept (PSC)** propose that the

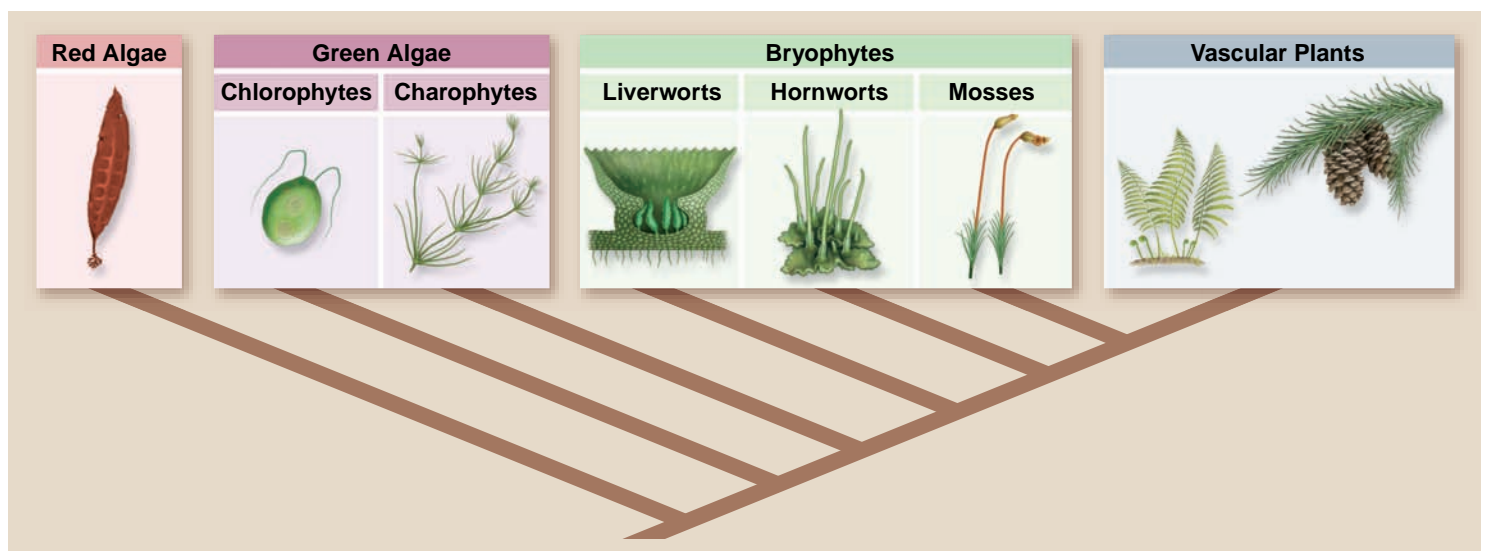

term *species* should be applied to groups of populations that have been evolving independently of other groups of populations. Moreover, they suggest that phylogenetic analysis is the way to identify such species. In this view, a species is a population or set of populations characterized by one or more shared derived characters.

This approach solves two of the problems with the BSC that were discussed in chapter 22. First, the BSC cannot be applied to allopatric populations because scientists cannot determine whether individuals of the populations would interbreed and produce fertile offspring if they ever came together. The PSC solves this problem: Instead of trying to predict what will happen in the future if allopatric populations ever come into contact, the PSC looks to the past to determine whether a population (or groups of populations) has evolved independently for a long enough time to develop its own derived characters.

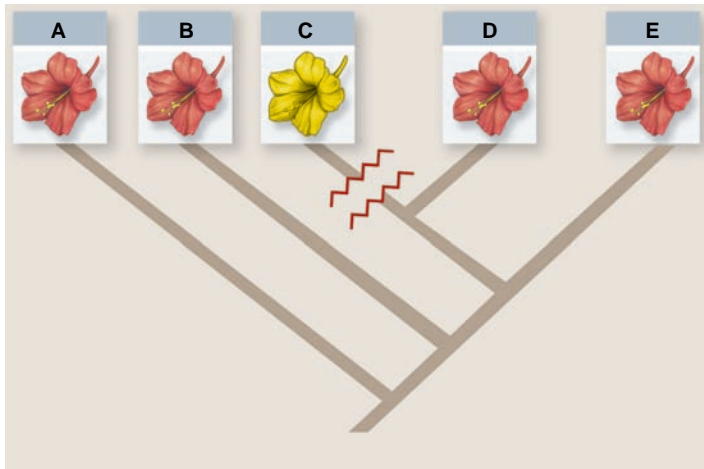

Second, the PSC can be applied equally well to both sexual and asexual species, in contrast to the BSC, which deals only with sexual forms.

### The PSC also has drawbacks
