## The Digestive System

### Chapter Outline

- 48.1 Types of Digestive Systems
- 48.2 The Mouth and Teeth: Food Capture and Bulk Processing
- 48.3 The Esophagus and the Stomach: The Beginning of Digestion
- 48.4 The Intestines: Breakdown, Absorption, and Elimination
- 48.5 Variations in Vertebrate Digestive Systems
- 48.6 Neural and Hormonal Regulation of the Digestive Tract
- 48.7 Accessory Organ Function
- 48.8 Food Energy, Energy Expenditure, and Essential Nutrients

### Introduction

Plants and other photosynthetic organisms can produce the organic molecules they need from inorganic components. Therefore, they are autotrophs, or self-sustaining. Animals, such as the chipmunk shown, are heterotrophs: They must consume organic molecules present in other organisms. The molecules heterotrophs eat must be digested into smaller molecules in order to be absorbed into the animal's body. Once these products of digestion enter the body, the animal can use them for energy in cellular respiration or for the construction of the larger molecules that make up its tissues. The process of animal digestion is the focus of this chapter.

## 48.1 Types of Digestive Systems

### Learning Outcomes

1. Distinguish between incomplete and complete digestive systems.
2. List the components of the vertebrate digestive tract.
3. Describe the tissue layers of the gastrointestinal tract.

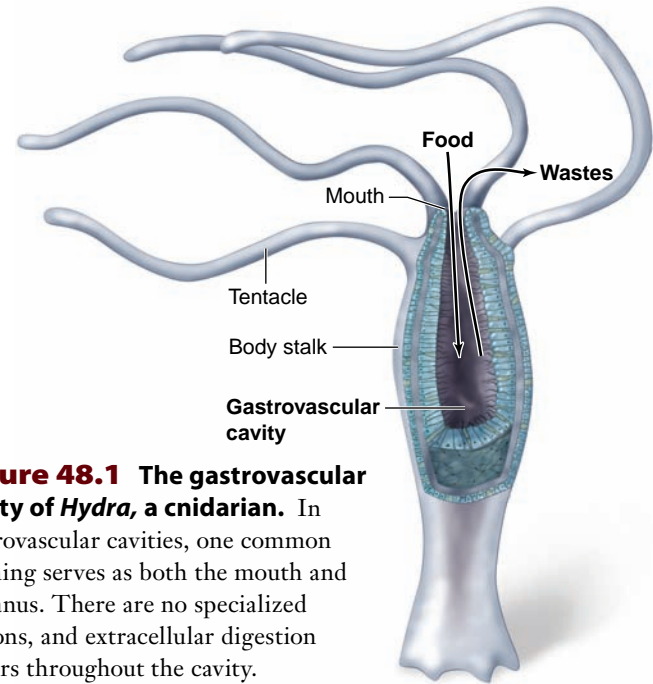

Heterotrophs are divided into three groups on the basis of their food sources. Animals that eat plants exclusively are classified as **herbivores**; common examples include algae-eating snails, sapsucking insects, and vertebrates such as cattle, horses, rabbits, and sparrows. Animals that eat other animals, such as crabs, squid, many insects, cats, eagles, trout, and frogs, are **carnivores**. Animals that eat both plants and other animals are **omnivores**. Humans are omnivores, as are pigs, bears, and crows.

### Invertebrate digestive systems are bags or tubes

Single-celled organisms as well as sponges digest their food intracellularly. Other multicellular animals digest their food extracellularly, within a digestive cavity. In this case, the digestive enzymes are released into a cavity that is continuous with the animal's external environment. In cnidarians and in flatworms such as planarians, the digestive cavity has only one opening that serves as both mouth and anus (see chapter 33). There is no specialization within this type of digestive system, called a *gastrovascular cavity*, because every cell is exposed to all stages of food digestion (figure 48.1).

Specialization occurs when the digestive tract, or alimentary canal, has a separate mouth and anus, so that transport of food is one-way. The most primitive digestive tract is seen in nematodes (phylum Nematoda), where it is simply a tubular *gut* lined by an epithelial membrane. Earthworms (phylum Annelida) have a digestive tract specialized in different regions for the ingestion, storage, fragmentation, digestion, and absorption of food. All more complex animal groups, including all vertebrates, show similar specializations (figure 48.2).

The ingested food may be stored in a specialized region of the digestive tract or it may first be subjected to physical frag-

**Figure 48.1** The gastrovascular cavity of *Hydra*, a cnidarian. In gastrovascular cavities, one common opening serves as both the mouth and the anus. There are no specialized regions, and extracellular digestion occurs throughout the cavity.

mentation. This fragmentation may occur through the chewing action of teeth (in the mouth of many vertebrates) or the grinding action of pebbles (in the gizzard of earthworms and birds). Chemical digestion then occurs, breaking down the larger food molecules of polysaccharides and disaccharides, fats, and proteins into their smallest subunits.

Chemical digestion involves hydrolysis reactions that liberate the subunit molecules—primarily monosaccharides, amino acids, and fatty acids—from the food. These products of chemical digestion pass through the epithelial lining of the gut into the blood, in a process known as *absorption*. Any molecules in the food that are not absorbed cannot be used by the animal. These waste products are excreted, or defecated, from the anus.

### Vertebrate digestive systems include highly specialized structures molded by diet

In humans and other vertebrates, the digestive system consists of a tubular gastrointestinal tract and accessory digestive organs (figure 48.3).

**Figure 48.2** The one-way digestive tract of nematodes, earthworms, and vertebrates. One-way movement through the digestive tract allows different regions of the digestive system to become specialized for different functions.

**Figure 48.3 The human digestive system.** The human digestive system consists of the oral cavity, esophagus, stomach, small intestine, large intestine, rectum, and anus; and is aided by accessory organs.

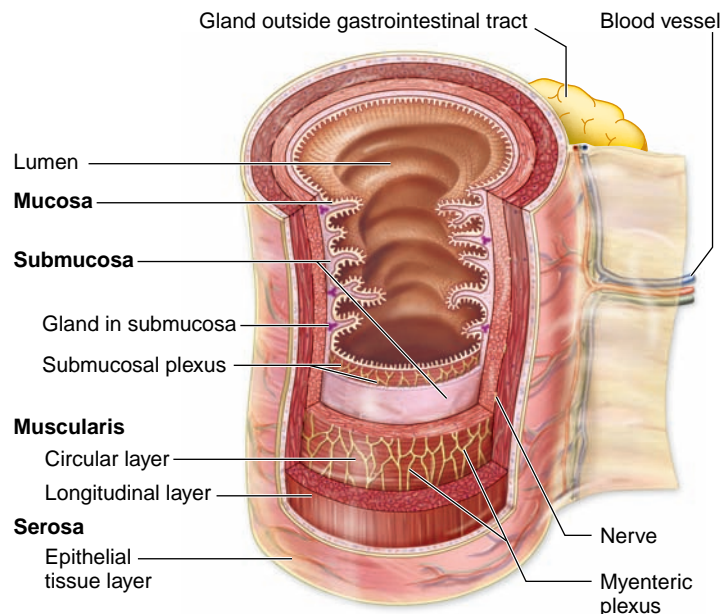

### Overview of the digestive tract

The initial components of the gastrointestinal tract are the mouth and the pharynx, which is the common passage of the oral and nasal cavities. The pharynx leads to the esophagus, a muscular tube that delivers food to the stomach, where some preliminary digestion occurs.

From the stomach, food passes to the small intestine, where a battery of digestive enzymes continues the digestive process. The products of digestion, together with minerals and water, are absorbed across the wall of the small intestine into the bloodstream. What remains is emptied into the large intestine, where some of the remaining water and minerals are absorbed.

In most vertebrates other than mammals, the waste products emerge from the large intestine into a cavity called the cloaca (see figure 48.2), which also receives the products of the urinary and reproductive systems. In mammals, the urogenital products are separated from the fecal material in the large intestine; the fecal material enters the rectum and is expelled through the anus.

The accessory digestive organs include the liver, which produces *bile* (a green solution that emulsifies fat), the gallbladder, which stores and concentrates the bile, and the pancreas. The pancreas produces *pancreatic juice*, which contains digestive enzymes and bicarbonate buffer. Both bile and pancreatic juice

**Figure 48.4 The layers of the gastrointestinal tract.**

The mucosa contains an epithelial lining; the submucosa is composed of connective tissue; and the muscularis consists of smooth muscles. Glands secrete substances via ducts into specific regions of the tract.

are secreted into the first region of the small intestine, the duodenum, where they aid digestion.

### Tissues of the digestive tract

The tubular gastrointestinal tract of a vertebrate has a characteristic layered structure (figure 48.4). The innermost layer is the **mucosa**, an epithelium that lines the interior, or lumen, of the tract. The next major tissue layer, made of connective tissue, is called the **submucosa**.

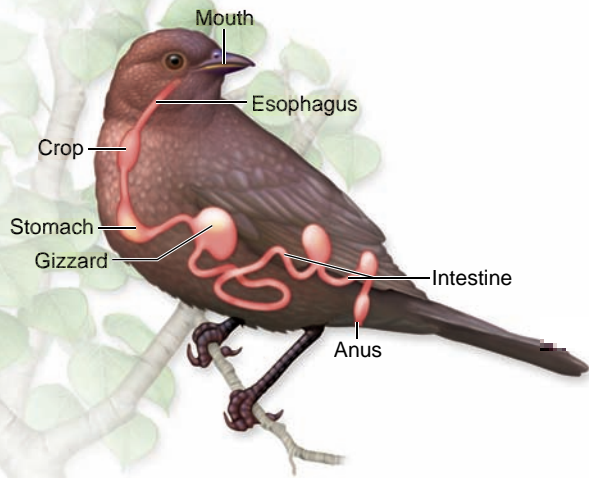

Just outside the submucosa is the **muscularis**, which consists of a double layer of smooth muscles. The muscles in the inner layer have a circular orientation and serve to constrict the gut, whereas those in the outer layer are arranged longitudinally and work to shorten it. Another epithelial tissue layer, the **serosa**, covers the external surface of the tract. Nerve networks, intertwined in *plexuses* between muscle layers, are located in the submucosa and help regulate the gastrointestinal activities.

In the rest of this chapter, we focus on the details of the vertebrate digestive system's structure and function. We close the chapter with discussion of nutrients that are essential to vertebrates.

### Learning Outcomes Review 48.1

Incomplete digestive tracts have only one opening; complete digestive tracts are flow-through, with a mouth and an anus. The digestive system of vertebrates includes mouth and pharynx, esophagus, stomach, small and large intestines, cloaca or rectum, anus, and accessory organs. The layers of tissue that compose the tubular tract are the mucosa, the submucosa, the muscularis, and the serosa.

- What might be the advantages of a one-way digestive system?

**Figure 48.5 The digestive tract of birds.** Birds lack teeth but have a muscular chamber called the gizzard that works to break down food. Birds swallow gritty objects or pebbles that lodge in the gizzard and pulverize food before it passes into the intestine. Food is stored in the crop.

## 48.2 The Mouth and Teeth: Food Capture and Bulk Processing

### Learning Outcomes

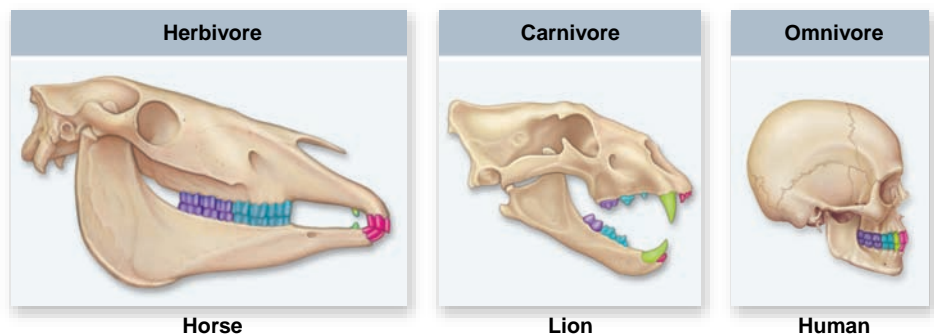

1. Identify adaptive variation in vertebrate tooth shape.
2. Understand the role of the mouth in the digestive process.

Specializations of the digestive systems in different kinds of vertebrates reflect the way these animals live. Birds, which lack teeth, break up food in their two-chambered stomachs (figure 48.5). In one of these chambers, called the *gizzard*, small pebbles ingested by the bird are churned together with the food by muscular action. This churning grinds up the seeds and other hard plant material into smaller chunks that can be digested more easily.

### Vertebrate teeth are adapted to different types of food items

Many vertebrates have teeth (figure 48.6), used for chewing, or *mastication*, that break up food into small particles and mix it

**Figure 48.6 Patterns of dentition depend on diet.** Different vertebrates (herbivore, carnivore, or omnivore) have evolved specific variations from a generalized pattern of dentition depending on their diets.

with fluid secretions. Carnivorous mammals have pointed teeth that lack flat grinding surfaces. Such teeth are adapted for cutting and shearing. Carnivores often tear off pieces of their prey but have little need to chew them, because digestive enzymes can act directly on animal cells. By contrast, grass-eating herbivores must pulverize the cellulose cell walls of plant tissue before the bacteria in their rumens or cecae can digest them. These animals have large, flat teeth with complex ridges well suited to grinding.

Human teeth are specialized for eating both plant and animal food. Viewed simply, humans are carnivores in the front of the mouth and herbivores in the back (see figure 48.6). The four front teeth in the upper and lower jaws are sharp, chisel-shaped incisors used for biting. On each side of the incisors are sharp, pointed teeth called cuspids (sometimes referred to as “canine” teeth), which are used for tearing food. Behind the canines are two premolars and three molars, all with flattened, ridged surfaces for grinding and crushing food.

### The mouth is a chamber for ingestion and initial processing

Inside the mouth, the tongue mixes food with a mucous solution, saliva. In humans, three pairs of salivary glands secrete saliva into the mouth through ducts in the mouth’s mucosal lining. Saliva moistens and lubricates the food so that it is easier to swallow and does not abrade the tissue of the esophagus as it passes through.

Saliva also contains the hydrolytic enzyme salivary amylase, which initiates the breakdown of the polysaccharide starch into the disaccharide maltose. This digestion is usually minimal in humans, however, because most people don’t chew their food very long.

### Stimulation of salivation

The secretions of the salivary glands are controlled by the nervous system, which in humans maintains a constant flow of about half a milliliter per minute when the mouth is empty of food. This continuous secretion keeps the mouth moist.

The presence of food in the mouth triggers an increased rate of secretion. Taste buds as well as olfactory (smell) neurons send impulses to the brain, which responds by stimulating the salivary glands (see chapter 46). The most potent stimuli are acidic solutions; lemon juice, for example, can increase the rate of salivation eightfold. The sight, sound, or smell of food can stimulate salivation markedly in many

1. As food moves to the back of the mouth, the soft palate seals off the nasal cavity.
2. During swallowing, the larynx rises and is sealed off by the epiglottis. This forces the bolus into the esophagus and prevents entry into the trachea. As the bolus moves into the esophagus the larynx relaxes.

**Figure 48.7 The mechanics of swallowing.** Cross section through head and throat showing relevant structures (left). During swallowing (right) the tongue pushes the palate upward, and the soft palate seals off the nasal cavity. Elevation of the larynx causes the epiglottis to seal off the trachea, thus preventing food from entering the airway.

### Inquiry question

? What goes wrong to cause someone to choke?

animals; in humans, thinking or talking about food can also have this effect.

### Swallowing

Swallowing is initiated by voluntary action, then is continued under involuntary control. When food is ready to be swallowed, the tongue moves it to the back of the mouth. In mammals, the process of swallowing begins when the soft palate elevates, pushing against the back wall of the pharynx (figure 48.7). Elevation of the soft palate seals off the nasal cavity and prevents food from entering it. Pressure against the pharynx triggers an automatic, involuntary response, the swallowing reflex. Because it is a reflex, swallowing cannot be stopped once it is initiated.

Neurons within the walls of the pharynx send impulses to the swallowing center in the brain. In response, electrical impulses in motor neurons stimulate muscles to contract and raise the **larynx** (voice box). This pushes the glottis, the opening from the larynx into the trachea (windpipe), against a flap of tissue called the **epiglottis**. These actions keep food out of the respiratory tract, directing it instead into the esophagus.

### Learning Outcomes Review 48.2

In vertebrates with teeth, tooth shape exhibits adaptations to diet: herbivores have large, flat teeth for grinding, whereas carnivores have pointed teeth for tearing. The mouth serves as an initial processing center, tasting ingested food, breaking it down, and beginning digestion with saliva secretion prior to swallowing.

- Which parts of the food ingestion process are voluntary and which are involuntary?

## 48.3 The Esophagus and the Stomach: The Early Stages of Digestion

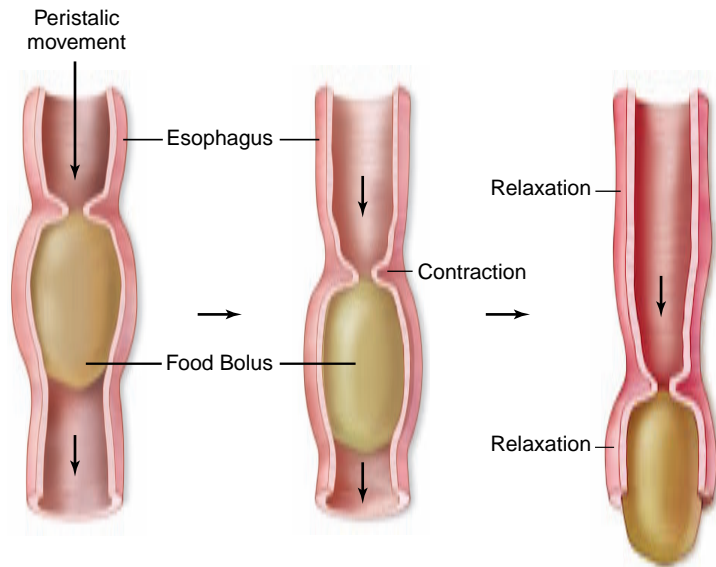

### Learning Outcomes

1. Describe how food moves through the esophagus.
2. Explain what digestive processes take place in the stomach.

Swallowed food enters a muscular tube called the esophagus, which connects the pharynx to the stomach. The esophagus actively moves a processed lump of food, called a **bolus**, through the action of muscles. Food from a meal is stored in the stomach where it undergoes early stages of digestion.

### Muscular contractions of the esophagus move food to the stomach

In adult humans, the esophagus is about 25 cm long; the upper third is enveloped in skeletal muscle for voluntary control of swallowing, whereas the lower two-thirds is surrounded by involuntary smooth muscle. The swallowing center stimulates successive one-directional waves of contraction in these muscles that move food along the esophagus to the stomach. These rhythmic waves of muscular contraction are called

**Figure 48.8** The esophagus and peristalsis. After food has entered the esophagus, rhythmic waves of muscular contraction, called peristalsis, move the food down to the stomach.

**peristalsis** (figure 48.8); they enable humans and other vertebrates to swallow even if they are upside down.

In many vertebrates, the movement of food from the esophagus into the stomach is controlled by a ring of circular smooth muscle, or a *sphincter*, that opens in response to the pressure exerted by the food. Contraction of this sphincter prevents food in the stomach from moving back into the esophagus. Rodents and horses have a true sphincter at this site, and as a result

they cannot regurgitate; humans lack a true sphincter. Normally, the esophagus is closed off except during swallowing.

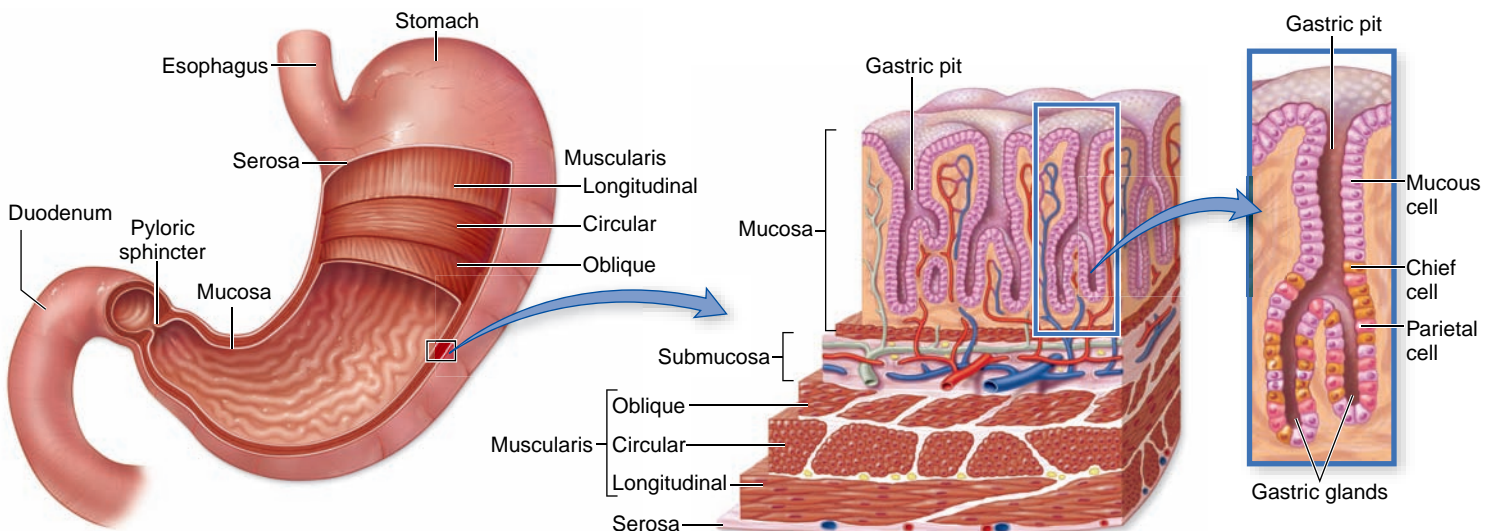

## The stomach is a “holding station” involved in acidic breakdown of food

The **stomach** (figure 48.9) is a saclike portion of the digestive tract. Its inner surface is highly convoluted, enabling it to fold up when empty and open out like an expanding balloon as it fills with food. For example, the human stomach has a volume of only about 50 mL when empty, but, it may expand to contain 2 to 4 L of food when full. Carnivores that engage in sporadic gorging as an important survival strategy possess stomachs that are able to distend even more.

### Secretory systems

The stomach contains a third layer of smooth muscle for churning food and mixing it with **gastric juice**, an acidic secretion of the tubular gastric glands of the mucosa (see figure 48.9). These exocrine glands contain three kinds of secretory cells: *mucus-secreting cells*, *parietal cells*, which secrete hydrochloric acid (HCl), and *chief cells*, which secrete **pepsinogen**, the inactive form of the protease (protein-digesting enzyme) **pepsin**.

Pepsinogen has 44 additional amino acids that block its active site. HCl causes pepsinogen to unfold, exposing the active site, which then acts to remove the 44 amino acids. This yields the active protease, pepsin. This process of secreting an inactive form that is then converted into an active enzyme outside the cell prevents the chief cells from digesting themselves. In the stomach, mucus produced by mucus-secreting cells serves

**Figure 48.9** The stomach and duodenum. Food enters the stomach from the esophagus. A ring of smooth muscle called the pyloric sphincter controls the entrance to the duodenum, the upper part of the small intestine. The epithelial walls of the stomach are dotted with deep infoldings called gastric pits that contain gastric glands. The gastric glands consist of mucous cells, chief cells that secrete pepsinogen, and parietal cells that secrete HCl. Gastric pits are the openings of the gastric glands.

### Inquiry question

How does the digestive system keep from being digested by the gastric secretions it produces?

the same purpose, covering the interior walls and preventing them from being digested.

In addition to producing HCl, the parietal cells of the stomach also secrete **intrinsic factor**, a polypeptide needed for the intestinal absorption of vitamin B<sub>12</sub>. Because this vitamin is required for the production of red blood cells, people who lack sufficient intrinsic factor develop a type of anemia (low red blood cell count) called *pernicious anemia*.

### Action of acid

The human stomach produces about 2 L of HCl and other gastric secretions every day, creating a very acidic solution. The concentration of HCl in this solution is about 10 millimolar (mM), equal to a pH of 2. Thus, gastric juice is about 250,000 times more acidic than blood, whose normal pH is 7.4.

The low pH in the stomach helps denature food proteins, making them easier to digest, and keeps pepsin maximally active. Active pepsin hydrolyzes food proteins into shorter chains of polypeptides that are not fully digested until the mixture enters the small intestine. The mixture of partially digested food and gastric juice is called **chyme**. In adult humans, only proteins are partially digested in the stomach—no significant digestion of carbohydrates or fats occurs there.

The acidic solution within the stomach also kills most of the bacteria that are ingested with the food. The few bacteria that survive the stomach and enter the intestine intact are able to grow and multiply there, particularly in the large intestine. In fact, vertebrates harbor thriving colonies of bacteria within their intestines, and bacteria are a major component of feces. As we discuss later, bacteria that live within the digestive tracts of ruminants play a key role in the ability of these mammals to digest cellulose.

### Ulcers

Overproduction of gastric acid can occasionally eat a hole through the wall of the stomach or the duodenum, causing a peptic ulcer. Although we once blamed consumption of spicy food, the most common cause of peptic ulcers is now thought to be infection with the bacterium *Helicobacter pylori*.

*H. pylori* can grow on the lining of the human stomach, surviving the acid pH by secreting substances that buffer the pH of its immediate surroundings. Although infection with *H. pylori* is common in the United States (about 20% of people younger than 40 and 50% older than 60), most people are asymptomatic. However, in some cases, infection by *H. pylori* can reduce or weaken the mucosal layer in the stomach or duodenum, allowing acidic secretions to attack the underlying epithelium. Antibiotic treatment of the infection can reduce symptoms and often even cure the ulcer.

### Leaving the stomach

Chyme leaves the stomach through the *pyloric sphincter* (see figure 48.9) to enter the small intestine. This is where all terminal digestion of carbohydrates, lipids, and proteins occurs and where the products of digestion—amino acids, glucose, and so on—are absorbed into the blood. Only some of the water in

chyme and a few substances, such as aspirin and alcohol, are absorbed through the wall of the stomach.

### Learning Outcomes Review 48.3

Peristaltic waves of contraction and relaxation of smooth muscle propel food along the esophagus to the stomach. Gastric juice contains strong hydrochloric acid and the enzyme pepsin, a protease that begins the breakdown of proteins into shorter polypeptides. The acidic chyme is then transferred through the pyloric sphincter into the small intestine.

- Suppose you ate a chicken sandwich (chicken breast on bread with mayonnaise). Which of these foods would begin its breakdown in the stomach?

## 48.4 The Intestines: Breakdown, Absorption, and Elimination

### Learning Outcomes

1. Compare the structures of the small and large intestines.
2. Name the accessory organs and describe their roles.
3. Explain how absorbed nutrients move into the blood or lymph capillaries.

The capacity of the small intestine is limited, and its digestive processes take time. Consequently, efficient digestion requires that only relatively small amounts of chyme be introduced from the stomach into the small intestine at any one time. Coordination between gastric and intestinal activities is regulated by neural and hormonal signals, which we will describe in section 48.6.

### The structure of the small intestine is specialized for digestion and nutrient uptake

The small intestine is approximately 4.5 m long in a living person, but 6 m long at autopsy when all the muscles have relaxed. The first 25 cm is the **duodenum**; the remainder of the small intestine is divided into the **jejunum** and the **ileum**.

The duodenum receives acidic chyme from the stomach, digestive enzymes and bicarbonate from the pancreas, and bile from the liver and gallbladder. Enzymes in the pancreatic juice digest larger food molecules into smaller fragments. This digestion occurs primarily in the duodenum and jejunum.

The epithelial wall of the small intestine is covered with tiny, fingerlike projections called **villi** (singular, *villus*; figure 48.10). In turn, each epithelial cell lining the villi is covered on its apical surface (the side facing the lumen) by many foldings of the plasma membrane that form cytoplasmic extensions called **microvilli**. These are quite tiny and can be seen clearly only with an electron microscope. Under a light micrograph, the microvilli resemble the

**Figure 48.10 The small intestine.** Successive enlargements show folded epithelium studded with villi that increase the surface area. The micrograph shows an epithelial cell with numerous microvilli.

bristles of a brush, and for that reason the epithelial wall of the small intestine is also called a *brush border*.

The villi and microvilli greatly increase the surface area of the small intestine; in humans, this surface area is 300 m<sup>2</sup>—about 3200 square feet, larger than a tennis court! It is over this vast surface that the products of digestion are absorbed.

The microvilli also participate in digestion because a number of digestive enzymes are embedded within the epithelial cells' plasma membranes, with their active sites exposed to the chyme. These brush border enzymes include those that hydrolyze the disaccharides lactose and sucrose, among others. Many adult humans lose the ability to produce the brush border enzyme lactase and therefore cannot digest lactose (milk sugar), a rather common condition called *lactose intolerance*. The brush border enzymes complete the digestive process that started with the action of salivary amylase in the mouth.

### Accessory organs secrete enzymes into the small intestine

The main organs that aid digestion are the pancreas, liver, and gallbladder. They empty their secretions, primarily enzymes, through ducts directly into the small intestine.

#### Secretions of the pancreas

The pancreas (figure 48.11), a large gland situated near the junction of the stomach and the small intestine, secretes pancreatic fluid into the duodenum through the *pancreatic duct*; thus, the pancreas functions as an exocrine gland. This fluid contains a host of enzymes, including **trypsin** and **chymotrypsin**, which digest proteins; **pancreatic amylase**, which digests starch; and **lipase**, which digests fat. Like pepsin in the stomach, these enzymes are released into the duodenum primarily as inactive enzymes and are then activated by trypsin, which is first activated by a brush border enzyme of the intestine.

Pancreatic enzymes digest proteins into smaller polypeptides, polysaccharides into shorter chains of sugars, and fats

into free fatty acids and monoglycerides. Digestion of proteins and carbohydrates is then completed by the brush border enzymes. Pancreatic fluid also contains bicarbonate, which neutralizes the HCl from the stomach and gives the chyme in the duodenum a slightly alkaline pH. The digestive enzymes and

**Figure 48.11 The pancreas.** The pancreatic and bile ducts empty into the duodenum. The pancreas secretes pancreatic juice into the pancreatic duct. The pancreatic islets of Langerhans secrete hormones into the blood;  $\alpha$  cells secrete glucagon, and  $\beta$  cells secrete insulin. The liver secretes bile, which consists of bile pigments (waste products from the liver) and bile salts. Bile salts play a role in the digestion of fats. Bile is concentrated and stored in the gallbladder until it is needed in the duodenum on the arrival of fatty food.

bicarbonate are produced by clusters of secretory cells known as **acini**.

In addition to its exocrine role in digestion, the pancreas also functions as an endocrine gland, secreting several hormones into the blood that control the blood levels of glucose and other nutrients. These hormones are produced in the **islets of Langerhans**, clusters of endocrine cells scattered throughout the pancreas. The two most important pancreatic hormones, insulin and glucagon, were described in chapter 46; their actions are also discussed later on.

### Liver and gallbladder

The **liver** is the largest internal organ of the body (see figure 48.3). In an adult human, the liver weighs about 1.5 kg and is the size of a football. The main exocrine secretion of the liver is bile, a fluid mixture consisting of *bile pigments* and *bile salts* that is delivered into the duodenum during the digestion of a meal.

The bile pigments do not participate in digestion; they are waste products resulting from the liver's destruction of old red blood cells and are ultimately eliminated with the feces. If the excretion of bile pigments by the liver is blocked, the pigments can accumulate in the blood and cause a yellow staining of the tissues known as *jaundice*.

In contrast, the bile salts play a very important role in preparing fats for subsequent enzymatic digestion. Because fats are insoluble in water, they enter the intestine as drops within the watery chyme. The bile salts, which are partly lipid-soluble and partly water-soluble, work like detergents, dispersing the large drops of fat into a fine suspension of smaller droplets. This emulsification action produces a greater surface area of fat for the action of lipase enzymes, and thus allows the digestion of fat to proceed more rapidly.

After bile is produced in the liver, it is stored and concentrated in the gallbladder. The arrival of fatty food in the duodenum triggers a neural and endocrine reflex that stimulates the gallbladder to contract, causing bile to be transported through the common bile duct and injected into the duodenum (these reflexes are the topic of a later section). Gallstones are hardened precipitates of cholesterol that form in some individuals. If these stones block the bile duct, contraction of the gallbladder causes intense pain, often felt in the back. In severe cases of blockage, surgical removal of the gallbladder may be performed.

### Absorbed nutrients move into blood or lymph capillaries

After their enzymatic breakdown, proteins and carbohydrates are absorbed as amino acids and monosaccharides, respectively. They are transported across the brush border into the epithelial cells that line the intestine by a combination of active transport and facilitated diffusion (figure 48.12*a*). Glucose is transported by coupled transport with  $\text{Na}^+$  ions (also called secondary active transport). Fructose, found in most fruit, is transported by facilitated diffusion. Most amino acids are transported by active transport using a variety of different transporters. Some of these carrier proteins use cotransport with  $\text{Na}^+$  ions; others transport only amino acids. Once they have entered epithelial cells across the apical membrane, these monosaccharides and amino acids move through the cytoplasm and are transported across the basolateral membrane and into the blood capillaries within the villi.

The blood carries these products of digestion from the intestine to the liver via the hepatic portal vein. A portal vein connects two beds of capillaries instead of returning to the heart. In

**Figure 48.12 Absorption of the products of digestion.** *a.* Monosaccharides and amino acids are transported into blood capillaries. *b.* Fatty acids and monoglycerides within the intestinal lumen are absorbed and converted within the intestinal epithelial cells into triglycerides. These are then coated with proteins to form structures called chylomicrons, which enter lymphatic capillaries.

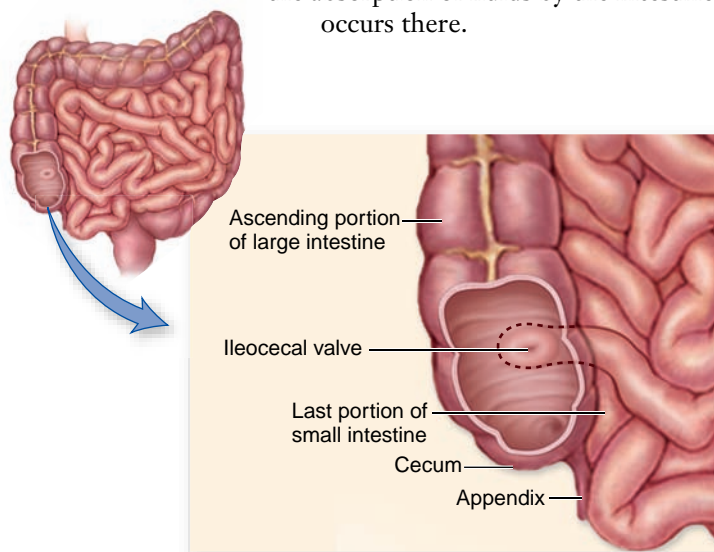

this case, the intestine is connected to the liver by the hepatic portal vein, thus the liver receives blood-borne molecules from the intestine. Because of the hepatic portal vein, the liver is the first organ to receive most of the products of digestion, except for fat.

The products of fat digestion are absorbed by a different mechanism (figure 48.12*b*). Fats (triglycerides) are hydrolyzed into fatty acids and monoglycerides by digestion. These fatty acids and monoglycerides are nonpolar and can thus enter epithelial cells by simple diffusion. Once inside the intestinal epithelial cells they are reassembled into triglycerides. The triglycerides then combine with proteins to form small particles called **chylomicrons**, which are too bulky to enter blood capillaries in the intestine. Instead of entering the hepatic portal circulation, the chylomicrons are absorbed into lymphatic capillaries (see chapter 50), which empty their contents into the blood in veins near the neck. Chylomicrons can make the blood plasma appear cloudy if a sample of blood is drawn after a fatty meal.

The amount of fluid passing through the small intestine in a day is startlingly large: approximately 9 L. However, almost all of this fluid is absorbed into the body rather than eliminated in the feces: About 8.5 L is absorbed in the small intestine and an additional 350 mL in the large intestine. Only about 50 g of solid and 100 mL of liquid leaves the body as feces. The normal fluid absorption efficiency of the human digestive tract approaches 99%, which is very high indeed.

### The large intestine eliminates waste material

The large intestine, or **colon**, is much shorter than the small intestine, occupying approximately the last meter of the digestive tract; it is called “large” because of its larger diameter, not its length. The small intestine empties directly into the large intestine at a junction where two vestigial structures, the **cecum** and the **appendix**, remain (figure 48.13). No digestion takes place within the large intestine, and only about 4% of the absorption of fluids by the intestine occurs there.

**Figure 48.13** The junction of the small and large intestines in humans. The large intestine, or colon, starts with the cecum, which is relatively small in humans compared with that in other mammals. A vestigial structure called the appendix extends from the cecum.

The large intestine is not as convoluted as the small intestine, and its inner surface has no villi. Consequently, the large intestine has less than 1/30 the absorptive surface area of the small intestine. The function of the large intestine is to absorb water, remaining electrolytes, and products of bacterial metabolism (including vitamin K). The large intestine prepares waste material to be expelled from the body.

Many bacteria live and reproduce within the large intestine, and the excess bacteria are incorporated into the refuse material, called *feces*. Bacterial fermentation produces gas within the colon at a rate of about 500 mL per day. This rate increases greatly after the consumption of beans or other types of vegetables because the passage of undigested plant material (fiber) into the large intestine provides substrates for bacterial fermentation.

The human colon has evolved to process food with a relatively high fiber content. Diets that are low in fiber, which are common in the United States and other developed countries, result in a slower passage of food through the colon. Low dietary fiber content is thought to be associated with the level of colon cancer in the United States, which is among the highest in the world.

Compacted feces, driven by peristaltic contractions of the large intestine, pass from the large intestine into a short tube called the rectum. From the rectum, the feces exit the body through the anus. Two sphincters control passage through the anus. The first is composed of smooth muscle and opens involuntarily in response to pressure inside the rectum. The second, composed of striated muscle, can be controlled voluntarily by the brain, thus permitting a conscious decision to delay defecation.

### Learning Outcomes Review 48.4

The small intestine is where most digestion takes place; its inner surface is covered with villi that increase its absorptive surface area. The large intestine absorbs water, electrolytes, and bacterial metabolites. Digestion is accomplished by a combination of enzymes from the pancreas and by bile salts released from the liver. Glucose and amino acids are absorbed by active transport and facilitated diffusion. Fat is absorbed by simple diffusion.

- Why does fat not require transport to cross the intestinal epithelium?

## 48.5 Variations in Vertebrate Digestive Systems

### Learning Outcomes

1. Explain how vertebrates digest cellulose.
2. Describe how rumination works.
3. Discuss convergent evolution at the molecular level in herbivores.

Animals lack the enzymes necessary to digest cellulose, but the digestive tracts of some animals contain bacteria and

**Figure 48.14** The digestive systems of different mammals reflect their diets. Herbivores, such as rabbits and deer, require long digestive tracts with specialized compartments for the breakdown of plant matter. Diets composed of animal matter, thus lacking cellulose, are more easily digested; insectivorous and carnivorous mammals, such as voles and foxes, respectively, have short digestive tracts with few specialized pouches.

protists that convert cellulose into substances the host can absorb. Although digestion by gastrointestinal microorganisms plays a relatively small role in human nutrition, it is an essential element in the nutrition of many other kinds of animals, including insects such as termites and cockroaches, and a few groups of herbivorous mammals. The relationships between these microorganisms and their animal hosts are mutually beneficial and provide an excellent example of symbiosis (see chapter 57).

Plant cellulose is particularly resistant to digestion. As a result, herbivores tend to have much longer digestive tracts than carnivores, allowing greater time for digestion to occur (figure 48.14). In addition, many herbivores have modified their digestive tracts to enhance digestion of plant material.

### Ruminants rechew regurgitated food

Ruminants have a four-chambered stomach (figure 48.15). The first three portions include the reticulum, the rumen, and the omasum. These are followed by the true stomach, the abomasum.

The rumen, which may hold up to 50 gallons, serves as a fermentation vat where bacteria and protists convert cellulose and other molecules into a variety of simpler compounds. The location of the rumen at the front of the four chambers allows the animal to regurgitate and rechew the contents of the rumen, an activity called *ruminating*, or “chewing the cud.” This

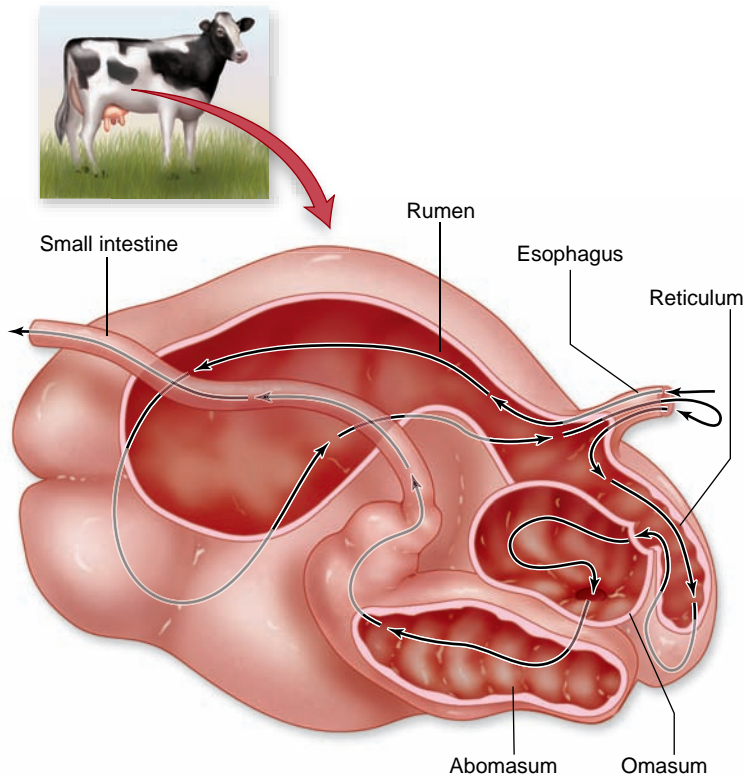

breaks tougher fiber in the diet into smaller particles, increasing the surface area for microbial attachment.

After chewing, the cud is swallowed for further microbial digestion in the rumen, then passes to the omasum, and then to the abomasum, where it is finally mixed with gastric juice. This process leads to far more efficient digestion of cellulose in ruminants than in mammalian herbivores such as horses, that lack a rumen.

### Foregut fermentation has evolved convergently many times

Although the four-chambered stomach has only evolved once, many other types of herbivores—including hippopotamuses, langur monkeys, sloths, kangaroos, and hoatzins (a type of bird)—have evolved large stomachs to enhance microbial fermentation. In many cases, these species have evolved a variety of other anatomical structures that serve to slow down the passage of food through the stomach, leading to increased time for fermentation.

A remarkable case of convergent evolution at the molecular level is exhibited by ruminants and the langur monkey, which subsists primarily on leaves. In most mammals, lysozymes are enzymes found in saliva and tears, which attack invading bacteria. However, in ruminants and langurs, lysozymes have been modified to take on a new role, digesting bacteria in the stomach. In both cases, five identical amino acid changes have

**Figure 48.15** Four-chambered stomach of a ruminant.

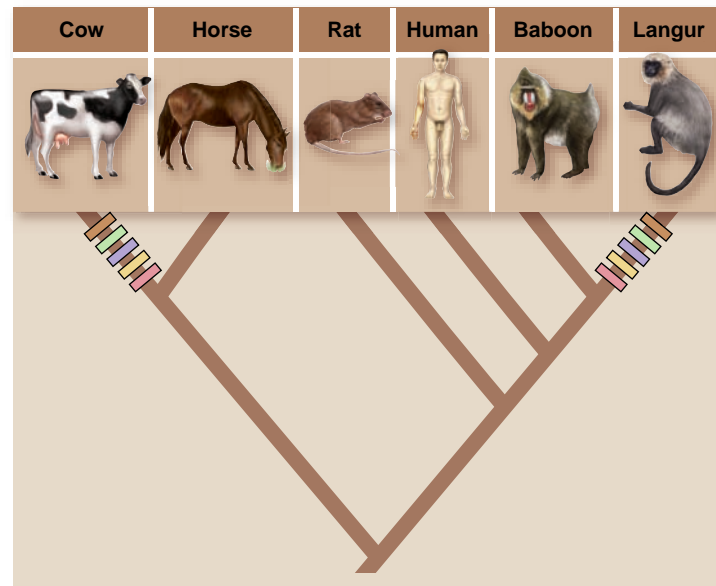

Grass and other plants eaten by ruminants enter the rumen, where they are partially digested. The rumen contains bacteria that break down cellulose from the plant cell walls. Before moving into a second chamber, the reticulum, the food may be regurgitated and rechewed. The food is then transferred to the rear two chambers: the omasum and abomasum. Only the abomasum secretes gastric juice as in the human stomach.

evolved (figure 48.16); the result is that the lysozyme molecules of ruminants and langurs are more similar to each other than they are to lysozymes in more closely related species. In contrast to many cases of convergent evolution, this example illustrates that convergent evolution has occurred in distantly related species by the exact same evolutionary changes.

### Other herbivores have alternative strategies for digestion

In some animals, such as rodents, horses, deer, and lagomorphs (rabbits and hares), the digestion of cellulose by microorganisms takes place in the cecum, which is greatly enlarged (see figure 48.14). Because the cecum is located beyond the stomach, regurgitation of its contents is impossible.

Rodents and lagomorphs have evolved another way to capture nutrients from cellulose that achieves a degree of efficiency similar to ruminant digestion. They do this by eating their feces, a practice known as coprophagy—thus passing the food through their digestive tract a second time. The second passage allows the animal to absorb the nutrients produced by the microorganisms in its cecum. Coprophagic animals cannot remain healthy if they are prevented from eating their feces.

**Figure 48.16** Convergent evolution of lysozyme structure in ruminants (represented by the cow) and leaf-eating hanuman langur (*Presbytis entellus*). The same five amino acid changes evolved independently in both groups.

### Inquiry question

**?** If you constructed a phylogeny using molecular data from lysozyme, what would it look like?

Animals with diets that don't include cellulose, such as insectivores or carnivores, don't have a cecum, or if they do, it is greatly reduced.

### Vitamin K

Another example of the way intestinal microorganisms function in the metabolism of their animal hosts is provided by the synthesis of vitamin K. All mammals rely on intestinal bacteria to synthesize this vitamin, which is necessary for the clotting of blood. Birds, which lack these bacteria, must consume the required quantities of vitamin K in their food.

In humans, prolonged treatment with antibiotics greatly reduces the populations of bacteria in the intestine; under such circumstances, it may be necessary to provide supplementary vitamin K. Restoring the normal flora of the digestive tract with beneficial bacteria may also help replace vitamin K.

### Learning Outcomes Review 48.5

The digestive tracts of many herbivores harbor colonies of cellulose-digesting microorganisms. Complex fermentation chambers have also evolved in the digestive tract. In rumination, partially digested food is regurgitated from the rumen for additional processing by the mouth. In distantly related herbivorous species, similar digestive enzymes have evolved by identical but independent changes.

- **Would you expect identical mutations to be successful in different species? Why or why not?**

## 48.6 Neural and Hormonal Regulation of the Digestive Tract

### Learning Outcomes

1. Explain how the nervous system stimulates the digestive process.
2. Identify the major enterogastrones.

The activities of the gastrointestinal tract are coordinated by the nervous system and the endocrine system. The nervous system, for example, stimulates salivary and gastric secretions in response to the sight, smell, and consumption of food. When food arrives in the stomach, proteins in the food stimulate the secretion of a stomach hormone called **gastrin**, which in turn stimulates the secretion of pepsinogen and HCl from the gastric glands (figure 48.17). The secreted HCl then lowers the pH of the gastric juice, which acts to inhibit further secretion of gastrin in a negative feedback loop. In this way, the secretion of gastric acid is kept under tight control.

The passage of chyme from the stomach into the duodenum of the small intestine inhibits the contractions of the stomach, so that no additional chyme can enter the duodenum until the previous amount can be processed. This stomach or gastric inhibition is mediated by a neural reflex and by duodenal hormones secreted into the blood. These hormones are collectively known as the **enterogastrones**.

The major enterogastrones include **cholecystokinin (CCK)**, **secretin**, and **gastric inhibitory peptide (GIP)**. Chyme with high fat content is the strongest stimulus for CCK and GIP secretions, whereas increasing chyme acidity primarily influences the release of secretin. All three of these enterogastrones inhibit gastric motility (churning action) and gastric juice secretions; the result is that fatty meals remain in the stomach longer than nonfatty meals, allowing more time for digestion of complex fat molecules.

In addition to gastric inhibition, CCK and secretin have other important regulatory functions in digestion. CCK also stimulates increased pancreatic secretions of digestive enzymes and gallbladder contractions. Gallbladder contractions inject more bile into the duodenum, which enhances the emulsification and efficient digestion of fats. The other major function of secretin is to stimulate the pancreas to release more bicarbonate, which neutralizes the acidity of the chyme. Secretin has the distinction of being the first hormone ever discovered. Table 48.1 summarizes the actions of the digestive hormones and enzymes.

### Learning Outcomes Review 48.6

Sensory input such as sight, smell, and taste stimulate salivary and gastric activity, as does the arrival of food in the stomach. The major enterogastrones are cholecystokinin (CCK), secretin, and gastric inhibitory peptide (GIP); these regulate passage of chyme into the duodenum and also release of pancreatic enzymes and bile.

- Would you expect anosmia, an inability to perceive scents, to affect digestion?

**Figure 48.17** Hormonal control of the gastrointestinal tract. Gastrin, secreted by the mucosa of the stomach, stimulates the secretion of HCl and pepsinogen (which is converted into pepsin). The duodenum secretes three hormones: cholecystokinin (CCK), which stimulates contraction of the gallbladder and secretion of pancreatic enzymes; secretin, which stimulates secretion of pancreatic bicarbonate; and gastric inhibitory peptide (GIP), which inhibits stomach emptying.

**TABLE 48.1** Hormones and Enzymes of Digestion

H O R M O N E S					
Hormone	Class	Source	Stimulus	Action	Note
Gastrin	Polypeptide	Pyloric portion of stomach	Entry of food into stomach	Stimulates secretion of HCl and pepsinogen by stomach	Acts on same organ that secretes it
Cholecystokinin (CCK)	Polypeptide	Duodenum	Fatty chyme in duodenum	Stimulates gallbladder contraction and secretion of digestive enzymes by pancreas	Structurally similar to gastrin
Gastric inhibitory peptide (GIP)	Polypeptide	Duodenum	Fatty chyme in duodenum	Inhibits stomach emptying	Also stimulates insulin secretion
Secretin	Polypeptide	Duodenum	Acidic chyme in duodenum	Stimulates secretion of bicarbonate by pancreas	The first hormone to be discovered (1902)
E N Z Y M E S					
Location		Enzymes		Substrates	Digestion Products
Salivary glands		Amylase		Starch, glycogen	Disaccharides
Stomach		Pepsin		Proteins	Short peptides
Pancreas		Lipase		Triglycerides	Fatty acids, monoglycerides
		Trypsin, chymotrypsin		Proteins	Peptides
		DNase		DNA	Nucleotides
		RNase		RNA	Nucleotides
Small intestine (brush border)		Peptidases		Short peptides	Amino acids
		Nucleases		DNA, RNA	Sugars, nucleic acid bases
		Lactase, maltase, sucrase		Disaccharides	Monosaccharides

## 48.7 Accessory Organ Function

### Learning Outcomes

1. Describe the liver's role in maintaining homeostasis.
2. Explain how the pancreas acts to control blood glucose concentration.

The liver and pancreas both have critical roles beyond the production of digestive enzymes. The liver is a key organ in the breakdown of toxins, and the pancreas secretes hormones that regulate the blood glucose level, in part through actions on liver cells.

### The liver modifies chemicals to maintain homeostasis

Because the hepatic portal vein carries blood from the stomach and intestine directly to the liver, the liver is in a position to chemically modify the substances absorbed in the gastrointestinal tract before they reach the rest of the body. For example, ingested alcohol and other drugs are taken into liver cells and metabolized; this is one reason that the liver is often damaged as a result of alcohol and drug abuse.

The liver also removes toxins, pesticides, carcinogens, and other poisons, converting them into less toxic forms. For example, the liver's converts the toxic ammonia produced by

intestinal bacteria into urea, a compound that can be contained safely and carried by the blood at higher concentrations.

Similarly, the liver regulates the levels of many compounds produced within the body. Steroid hormones, for instance, are converted into less active and more water-soluble forms by the liver. These molecules are then included in the bile and eliminated from the body in the feces or are carried by the blood to the kidneys and excreted in the urine.

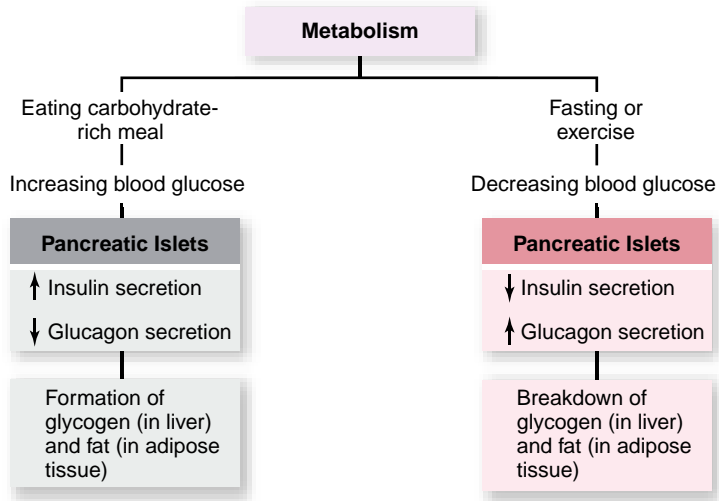

The liver also produces most of the proteins found in blood plasma. The total concentration of plasma proteins is significant because it must be kept within certain limits to maintain osmotic balance between blood and interstitial (tissue) fluid. If the concentration of plasma proteins drops too low, as can happen as a result of liver disease such as cirrhosis, fluid accumulates in the tissues, a condition called *edema*.

### Blood glucose concentration is maintained by the actions of insulin and glucagon

The neurons in the brain obtain energy primarily from the aerobic respiration of glucose obtained from the blood plasma. It is therefore vitally important that the blood glucose concentration not fall too low, as might happen during fasting or prolonged exercise. It is also important that the blood glucose concentration not stay at too high a level, as it does in people with untreated diabetes mellitus, because too high a level can lead to tissue damage.

After a carbohydrate-rich meal, the liver and skeletal muscles remove excess glucose from the blood and store it as the polysaccharide glycogen. This process is stimulated by the

## 48.8 Food Energy, Energy Expenditure, and Essential Nutrients

**Figure 48.18** The actions of insulin and glucagon.

After a meal, an increased secretion of insulin by the  $\beta$  cells of the pancreatic islets promotes the deposition of glycogen and fat. During fasting or exercising, increased glucagon secretion by the  $\alpha$  cells of the pancreatic islets and decreased insulin secretion promote the breakdown (through hydrolysis reactions) of glycogen and fat.

hormone insulin, secreted by the  $\beta$  (beta) cells in the pancreatic islets of Langerhans (figure 48.18).

When blood glucose levels decrease, as they do between meals, during periods of fasting, and during exercise, the liver secretes glucose into the blood. This glucose is obtained in part from the breakdown of liver glycogen to glucose-6-phosphate, a process called **glycogenolysis**. The phosphate group is then removed, and free glucose is secreted into the blood. Skeletal muscles lack the enzyme needed to remove the phosphate group, and so, even though they have glycogen stores, they cannot secrete glucose into the blood. However, muscle cells can use this glucose directly for energy metabolism because glucose-6-phosphate is actually the product of the first reaction in glycolysis. The breakdown of liver glycogen is stimulated by another hormone, glucagon, which is secreted by the  $\alpha$  (alpha) cells of the islets of Langerhans in the pancreas (see figure 48.18).

If fasting or exercise continues, the liver begins to convert other molecules, such as amino acids and lactic acid, into glucose. This process is called **gluconeogenesis** (“new formation of glucose”). The amino acids used for gluconeogenesis are obtained from muscle protein, which explains the severe muscle wasting that occurs during prolonged fasting.

### Learning Outcomes Review 48.7

The liver is responsible for neutralizing potentially harmful toxins and also for modification of steroid hormones. The liver also produces vital plasma proteins. Pancreatic hormones and the liver regulate blood glucose concentrations. Insulin stimulates the formation of glycogen and fat in the liver. Glucagon stimulates the breakdown of glycogen in the liver, which releases glucose into the blood.

- **What is one important advantage of the hepatic portal system?**

### Learning Outcomes

1. Explain the basal metabolic rate and the effect of exercise.
2. List hormones involved in regulating appetite and body weight.
3. Name the essential nutrients.

The ingestion of food serves two primary functions: It provides a source of energy and it provides raw materials the animal is unable to manufacture for itself.

Even an animal completely at rest requires energy to support its metabolism; the minimum rate of energy consumption under defined resting conditions is called the **basal metabolic rate (BMR)**. The BMR is relatively constant for a given individual, depending primarily on the person’s age, sex, and body size.

### Exertion increases metabolic rate

Physical exertion raises the metabolic rate above the basal levels, so the amount of energy the body consumes per day is determined not only by the BMR but also by the level of physical activity. If food energy taken in is greater than the energy consumed per day, the excess energy will be stored in glycogen and fat (figure 48.18). Because glycogen reserves are limited, however, continued ingestion of excess food energy results primarily in the accumulation of fat.

The intake of food energy is measured in **kilocalories** (1 kilocalorie = 1000 calories; nutritionists use Calorie with a capital C instead of kilocalorie). The measurement of kilocalories in food is determined by the amount of heat generated when the food is “burned,” either literally, in a testing device called a calorimeter, or in the body, when the food is digested and later oxidized during cellular respiration. Caloric intake can be altered by the choice of foods, and the amount of energy expended can be changed by the choice of lifestyle.

The daily energy expenditures (metabolic rates) of humans vary between 1300 and 5000 kilocalories per day, depending on the person’s BMR and level of physical activity. When the total kilocalories ingested exceeds the metabolic rate for a sustained period, a person accumulates an amount of fat that is deleterious to health, a condition called obesity. In the United States, about 34% of all adults between 40 and 59 are classified as obese. If 20- to 40-year-olds are added to this group, the percentage of obese individuals drops some but is still fully 30%.

### Food intake is under neuroendocrine control

For many years the neuronal and hormonal basis of appetite was a mystery. Experiments with fasting and overfeeding in rats showed an increase in food intake when fasting ends. This

increase restores lost body weight to baseline values and food intake then drops. These experiments indicated the existence of control mechanisms to link food intake to energy balance. The presence of a hormonal *satiety factor* produced by adipose tissue was hypothesized to explain these observations. It has also been shown that regions of the hypothalamus are involved in feeding behavior. Other studies in rodent models had identified a number of genes that can lead to obesity. As modern molecular genetics has allowed the cloning of many of these genes, the outlines of a model to link dietary intake to energy balance have emerged. This model involves afferent signaling from adipose tissue and feeding behavior into the central nervous system (CNS), and efferent signaling outward from the CNS tied to energy expenditure, storage, reproduction and feeding behavior. We will discuss the relevant hormones first, then show how they fit into an overall control circuit.

### Leptin

One of the rodent models for obesity, the obese mouse, is caused by a mutation in a single gene named *ob* (for obese). Animals homozygous for the recessive mutant allele become obese compared with wild-type mice (figure 48.19). When the gene responsible for this dramatic phenotype was isolated, it proved to encode a peptide hormone named leptin, leading to the hypothesis that the lack of leptin production in mutant individuals is responsible for obesity. Sure enough, when *ob/ob* animals are injected with leptin, they stop overeating and lose weight (see figure 48.19). These experiments identified leptin as the main satiety factor, and the key to the control of appetite. The gene for the leptin receptor (*lb*) has also been isolated and it is expressed in brain neurons in the hypothalamus involved in energy intake.

Leptin is now thought to be the main signaling molecule in the afferent portion of the control circuit for energy sensing, food intake, and energy expenditure. Leptin is produced by adipose tissue in response to feeding, and leptin levels correlate with feeding behavior and amount of body fat. Dietary restriction reduces leptin levels, signaling the brain that food intake is necessary, whereas re-feeding after fasting leads to rapid increase in leptin levels and a loss of appetite. The efferent part of this control circuit is complex and includes control of energy expenditure, energy storage, and feeding behavior by the CNS. Reproduction is even affected by this system as reproduction is inhibited under starvation conditions.

The leptin gene has also been isolated in humans and leptin appears to function in humans much as it does in mice. However, recent studies in humans show that the activity of the *ob* gene and the blood concentrations of leptin are actually higher in obese than in lean people, and that the leptin produced by obese people appears to be normal. It has been suggested that, in contrast with the mutant mice, most cases of human obesity may result from a reduced sensitivity to the actions of leptin in the brain, rather than from reduced leptin production by adipose cells. Research on leptin in humans is ongoing and is of great interest to both academic scientists and to the pharmaceutical industry.

### Insulin

Although the extreme obesity associated with the loss-of-function mutations in the *ob* gene indicate that other hormonal signals cannot substitute for leptin signaling, other hormones are also in-

## SCIENTIFIC THINKING

**Question:** Why are *ob/ob* mice obese?

**Hypothesis:** Lack of leptin production stimulates appetite and leads to overeating.

**Experiment:** Inject mutant mice with leptin.

**Results:** In just two weeks, injected mice lost 30% of their body weight with no apparent side effects.

**Interpretation:** What is the molecular mechanism by which leptin has its effect? Could mutations in other genes have the same effect?

**Figure 48.19** Effects of the hormone leptin.

involved. Insulin has been implicated in signaling satiety as well, and insulin levels also fall with fasting and rise with obesity. As insulin's primary role is homeostasis of blood glucose, as described earlier, its role in the control circuit of energy balance is complex.

### Gut hormones (enterogastrones)

The gut produces a number of hormones that control the physiology of digestion described earlier. Several of these have also been implicated in the regulation of food intake. They are produced directly in response to feeding, necessary for their role in digestion.

The hormones GIP and CCK have receptors in the hypothalamus and seem to send the same kind of inhibitory signals to the brain as leptin and insulin. The levels of these gut hormones also vary with feeding behavior in a pattern similar to leptin and insulin.

The gut hormone ghrelin has the opposite effect of these appetite-suppressing hormones. Ghrelin also has receptors in the hypothalamus, but ghrelin appears to stimulate food intake. This role is supported by studies in rats showing that chronic administration of ghrelin leads to obesity. Ghrelin levels appear to rise before feeding and may be involved in initiating feeding behavior. One of the treatments for severe obesity, gastric bypass surgery, leads to reduced levels of ghrelin. It has been suggested that this is one of the reasons for the suppression of appetite seen after this surgery.

### Neuropeptides

The efferent control over feeding and energy balance is less clear than the afferent control detailed earlier. The central

regulator is the hypothalamus and two brain neuropeptides have been implicated: neuropeptide Y (NPY) and alpha-melanocyte-stimulating hormone ( $\alpha$ -MSH). These peptides are antagonistic, with NPY inducing feeding activity and  $\alpha$ -MSH suppressing it.

Evidence for this comes from experiments that show that production and release of  $\alpha$ -MSH is stimulated by leptin and that administration of  $\alpha$ -MSH suppresses feeding. Loss of function for the  $\alpha$ -MSH receptor also leads to obesity. In contrast, the expression of NPY is negatively regulated by leptin and administration of NPY stimulates feeding behavior.

### Model for energy balance

The current model for energy balance and feeding behavior is summarized in figure 48.20. The role of both leptin and insulin is long-term regulation of the afferent portion of this signaling network. Leptin and insulin are produced by adipose tissue and the pancreas, respectively, in response to the effects of feeding behavior, not as a direct response to feeding itself. This leads to circulating levels of leptin that correlate with the amount of adipose tissue. The extreme example of this is the very high level of leptin seen in obese individuals. High levels of leptin and insulin then act on the hypothalamus to increase levels of  $\alpha$ -MSH and reduce levels of NPY. This causes a reduction in appetite and increased energy expenditure and al-

lows reproduction and growth. Low levels of these hormones act on the hypothalamus to reduce  $\alpha$ -MSH levels and increase NPY levels. This leads to increased appetite and decreased energy expenditure. If very low levels of leptin persist, this can inhibit reproduction and growth.

The gut hormones CCK and GIP are produced in response to feeding and represent short-term regulators of the afferent portion of the energy balance control circuit. Their action is the same as that of leptin and insulin. The gut hormone ghrelin is also a short-term regulator that stimulates feeding.

### Essential nutrients are those that the body cannot manufacture

Over the course of evolution, many animals have lost the ability to synthesize certain substances that nevertheless continue to play critical roles in their metabolism. Substances that an animal cannot manufacture for itself but that are necessary for its health and must be obtained in the diet are referred to as essential nutrients.

Included among the essential nutrients are **vitamins**, certain organic substances required in trace amounts. For example, humans, apes, monkeys, and guinea pigs have lost the ability to synthesize ascorbic acid (vitamin C). If vitamin C is

**Figure 48.20** Hormonal control of feeding behavior. The control of feeding behavior is under both long-term control related to the amount of adipose tissue, and short-term control related to the act of feeding. This control is mediated by the CNS. The major brain region involved is the hypothalamus.

### Inquiry question

Suppose the GIP and CCK sensors in the hypothalamus didn't work. How would this affect levels of leptin production?

TABLE 48.2

## Major Vitamins Required by Humans

Vitamin	Function	Source	Deficiency Symptoms
Vitamin A (retinol)	Used in making visual pigments, maintaining epithelial tissues	Green vegetables, milk products, liver	Night blindness, flaky skin
B-complex vitamins			
B <sub>1</sub>	Coenzyme in CO <sub>2</sub> removal during cellular respiration	Meat, grains, legumes	Beriberi, weakening of heart, edema
B <sub>2</sub> (riboflavin)	Part of coenzymes FAD and FMN, which play metabolic roles	Many different kinds of foods	Inflammation and breakdown of skin, eye irritation
B <sub>3</sub> (niacin)	Part of coenzymes NAD <sup>+</sup> and NADP <sup>+</sup>	Liver, lean meats, grains	Pellagra, inflammation of nerves, mental disorders
B <sub>5</sub> (pantothenic acid)	Part of coenzyme-A, a key connection between carbohydrate and fat metabolism	Many different kinds of foods	Rare: fatigue, loss of coordination
B <sub>6</sub> (pyridoxine)	Coenzyme in many phases of amino acid metabolism	Cereals, vegetables, meats	Anemia, convulsions, irritability
B <sub>12</sub> (cyanocobalamin)	Coenzyme in the production of nucleic acids	Red meats, dairy products	Pernicious anemia
Biotin	Coenzyme in fat synthesis and amino acid metabolism	Meat, vegetables	Rare: depression, nausea
Folic acid	Coenzyme in amino acid and nucleic acid metabolism	Green vegetables	Anemia, diarrhea
Vitamin C	Important in forming collagen, cementum of bone, teeth, connective tissue of blood vessels; may help maintain resistance to infection	Fruit, green leafy vegetables	Scurvy, breakdown of skin, blood vessels
Vitamin D (calciferol)	Increases absorption of calcium and promotes bone formation	Dairy products, cod liver oil	Rickets, bone deformities
Vitamin E (tocopherol)	Protects fatty acids and cell membranes from oxidation	Margarine, seeds, green leafy vegetables	Rare
Vitamin K	Essential to blood clotting	Green leafy vegetables	Severe bleeding

not supplied in sufficient quantities in their diets, these mammals develop scurvy, a potentially fatal disease that results in degeneration of connective tissues. Humans require at least 13 different vitamins (table 48.2).

Some essential nutrients are required in more than trace amounts. Many vertebrates, for example, are unable to synthesize one or more of the 20 amino acids. These *essential amino acids* must be obtained from food they eat. Humans require nine amino acids. People who are strict vegetarians must choose their foods so that the essential amino acids in one food complement those in another. Vegetarians may also need supplements to provide certain vitamins not found in large amounts in plants, such as some B vitamins.

In addition, all vertebrates have lost the ability to synthesize certain long-chain unsaturated fatty acids and therefore must obtain them in food. In contrast, some essential nutrients that vertebrates can synthesize cannot be manufactured by the members of other animal groups. For example, vertebrates can synthesize cholesterol, a key component of steroid hormones, but some carnivorous insects cannot.

Food also supplies essential minerals such as calcium, magnesium, phosphorus, and other inorganic substances, in-

cluding a wide variety of *trace elements* such as zinc and molybdenum, which are required in very small amounts. Animals obtain trace elements either directly from plants or from animals that have eaten plants.

### Learning Outcomes Review 48.8

Basal metabolic rate is the minimum amount of energy consumption under defined resting conditions. Exercise does not increase the basal metabolic rate, but it does add to the body's total energy expenditure. Obesity results if the amount of ingested food energy exceeds energy expenditure over a prolonged period. Hormones involved in regulating appetite are leptin; insulin; the enterogastrones including CCK, GIP, and ghrelin; and neuropeptides associated with the hypothalamus. The essential nutrients for humans are 13 vitamins, essential minerals, and essential amino acids and fatty acids that the body cannot synthesize.

- What might explain obesity in a person with normal leptin levels?

## Chapter Review

### 48.1 Types of Digestive Systems

***Invertebrate digestive systems are bags or tubes.***

In cnidarians and flatworms, the incomplete digestive system is a gastrovascular cavity with only one opening (see figure 48.1). In contrast, a complete digestive system, with a one-way tube from mouth to anus, allows specialization of digestive organs.

***Vertebrate digestive systems include highly specialized structures molded by diet.***

The gastrointestinal tract includes the mouth and pharynx, esophagus, stomach, small and large intestines, cloaca or rectum, and anus (see figure 48.3). The four tissue layers of the tract are the mucosa, submucosa, muscularis, and serosa (see figure 48.4).

### 48.2 The Mouth and Teeth: Food Capture and Bulk Processing

***Vertebrate teeth are adapted to different types of food items.***

Birds lack teeth but have a gizzard where small pebbles grind food. The teeth of mammals are adapted to reflect their feeding habits (see figure 48.6).

***The mouth is a chamber for ingestion and initial processing.***

Salivary glands secrete saliva containing amylase that moistens food and begins digestion as the food is chewed. Swallowing, once begun, is involuntary (see figure 48.7).

### 48.3 The Esophagus and the Stomach: The Early Stages of Digestion

***Muscular contractions of the esophagus move food to the stomach.***

Rhythmic muscular contractions and relaxation, called peristalsis, propel a bolus of food to the stomach.

***The stomach is a “holding station” involved in acidic breakdown of food.***

In the stomach, hydrochloric acid breaks down food and converts pepsinogen into pepsin, an active protease. The mixture of food and gastric juice, termed chyme, moves through the pyloric sphincter to the small intestine.

### 48.4 The Intestines: Breakdown, Absorption, and Elimination

***The structure of the small intestine is specialized for digestion and nutrient uptake.***

The surface area of the small intestine is increased by fingerlike projections called villi (see figure 48.10). The duodenum receives digestive secretions from the pancreas and liver.

***Accessory organs secrete enzymes into the small intestine.***

Accessory organs include the salivary glands, pancreas, liver, and gallbladder (see figure 48.11). The pancreas secretes digestive enzymes and bicarbonate. The liver secretes bile, which is stored in the gallbladder. Bile disperses fats into small droplets.

***Absorbed nutrients move into blood or lymph capillaries.***

Amino acids and monosaccharides move into epithelial cells by active transport and facilitated diffusion (see figure 48.12) and then pass into the bloodstream. Fatty acids and monoglycerides simply diffuse into epithelial cells. They are reassembled into chylomicrons that enter the lymphatic system.

Absorbed molecules that pass into the bloodstream are transported to the liver through the hepatic portal vein.

***The large intestine eliminates waste material.***

The large intestine absorbs water and concentrates waste material, which is stored in the rectum until it can be eliminated.

### 48.5 Variations in Vertebrate Digestive Systems

***Ruminants rechew regurgitated food.***

The four-chambered stomach of ruminants consists of the rumen, reticulum, omasum, and abomasum. Food initially processed in the rumen is regurgitated for further chewing.

***Foregut fermentation has evolved convergently many times.***

Enlarged foreguts have evolved in many species to provide a chamber for microbial fermentation. In some unrelated herbivores, identical changes in lysozyme have evolved.

***Other herbivores have alternative strategies for digestion.***

In some herbivores, digestion of cellulose by microorganisms takes place in the cecum, located beyond the stomach.

### 48.6 Neural and Hormonal Regulation of the Digestive Tract

The activities of the gastrointestinal tract are coordinated by the nervous and endocrine systems.

Duodenal hormones regulate passage of chyme into the duodenum. High fat content in the chyme stimulates the release of CCK and GIP; low chyme pH stimulates the release of secretin. In turn, CCK stimulates release of pancreatic enzymes and bile. Secretin stimulates release of bicarbonate.

### 48.7 Accessory Organ Function

***The liver modifies chemicals to maintain homeostasis.***

The liver is involved in detoxification, regulation of steroid hormone levels, and production of proteins found in the blood plasma.

***Blood glucose concentration is maintained by the actions of insulin and glucagon.***

Insulin lowers blood glucose and increases glycogen storage; glucagon increases blood glucose and utilization of glycogen.

### 48.8 Food Energy, Energy Expenditure, and Essential Nutrients

***Exertion increases metabolic rate.***

The basal metabolic rate is the minimum rate of energy consumption under resting conditions. Activity leads to an increase in the metabolic rate.

***Food intake is under neuroendocrine control.***

Food intake is regulated by the hormones leptin and insulin, by enterogastrones, and by neuropeptides (see figure 48.20).

***Essential nutrients are those that the body cannot manufacture.***

Essential nutrients are those that cannot be synthesized by animals. For humans, they are 13 vitamins (see table 48.2), the essential amino acids, essential minerals, and certain fatty acids.

## Review Questions

### UNDERSTAND

- How is the digestion of fats different from that of proteins and carbohydrates?
  - Fat digestion occurs in the small intestine, and the digestion of proteins and carbohydrates occurs in the stomach.
  - Fats are absorbed into cells as fatty acids and monoglycerides but are then modified for absorption; amino acids and glucose are not modified further.
  - Fats enter the hepatic portal circulation, but digested proteins and carbohydrates enter the lymphatic system.
  - Digested fats are absorbed in the large intestine, and digested proteins and carbohydrates are absorbed in the small intestine.
- Although the stomach is normally thought of as the major player in the digestive process, the bulk of chemical digestion actually occurs in the
  - mouth.
  - appendix.
  - duodenum.
  - large intestine.
- After being absorbed through the intestinal mucosa, glucose and amino acids are
  - absorbed directly into the systemic circulation.
  - used to build glycogen and peptides before being released to the body cells.
  - transported directly to the liver by the hepatic portal vein.
  - further digested by bile before release into the circulation.
- Which of these pairings is incorrect?
  - Fat transport/lymphatic system
  - Glucose transport/lymphatic system
  - Amino acid transport/circulatory system
  - All of these pairings are correct.
- Intestinal microorganisms aid digestion and absorption by
  - digesting cellulose.
  - producing glucose.
  - synthesizing vitamin K.
  - both a and c.
- The \_\_\_\_\_ and \_\_\_\_\_ play important roles in the digestive process by producing chemicals that are required to digest proteins, lipids, and carbohydrates.
  - liver; pancreas
  - liver; gallbladder
  - kidneys; appendix
  - pancreas; gallbladder
- Which of the following represents the action of insulin?
  - Increases blood glucose levels by the hydrolysis of glycogen
  - Increases blood glucose levels by stimulating glucagon production
  - Decreases blood glucose levels by forming glycogen
  - Increases blood glucose levels by promoting cellular uptake of glucose

### APPLY

- The small intestine is specialized for absorption because it
  - is the last section of the digestive tract and retains food the longest.
  - has saclike extensions along its length that collect food.
  - has no outlet so food remains within it for longer periods of time.
  - has an extremely large surface area that allows extended exposure to food.

- The primary function of the large intestine is to concentrate wastes into solid form (feces) for release from the body. How does it accomplish this?
  - By adding additional cells from the mucosal layer
  - By absorbing water
  - By releasing salt
  - All of these are methods used by the large intestine.
- Inactive forms of some molecules are secreted
  - because they take less material and energy.
  - because they must combine with water to be activated.
  - so their activity can be regulated.
  - to prevent them from clogging the gland from which they are secreted.
- Obese humans probably have high levels of leptin because
  - leptin stimulates eating.
  - something is wrong with the leptin receptors in their brain, leading to increased leptin production to make up for the apparent shortage.
  - weight gain leads to the production of leptin.
  - leptin responds to mechanical stimulation in the adrenal cortex.

### SYNTHESIZE

- Many birds possess crops, although few mammals do. Suggest a reason for this difference between birds and mammals.
- Suppose that you wanted to develop a new treatment for obesity based on the hormone leptin. What structures in the body produce leptin? What does it do? Should your treatment cause an increase in blood levels of leptin or a decrease? Could this treatment affect any other systems in the body?
- How could a drop in plasma proteins and a decrease in bile production be related to alcohol and drug abuse?
- Unlike many cases of convergence (see section 47.5), ruminants and langur monkeys have modified the enzyme lysozyme in the same way to achieve the same end result. Why might this case be different?
- Birds do not have teeth. Do you think they have adaptations to processing different types of food, comparable to the diversity seen in mammals? If so, what might these adaptive differences be?

# Chapter 49

## The Respiratory System

### Chapter Outline

---

- 49.1** Gas Exchange Across Respiratory Surfaces
- 49.2** Gills, Cutaneous Respiration, and Tracheal Systems
- 49.3** Lungs
- 49.4** Structures and Mechanisms of Ventilation in Mammals
- 49.5** Transport of Gases in Body Fluids

### Introduction

---

*Every cell in the animal body must exchange materials with its surrounding environment. In single-celled organisms, this exchange occurs directly across the cell membrane to and from the external environment. In multicellular organisms, however, most cells are not in contact with the external environment and must rely on specialized systems for transport and exchange. Although these systems aid in bulk transport, the properties of transport across the plasma membrane do not change. Many structural adaptations throughout the animal kingdom increase surface areas where transport occurs, so that the needs of every cell are met. The interface between air from the environment and blood in the mammalian lungs provides an excellent example of the efficiency associated with increased surface area. In the time it takes you to breathe in, trillions of oxygen molecules have been transported across 80 m<sup>2</sup> of alveolar membrane into blood capillaries. In this and the next chapter, we describe respiration and circulation, the two systems that directly support the other organ systems and tissues of the body.*

## 49.1 Gas Exchange Across Respiratory Surfaces

### Learning Outcomes

1. Describe gas exchange across membranes.
2. Explain Fick's Law of Diffusion.
3. Compare evolutionary strategies for maximizing gas diffusion.

One of the major physiological challenges facing all multicellular animals is obtaining sufficient oxygen and disposing of excess carbon dioxide (figure 49.1). Oxygen is used in mitochondria for cellular respiration—a process that also produces CO<sub>2</sub> as waste (see chapter 7). Respiration at the body system level involves a host of processes not found at the cellular level, ranging from the mechanics of breathing to the exchange of oxygen and carbon dioxide in respiratory organs.

Invertebrates display a wide variety of respiratory organs, including the epithelium, tracheae, and gills. Some vertebrates, such as fish and larval amphibians, also use gills; adult amphibians use their skin or other epithelia either as a supplemental or primary external respiratory organ.

Many adult amphibians, reptiles, birds, and mammals have lungs to perform external respiration. In both aquatic and terrestrial animals, these highly vascularized respiratory organs are the site at which oxygen diffuses into the blood, and carbon dioxide diffuses out. In the body tissues, the

**Figure 49.1** Elephant seals are respiratory champions. Diving to great depths, elephant seals can hold their breath for over 2 hr, descend and ascend rapidly in the water, and endure repeated dives without suffering any apparent respiratory distress.

direction of gas diffusion is the reverse of that in the respiratory organs.

The mechanics, structure, and evolution of respiratory systems, along with the principles of gas diffusion between the blood and tissues, are the subjects of this chapter.

### Gas exchange involves diffusion across membranes

Because plasma membranes must be surrounded by water to be stable, the external environment in gas exchange is always aqueous. This is true even in terrestrial vertebrates; in these cases, oxygen from air dissolves in a thin layer of fluid that covers the respiratory surfaces.

In vertebrates, the gases diffuse into the aqueous layer covering the epithelial cells that line the respiratory organs. The diffusion process is passive, driven only by the difference in O<sub>2</sub> and CO<sub>2</sub> concentrations on the two sides of the membranes and their relative solubilities in the plasma membrane. For dissolved gases, concentration is usually expressed as pressure; we explain this more fully a little later.

In general, the rate of diffusion between two regions is governed by a relationship known as **Fick's Law of Diffusion**. Fick's Law states that for a dissolved gas, the rate of diffusion ( $R$ ) is directly proportional to the pressure difference ( $\Delta p$ ) between the two sides of the membrane and the area ( $A$ ) over which the diffusion occurs. Furthermore,  $R$  is inversely proportional to the distance ( $d$ ) across which the diffusion must occur. A molecule-specific diffusion constant,  $D$ , accounts for the size of molecule, membrane permeability, and temperature. Shown as a formula, Fick's Law is stated as:

$$R = \frac{DA\Delta p}{d}$$

Major evolutionary changes in the mechanism of respiration have occurred to optimize the rate of diffusion (see figure 49.1).  $R$  can be optimized by changes that (1) increase the surface area,  $A$ ; (2) decrease the distance,  $d$ ; or (3) increase the concentration difference, as indicated by  $\Delta p$ . The evolution of respiratory systems has involved changes in all of these factors.

### Inquiry question

? What part of the vertebrate cardiovascular system maximizes surface area?

### Evolutionary strategies have maximized gas diffusion

The levels of oxygen needed for cellular respiration cannot be obtained by diffusion alone over distances greater than about 0.5 mm. This restriction severely limits the size and structure of organisms that obtain oxygen entirely by diffusion from the environment. Bacteria, archaea, and protists are small enough that such diffusion can be adequate, even in some colonial forms (figure 49.2a), but most multicellular animals require structural adaptations to enhance gas exchange.

**Figure 49.2 Different gas exchange systems in animals.** *a.* Gases diffuse directly into single-celled organisms. *b.* Most amphibians and many other animals respire across their skin. Amphibians also exchange gases via lungs. *c.* Echinoderms have protruding papulae, which provide an increased respiratory surface area. *d.* Insects respire through an extensive tracheal system. *e.* The gills of fishes provide a very large respiratory surface area and countercurrent exchange. *f.* The alveoli in mammalian lungs provide a large respiratory surface area but do not permit countercurrent exchange. Inhaled fresh air contains some CO<sub>2</sub>, but levels are higher in the lungs, so more CO<sub>2</sub> is exhaled than inhaled; similarly, O<sub>2</sub> levels are higher in fresh air, leading to an influx of O<sub>2</sub>.

### Increasing oxygen concentration difference

Most phyla of invertebrates lack specialized respiratory organs, but they have developed means of improving diffusion. Many organisms create a water current that continuously replaces the water over the respiratory surfaces; often, beating cilia produce this current. Because of this continuous replenishment of water, the external oxygen concentration does not decrease along the diffusion pathway. Although some of the oxygen molecules that pass into the organism have been removed from the surrounding water, new water continuously replaces the oxygen-depleted water. This maximizes the concentration difference—the  $\Delta p$  of the Fick equation.

### Increasing area and decreasing distance

Other invertebrates (mollusks, arthropods, echinoderms) and vertebrates possess respiratory organs—such as gills, tracheae, and lungs—that increase the surface area available for diffu-

sion (see figure 49.2). These adaptations also bring the external environment (either water or air) close to the internal fluid, which is usually circulated throughout the body—such as blood or hemolymph. The respiratory organs thus increase the rate of diffusion by maximizing surface area ( $A$ ) and decreasing the distance ( $d$ ) the diffusing gases must travel.

### Learning Outcomes Review 49.1

Gases must be dissolved to diffuse across living membranes. Direction of diffusion is driven by a concentration difference (gradient) between the two sides. Fick's Law states that the rate of diffusion is increased by a greater pressure difference and membrane area, and decreased by greater distance. Evolutionary strategies have therefore aimed to increase gradient and area and to lessen the distance gases must travel.

- Which factor is affected by continuously beating cilia?

## 49.2 Gills, Cutaneous Respiration, and Tracheal Systems

### Learning Outcomes

1. Describe how gills work.
2. Explain the advantage of countercurrent flow.

**Gills** are specialized extensions of tissue that project into water. Gills can be simple, as in the papulae of echinoderms (figure 49.2c), or complex, as in the highly convoluted gills of fish (figure 49.2e). The great increase in diffusion surface area that gills provide enables aquatic organisms to extract far more oxygen from water than would be possible from their body surface alone. In this section we concentrate on gills found in vertebrate animals.

Other moist external surfaces are also involved in gas exchange in some vertebrates and invertebrates. For example, gas exchange across the skin is a common strategy in many amphibian groups.

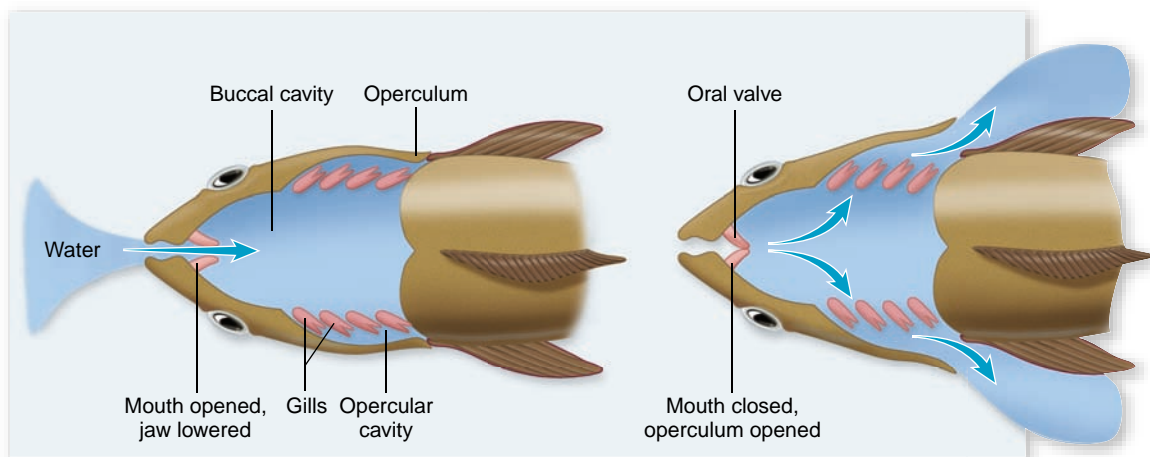

Terrestrial arthropods such as insects take an alternative approach; their tracheal systems allow gas exchange through their hard exoskeletons (figure 49.2d).

### External gills are found in fish and amphibian larvae

External gills are not enclosed within body structures. Examples of vertebrates with external gills are the larvae of many fish and amphibians, as well as amphibians such as the axolotl, which retains larval features throughout life (figure 49.3).

One of the disadvantages of external gills is that they must constantly be moved to ensure contact with fresh water having high oxygen content. The highly branched gills, however, offer significant resistance to movement, making this form of respiration ineffective except in smaller animals. Another disadvantage is that external gills, with their thin epithelium for gas exchange, are easily damaged.

**Figure 49.4** How most bony fishes respire. The gills are suspended between the buccal (mouth) cavity and the opercular cavity. Respiration occurs in two stages. The oral valve in the mouth is opened and the jaw is depressed, drawing water into the buccal cavity while the opercular cavity is closed. The oral valve is closed and the operculum is opened, drawing water through the gills to the outside.

**Figure 49.3** Some amphibians have external gills.

External gills are used by aquatic amphibians, both larvae and some species that live their entire lives in water such as this axolotl, to extract oxygen from the water.

### Branchial chambers protect gills of some invertebrates

Other types of aquatic animals evolved specialized *branchial chambers*, which provide a means of pumping water past stationary gills. The internal *mantle cavity* of mollusks opens to the outside and contains the gills. Contraction of the muscular walls of the mantle cavity draws water in through the inhalant siphon and then expels it through the exhalant siphon (see chapter 34).

In crustaceans, the branchial chamber lies between the bulk of the body and the hard exoskeleton of the animal. This chamber contains gills and opens to the surface beneath a limb. Movement of the limb draws water through the branchial chamber, thus creating currents over the gills.

### Gills of bony fishes are covered by the operculum

The gills of bony fishes are located between the oral cavity, sometimes called the buccal (mouth) cavity, and the *opercular cavities* where the gills are housed (figure 49.4). The two sets

of cavities function as pumps that expand alternately to move water into the mouth, through the gills, and out of the fish through the open operculum, or gill cover.

Some bony fishes that swim continuously, such as tuna, have practically immobile opercula. These fishes swim with their mouths partly open, constantly forcing water over the gills in what is known as *ram ventilation*. Most bony fishes, however, have flexible gill covers. For example, the remora, a fish that rides “piggyback” on sharks, uses ram ventilation while the shark is swimming, but employs the pumping action of its opercula when the shark stops swimming.

There are between three and seven gill arches on each side of the fish’s head. Each gill arch is composed of two rows of *gill filaments*, and each gill filament contains thin membranous plates, or *lamellae*, that project out into the flow of water (figure 49.5). Water flows past the lamellae in one direction only.

**Figure 49.5 Structure of a fish gill.** Water passes from the gill arch over the filaments (from left to right in the diagram). Water always passes the lamellae in a direction opposite to the direction of blood flow through the lamellae. The success of the gill’s operation critically depends on this countercurrent flow of water and blood.

Within each lamella, blood flows opposite to the direction of water movement. This arrangement is called **countercurrent flow**, and it acts to maximize the oxygenation of the blood by maintaining a positive oxygen gradient along the entire pathway for diffusion, increasing  $\Delta p$  in Fick’s Law of Diffusion. The advantages of a countercurrent flow system are illustrated in figure 49.6a. Countercurrent flow ensures that an oxygen concentration gradient remains between blood and water throughout the length of the gill lamellae. This permits oxygen to continue to diffuse all along the lamellae, so that the blood leaving the gills has nearly as high an oxygen concentration as the water entering the gills.

If blood and water flowed in the same direction, the flow would be *concurrent* (figure 49.6b). In this case, the concentration difference across the gill lamellae would fall rapidly as the water lost oxygen to the blood, and net diffusion of oxygen

**Figure 49.6 Countercurrent exchange.** This process allows for the most efficient blood oxygenation. When blood and water flow in opposite directions (a), the initial oxygen ( $O_2$ ) concentration difference between water and blood is small, but is sufficient for  $O_2$  to diffuse from water to blood. As more  $O_2$  diffuses into the blood, raising the blood’s  $O_2$  concentration, the blood encounters water with ever higher  $O_2$  concentrations. At every point, the  $O_2$  concentration is higher in the water, so that diffusion continues. In this example, blood attains an  $O_2$  concentration of 85%. When blood and water flow in the same direction (b),  $O_2$  can diffuse from the water into the blood rapidly at first, but the diffusion rate slows as more  $O_2$  diffuses from the water into the blood, until finally the concentrations of  $O_2$  in water and blood are equal. In this example, blood’s  $O_2$  concentration cannot exceed 50%.

## 49.3 Lungs

### Learning Outcomes

1. Explain why lungs work better than gills in air.
2. Compare the breathing mechanisms of amphibians and reptiles.
3. Describe the breathing cycle of birds.

would cease when the level of oxygen became the same in the water and in the blood.

Because of the countercurrent exchange of gases, fish gills are the most efficient of all respiratory organs.

### Cutaneous respiration requires constant moisture

Oxygen and carbon dioxide can diffuse across cutaneous (skin) surfaces in some vertebrates (see figure 49.2*b*). Most commonly, these vertebrates are aquatic, such as amphibians and some turtles, and they have highly vascularized areas of thin epidermis. The process of exchanging oxygen and carbon dioxide across the skin is called **cutaneous respiration**. In amphibians, cutaneous respiration supplements—and sometimes replaces—the action of lungs. Although not common, some terrestrial amphibians, such as plethodontid salamanders, rely on cutaneous respiration exclusively.

Terrestrial reptiles have dry, tough, scaly skins that not only prevent desiccation, but also prohibit cutaneous respiration, which is utilized by many amphibians. Some aquatic reptiles, however, have the ability to respire cutaneously. For example, soft-shelled turtles can remain submerged and inactive in river sediment for hours without having to ventilate their lungs. At that level of activity, cutaneous respiration occurring through the skin lining the throat provides enough oxygen to the tissues. Even the common pond slider uses cutaneous respiration to help stay submerged. During the winter, these turtles can stay submerged for many days without needing to breathe air.

### Tracheal systems are found in arthropods

The arthropods have no single respiratory organ. The respiratory system of most terrestrial arthropods consists of small, branched cuticle-lined air ducts called *tracheae* (see figure 49.2*d*). These trachea, which ultimately branch into very small tracheoles, are a series of tubes that transmit gases throughout the body. Tracheoles are in direct contact with individual cells, and oxygen diffuses directly across the plasma membranes.

Air passes into the trachea by way of specialized openings in the exoskeleton called *spiracles*, which, in most terrestrial arthropods, can be opened and closed by valves. The ability to prevent water loss by closing the spiracles was a key adaptation that facilitated the invasion of land by arthropods.

#### Learning Outcomes Review 49.2

Gills are highly subdivided structures providing a large surface area for exchange. In countercurrent flow, blood in the gills flows opposite to the direction of water to maintain a gradient difference and maximize gas exchange. Some amphibians rely on cutaneous respiration. Highly subdivided tracheal systems have evolved in arthropods, and these have been modified with valves as an adaptation to terrestrial life.

- What are the anatomical requirements for a countercurrent flow system?

Despite the high efficiency of gills as respiratory organs in aquatic environments, gills were replaced in terrestrial animals for two principal reasons:

1. **Air is less supportive than water.** The fine membranous lamellae of gills lack inherent structural strength and rely on water for their support. A fish out of water, although awash in oxygen, soon suffocates because its gills collapse into a mass of tissue. Unlike gills, internal air passages such as trachea and lungs can remain open because the body itself provides the necessary structural support.
2. **Water evaporates.** Air is rarely saturated with water vapor, except immediately after a rainstorm. Consequently, terrestrial organisms constantly lose water to the atmosphere. Gills would provide an enormous surface area for water loss.

The lung minimizes evaporation by moving air through a branched tubular passage. The tracheal system of arthropods also uses internal tubes to minimize evaporation.

The air drawn into the respiratory passages becomes saturated with water vapor before reaching the inner regions of the lung. In these areas, a thin, wet membrane permits gas exchange. Unlike the one-way flow of water that is so effective in the respiratory function of gills, gases move in and out of lungs by way of the same airway passages, a two-way flow system. Birds have an exceptional respiratory system, as described later on.

### Breathing of air takes advantage of partial pressures of gases

Dry air contains 78.09% nitrogen, 20.95% oxygen, 0.93% argon and other inert gases, and 0.03% carbon dioxide. Convection currents cause the atmosphere to maintain a constant composition to altitudes of at least 100 km, although the *amount* (number of molecules) of air that is present decreases as altitude increases.

Because of the force of gravity, air exerts a pressure downward on objects below it. An apparatus that measures air pressure is called a *barometer*, and 760 mm Hg is the barometric pressure of the air at sea level. A pressure of 760 mm Hg is also defined as one atmosphere (1.0 atm) of pressure.

Each type of gas contributes to the total atmospheric pressure according to its fraction of the total molecules present. The pressure contributed by a gas is called its **partial pressure**, and it is indicated by  $P_{N_2}$ ,  $P_{O_2}$ ,  $P_{CO_2}$ , and so

on. At sea level, the partial pressures of  $N_2$ ,  $O_2$ , and  $CO_2$  are as follows:

$$P_{N_2} = 760 \times 79.02\% = 600.6 \text{ mm Hg}$$

$$P_{O_2} = 760 \times 20.95\% = 159.2 \text{ mm Hg}$$

$$P_{CO_2} = 760 \times 0.03\% = 0.2 \text{ mm Hg}$$

Humans do not survive for long at altitudes above 6000 m. Although the air at these altitudes still contains 20.95% oxygen, the atmospheric pressure is only about 380 mm Hg, so the  $P_{O_2}$  is only 80 mm Hg ( $380 \times 20.95\%$ ), half the amount of oxygen available at sea level.

In the following sections, we describe respiration in vertebrates with lungs, beginning with reptiles and amphibians. We then summarize mammalian lungs and the highly adapted and specialized lungs of birds.

## Amphibians and reptiles breathe in different ways

The lungs of amphibians are formed as saclike outpouchings of the gut (figure 49.7). Although the internal surface area of these sacs is increased by folds, much less surface area is available for gas exchange in amphibian lungs than in the lungs of other terrestrial vertebrates. Each amphibian lung is connected to the rear of the oral cavity, or pharynx, and the opening to each lung is controlled by a valve, the glottis.

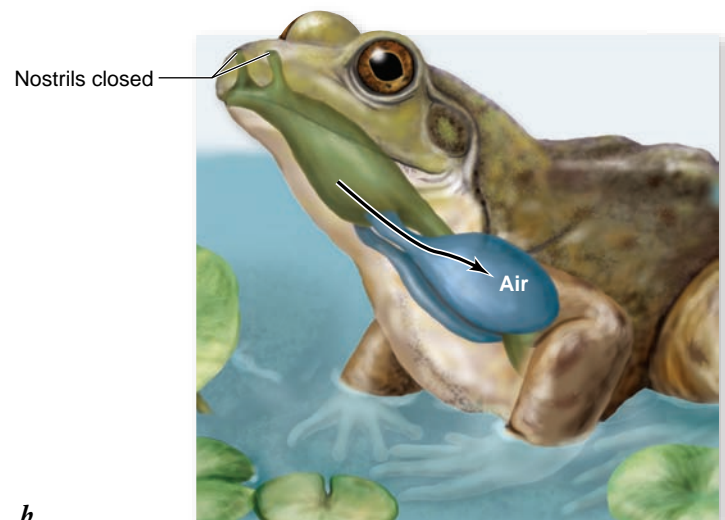

Amphibians do not breathe the same way as other terrestrial vertebrates. Amphibians force air into their lungs; they fill their oral cavity with air (figure 49.7a), close their mouth and nostrils, and then elevate the floor of their oral cavity. This pushes air into their lungs in the same way that a pressurized tank of air is used to fill balloons (figure 49.7b). This is called **positive pressure breathing**; in humans, it would be analogous to forcing air into a person's lungs by performing mouth-to-mouth resuscitation.

Most reptiles breathe in a different way, by expanding their rib cages by muscular contraction. This action creates a lower pressure inside the lungs compared with the atmosphere, and the greater atmospheric pressure moves air into the lungs. This type of ventilation is termed **negative pressure breathing** because of the air being “pulled in” by the animal, like sucking water through a straw, rather than being “pushed in.”

## Mammalian lungs have greatly increased surface area

Endothermic animals, such as birds and mammals, have consistently higher metabolic rates and thus require more oxygen (see chapter 7). Both these vertebrate groups exhibit more complex and efficient respiratory systems than ectothermic animals. The evolution of more efficient respiratory systems accommodates the increased demands on cellular respiration of endothermy.

The lungs of mammals are packed with millions of **alveoli**, tiny sacs clustered like grapes (figure 49.8). This provides each lung with an enormous surface area for gas exchange. Each alveolus is composed of an epithelium only one cell thick,

**Figure 49.7 Amphibian lungs.** Each lung of this frog is an outpouching of the gut and is filled with air by the creation of a positive pressure in the buccal cavity. **a.** The buccal cavity is expanded and air flows through the open nostrils. **b.** The nostrils are closed and the buccal cavity is compressed, thus creating the positive pressure that fills the lungs. The amphibian lung lacks the structures present in the lungs of other terrestrial vertebrates that provide an enormous surface area for gas exchange, and so are not as efficient as the lungs of other vertebrates.

and is surrounded by blood capillaries with walls that are also only one cell layer thick. Thus, the distance  $d$  across which gas must diffuse is very small—only 0.5 to 1.5  $\mu\text{m}$ .

Inhaled air is taken in through the mouth and nose past the pharynx to the larynx (voice box), where it passes through an opening in the vocal cords, the *glottis*, into a tube supported by C-shaped rings of cartilage, the trachea (windpipe). The term *trachea* is used both for the vertebrate windpipe and the respiratory tubes of arthropods, although the structures are obviously not homologous. The mammalian trachea bifurcates into right and left bronchi (singular, *bronchus*), which enter each lung and further subdivide into bronchioles that deliver the air into the alveoli.

The alveoli are surrounded by an extensive capillary network. All gas exchange between the air and blood takes place

**Figure 49.8** The human respiratory system and the structure of the mammalian lung. The lungs of mammals have an enormous surface area because of the millions of alveoli that cluster at the ends of the bronchioles. This provides for efficient gas exchange with the blood.

across the walls of the alveoli. The branching of bronchioles and the vast number of alveoli combine to increase the respiratory surface area far above that of amphibians or reptiles. In humans, each lung has about 300 million alveoli, and the total surface area available for diffusion can be as much as 80 m<sup>2</sup>, or about 42 times the surface area of the body. Details of gas exchange at the alveolar interface with blood capillaries is described in sections that follow.

### The respiratory system of birds is a highly efficient flow-through system

The avian respiratory system is a unique structure that affords birds the most efficient respiration of all terrestrial vertebrates. Unlike the mammalian lung, which ends in blind alveoli, the bird lung channels air through tiny air vessels called parabronchi, where gas exchange occurs. Air flows through the parabronchi in one direction only. This flow is similar to the unidirectional flow of water through a fish gill.

In other terrestrial vertebrates, inhaled fresh air is mixed with “old,” oxygen-depleted air left from the previous breathing cycle. The lungs of amphibians, reptiles, and mammals are never completely empty of the gases within them. In birds, only fresh air enters the parabronchi of the lung, and the “old” air exits the lung by a different route. The unidirectional flow of air is achieved through the action of anterior and posterior air sacs unique to birds (figure 49.9*a*). When these sacs are expanded during inhalation, they take in air, and when they are compressed during exhalation, they push air into and through the lungs.

Respiration in birds occurs in two cycles (figure 49.9*b*). Each cycle has an inhalation and exhalation phase—but the air inhaled in one cycle is not exhaled until the second cycle.

Upon inhalation, both anterior and posterior air sacs expand. The inhaled air, however, only enters the posterior air sacs; the anterior air sacs fill with air pulled from the lungs. Upon exhalation, the air forced out of the anterior air sacs is released outside the body, but the air forced out of the posterior air sacs now enters the lungs. This process is repeated in the second cycle.

The unidirectional flow of air also permits further respiratory efficiency: The flow of blood through the avian lung runs at a 90° angle to the air flow. This crosscurrent flow is not as efficient as the 180° countercurrent flow in fishes’ gills, but it has a greater capacity to extract oxygen from the air than does a mammalian lung.

Because of these respiratory adaptations, a sparrow can be active at an altitude of 6000 m, whereas a mouse, which has a similar body mass and metabolic rate, would die from lack of oxygen in a fairly short time.

#### Learning Outcomes Review 49.3

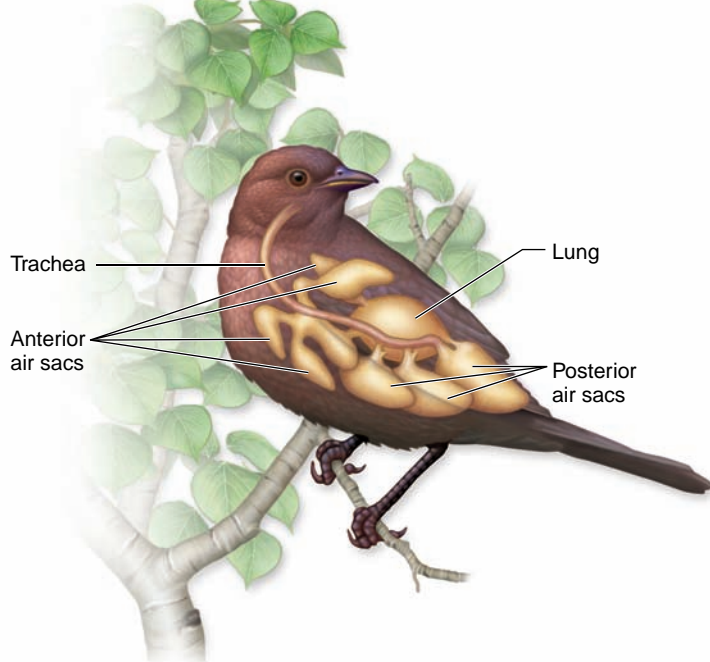

Lungs provide a large surface area for gas exchange while minimizing evaporation; unlike gills, they contain structural support that prevents their collapse. Amphibians push air into their lungs; most reptiles and all birds and mammals pull air into their lungs by expanding the thoracic cavity. The respiratory system of birds has efficient, one-way air flow and crosscurrent blood flow through the lungs.

- **What selection pressure would bring about the evolution of birds’ highly efficient lungs?**

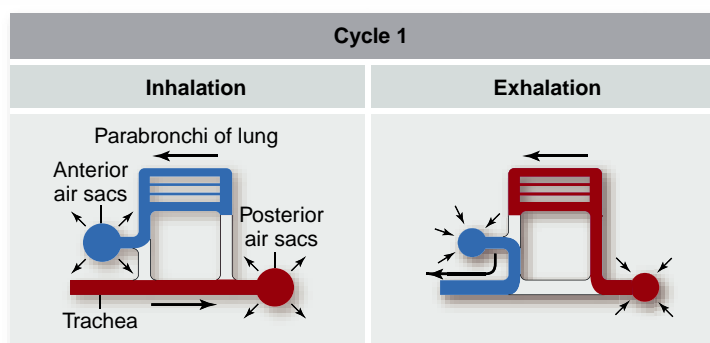

## 49.4 Structures and Mechanisms of Ventilation in Mammals

### Learning Outcomes

1. Explain what is meant by anatomical dead space.
2. Describe how the nervous system regulates breathing.
3. List and characterize the major respiratory diseases.

a.

b.

**Figure 49.9 How a bird breathes.** *a.* Birds have a system of air sacs, divided into an anterior group and posterior group, that extend between the internal organs and into the bones. *b.* Breathing occurs in two cycles. Cycle 1: Inhaled air (shown in red) is drawn from the trachea into the posterior air sacs (shown expanding as it fills with air) and then is exhaled into the lungs (posterior air sacs deflate). Cycle 2: Air is drawn from the lungs into the anterior air sacs, which expand, and then is exhaled from these air sacs through the trachea. Passage of air through the lungs is always in the same direction, from posterior to anterior (right to left in this diagram). These cycles are always going on simultaneously; during inhalation, fresh air enters the posterior air sacs at the same time that air from the previous breath that was in the lungs moves into the anterior air sacs. In exhalation, the newer air moves from the posterior air sacs to the lung at the same time that air in the anterior air sacs is exhaled from the body. At the same time, another breath of inhaled air (purple) is moving through cycle 1.

About 30 billion capillaries can be found in each lung, roughly 100 capillaries per alveolus. Thus, an alveolus can be visualized as a microscopic air bubble whose entire surface is bathed by blood. Gas exchange occurs very rapidly at this interface.

Blood returning from the systemic circulation, depleted in oxygen, has a partial oxygen pressure ( $P_{O_2}$ ) of about 40 mm Hg. By contrast, the  $P_{O_2}$  in the alveoli is about 105 mm Hg. The difference in pressures, namely the  $\Delta p$  of Fick's Law, is 65 mm Hg, leading to oxygen moving into the blood. The blood leaving the lungs, as a result of this gas exchange, normally contains a  $P_{O_2}$  of about 100 mm Hg. As you can see, the lungs do a very effective, but not perfect, job of oxygenating the blood. These changes in the  $P_{O_2}$  of the blood, as well as the changes in plasma carbon dioxide (indicated as the  $P_{CO_2}$ ), are shown in figure 49.10.

### Lung structure and function supports the respiratory cycle

In humans and other mammals, the outside of each lung is covered by a thin membrane called the **visceral pleural membrane**. A second membrane, the **parietal pleural membrane**, lines the inner wall of the thoracic cavity. The space between these two membrane sheets, the **pleural cavity**, is normally very small and filled with fluid. This fluid causes the two membranes to adhere, effectively coupling the lungs to the thoracic cavity. The pleural membranes package each lung separately—if one lung collapses due to a perforation of the membranes, the other lung can still function.

During inhalation, the thoracic volume is increased through contraction of two sets of muscles: the *external intercostal muscles* and the *diaphragm*. Contraction of the external intercostal muscles between the ribs raises the ribs and expands the rib cage. Contraction of the **diaphragm**, a convex sheet of striated muscle separating the thoracic cavity from the abdominal cavity, causes the diaphragm to lower and assume a more flattened shape. This expands the volume of the thorax and lungs, bringing about negative pressure ventilation, while it increases the pressure on the abdominal organs (figure 49.11*a*).

The thorax and lungs have a degree of elasticity; expansion during inhalation places these structures under elastic tension. The relaxation of the external intercostal muscles and diaphragm produces unforced exhalation because the elastic tension is released, allowing the thorax and lungs to recoil. You can produce a greater exhalation force by actively contracting your abdominal muscles—such as when blowing up a balloon (figure 49.11*b*).

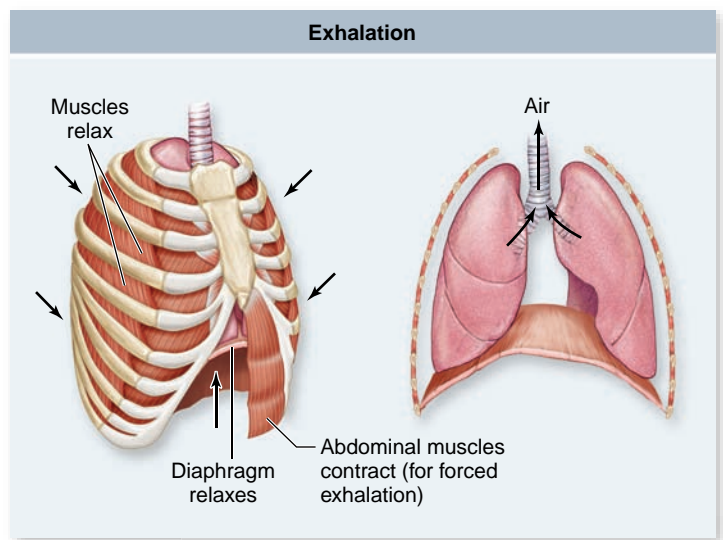

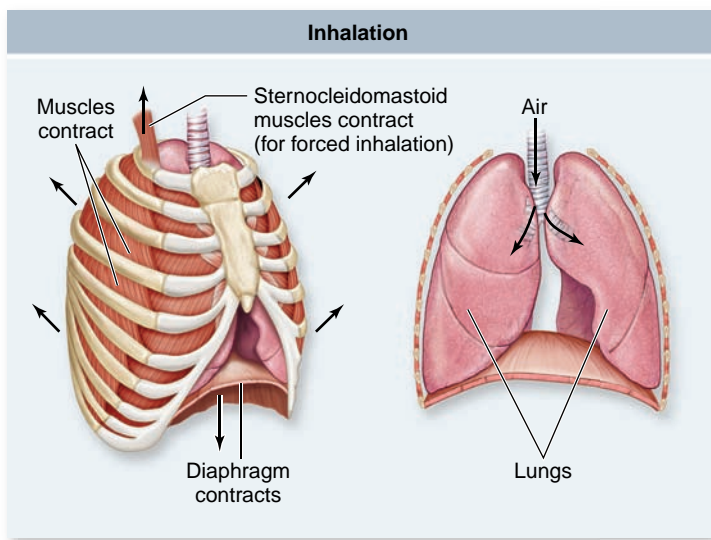

**Figure 49.10 Gas exchange in the blood capillaries of the lungs and systemic circulation.** As a result of gas exchange in the lungs, the systemic arteries carry oxygenated blood with a relatively low carbon dioxide ( $CO_2$ ) concentration. After the oxygen ( $O_2$ ) is unloaded to the tissues, the blood in the systemic veins has a lowered  $O_2$  content and an increased  $CO_2$  concentration.

### Ventilation efficiency depends on lung capacity and breathing rate

A variety of terms are used to describe the volume changes of the lung during breathing. In a person at rest, each breath moves a tidal volume of about 500 mL of air into and out of the lungs. About 150 mL of the tidal volume is contained in the tubular passages (trachea, bronchi, and bronchioles), where no gas exchange occurs—termed the *anatomical dead space*. The gases in this space mix with fresh air during inhalation. This mixing is one reason that respiration in mammals is not as efficient as in birds, where air flow through the lungs is one-way.

The maximum amount of air that can be expired after a forceful, maximum inhalation is called the vital capacity. This measurement, which averages 4.6 L in young men and 3.1 L in young women, can be clinically important because an abnormally low vital capacity may indicate damage to the alveoli in various pulmonary disorders.

The rate and depth of breathing normally keeps the blood  $P_{O_2}$  and  $P_{CO_2}$  within a normal range. If breathing is insufficient to maintain normal blood gas measurements (a rise in the blood  $P_{CO_2}$  is the best indicator), the person is hypoventilating. If breathing is excessive, so that the blood  $P_{CO_2}$  is abnormally lowered, the person is said to be **hyperventilating**.

**Figure 49.11 How a human breathes.** *a.* Inhalation. The diaphragm contracts and the walls of the chest cavity expand, increasing the volume of the chest cavity and lungs. As a result of the larger volume, air is drawn into the lungs. *b.* Exhalation. The diaphragm and chest walls return to their normal positions as a result of elastic recoil, reducing the volume of the chest cavity and forcing air out of the lungs through the trachea. Note that inhalation can be forced by contracting accessory respiratory muscles (such as the sternocleidomastoid), and exhalation can be forced by contracting abdominal muscles.

The increased breathing that occurs during moderate exertion is not necessarily hyperventilation because the faster and more forceful breathing is matched to the higher metabolic rate, and blood gas measurements remain normal. Next, we describe how breathing is regulated to keep pace with metabolism.

## Ventilation is under nervous system control

Each breath is initiated by neurons in a *respiratory control center* located in the medulla oblongata. These neurons stimulate the diaphragm and external intercostal muscles to contract, causing inhalation. When these neurons stop producing impulses, the inspiratory muscles relax and exhalation occurs. Although the muscles of breathing are skeletal muscles, they are usually controlled

automatically. This control can be voluntarily overridden, however, as in hypoventilation (breath holding) or hyperventilation.

Neurons of the medulla oblongata must be responsive to changes in blood  $P_{O_2}$  and  $P_{CO_2}$  in order to maintain homeostasis. You can demonstrate this mechanism by simply holding your breath. Your blood carbon dioxide level immediately rises, and your blood oxygen level falls. After a short time, the urge to breathe induced by the changes in blood gases becomes overpowering. The rise in blood carbon dioxide, as indicated by a rise in  $P_{CO_2}$ , is the primary initiator, rather than the fall in oxygen levels.

A rise in  $P_{CO_2}$  causes an increased production of carbonic acid ( $H_2CO_3$ ), which lowers the blood pH. A fall in blood pH stimulates chemosensitive neurons in the **aortic** and **carotid bodies**, in the aorta and the carotid artery (figure 49.12*b*). These

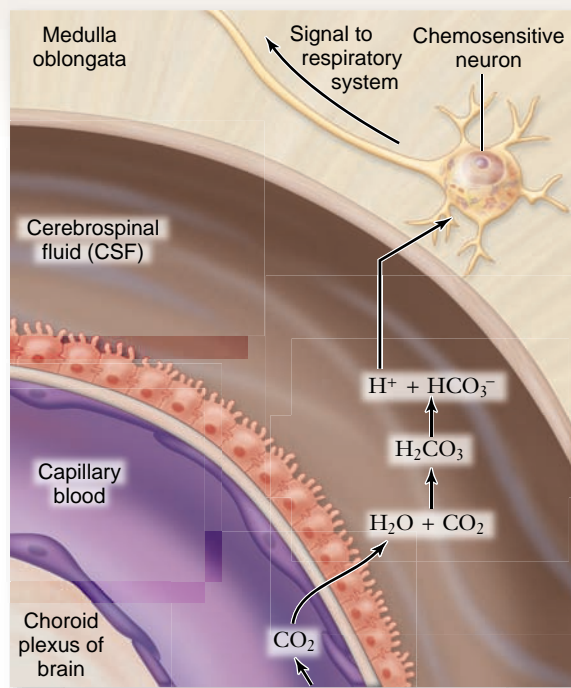

### SCIENTIFIC THINKING

**Question:** What is the relationship between cerebrospinal fluid (CSF) pH, rate of respiration, and partial pressure of carbon dioxide in the blood ( $P_{CO_2}$ )?

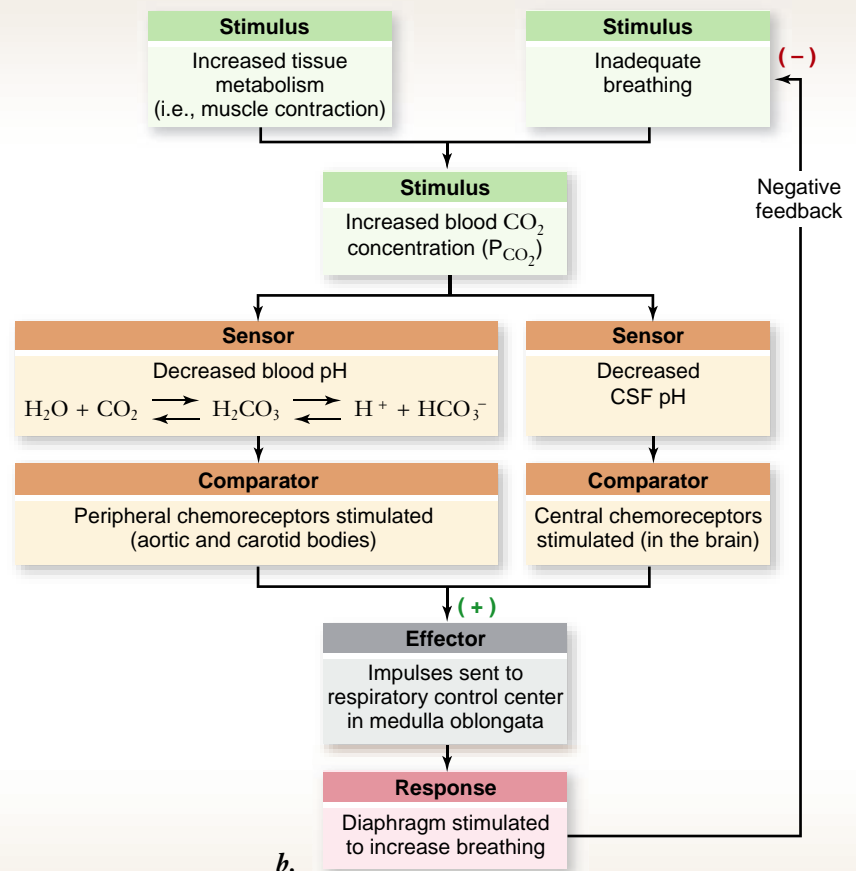

**Hypothesis:** The pH of CSF, detected by pH-sensitive chemoreceptors in the brain, affects the rate of respiration.

**Prediction:** Lowering the pH of the CSF (by reducing the concentration of  $HCO_3^-$ ) will stimulate increased respiration and, subsequently, reduce blood  $P_{CO_2}$ .

**Experiment:** Patients with chronic obstructive respiratory disease (COPD) have higher than average CSF levels of  $HCO_3^-$ . Some of the CSF in these patients was replaced with CSF with normal  $HCO_3^-$  levels, and subsequent  $P_{CO_2}$  levels were measured.

a.

b.

**Result:** The reduced  $HCO_3^-$  levels (and corresponding drop in CSF pH) resulted in increased respiration, which subsequently resulted in lower arterial  $P_{CO_2}$ .

**Conclusion:** The drop in pH (caused by the change in  $HCO_3^-$  levels) is detected by  $H^+$  ion chemoreceptors in the brain. The brain sends impulses to the respiratory control center in the medulla oblongata, which directs an increase in breathing. Likewise, when the concentration of  $CO_2$  in the blood rises as a result of inadequate breathing or increased tissue metabolism, the pH of the blood and the CSF decreases, stimulating the central chemoreceptors in the brain and the peripheral chemoreceptors in the aortic and carotid bodies. The receptors signal the brain stem control center, increasing ventilation and reducing the  $P_{CO_2}$  to normal levels.

**Figure 49.12** Regulation of breathing by pH-sensitive chemoreceptors.

peripheral receptors send impulses to the respiratory control center, which then stimulates increased breathing. The brain also contains central chemoreceptors that are stimulated by a drop in the pH of cerebrospinal fluid (CSF) (figure 49.12a).

A person cannot voluntarily hyperventilate for too long. The decrease in plasma  $P_{CO_2}$  and increase in pH of plasma and CSF caused by hyperventilation suppress the reflex drive to breathe. Deliberate hyperventilation allows people to hold their breath longer—not because it increases oxygen in the blood, but because the carbon dioxide level is lowered and takes longer to build back up, postponing the need to breathe.

In people with normal lungs,  $P_{O_2}$  becomes a significant stimulus for increased breathing rates only at high altitudes, where the  $P_{O_2}$  of the atmosphere is low. The symptoms of low oxygen at high altitude are known as mountain sickness, which may include feelings of weakness, headache, nausea, vomiting, and reduced mental function. All of these symptoms are related to the low  $P_{O_2}$ , and breathing supplemental oxygen often can remove all symptoms.

## Respiratory diseases restrict gas exchange

**Chronic obstructive pulmonary disease (COPD)** refers to any disorder that obstructs airflow on a long-term basis. The major COPDs are asthma, chronic bronchitis, and emphysema. In **asthma**, an allergen triggers the release of histamine and other inflammatory chemicals that cause intense constriction of the bronchi and sometimes suffocation. Other COPDs are commonly caused by cigarette smoking but can also result from air pollution or occupational exposure to airborne irritants.

### Emphysema

In **emphysema**, alveolar walls break down and the lung exhibits larger but fewer alveoli. The lungs also become fibrotic and less elastic. The air passages open adequately during inhalation but they tend to collapse and obstruct the outflow of air. People with emphysema become exhausted because they expend three to four times the normal amount of energy just to breathe. Eighty to 90% of emphysema deaths are caused by cigarette smoking.

### Inquiry question

? How does emphysema affect the diffusion of gases in and out of the lung, based on Fick's Law?

### Lung cancer

**Lung cancer** accounts for more deaths than any other form of cancer. The most important cause of lung cancer is cigarette smoking, distantly followed by air pollution (figure 49.13). Lung cancer follows or accompanies COPD.

Over 90% of lung tumors originate in the mucous membranes of the large bronchi. As a tumor invades the bronchial wall and grows around it, it compresses the airway and may cause collapse of more distal parts of the lung. Growth of a tumor often produces coughing, but coughing is such an everyday occurrence for smokers, it seldom causes alarm. Often, the first sign of serious trouble is the coughing up of blood.

Lung cancer metastasizes (spreads) so rapidly that it has usually invaded other organs by the time it is diagnosed. The

Healthy Lungs

Cancerous Lungs

**Figure 49.13**  
Comparison of healthy lung (a) and a lung with cancer (b).

chance of recovery from metastasized lung cancer is poor, with only 3% of patients surviving for 5 years after diagnosis.

### Learning Outcomes Review 49.4

In humans, each breath moves a tidal volume of about 500 mL in and out of the lungs; 150 mL remains in the tubular passages where no gases are exchanged (anatomical dead space). Depth and rate of ventilation is regulated primarily by neurons in the medulla oblongata that detect  $CO_2$  concentration. Diseases such as COPD limit gas exchange by obstructing airflow. Lung cancer, associated with tobacco use, has a low survival rate.

- How do mammals breathe differently from birds?

## 49.5 Transport of Gases in Body Fluids

### Learning Outcomes

1. Depict the structure of hemoglobin.
2. Describe how hemoglobin's oxygen affinity changes depending on environmental conditions.
3. Explain how carbon dioxide is transported by the blood.

The amount of oxygen that can be dissolved in the blood plasma depends directly on the  $P_{O_2}$  of the air in the alveoli, as explained earlier. When mammalian lungs are functioning normally,

the blood plasma leaving the lungs has almost as much dissolved oxygen as is theoretically possible, given the  $P_{O_2}$  of the air. Because of oxygen's low solubility, however, blood plasma can contain a maximum of only about 3 mL of  $O_2$  per liter. But whole blood normally carries almost 200 mL of  $O_2$  per liter. Most of the oxygen in the blood is bound to molecules of hemoglobin inside red blood cells.

## Respiratory pigments bind oxygen for transport

**Hemoglobin** is a protein composed of four polypeptide chains and four organic compounds called *heme groups*. At the center of each heme group is an atom of iron, which can bind to a molecule of oxygen (figure 49.14). Thus, each hemoglobin molecule can carry up to four molecules of oxygen.

Hemoglobin loads up with oxygen in the alveolar capillaries of the pulmonary circulation, forming oxyhemoglobin. This molecule has a bright red color. As blood passes through capillaries in the systemic circulation, some of the oxyhemoglobin releases oxygen, becoming **deoxyhemoglobin**. Deoxyhemoglobin has a darker red color; but it imparts a bluish tinge to tissues. Illustrations of the cardiovascular system show vessels carrying oxygenated blood with a red color and vessels that carry oxygen-depleted blood with a blue color.

Hemoglobin is an ancient protein; it is not only the oxygen-carrying molecule in all vertebrates, but is also used as an oxygen carrier by many invertebrates, including annelids, mollusks, echinoderms, flatworms, and even some protists. Many other invertebrates, however, employ different oxygen carriers, such as **hemocyanin**. In hemocyanin, the oxygen-binding atom is copper instead of iron. Hemocyanin is not found associated with blood cells, but is instead one of the free proteins in the circulating fluid (hemolymph) of arthropods and some mollusks.

### Inquiry question

? If oxygen-depleted vessels have a bluish color, does this mean that all veins in the body have a bluish color? Why or why not?

**Figure 49.14** The structure of the adult hemoglobin protein. Hemoglobin consists of four polypeptide chains: two  $\alpha$  chains and two  $\beta$  chains. Each chain is associated with a heme group (in white), and each heme group has a central iron atom (red ball), which can bind to a molecule of  $O_2$ .

## Hemoglobin and myoglobin provide an oxygen reserve

At a blood  $P_{O_2}$  of 100 mm Hg, the level found in blood leaving the alveoli, approximately 97% of the hemoglobin within red blood cells is in the form of oxyhemoglobin—indicated as a percent oxyhemoglobin saturation of 97%.

In a person at rest, blood that returns to the heart in the systemic veins has a  $P_{O_2}$  that is decreased to about 40 mm Hg. At this lower  $P_{O_2}$ , the percent saturation of hemoglobin is only 75%. In a person at rest, therefore, 22% (97% minus 75%) of the oxyhemoglobin has released its oxygen to the tissues. Put another way, roughly one-fifth of the oxygen is unloaded in the tissues, leaving four-fifths of the oxygen in the blood as a reserve. A graphic representation of these changes is called an oxyhemoglobin dissociation curve (figure 49.15).

This large reserve of oxygen serves an important function. It enables the blood to supply the body's oxygen needs during exertion as well as at rest. During exercise, for example, the muscles' accelerated metabolism uses more oxygen and decreases the venous blood  $P_{O_2}$ . The  $P_{O_2}$  of the venous blood

**Figure 49.15** The oxyhemoglobin dissociation curve. Hemoglobin combines with  $O_2$  in the lungs, and this oxygenated blood is carried by arteries to the body cells. After  $O_2$  is removed from the blood to support cellular respiration, the blood entering the veins contains less  $O_2$ .

### Inquiry question

? How would you determine how much oxygen was unloaded to the tissues?

could drop to 20 mm Hg; in this case, the percent saturation of hemoglobin would be only 35% (see figure 49.15). Because arterial blood would still contain 97% oxyhemoglobin, the amount of oxygen unloaded would now be 62% (97% minus 35%), instead of the 22% at rest.

In addition to this function, the oxygen reserve also ensures that the blood contains enough oxygen to maintain life for 4 to 5 min if breathing is interrupted or if the heart stops pumping.

A second oxygen reserve is available in myoglobin, an oxygen-binding molecule found in muscle cells. Myoglobin is composed of a single polypeptide chain with an iron atom that can bind to an O<sub>2</sub> molecule. Myoglobin has a higher affinity for oxygen than hemoglobin, which means that when oxygen levels fall in muscle cells, myoglobin will contain oxygen after the hemoglobin supplies have been exhausted. Deep sea-diving mammals, such as the elephant seal in figure 49.1, are able to stay under water for long periods in part because of the high levels of oxygen stored in the myoglobin in their muscles.

### Inquiry question

?

Based on the preceding information, would an otherwise healthy person benefit significantly from breathing 100% oxygen following a bout of intense exercise such as a 400-m sprint?

## Hemoglobin's affinity for oxygen is affected by pH and temperature

Oxygen transport in the blood is affected by other conditions including temperature and pH. The CO<sub>2</sub> produced by metaboliz-

ing tissues combines with H<sub>2</sub>O to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>). H<sub>2</sub>CO<sub>3</sub> dissociates into bicarbonate (HCO<sub>3</sub><sup>-</sup>) and H<sup>+</sup>, thereby lowering blood pH. This reaction occurs primarily inside red blood cells, where the lowered pH reduces hemoglobin's affinity for oxygen, causing it to release oxygen more readily.

The effect of pH on hemoglobin's affinity for oxygen, known as the **Bohr effect** or **Bohr shift**, is the result of H<sup>+</sup> binding to hemoglobin. It is shown graphically by a shift of the oxyhemoglobin dissociation curve to the right (figure 49.16*a*).

Increasing temperature has a similar effect on hemoglobin's affinity for oxygen (figure 49.16*b*). Because skeletal muscles produce carbon dioxide more rapidly during exercise, and because active muscles produce heat, the blood unloads a higher percentage of the oxygen it carries during exercise.

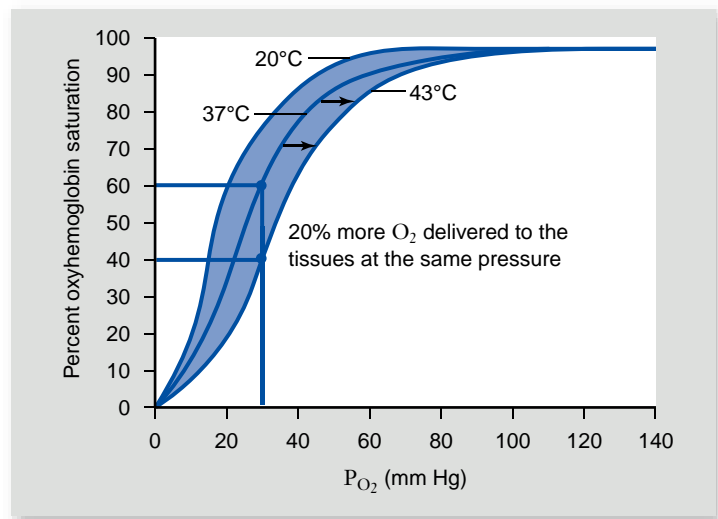

## Carbon dioxide is primarily transported as bicarbonate ion

About 8% of the CO<sub>2</sub> in blood is simply dissolved in plasma; another 20% is bound to hemoglobin. Because CO<sub>2</sub> binds to the protein portion of hemoglobin, and not to the iron atoms of the heme groups, it does not compete with oxygen; however, it does cause hemoglobin's shape to change, lowering its affinity for oxygen.

The remaining 72% of the CO<sub>2</sub> diffuses into the red blood cells, where the enzyme carbonic anhydrase catalyzes the combining of CO<sub>2</sub> with water to form H<sub>2</sub>CO<sub>3</sub>. H<sub>2</sub>CO<sub>3</sub> dissociates into HCO<sub>3</sub><sup>-</sup> and H<sup>+</sup> ions. The H<sup>+</sup> binds to deoxyhemoglobin, and the HCO<sub>3</sub><sup>-</sup> moves out of the erythrocyte into the plasma via a transporter that exchanges one Cl<sup>-</sup> for a HCO<sub>3</sub><sup>-</sup> (this is called the "chloride shift").

*a.* pH shift

*b.* Temperature shift

**Figure 49.16** The effect of pH and temperature on the oxyhemoglobin dissociation curve. *a.* Lower blood pH and *(b)* higher blood temperatures shift the oxyhemoglobin dissociation curve to the right, facilitating O<sub>2</sub> unloading. In this example, this can be seen as a lowering of the oxyhemoglobin percent saturation from 60% to 40%, indicating that the difference of 20% more O<sub>2</sub> is unloaded to the tissues.

### Inquiry question

?

What effect does high blood pressure have on oxygen unloading to the tissues during exercise?

This reaction removes large amounts of  $\text{CO}_2$  from the plasma, maintaining a diffusion gradient that allows additional  $\text{CO}_2$  to move into the plasma from the surrounding tissues (figure 49.17*a*). The formation of  $\text{H}_2\text{CO}_3$  is also important in maintaining the acid–base balance of the blood;  $\text{HCO}_3^-$  serves as the major buffer of the blood plasma.

In the lungs, the lower  $P_{\text{CO}_2}$  of the gas mixture inside the alveoli causes the carbonic anhydrase reaction to proceed in the reverse direction, converting  $\text{H}_2\text{CO}_3$  into  $\text{H}_2\text{O}$  and  $\text{CO}_2$  (figure 49.17*b*). The  $\text{CO}_2$  diffuses out of the red blood cells and into the alveoli, so that it can leave the body in the next exhalation.

Other dissolved gases are also transported by hemoglobin, most notably nitric oxide (NO), which plays an important role in vessel dilation. Carbon monoxide (CO) binds more strongly to hemoglobin than does oxygen, which is why carbon monoxide poi-

soning can be deadly. Victims of carbon monoxide poisoning often have bright red skin due to hemoglobin's binding with CO.

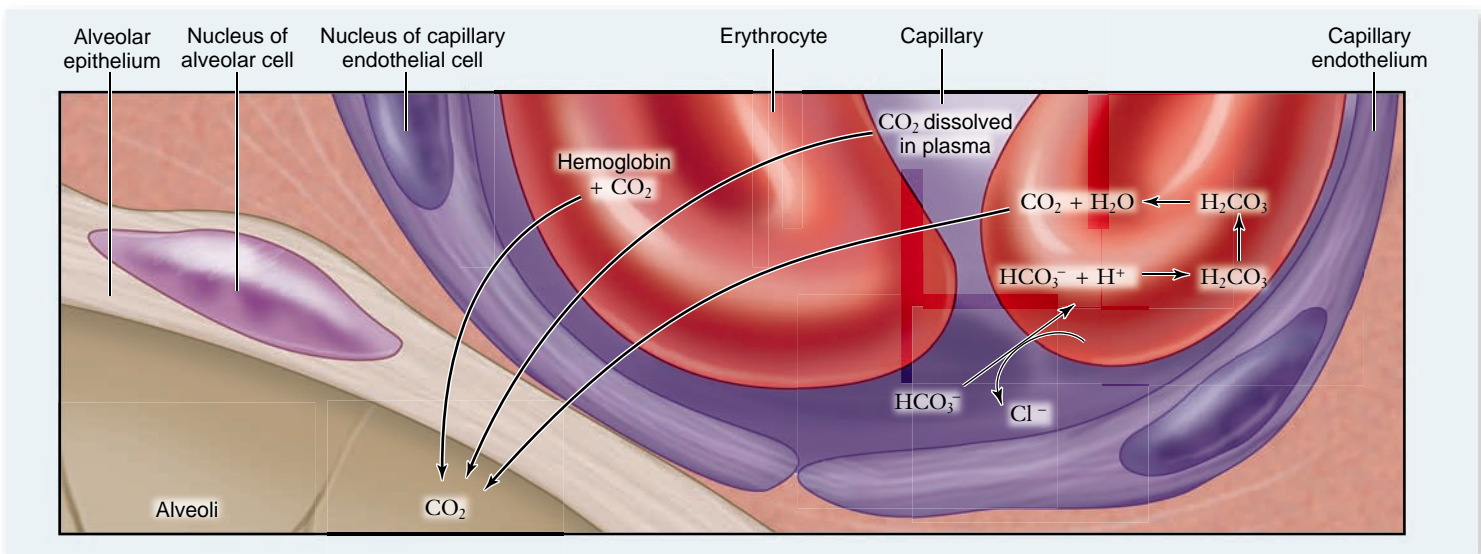

### Learning Outcomes Review 49.5

Hemoglobin consists of four polypeptide chains, each associated with an iron-containing heme group that can bind  $\text{O}_2$ . Hemoglobin's affinity for oxygen is affected by pH and temperature; more  $\text{O}_2$  is released into tissues at lower pH and at higher temperature. Carbon dioxide is transported in the blood in three ways: dissolved in the plasma, bound to hemoglobin, and as bicarbonate in the plasma following a reaction with carbonic anhydrase in the red blood cells.

- What are the differences in the way that oxygen and carbon dioxide are transported in blood?

*a.*

*b.*

**Figure 49.17 The transport of carbon dioxide by the blood.** *a.* Passage into bloodstream.  $\text{CO}_2$  is transported in three ways: dissolved in plasma, bound to the protein portion of hemoglobin, and as bicarbonate ( $\text{HCO}_3^-$ ), which forms in red blood cells. The reaction of  $\text{CO}_2$  with  $\text{H}_2\text{O}$  to form  $\text{H}_2\text{CO}_3$  (carbonic acid) is catalyzed by the enzyme carbonic anhydrase in red blood cells. *b.* Removal from bloodstream. When the blood passes through the pulmonary capillaries, these reactions are reversed so that  $\text{CO}_2$  gas is formed, which is exhaled.

## Chapter Review

### 49.1 Gas Exchange Across Respiratory Surfaces

**Gas exchange involves diffusion across membranes.**

Diffusion is a passive process; the rate of diffusion ( $R$ ) increases with a higher concentration gradient and greater surface area, but decreases with distance (Fick's Law).

**Evolutionary strategies have maximized gas diffusion.**

Most invertebrate phyla lack specialized respiratory organs, but have evolved ways to increase oxygen concentration differences. Most other animals possess respiratory organs.

### 49.2 Gills, Cutaneous Respiration, and Tracheal Systems

**External gills are found in fish and amphibian larvae.**

Gills increase the respiratory surface area for gas exchange; however, they require an aqueous environment.

**Branchial chambers protect gills of some invertebrates.**

Some aquatic invertebrates have branchial chambers in which oxygenated water is pumped past stationary gills. Mollusks possess a mantle in which water is drawn in and expelled.

**Gills of bony fishes are covered by the operculum.**

In bony fishes, diffusion of gases is maximized by countercurrent exchange, in which blood in gills flows in a direction opposite the flow of water over the gills (see figures 49.4 and 49.5).

**Cutaneous respiration requires constant moisture.**

Many amphibians and a few reptiles use cutaneous respiration for gas exchange.

**Tracheal systems are found in arthropods.**

Tracheae and tracheoles are a series of small tubes, connected with the outside environment by spiracles, that carry air directly to the cells. The ability to open and close the spiracles allowed arthropods to invade the land.

### 49.3 Lungs

Lungs minimize evaporation and contain supporting tissues to prevent collapse of exchange membranes, and thus have become well adapted to terrestrial living (see figure 49.8).

**Breathing of air takes advantage of partial pressures of gases.**

The partial pressure of gases refers to the proportion of atmospheric pressure attributed to each gas. It is responsible for the pressure gradient that brings about gas exchange.

**Amphibians and reptiles breathe in different ways.**

Amphibians force air into their lungs by positive pressure; reptiles pull air in using negative pressure (see figure 49.7).

**Mammalian lungs have greatly increased surface area.**

The surface area of mammalian lungs is enormous due to numerous alveoli, encased by an extensive capillary network (see figure 49.8).

**The respiratory system of birds is a highly efficient flow-through system.**

The respiratory system of birds involves one-way direction of air flow. Air moves through the respiratory system in a two-cycle process so that fresh and used air never mix (see figure 49.9).

### 49.4 Structures and Mechanisms of Ventilation in Mammals

**Lung structure and function supports the respiratory cycle.**

Gas exchange is driven by differences in partial pressures. Lungs are filled by contraction of the diaphragm and external intercostal muscles, creating negative pressure (see figure 49.11).

**Ventilation efficiency depends on lung capacity and breathing rate.**

Normal rates of breathing keep the partial pressure of oxygen and carbon dioxide within a limited range of values. Hypoventilation occurs when carbon dioxide levels are too high, and hyperventilation when they are too low.

**Ventilation is under nervous system control.**

Each breath is initiated by neurons in the respiratory control center, primarily those that detect  $\text{CO}_2$  levels. Humans can voluntarily hypo- or hyperventilate, but only for a limited time.

**Respiratory diseases restrict gas exchange.**

Emphysema occurs when alveolar walls break down, which makes breathing very energetically expensive. Lung cancer is highly deadly and caused primarily by smoking.

### 49.5 Transport of Gases in Body Fluids

**Respiratory pigments bind oxygen for transport.**

Hemoglobin increases the ability of the blood to transport oxygen beyond what can dissolve in plasma (see figure 49.15).

Hemoglobin consists of four polypeptide chains, two  $\alpha$  chains and two  $\beta$  chains; each of these is associated with an iron-containing heme group that can bind to  $\text{O}_2$  (see figure 49.14).

**Hemoglobin and myoglobin provide an oxygen reserve.**

Most oxygen carried by hemoglobin remains in the blood and is available when needed. In addition, myoglobin molecules in muscle cells retain oxygen at lower partial pressures than hemoglobin and thus serve as an additional oxygen reserve.

**Hemoglobin's affinity for oxygen is affected by pH and temperature.**

The affinity of hemoglobin for oxygen decreases as pH decreases and as temperature increases (see figure 49.16). Therefore at lower pH and higher temperature, more oxygen is released.

**Carbon dioxide is primarily transported as bicarbonate ion.**

Most carbon dioxide diffuses into red blood cells and combines with water to form bicarbonate atoms in a reaction catalyzed by the enzyme carbonic anhydrase.

## Review Questions

### UNDERSTAND

- If you hold your breath for a long time, body  $\text{CO}_2$  levels are likely to \_\_\_\_, and the pH of body fluids is likely to \_\_\_\_.
  - increase; increase
  - decrease; increase
  - increase; decrease
  - decrease; decrease
- Increased efficiency of gas exchange in vertebrates has been brought about by all of the following mechanisms except
  - cutaneous respiration.
  - unidirectional air flow.
  - crosscurrent blood flow.
  - cartilaginous rings in the trachea.
- Which of the following is the primary method by which carbon dioxide is transported to the lungs?
  - Dissolved in plasma
  - Bound to hemoglobin
  - As carbon monoxide
  - As bicarbonate
- Gills are found in
  - fish.
  - amphibians.
  - aquatic invertebrates.
  - all of these.
- Fick's Law of Diffusion states the rate of diffusion is directly proportional to
  - the area differences between the cross section of the blood vessel and the tissue.
  - the pressure differences between the two sides of the membrane and area over which the diffusion occurs.
  - the pressure differences between the inside of the organism and the outside.
  - the temperature of the gas molecule.
- Cutaneous respiration requires
  - moist and highly vascularized skin.
  - the absence of gills and lungs.
  - an environment rich in oxygen.
  - low temperatures.
- Hyperventilation occurs
  - as a result of breathing rapidly.
  - when oxygen levels become low.
  - when tidal volumes are unusually low.
  - when the partial pressure of carbon dioxide is low.
- Most carbon dioxide is
  - dissolved in the plasma.
  - bound to hemoglobin.
  - combined with water in red blood cells to form carbonic acid.
  - stored in the lungs prior to exhalation.
- Marine mammals are able to hold their breath for extended periods underwater because
  - unlike humans, they don't hypoventilate.
  - partial pressure of carbon dioxide does not increase underwater.
  - myoglobin in muscle tissue provides an oxygen reserve.
  - the brains of marine mammals do not have receptors that respond to impulses initiated in the aortic and carotid bodies.
- Countercurrent flow systems do not occur in lungs because they
  - require oxygen suspended in flowing water.
  - are limited to fish.
  - only work in moving organisms.
  - cannot operate in the presence of carbon dioxide.
- Respiratory organs of invertebrates and vertebrates are similar in that
  - they use negative pressure breathing.
  - they take advantage of countercurrent flow systems.
  - they increase the surface area available for diffusion.
  - the air flows through the organ in one direction.
- Mountain climbers may have difficulty at high elevations because
  - the partial pressure of oxygen is lower at higher elevations.
  - more  $\text{CO}_2$  occurs at higher altitudes.
  - the concentration of all elements of the air is lower at higher elevations.
  - cooler temperatures restrict the metabolic activity of oxygen at high elevations.
- During exercise more oxygen is delivered to the muscles because
  - active muscles produce more  $\text{CO}_2$ , lowering the pH of the blood.
  - active muscles produce heat.
  - both a and b
  - neither a nor b

### SYNTHESIZE

- Compare the operation and efficiency of fish gills with amphibian, bird, and mammal lungs.
- What happens when, during exercise, the oxygen needs of the peripheral tissues increase greatly?
- Explain how bacteria, archaea, protists, and many phyla of invertebrates can survive without respiratory organs.

### APPLY

- When you take a deep breath, your stomach moves out because
  - swallowing air increases the volume of the thoracic cavity.
  - your stomach shouldn't move out when you take a deep breath because you want the volume of your chest cavity to increase, not your abdominal cavity.
  - contracting your abdominal muscles pushes your stomach out, generating negative pressure in your lungs.
  - when your diaphragm contracts, it moves down, pressing your abdominal cavity out.

# The Circulatory System

## Chapter Outline

- 50.1 The Components of Blood
- 50.2 Invertebrate Circulatory Systems
- 50.3 Vertebrate Circulatory Systems
- 50.4 The Four-Chambered Heart and the Blood Vessels
- 50.5 Characteristics of Blood Vessels
- 50.6 Regulation of Blood Flow and Blood Pressure

## Introduction

*In multicellular organisms, oxygen obtained by the respiratory system and nutrients processed by the digestive system must be transported to cells throughout the body. Conversely, carbon dioxide and other waste products produced within the cells must be returned to the respiratory, digestive, and urinary systems for elimination from the body. These tasks are the responsibility of the circulatory system. All multicellular organisms have a heart that pumps fluids through the body. Many invertebrates have an open system in which fluids move through the body cavity. Vertebrates also have a system like this that moves lymph through the body; however, the primary circulatory fluid is blood, which means through a closed system of blood vessels.*

## 50.1 The Components of Blood

### Learning Outcomes

1. Describe the functions of circulating blood.
2. Distinguish between the types of formed elements.
3. Delineate the process of blood clotting.

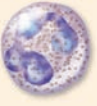

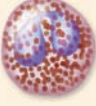

Blood is a connective tissue composed of a fluid matrix, called **plasma**, and several different kinds of cells and other **formed elements** that circulate within that fluid (figure 50.1). Blood

**platelets**, although included in figure 50.1, are not complete cells; rather, they are fragments of cells that are produced in the bone marrow. (We describe the action of platelets in blood clotting later in this section.)

Circulating blood has many functions:

1. **Transportation.** All of the substances essential for cellular metabolism are transported by blood. Red blood cells transport oxygen attached to hemoglobin; nutrient molecules are carried in the plasma, sometimes bound to carriers; and metabolic wastes are eliminated as blood passes through the liver and kidneys.
2. **Regulation.** The cardiovascular system transports regulatory hormones from the endocrine glands and also

Blood Plasma	Red Blood Cells	Platelets
<b>Plasma proteins (7%)</b> Albumin (54%) Globulins (38%) Fibrinogen (7%) All others (1%) <b>Water (91.5%)</b> <b>Other solutes (1.5%)</b> Electrolytes Nutrients Gases Regulatory substances Waste products	 4 million–6 million/ $\text{mm}^3$ blood	 150,000–300,000/ $\text{mm}^3$ blood
	Neutrophils	Eosinophils
	 60–70%	 2–4%
	Monocytes	Lymphocytes
	 3–8%	 20–25%
	Basophils	
	 0.5–1%	

**Figure 50.1** Composition of blood.

participates in temperature regulation. Contraction and dilation of blood vessels near the surface of the body, beneath the epidermis, helps to conserve or to dissipate heat as needed.

- 3. Protection.** The circulatory system protects against injury and foreign microbes or toxins introduced into the body. Blood clotting helps to prevent blood loss when vessels are damaged. White blood cells, or leukocytes, help to disarm or disable invaders such as viruses and bacteria (see chapter 52).

## Blood plasma is a fluid matrix

Blood plasma is the matrix in which blood cells and platelets are suspended. Interstitial (extracellular) fluids originate from the fluid present in plasma.

Although plasma is 92% water, it also contains the following solutes:

- 1. Nutrients, wastes, and hormones.** Dissolved within the plasma are all of the nutrients resulting from digestive breakdown that can be used by cells, including

glucose, amino acids, and vitamins. Also dissolved in the plasma are wastes such as nitrogen compounds and  $\text{CO}_2$  produced by metabolizing cells. Endocrine hormones released from glands are also carried through the blood to their target cells.

- 2. Ions.** Blood plasma is a dilute salt solution. The predominant plasma ions are  $\text{Na}^+$ ,  $\text{Cl}^-$ , and bicarbonate ions ( $\text{HCO}_3^-$ ). In addition, plasma contains trace amounts of other ions such as  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{K}^+$ , and  $\text{Zn}^{2+}$ .
- 3. Proteins.** As mentioned earlier, the liver produces most of the plasma proteins, including **albumin**, which constitutes most of the plasma protein; the alpha ( $\alpha$ ) and beta ( $\beta$ ) **globulins**, which serve as carriers of lipids and steroid hormones; and **fibrinogen**, which is required for blood clotting. Blood plasma with the fibrinogen removed is called **serum**.

## Formed elements include circulating cells and platelets

The formed elements of blood cells and cell fragments include red blood cells, white blood cells, and platelets. Each element has a specific function in maintaining the body's health and homeostasis.

### Erythrocytes

Each microliter of blood contains about 5 million **red blood cells**, or **erythrocytes**. The fraction of the total blood volume that is occupied by erythrocytes is called the blood's *hematocrit*; in humans, the hematocrit is typically around 45%.

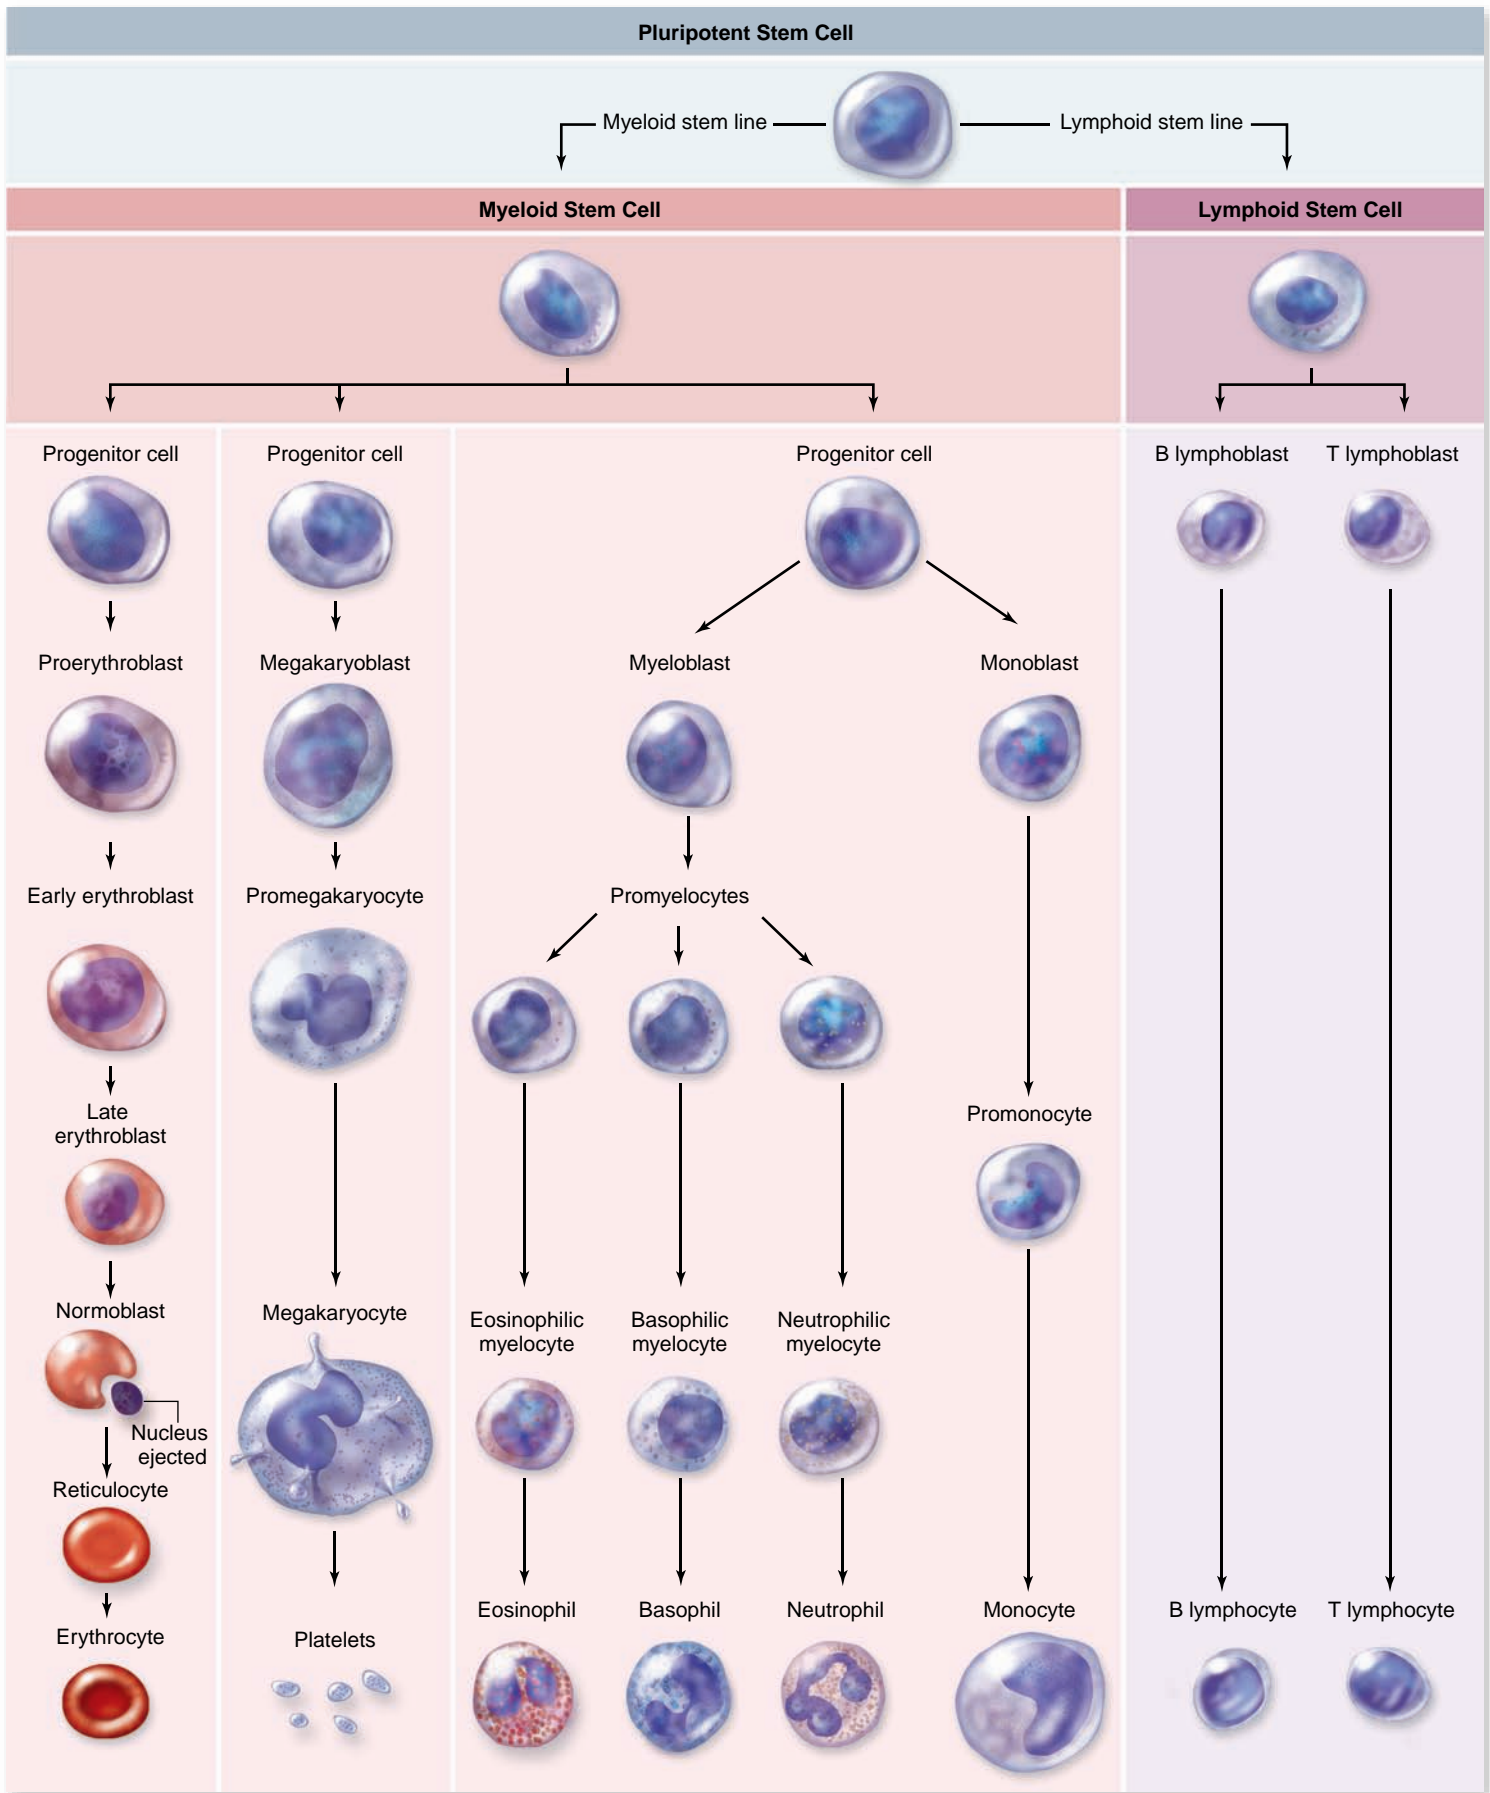

Each erythrocyte resembles a doughnut-shaped disk with a central depression that does not go all the way through. Mature mammalian erythrocytes lack nuclei. The erythrocytes of vertebrates contain hemoglobin, a pigment that binds and transports oxygen. (Hemoglobin was described more fully in the previous chapter when we discussed respiration.) In vertebrates, hemoglobin is found only in erythrocytes. In invertebrates, the oxygen-binding pigment (not always hemoglobin) is also present in plasma.

### Leukocytes

Less than 1% of the cells in human blood are **white blood cells**, or **leukocytes**; there are only 1 or 2 leukocytes for every 1000 erythrocytes. Leukocytes are larger than erythrocytes and have nuclei. Furthermore, leukocytes are not confined to the blood as erythrocytes are, but can migrate out of capillaries through the intercellular spaces into the surrounding interstitial (tissue) fluid.

Leukocytes come in several varieties, each of which plays a specific role in defending against invading microorganisms and other foreign substances, as described in chapter 52. **Granular leukocytes** include neutrophils, eosinophils, and basophils, which are named according to the staining properties of granules in their cytoplasm. **Nongranular leukocytes** include monocytes and lymphocytes. In humans, neutrophils are the most numerous of the leukocytes, followed in order by lymphocytes, monocytes, eosinophils, and basophils.

**Figure 50.2** Stem cells and the production of formed elements.

## Platelets

Platelets are cell fragments that pinch off from larger cells in the bone marrow. They are approximately 3  $\mu\text{m}$  in diameter, and following an injury to a blood vessel, the liver releases *prothrombin* into the blood. In the presence of this clotting factor, fibrinogen is converted into insoluble threads of **fibrin**. Fibrin then aggregates to form the clot.

## Formed elements arise from stem cells

The formed elements of blood each have a finite life span and therefore must be constantly replaced. Many of the old cell fragments are digested by phagocytic cells of the spleen; however, many products from the old cells, such as iron and amino acids, are incorporated into new formed elements. The creation of new formed elements begins in the bone marrow (see chapter 47).

All of the formed elements develop from **pluripotent stem cells** (see chapter 19). The production of blood cells occurs in the bone marrow and is called **hematopoiesis**. This process generates two types of stem cells with a more restricted fate: a lymphoid stem cell that gives rise to lymphocytes and a myeloid stem cell that gives rise to the rest of the blood cells (figure 50.2).

When the oxygen available in the blood decreases, the kidney converts a plasma protein into the hormone **erythropoietin**. Erythropoietin then stimulates the production of erythrocytes from the myeloid stem cells through a process called **erythropoiesis**.

In mammals, maturing erythrocytes lose their nuclei prior to release into circulation. In contrast, the mature erythrocytes of all other vertebrates remain nucleated. *Megakaryocytes* are examples of committed cells formed in bone marrow from stem cells. Pieces of cytoplasm are pinched off the megakaryocytes to form the platelets.

## Inquiry question

Why do you think the use of erythropoietin as a drug is banned in the Olympics and in some other sports?

## Blood clotting is an example of an enzyme cascade

When a blood vessel is broken or cut, smooth muscle in the vessel walls contracts, causing the vessel to constrict. Platelets then accumulate at the injured site and form a plug by sticking to one another and to the surrounding tissues (figure 50.3). A cascade of enzymatic reactions is triggered by the platelets, plasma factors, and molecules released from the damaged tissue.

One of the results of this cascade is that fibrinogen, normally dissolved in the plasma, comes out of solution in a reaction that forms fibrin. The platelet plug is then reinforced by fibrin threads, which contract to form a tighter mass. The tightening plug of platelets, fibrin, and often trapped erythrocytes constitutes a blood clot.

Once the tissue damage is healed, the careful process of dissolving the blood clot begins. This process is significant because if a clot breaks loose and travels in the circulatory system, it may end up blocking a blood vessel in the brain, causing a stroke, or in the heart, causing a heart attack.

## Learning Outcomes Review 50.1

The circulatory system functions in transport of materials, regulation of temperature and body processes, and protection of the body. Formed elements in blood include red blood cells, white blood cells, and platelets. Blood clotting involves a cascade of enzymatic reactions triggered by platelets and plasma factors to produce insoluble fibrin from fibrinogen.

- How does a blood clot form?

**Figure 50.3 Blood clotting.** Fibrin is formed from a soluble protein, fibrinogen, in the plasma. This reaction is catalyzed by the enzyme thrombin, which is formed from an inactive enzyme called prothrombin. The activation of thrombin is the last step in a cascade of enzymatic reactions that produces a blood clot when a blood vessel is damaged.

## 50.2 Invertebrate Circulatory Systems

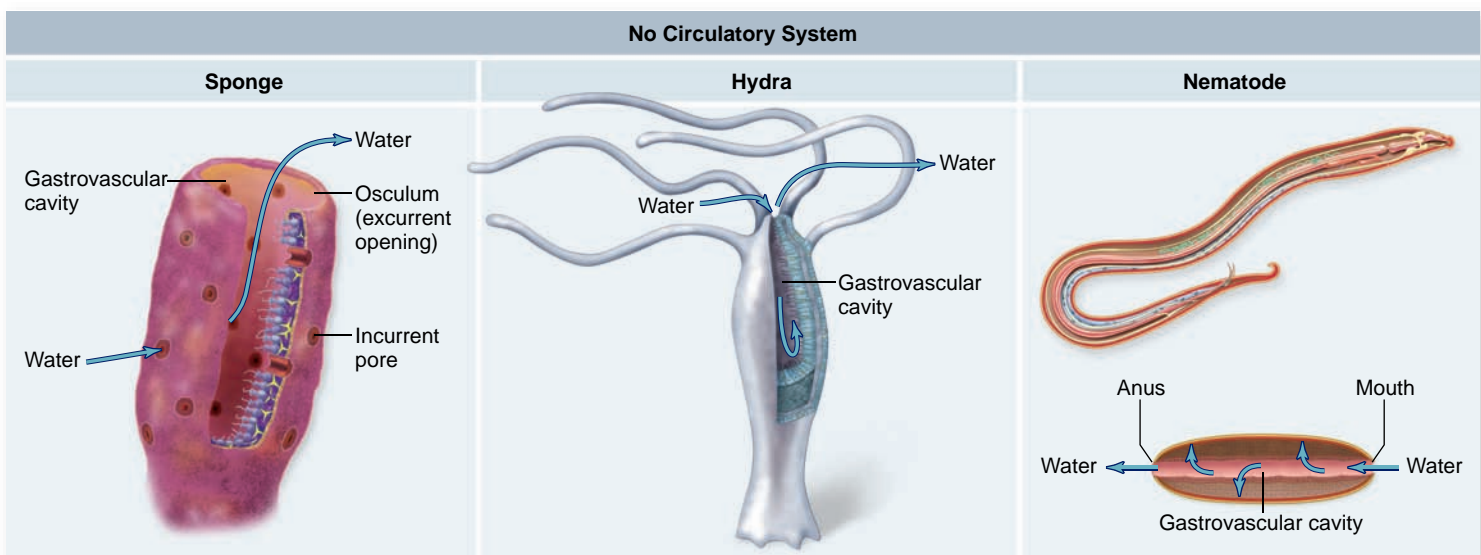

### Learning Outcomes

1. Distinguish between open and closed circulatory systems.
2. Define hemolymph.

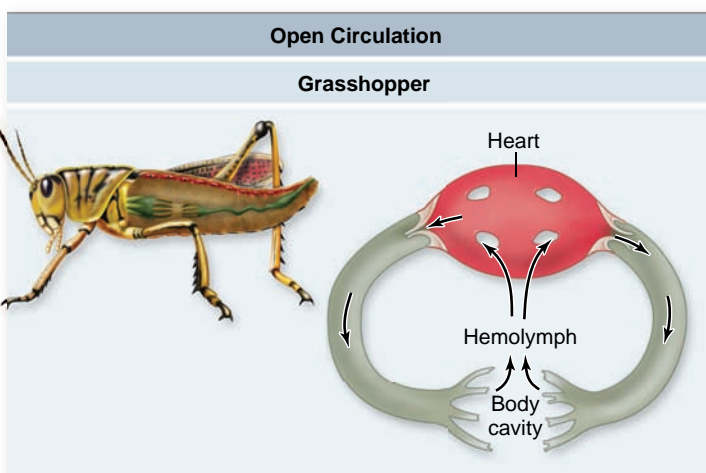

The nature of the circulatory system in multicellular invertebrates is directly related to the size, complexity, and lifestyle of the organism in question. Sponges and most cnidarians utilize

water from the environment as a circulatory fluid. Sponges pass water through a series of channels in their bodies, and *Hydra* and other cnidarians circulate water through a **gastrovascular cavity** (figure 50.4a). Because the body wall in *Hydra* species is only two cell layers thick, each cell layer is in direct contact with either the external environment or the gastrovascular cavity.

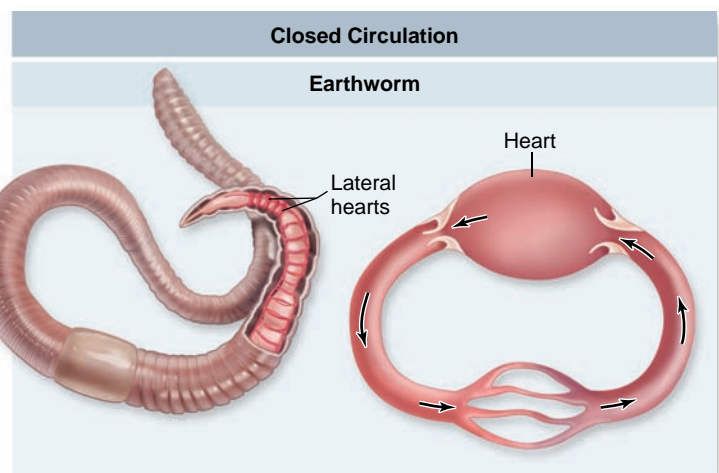

Pseudocoelomate invertebrates (roundworms, rotifers) use the fluids of the body cavity for circulation. Most of these invertebrates are quite small or are long and thin, and therefore adequate circulation is accomplished by movements of the body against the body fluids, which are in direct contact with the internal tissues and organs. Larger animals, however, have tissues that are several cell layers thick, so that many cells are

a.

b.

c.

**Figure 50.4** Circulatory systems of the animal kingdom. *a.* Sponges (left panel) do not have a separate circulatory system. They circulate water using many incurrent pores and one excurrent pore. The gastrovascular cavity of a hydra (middle panel) serves as both a digestive and a circulatory system, delivering nutrients directly to the tissue cells by diffusion from the digestive cavity. The nematode (right panel) is thin enough that the digestive tract can also be used as a circulatory system. Larger animals require a separate circulatory system to carry nutrients to and wastes away from tissues. *b.* In the open circulation of an insect, hemolymph is pumped from a tubular heart into cavities in the insect's body; the hemolymph then returns to the blood vessels so that it can be recirculated. *c.* In the closed circulation of the earthworm, blood pumped from the hearts remains within a system of vessels that returns it to the hearts. All vertebrates also have closed circulatory systems.

too far away from the body surface or digestive cavity to directly exchange materials with the environment. Instead, oxygen and nutrients are transported from the environment and digestive cavity to the body cells by an internal fluid within a circulatory system.

### Open circulatory systems move fluids in a one-way path

The two main types of circulatory systems are *open* and *closed*. In an open circulatory system, such as that found in most mollusks and in arthropods (figure 50.4*b*), there is no distinction between the circulating fluid and the extracellular fluid of the body tissues. This fluid is thus called **hemolymph**.

In insects, a muscular tube, or **heart**, pumps hemolymph through a network of channels and cavities in the body. The fluid then drains back into the central cavity.

### Closed circulatory systems move fluids in a loop

In a closed circulatory system, the circulating fluid, blood, is always enclosed within blood vessels that transport it away from and back to the heart (figure 50.4*c*). Some invertebrates, such as cephalopod mollusks and annelids (see chapter 34), and all vertebrates have a closed circulatory system.

In annelids such as earthworms, a dorsal vessel contracts rhythmically to function as a pump. Blood is pushed through five small connecting arteries, which also function as pumps, to a ventral vessel, which transports the blood posteriorly until it eventually reenters the dorsal vessel. Smaller vessels branch from each artery to supply the tissues of the earthworm with oxygen and nutrients and to remove waste products.

#### Learning Outcomes Review 50.2

In invertebrates, open circulatory systems pump hemolymph into tissues, from which it then drains into a central cavity. Closed circulatory systems move fluid in a loop to and from a muscular pumping region such as a heart. Hemolymph (invertebrates) is identical to the extracellular fluid in the tissues.

- In the open circulatory system of insects, how does hemolymph get back to the heart?

## 50.3 Vertebrate Circulatory Systems

#### Learning Outcomes

1. Trace the evolution of the chambered heart from lancelets to birds and mammals.
2. Delineate the flow of blood through the circulatory system in birds and mammals.

The evolution of large and complex hearts and closed circulatory systems put a premium on efficient circulation. In response, vertebrates have evolved a remarkable set of adaptations inextricably linking circulation and respiration, which has facilitated diversification throughout aquatic and terrestrial habitats and permitted the evolution of large body size.

### In fishes, more efficient circulation developed concurrently with gills

Chordates ancestral to the vertebrates are thought to have had simple tubular hearts, similar to those now seen in lancelets (see chapter 35). The heart was little more than a specialized zone of the ventral artery that was more heavily muscled than the rest of the arteries; it contracted in simple peristaltic waves.

The development of gills by fishes required a more efficient pump, and in fishes we see the evolution of a true chamber-pump heart. The fish heart is, in essence, a tube with four structures arrayed one after the other to form two pumping chambers (figure 50.5). The first two structures—the **sinus venosus** and **atrium**—form the first chamber; the second two, the **ventricle** and **conus arteriosus**, form the second chamber. The sinus venosus is the first to contract, followed by the atrium, the ventricle, and finally the conus arteriosus.

Despite shifts in the relative positions of these structures, this heartbeat sequence is maintained in all vertebrates. In fish, the electrical impulse that produces the contraction is initiated in the sinus venosus; in other vertebrates, the electrical impulse is initiated by a structure homologous to the sinus venosus—the **sinoatrial (SA) node**.

After blood leaves the conus arteriosus, it moves through the gills, becoming oxygenated. Blood leaving the gills then flows through a network of arteries to the rest of the body, finally returning to the sinus venosus. This simple loop has one serious limitation: in passing through the capillaries in the gills, blood pressure drops significantly. This slows circulation from the gills to the rest of the body and can limit oxygen delivery to tissues.

**Figure 50.5** The heart and circulation of a fish. Diagram of a fish heart, showing the structures in series with each other (sinus venosus; atrium; ventricles; conus arteriosus) that form two pumping chambers. Blood is pumped by the ventricle through the gills and then to the body. Blood rich in oxygen (oxygenated) is shown in red; blood low in oxygen (deoxygenated) is shown in blue.

## In amphibians and most reptiles, lungs required a separate circulation

The advent of lungs in amphibians (see chapter 49) involved a major change in the pattern of circulation, a second pumping circuit. After blood is pumped by the heart through the *pulmonary arteries* to the lungs, it does not go directly to the tissues of the body. Instead, it is returned via the *pulmonary veins* to the heart. Blood leaves the heart a second time to be circulated through other tissues. This system is termed **double circulation**: One system, the **pulmonary circulation**, moves blood between heart and lungs, and another, the **systemic circulation**, moves blood between the heart and the rest of the body.

### Amphibian circulation

Optimally, oxygenated blood from lungs would go directly to tissues, rather than being mixed in the heart with deoxygenated blood returning from the body. The amphibian heart has two structural features that significantly reduce this mixing (figure 50.6). First, the atrium is divided into two chambers: The right atrium receives deoxygenated blood from the systemic circulation, and the left atrium receives oxygenated blood from the lungs. These two types of blood, therefore, do not mix in the atria.

Because an amphibian heart has a single ventricle, the separation of the pulmonary and systemic circulations is incomplete. The extent of mixing when the contents of each atrium enter the ventricle is reduced by internal channels created by recesses in the ventricular wall. The conus arteriosus is partially separated by a dividing wall, which directs deoxygenated blood into the pulmonary arteries and oxygenated blood into the *aorta*, the major artery of the systemic circulation.

Amphibians living in water can obtain additional oxygen by diffusion through their skin. Thus, amphibians have a *pulmocutaneous circuit* that sends blood to both the lungs and the skin. Cutaneous respiration is also seen in many aquatic reptiles such as turtles.

### Reptilian circulation

Among reptiles, additional modifications have further reduced the mixing of blood in the heart. In addition to having two separate atria, reptiles have a septum that partially subdivides the ventricle. This separation is complete in one order of reptiles, the crocodylians, which have two separate ventricles divided by a complete septum (see the following section). Another change in the circulation of reptiles is that the conus arteriosus has become incorporated into the trunks of the large arteries leaving the heart.

**Figure 50.6 The heart and circulation of an amphibian.** *a.* The frog has a three-chambered heart with two atria but only one ventricle, which pumps blood both to the lungs and to the body. *b.* Despite the potential for mixing, the oxygenated and deoxygenated bloods (red and blue lines, respectively) mix little as they are pumped to the body and lungs. Oxygenation of blood also occurs by gas exchange through the skin.

## Mammals, birds, and crocodilians have two completely separated circulatory systems

Mammals, birds, and crocodilians have a four-chambered heart with two separate atria and two separate ventricles (figure 50.7). The hearts of birds and crocodiles exhibit some differences, but overall are quite similar, which is not surprising given their close evolutionary relationship (figure 50.8). However, the extreme similarity of the hearts of birds and mammals—so alike that a single illustration can suffice for both (see figure 50.7)—is a remarkable case of convergent evolution (see figure 50.8).

In a four-chambered heart, the right atrium receives deoxygenated blood from the body and delivers it to the right ventricle, which pumps the blood to the lungs. The left atrium receives oxygenated blood from the lungs and delivers it to the left ventricle, which pumps the oxygenated blood to the rest of the body (see figure 50.7).

The heart in these vertebrates is a two-cycle pump. Both atria fill with blood and simultaneously contract, emptying their blood into the ventricles. Both ventricles also contract at the same time, pushing blood simultaneously into the pulmonary and systemic circulations.

The increased efficiency of the double circulatory system in mammals and birds is thought to have been important in the evolution of endothermy. More efficient circulation is neces-

sary to support the high metabolic rate required for maintenance of internal body temperature about a set point.

Throughout the evolutionary history of the vertebrate heart, the sinus venosus has served as a pacemaker, the site where the impulses that initiate the heartbeat originate. Although the sinus venosus constitutes a major chamber in the fish heart, it is reduced in size in amphibians and is further reduced in reptiles. In mammals and birds, the sinus venosus is no longer present as a separate chamber, although some of its tissue remains in the wall of the right atrium. This tissue, the sinoatrial (SA) node, is still the site where each heartbeat originates as detailed later in the chapter.

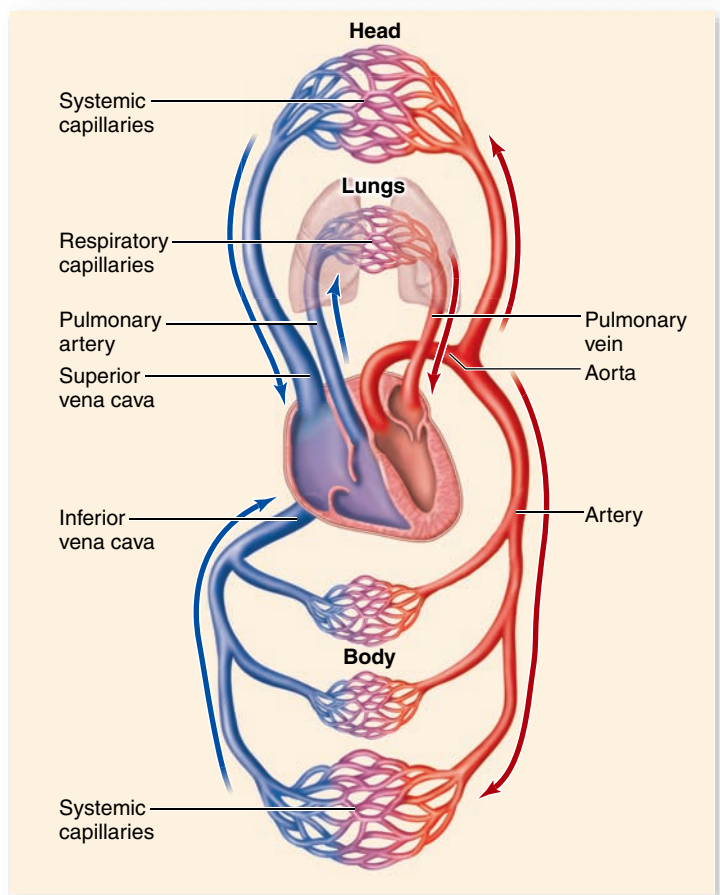

### Learning Outcomes Review 50.3

The chordate heart has evolved from a muscular region of a vessel, to the two-chambered heart of fish, the three-chambered heart of amphibians and most reptiles, and the four-chambered heart of crocodilians, birds, and mammals. Deoxygenated blood travels in the pulmonary circuit from the right atrium into the right ventricle and then to the lungs; it returns to the left atrium. Oxygenated blood travels in the systemic circuit from the left atrium into the left ventricle and then to the body; it returns to the right atrium.

- **What is the physiological advantage of having separated ventricles?**

a.

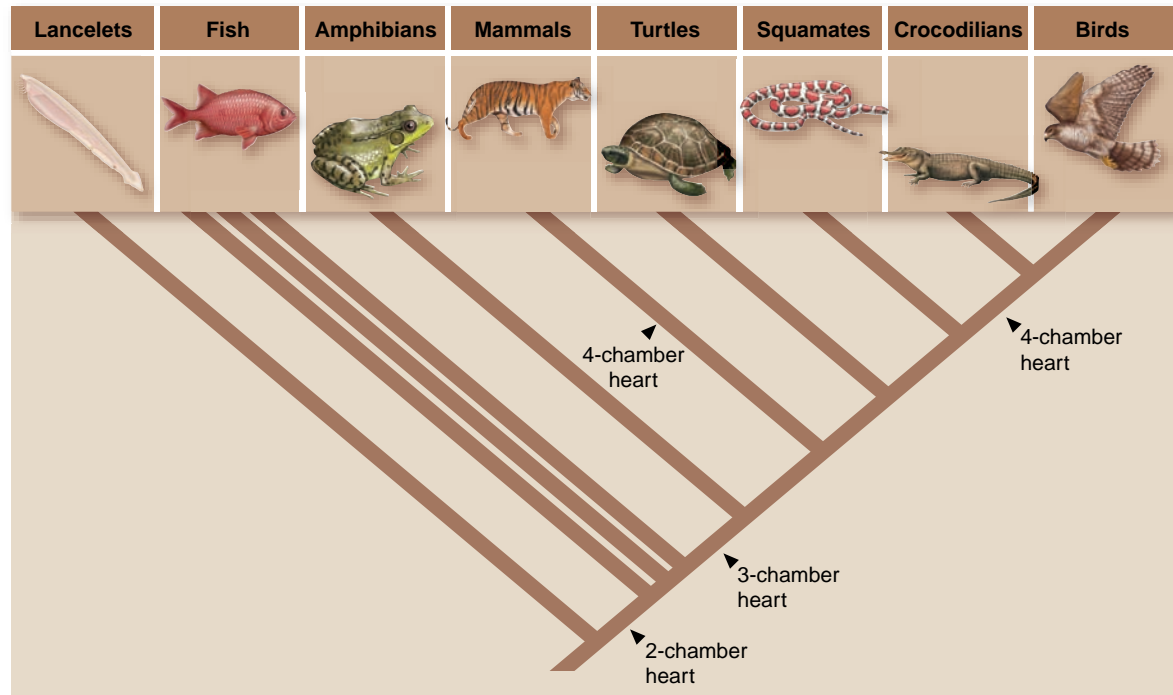

b.

**Figure 50.7** The heart and circulation of mammals and birds. *a.* The path of blood through the four-chambered heart. *b.* The right side of the heart receives deoxygenated blood and pumps it to the lungs; the left side of the heart receives oxygenated blood and pumps it to the body. In this way, the pulmonary and systemic circulations are kept completely separate.

**Figure 50.8**  
**Evolution of the heart in vertebrates.**

Despite their similarity, the four-chambered hearts of mammals and birds evolved convergently.

**50.4** *The Four-Chambered Heart and the Blood Vessels*

**Learning Outcomes**

1. Explain the cardiac cycle.
2. Describe the role of autorhythmic cells of the SA node.
3. Define blood pressure and how it is measured

As mentioned earlier, the heart of mammals, birds, and crocodilians goes through two contraction cycles, one of atrial contraction to send blood to the ventricles, and one of ventricular contraction to send blood to the pulmonary and systemic circuits. These two contractions plus the resting period between these make up the complete **cardiac cycle** encompassed by the heartbeat.

**The cardiac cycle drives the cardiovascular system**

The heart has two pairs of valves. One pair, the **atrioventricular (AV) valves**, maintains unidirectional blood flow between the atria and ventricles. The AV valve on the right side is the **tricuspid valve**, and the AV valve on the left is the **bicuspid, or mitral, valve**. Another pair of valves, together called the **semilunar valves**, ensure one-way flow out of the ventricles to the arterial systems. The **pulmonary valve** is located at the exit of the right ventricle, and the **aortic valve** is located at the exit of the left ventricle. These valves open and close as the heart goes through its cycle. The closing of these valves produces the “lub-dub” sounds heard with a stethoscope.

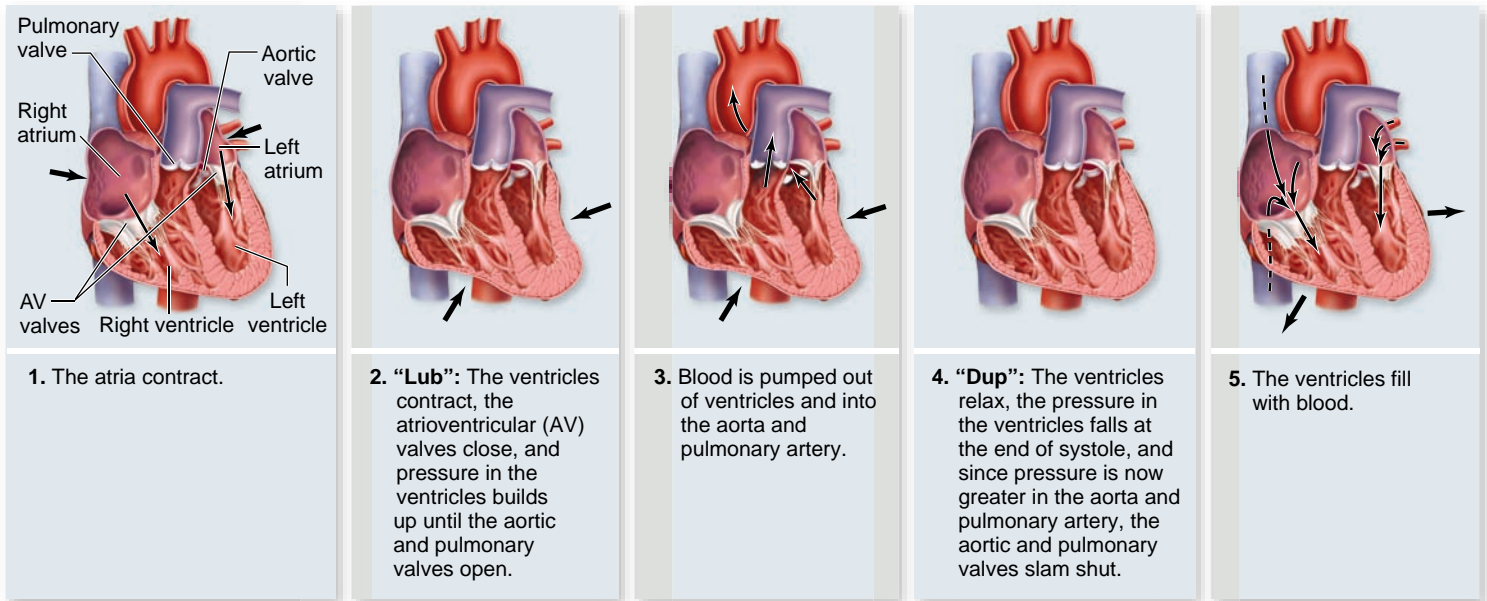

The cardiac cycle is portrayed in figure 50.9. It begins as blood returns to the resting heart through veins that empty into the right and left atria. As the atria fill and the pressure in them rises, the AV valves open and blood flows into the ventricles. The ventricles become about 80% filled during this time. Contraction of the atria tops up the final 20% of the 80 mL of blood the ventricles receive, on average, in a resting person. These events occur while the ventricles are relaxing, a period called ventricular **diastole**.

After a slight delay, the ventricles contract, a period called ventricular **systole**. Contraction of each ventricle increases the pressure within each chamber, causing the AV valves to forcefully close (the “lub” sound), preventing blood from backing up into the atria. Immediately after the AV valves close, the pressure in the ventricles forces the semilunar valves open and blood flows into the arterial systems. As the ventricles relax, closing of the semilunar valves prevents backflow (the “dub” sound).

**Contraction of heart muscle is initiated by autorhythmic cells**

As in other types of muscle, contraction of heart muscle is stimulated by membrane depolarization (see chapters 44 and 47). In skeletal muscles, only nerve impulses from motor neurons can normally initiate depolarization. The heart, by contrast, contains specialized “self-excitabile” muscle cells called autorhythmic fibers, which can initiate periodic action potentials without neural activation.

The most important group of autorhythmic cells is the sinoatrial (SA) node, described earlier (figure 50.10). Located in the wall of the right atrium, the SA node acts as a pacemaker for the rest of the heart by producing spontaneous action potentials at a faster rate than other autorhythmic cells. These spontaneous action potentials are due to a constant leakage of Na<sup>+</sup> ions into the cell that depolarize the membrane. When the

**Figure 50.9 The cardiac cycle.** *a.* Contraction and relaxation of the atria and ventricles moves blood through the heart. *b.* Blood pressure and volume changes through the cardiac cycle, shown here for the left ventricle.

threshold is reached, an action potential occurs. At the end of the action potential, the membrane is again below threshold and the process begins again. The cells of the SA node generate an action potential every 0.6 sec, equivalent to about 100 a minute. As we will see later in the chapter, the autonomic nervous system can modulate this rate.

Each depolarization initiated by this pacemaker is transmitted through two pathways: one to the cardiac muscle fibers of the left atrium, and the other to the right atrium and the atrioventricular (AV) node. Once initiated, depolarizations spread quickly from one muscle fiber to another in a wave that envelops the right and left atria nearly simultaneously. The rapid spread of depolarization is made possible because special conducting fibers are present and because the cardiac muscle cells are coupled by groups of gap junctions located within *intercalated disks* (see chapter 44).

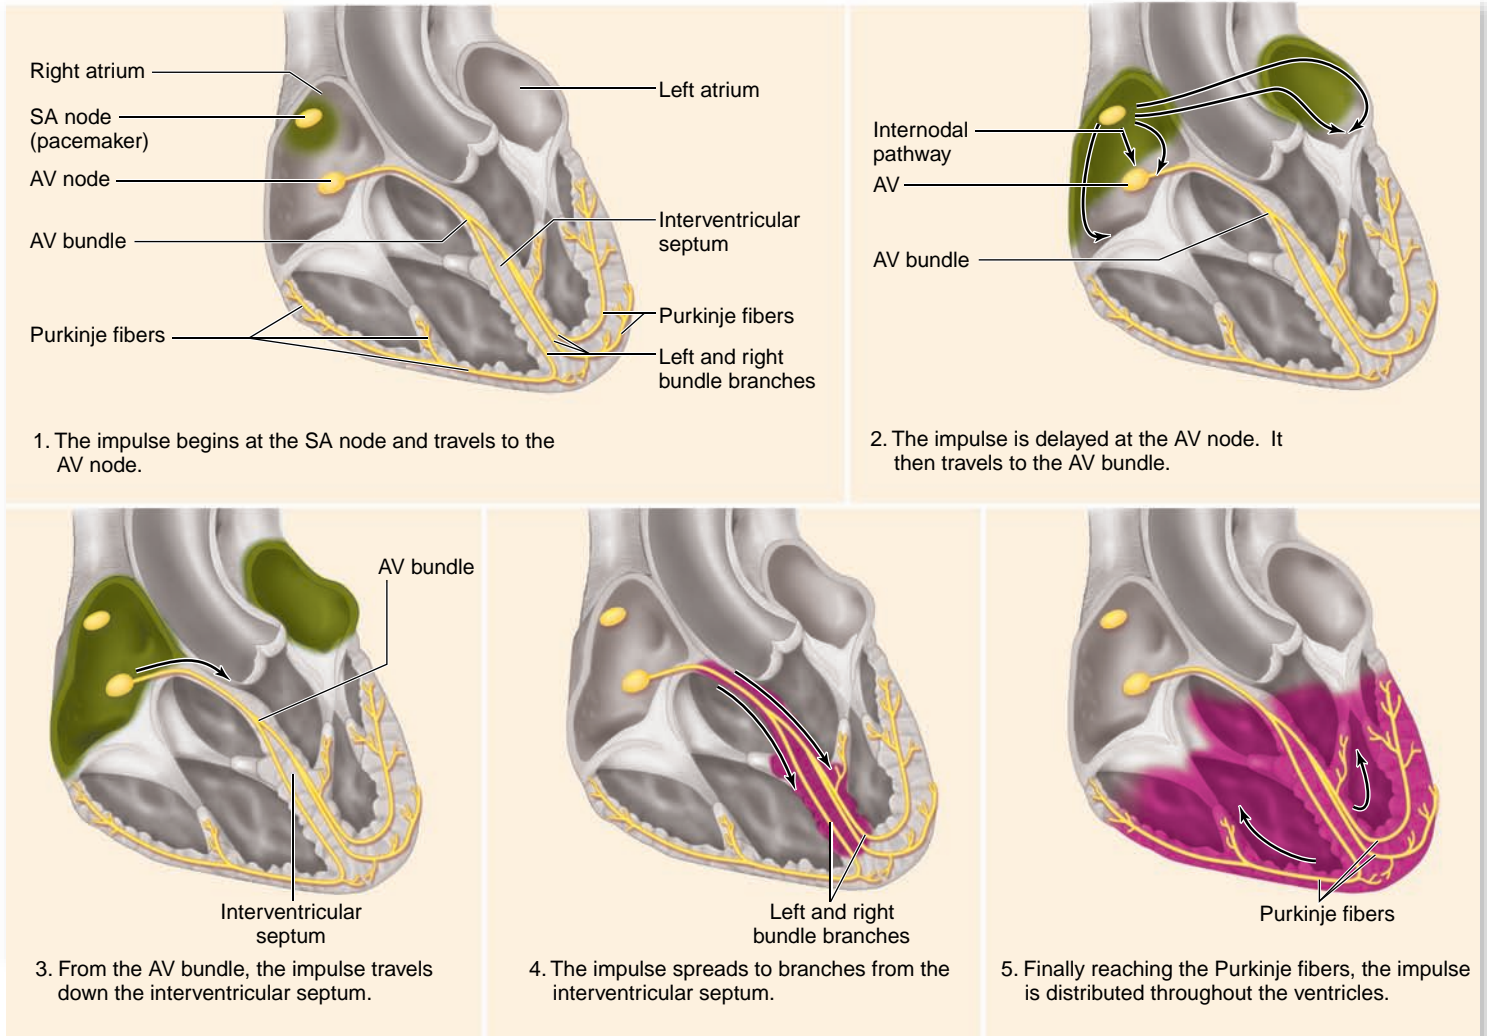

A sheet of connective tissue separating the atria from the ventricles blocks the spread of excitation through muscle fibers from one chamber to the other. The AV node provides the only pathway for conduction of the depolarization from the atria to the ventricles. The fibers of the AV node slow down the conduction of the depolarizing signals, delaying the contraction of

the ventricle by about 0.1 sec. This delay permits the atria to finish contracting and emptying their blood into the ventricles before the ventricles contract.

From the AV node, the wave of depolarization is conducted rapidly over both ventricles by a network of fibers called the atrioventricular bundle, or bundle of His. These fibers relay the depolarization to Purkinje fibers, which directly stimulate the myocardial cells of the left and right ventricles, causing their almost simultaneous contraction.

The stimulation of myocardial cells produces an action potential that leads to contraction. Contraction is controlled by  $\text{Ca}^{2+}$  and the troponin/tropomyosin system similar to skeletal muscle (see chapter 47), but the shape of the action potential is different. The initial rising phase due to an influx of  $\text{Na}^+$  from voltage-gated  $\text{Na}^+$  channels is followed by a plateau phase that leads to more sustained contraction. The plateau phase is due to the opening of voltage-gated  $\text{Ca}^{2+}$  channels. The resulting influx of  $\text{Ca}^{2+}$  keeps the membrane depolarized when the  $\text{Na}^+$  channels inactivate. This, in turn, leads to more voltage-gated  $\text{Ca}^{2+}$  channels in the sarcoplasmic reticulum opening. The additional  $\text{Ca}^{2+}$  in the cytoplasm produces a more sustained contraction. The  $\text{Ca}^{2+}$  is

**Figure 50.10 The path of electrical excitation in the heart.** The events occurring during contraction of the heart are correlated with the measurement of electrical activity by an electrocardiogram (ECG also called EKG). The depolarization/contraction of the atrium is shown in green above and corresponds to the P wave of the ECG (also in green). The depolarization/contraction of the ventricle is shown in red above and corresponds to the QRS wave of the ECG (also in red). The T wave on the ECG corresponds to the repolarization of the ventricles. The atrial repolarization is masked by the QRS wave.

removed from the cytoplasm by a pump in the sarcoplasmic reticulum similar to skeletal muscle, and an additional carrier in the plasma membrane pumps  $\text{Ca}^{2+}$  into the interstitial space.

The electrical activity of the heart can be recorded from the surface of the body with electrodes placed on the limbs and chest. The recording, called an electrocardiogram (ECG or EKG), shows how the cells of the heart depolarize and repolarize during the cardiac cycle (see figure 50.10). Depolarization causes contraction of the heart, and repolarization causes relaxation.

The first peak in the recording, P, is produced by the depolarization of the atria, and is associated with atrial systole.

The second, larger peak, QRS, is produced by ventricular depolarization; during this time, the ventricles contract (ventricular systole). The last peak, T, is produced by ventricular repolarization; at this time, the ventricles begin diastole.

### Arteries and veins branch to and from all parts of the body

The right and left **pulmonary arteries** deliver oxygen-depleted blood from the right ventricle to the right and left lungs. As

previously mentioned, the **pulmonary veins** return oxygenated blood from the lungs to the left atrium of the heart.

The **aorta** and all its branches are systemic arteries, carrying oxygen-rich blood from the left ventricle to all parts of the body. The **coronary arteries** are the first branches off the aorta; these supply oxygenated blood to the heart muscle itself (see figure 50.7*b*). Other systemic arteries branch from the aorta as it makes an arch above the heart and as it descends and traverses the thoracic and abdominal cavities.

The blood from the body's organs, now lower in oxygen, returns to the heart in the systemic veins. These eventually empty into two major veins: the **superior vena cava**, which drains the upper body, and the **inferior vena cava**, which drains the lower body. These veins empty into the right atrium, completing the systemic circulation.

The flow of blood through the arteries, capillaries, and veins is driven by the pressure generated by ventricular contraction. The ventricles must contract forcefully enough to move the blood through the entire circulatory system.

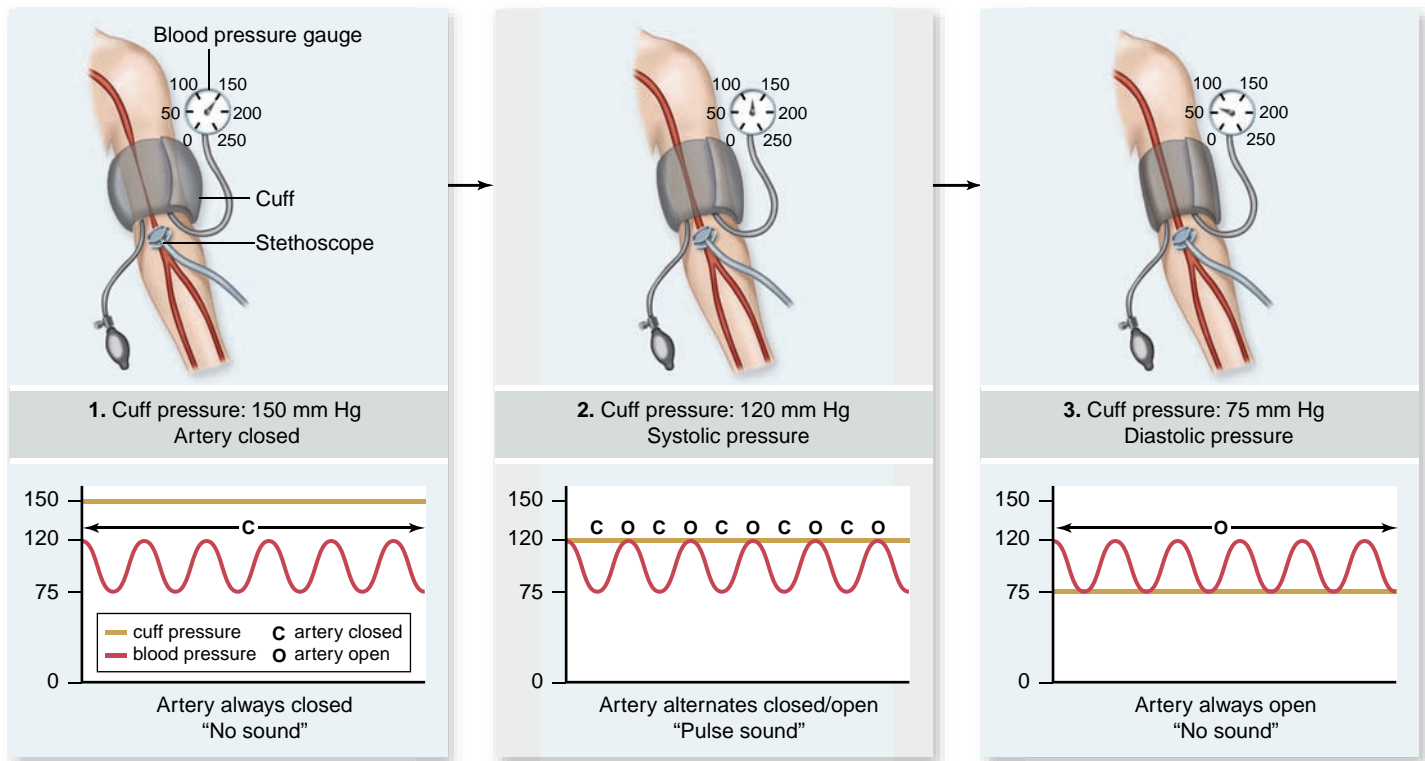

### Arterial blood pressure can be measured

As the ventricles contract, great pressure is generated within them and transferred through the arteries once the aortic valve opens. The pulse that you can detect in your wrist or

neck results from changes in pressure as elastic arteries expand and contract with the periodic blood flow. Doctors use blood pressure as an general indicator of cardiovascular health because a variety of conditions can cause increases or decreases in pressure.

A *sphygmomanometer* measures the blood pressure in the brachial artery found on the inside part of the arm, above the elbow (figure 50.11). A cuff wrapped around the upper part of the arm is tightened enough to stop the flow of blood to the lower part of the arm. As the cuff is slowly loosened, eventually the blood pressure produced by the heart is greater than the constricting pressure of cuff and blood begins pulsating through the artery, producing a sound that can be detected using a stethoscope. The point at which this pulsing sound begins marks the peak pressure, or **systolic pressure**, at which ventricles are contracting. As the cuff is loosened further, the point is reached where the pressure of the cuff is lower than the blood pressure throughout the cardiac cycle, at which time the blood vessel is no longer distorted and the pulsing sound stops. This point marks the minimum pressure between heartbeats or **diastolic pressure**, at which the ventricles are relaxed.

The blood pressure is written as a ratio of systolic over diastolic pressure, and for a healthy person in his or her twenties, a typical blood pressure is 120/75 (measured in millimeters

**Figure 50.11 Measurement of blood pressure.** The blood pressure cuff is tightened to stop the blood flow through the brachial artery. As the cuff is loosened, the maximal (systolic) pressure becomes greater than the cuff pressure and blood can momentarily pass through, producing a pulse that can be heard with a stethoscope. The pressure at this point is recorded as the systolic pressure. As the cuff pressure continues to drop, blood pressure is greater than cuff pressure for larger portions of the cardiac cycle. Eventually, even the minimum pressure during the cycle is greater than the cuff pressure, at which time the blood vessel is no longer distorted and silent laminar flow returns, replacing the pulsing sound. The diastolic pressure is recorded as the pressure at which a sound is no longer heard.

of mercury, or mm Hg). The medical condition called **hypertension** (high blood pressure) is defined as either a systolic pressure greater than 150 mm Hg or a diastolic pressure greater than 90 mm Hg.

### Learning Outcomes Review 50.4

The cardiac cycle consists of systole and diastole; the ventricles contract at systole and relax at diastole. The SA node in the right atrium initiates waves of depolarization that stimulate first the atria and then travel to the AV node, which stimulates the ventricles. Blood pressure is expressed as the ratio of systolic pressure over diastolic pressure and is measured with a device called a sphygmomanometer.

- What would happen without a delay between auricular and ventricular contraction?

## 50.5 Characteristics of Blood Vessels

### Learning Outcomes

1. Describe the four tissue layers in blood vessels.
2. Explain the distinctions among arteries, capillaries, and veins.
3. Describe how the lymphatic system operates.

You already know that blood leaves the heart through vessels known as **arteries**. These continually branch, forming a hollow “tree” that enters each organ of the body. The finest, microscopic branches of the arterial tree are the **arterioles**. Blood from the arterioles enters the **capillaries**, an elaborate latticework of very narrow, thin-walled tubes. After traversing the capillaries, the blood is collected into microscopic **venules**, which lead to larger vessels called **veins**, and these carry blood back to the heart.

### Larger vessels are composed of four tissue layers

Arteries, arterioles, veins, and venules all have the same basic structure (figure 50.12). The innermost layer is an epithelial sheet called the *endothelium*. Covering the endothelium is a thin layer of elastic fibers, a smooth muscle layer, and a connective tissue layer. The walls of these vessels, therefore, are thick enough to significantly reduce exchange of materials between the blood and the tissues outside the vessels.

The walls of capillaries, in contrast, are composed only of endothelium, so molecules and ions can leave the blood plasma by diffusion, by filtration through pores between the cells of the capillary walls, and by transport through the endothelial cells. Therefore, exchange of gases and metabolites between the blood and the interstitial fluids and cells of the body takes place through the capillaries.

### Arteries and arterioles have evolved to withstand pressure

The larger arteries contain more elastic fibers in their walls than other blood vessels, allowing them to recoil each time they receive a volume of blood pumped by the heart. Smaller arteries and arterioles are less elastic, but their relatively thick smooth muscle layer enables them to resist bursting.

The narrower the vessel, the greater the frictional resistance to flow. In fact, a vessel that is half the diameter of another has *16 times* the frictional resistance. Resistance to blood flow is inversely proportional to the fourth power of the radius of the vessel. Therefore, within the arterial tree, the small arteries and arterioles provide the greatest resistance to blood flow.

Contraction of the smooth muscle layer of the arterioles results in **vasoconstriction**, which greatly increases resistance and decreases flow. Relaxation of the smooth muscle layer results in **vasodilation**, decreasing resistance and increasing blood flow to an organ. Chronic vasoconstriction of the arterioles can result in hypertension, or high blood pressure.

**Figure 50.12** The structure of blood vessels. Arteries (*a*) and veins (*b*) have the same tissue layers, but the smooth muscle layer in arteries is much thicker and there are two elastic layers. *c*. Capillaries are composed of only a single layer of endothelial cells. (Not to scale.)

a.

b.

**Figure 50.13 Regulation of heat exchange.** The amount of heat gained or lost at the body's surface can be regulated by controlling the flow of blood to the surface. *a.* Constriction of surface blood vessels limits flow and heat loss when the animal is warmer than the surrounding air; when the animal is cooler than the surrounding air (not shown here), constriction minimizes heat gain; *(b)* dilation of these vessels increases flow and heat exchange.

Vasoconstriction and vasodilation are important means of regulating body heat in both ectotherms and endotherms (figure 50.13). By increasing blood flow to the skin, an animal can increase the rate of heat exchange, which is beneficial for gaining or losing heat. Conversely, shunting blood away from the skin is effective when an animal needs to minimize heat exchange, as might happen in cold weather.

### Capillaries form a vast network for exchange of materials

The huge number and extensive branching of the capillaries ensure that every cell in the body is within 100 micrometers ( $\mu\text{m}$ ) of a capillary. On the average, capillaries are about 1 mm long and  $8 \mu\text{m}$  in diameter, this diameter is only slightly larger than a red blood cell (5 to  $7 \mu\text{m}$  in diameter). Despite the close fit, normal red blood cells are flexible enough to squeeze through capillaries without difficulty.

The rate of blood flow through vessels is governed by hydrodynamics. The smaller the cross-sectional area of a vessel, the faster fluid moves through it. Given this, flow in the capillaries would be expected to be the fastest in the system. This would not be ideal for diffusion, and is actually not the case. Although each capillary is very narrow, so many of them exist that the capillaries have the greatest *total* cross-sectional area of any other type of vessel. Consequently, blood moving through capillaries goes more slowly and has more time to exchange materials with the surrounding extracellular fluid. By the time the blood reaches the end of a capillary, it has released some of its oxygen and nutrients and picked up carbon dioxide and other waste products. Blood loses pressure and velocity as it moves through the arterioles and capillaries, but as cross-sectional area decreases in the venous side, velocity increases.

### Venules and veins have less muscle in their walls

Venules and veins have the same tissue layers as arteries, but they have a thinner layer of smooth muscle. Less muscle is needed because the pressure in the veins is only about one-tenth that in the arteries. Most of the blood in the cardiovascular system is contained within veins, which can expand to hold additional amounts of blood. You can see the expanded veins in your feet when you stand for a long time.

The venous pressure alone is not sufficient to return blood to the heart from the feet and legs, but several other sources of pressure provide help. Most significantly, skeletal muscles surrounding the veins can contract to move blood by squeezing the veins, a mechanism called the **venous pump**. Blood moves in one direction through the veins back to the heart with the help of **venous valves** (figure 50.14). When a

### Figure 50.14 One-way flow of blood through veins.

Venous valves ensure that blood moves through the veins in only one direction, back to the heart.

person's veins expand too much with blood, the venous valves may no longer work and the blood may pool in the veins. Veins in this condition are known as varicose veins.

## The lymphatic system handles fluids that leave the cardiovascular system

The cardiovascular system is considered a closed system because all its vessels are connected with one another—none are simply open-ended. But a significant amount of water and solutes in the blood plasma filter through the walls of the capillaries to form the interstitial (tissue) fluid. Most of the fluid leaves the capillaries near their arteriolar ends, where the blood pressure is higher; it is returned to the capillaries near their venular ends (figure 50.15).

Fluid returns by osmosis (see chapter 5). Most of the plasma proteins cannot escape through the capillary pores because of their large size, and so the concentration of proteins in the plasma is greater than the protein concentration in the interstitial fluid. The difference in protein concentration produces an osmotic pressure gradient that causes water to move into the capillaries from the interstitial space.

High capillary blood pressure can cause too much interstitial fluid to accumulate. In pregnant women, for example, the enlarged uterus, carrying the fetus, compresses veins in the abdominal cavity, thereby adding to the capillary blood pressure in the woman's lower limbs. The increased interstitial fluid can cause swelling of the tissues, or **edema**, of the feet.

Edema may also result if the plasma protein concentration is too low. Fluids do not return to the capillaries, but remain as interstitial fluid. Low protein concentration in the plasma may be caused either by liver disease, because the liver produces most of the plasma proteins, or by insufficient dietary protein such as occurs in starvation.

Even under normal conditions, the amount of fluid filtered out of the capillaries is greater than the amount that returns to the capillaries by osmosis. The remainder does eventually return to the cardiovascular system by way of an open circulatory system called the **lymphatic system**.

The lymphatic system consists of lymphatic capillaries, lymphatic vessels, lymph nodes, and lymphatic organs, including the spleen and thymus. Excess fluid in the tissues drains into blind-ended lymph capillaries with highly permeable walls. This fluid, now called **lymph**, passes into progressively larger lymphatic vessels, which resemble veins and have one-way valves (similar to figure 50.14). The lymph eventually enters two major lymphatic vessels, which drain into the left and right subclavian veins located under the collarbones.

Movement of lymph in mammals results as skeletal muscles squeeze against the lymphatic vessels, a mechanism similar to the venous pump that moves blood through veins. In some cases, the lymphatic vessels also contract rhythmically. In many fishes, all amphibians and reptiles, bird embryos, and some adult birds, movement of lymph is propelled by **lymph hearts**.

As the lymph moves through lymph nodes and lymphatic organs, it is modified by phagocytic cells (see chapter 4) that line the channels of those organs. In addition, the lymph nodes

a.

b.

**Figure 50.15 Relationship between blood, lymph, and interstitial fluid.** a. Vessels of the circulatory and lymphatic systems with arrows indicating the direction of flow of fluid in the vessels. b. Plasma fluid, minus proteins, is filtered out of capillaries, forming interstitial fluid that bathes tissues. Much of this fluid is returned to the capillaries by osmosis due to the higher protein concentration in plasma. Excess interstitial fluid drains into open-ended lymphatic capillaries, which ultimately return the fluid to the cardiovascular system.

and lymphatic organs contain *germinal centers*, where the activation and proliferation of lymphocytes occurs.

## Cardiovascular diseases affect the delivery system

Cardiovascular diseases are the leading cause of death in the United States; more than 80 million people have some form of cardiovascular disease. Many disease conditions result from problems in arteries, such as blockage or rupture.

**Atherosclerosis, or hardening of the arteries**, is an accumulation within the arteries of fatty materials, abnormal amounts of smooth muscle, deposits of cholesterol or fibrin, or various kinds of cellular debris. These accumulations cause an increase in vascular resistance, which impedes blood flow (figure 50.16). The lumen (interior) of the artery may be further narrowed by a clot that forms as a result of the atherosclerosis. In the severest cases, the artery becomes completely blocked.

The accumulation of cholesterol in vessels is affected by a number of factors including total serum cholesterol and the levels of different cholesterol carrier proteins. Because cholesterol is not very water-soluble, it is carried in blood in the form of lipoprotein complexes. Two main forms are observed that differ in density: low-density lipoproteins (LDL) and high-density lipoproteins (HDL)—often called “bad cholesterol” and “good cholesterol,” respectively. The reason for this is that HDLs tend to take cholesterol out of circulation, transporting it to the liver for elimination, and LDL is the carrier that brings cholesterol to all cells in the body. The problem arises when cells have enough cholesterol. This causes a reduction in the amount of LDL receptors, leading to high levels of circulating LDLs, which can end up being deposited in blood vessels.

Atherosclerosis is promoted by genetic factors, smoking, hypertension (high blood pressure), and the effects of cholesterol just discussed. Stopping smoking is the single most effective action a smoker can take to reduce the risk of atherosclerosis.

**Arteriosclerosis** occurs when calcium is deposited in arterial walls. It tends to occur when atherosclerosis is severe. Not only do such arteries have restricted blood flow, but they also lack the ability to expand as normal arteries do. This decrease in flexibility forces the heart to work harder because blood pressure increases to maintain flow.

**Heart attacks** (myocardial infarctions) are the main cause of cardiovascular deaths in the United States, accounting for about one-fifth of all deaths. Heart attacks result from an insufficient supply of blood to one or more parts of the heart muscle, which causes myocardial cells in those parts to die. Heart attacks may be caused by a blood clot forming somewhere in the coronary arteries and may also result if an artery is blocked by atherosclerosis. Recovery from a heart attack is possible if the portion of the heart that was damaged is small enough that the heart can still contract as a functional unit.

**Angina pectoris**, which literally means “chest pain,” occurs for reasons similar to those that cause heart attacks, but it is not as severe. The pain may occur in the heart and often also in the left arm and shoulder. Angina pectoris is a warning sign that the blood supply to the heart is inadequate but is still sufficient to avoid myocardial cell death.

**Strokes** are caused by an interference with the blood supply to the brain. They may occur when a blood vessel bursts in the brain (hemorrhagic stroke), when blood flow in a cerebral artery is blocked by a blood clot or by atherosclerosis (ischemic stroke). The effects of a stroke depend on the severity of the damage and where in the brain the stroke occurs.

### Learning Outcomes Review 50.5

The four layers of blood vessels are (1) endothelium, (2) an elastic layer, (3) smooth muscle, and (4) connective tissue. In contrast, capillaries have only endothelium. Arteries have more muscle in their walls than do veins to help withstand greater pressure; large arteries also have more elastic fibers for recoil. Excess interstitial fluid, called lymph, is returned to the cardiovascular system via the lymphatic system, a one-way system.

- What is the connection between the lymphatic and circulatory systems?

**Figure 50.16 Atherosclerosis.** *a.* The coronary artery shows only minor blockage. *b.* The artery exhibits severe atherosclerosis—much of the passage is blocked by buildup on the interior walls of the artery. *c.* The coronary artery is essentially completely blocked.

## 50.6 Regulation of Blood Flow and Blood Pressure

### Learning Outcomes

1. Describe how exertion affects cardiac output.
2. Explain how hormones regulate blood volume.

Although the autonomic nervous system does not initiate the heartbeat, it does modulate its rhythm and force of contraction. In addition, several mechanisms regulate characteristics of the cardiovascular system, including cardiac output, blood pressure, and blood volume.

### The nervous system may speed up or slow down heart rate

Heart rate is under the control of the autonomic nervous system. The cardiac center of the medulla oblongata (a part of the hindbrain; see chapter 44) consists of two neuronal centers that modulate heart rate. The **cardioacceleratory center** sends signals by way of the sympathetic cardiac accelerator nerves to the SA node, AV node, and myocardium. These nerves secrete norepinephrine, which increases the heart rate. Sympathetic nervous system stimulation can also increase contractility of the heart muscle itself, thus ejecting more blood per contraction (stroke volume).

The **cardioinhibitory center** sends signals via the parasympathetic fibers in the vagus nerve to the SA and AV nodes. The vagus nerve secretes acetylcholine, which inhibits the development of action potentials and so slows the heart down.

### Cardiac output increases with exertion

**Cardiac output** is the volume of blood pumped by each ventricle per minute. It is calculated by multiplying the heart rate by the *stroke volume*, which is the volume of blood ejected by each ventricle per beat. For example, if the heart rate is 72 beats per minute and the stroke volume is 70 mL, the cardiac output is 5 L/min, which is about average in a resting human.

Cardiac output increases during exertion because of an increase in both heart rate and stroke volume. When exertion begins, such as running, the heart rate increases up to about 100 beats per minute to provide more oxygen to cells in the body. As movement becomes more intense, skeletal muscles squeeze on veins more vigorously, returning blood to the heart more rapidly. In addition, the ventricles contract more strongly, so they empty more completely with each beat.

During exercise, the cardiac output increases to a maximum of about 25 L/min in an average young adult. Although the cardiac output has increased fivefold, not all organs receive five times the blood flow; some receive more, others less. Arterioles in some organs, such as in the digestive system, constrict, while the arterioles in the working muscles and heart dilate.

### The baroreceptor reflex maintains homeostasis in blood pressure

The arterial blood pressure (BP) depends on two factors: the cardiac output (CO) and the resistance (R) to blood flow in the vascular system. This relationship can be expressed as:

$$BP = CO \times R$$

An increased blood pressure, therefore, could be produced by an increase in either heart rate or blood volume (because both increase the cardiac output), or by vasoconstriction, which increases the resistance to blood flow. Conversely, blood pressure falls if the heart rate slows or if the blood volume is reduced—for example, by dehydration or excessive bleeding (hemorrhage).

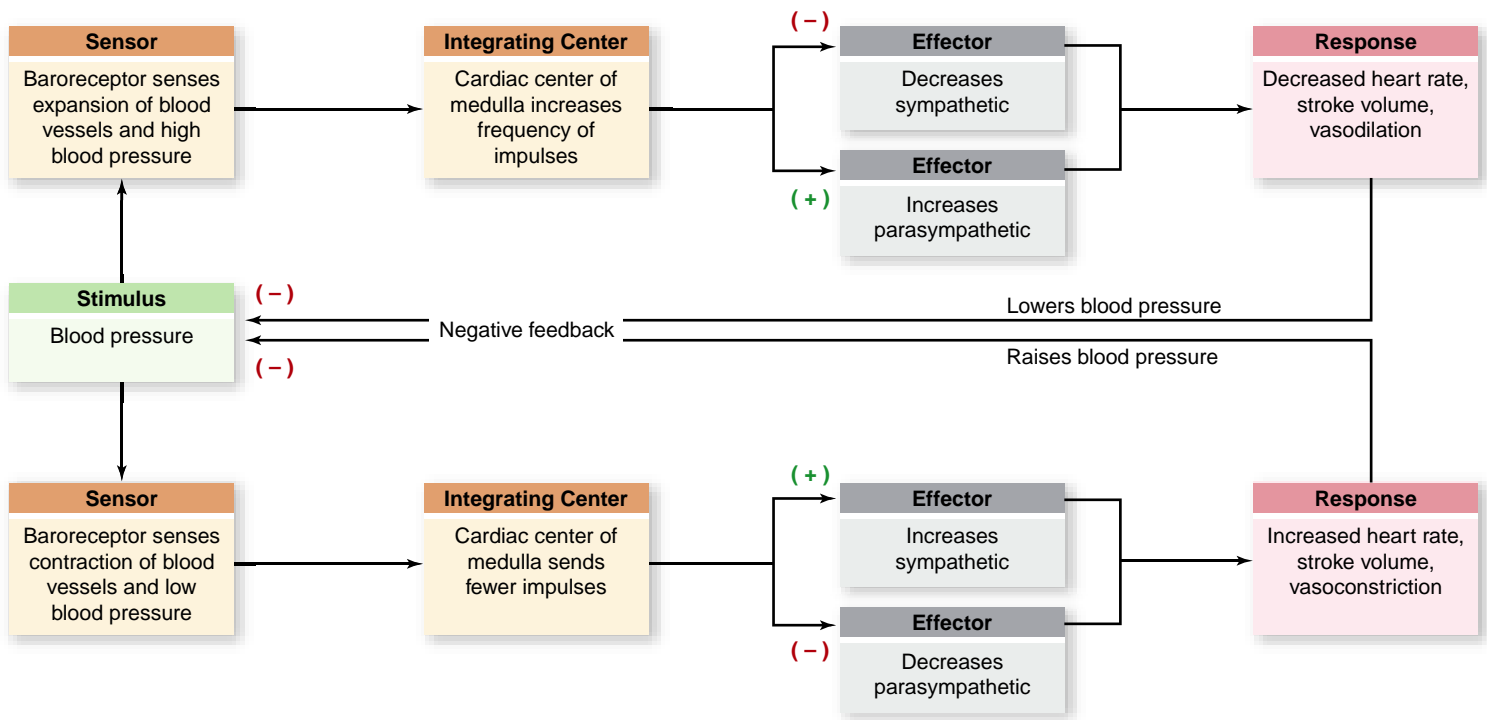

Changes in arterial blood pressure are detected by **baroreceptors** located in the arch of the aorta and in the carotid arteries (see chapter 46). These sensors are stretch receptors sensitive to expansion and contraction of arteries. When the baroreceptors detect a fall in blood pressure, the number of impulses to the cardiac center is decreased, resulting in increased sympathetic stimulation and decreased parasympathetic stimulation of the heart and other targets. This increases heart rate and stroke volume to amplify cardiac output. This also causes vasoconstriction of blood vessels in the skin and viscera, raising resistance. These combine to increase blood pressure, closing the feedback loop in this direction (figure 50.17, top).

When baroreceptors detect a rise in blood pressure, the number of impulses to the cardiac center is increased. This has the opposite effect of decreasing sympathetic stimulation and increasing parasympathetic stimulation of the heart. This lowers heart rate and stroke volume to reduce cardiac output. The cardiac center also sends signals causing vasodilation of blood vessels in the skin and viscera, lowering resistance. These combine to decrease blood pressure closing the feedback loop in this direction. Thus, the baroreceptor reflex forms a negative feedback loop responding to changes in blood pressure (figure 50.17, bottom).

### Blood volume is regulated by hormones

Blood pressure depends in part on the total blood volume because this can affect the cardiac output. A decrease in blood volume decreases blood pressure, if all else remains equal. Blood volume regulation involves the effects of four hormones: (1) antidiuretic hormone, (2) aldosterone, (3) atrial natriuretic hormone, and (4) nitric oxide.

**Antidiuretic hormone (ADH)**, also called **vasopressin**, is secreted by the posterior-pituitary gland in response to an increase in the osmolarity of the blood plasma (see chapter 46). Dehydration, for example, causes the blood volume to decrease. Osmoreceptors in the hypothalamus promote thirst and stimulate ADH secretion from the posterior pituitary gland. ADH, in turn, stimulates the kidneys to retain more water in the blood, excreting less in the urine. A dehydrated person thus drinks more and urinates less, helping to raise the blood volume and restore homeostasis.

**Figure 50.17 Baroreceptor negative feedback loops control blood pressure.** Baroreceptors form the afferent portion of a feedback loop controlling blood pressure. The frequency of nerve impulses from these stretch receptors correlates with blood pressure. This information is processed in the cardiac center of the medulla. The efferent portion of the loop involves sympathetic and parasympathetic nerves that innervate the heart. This control can raise or lower heart rate and stroke volume to raise and lower blood pressure in response to baroreceptors signaling.

Whenever the kidneys experience a decreased blood flow, a group of kidney cells initiate the release of an enzyme known as renin into the blood. Renin activates a blood protein, angiotensin, which stimulates vasoconstriction throughout the body while stimulating the adrenal cortex to secrete **aldosterone**. This steroid hormone acts on the kidneys to promote the retention of  $\text{Na}^+$  and water in the blood (see chapter 46).

When excess  $\text{Na}^+$  is present, less aldosterone is secreted by the adrenals, so that less  $\text{Na}^+$  is retained by the kidneys.  $\text{Na}^+$  excretion in the urine is promoted by another hormone, **atrial natriuretic hormone**. This hormone is secreted by the right atrium of the heart in response to stretching caused by an increased blood volume. The action of atrial natriuretic hormone completes a negative feedback loop, lowering the blood volume and pressure.

**Nitric oxide (NO)** is a gas produced by endothelial cells of blood vessels. As described in chapter 46, it is one of a number of paracrine regulators of blood vessels. In solution, NO

passes outward through the cell layers of the vessel, causing the smooth muscles that encase it to relax and the blood vessels to dilate (become wider). For over a century, heart patients have been prescribed nitroglycerin to relieve chest pain, but only now has it become clear that nitroglycerin acts by releasing nitric oxide.

### Learning Outcomes Review 50.6

Cardiac output is the heart rate times the heart's stroke volume. As exertion increases, cardiac output increases to meet the body's demands. Blood pressure depends on cardiac output and the resistance to blood flow due to constriction of the arteries. The blood volume is regulated by antidiuretic hormone, aldosterone, and atrial natriuretic hormone; nitric oxide causes vasodilation that lessens resistance.

- *What are the connections between regulation of heart rate and breathing rate?*

### 50.1 The Components of Blood

#### **Blood plasma is a fluid matrix.**

Plasma is 92% water plus nutrients, hormones, ions, plasma proteins, and wastes (see figure 50.1).

#### **Formed elements include circulating cells and platelets.**

Blood cells include erythrocytes (red cells), leukocytes (white cells), and platelets. Erythrocytes contain hemoglobin for oxygen transport, and leukocytes are part of the immune system. Platelets help initiate blood clotting (see figure 50.3).

#### **Formed elements arise from stem cells.**

Blood cells are derived from pluripotent stem cells in bone marrow by hematopoiesis (see figure 50.2).

#### **Blood clotting is an example of an enzyme cascade.**

Upon initiation of clotting, fibrinogen, normally dissolved in the plasma, is turned into fibrin, an insoluble protein, via an enzyme cascade. As a wound heals, the clot must be dissolved.

### 50.2 Invertebrate Circulatory Systems

#### **Open circulatory systems move fluids in a one-way path.**

Sponges pass water through channels, and cnidarians circulate water through a gastrovascular cavity. Small animals can use body cavity fluids for circulation.

#### **Closed circulatory systems move fluids in a loop.**

Closed systems have a distinct circulatory fluid, such as blood, enclosed in vessels and transported in a loop.

### 50.3 Vertebrate Circulatory Systems

#### **In fishes, more efficient circulation developed concurrently with gills.**

Fishes have a linear heart with two pumping chambers to increase efficiency of blood flow through the gills; from the gills, the blood moves into the rest of the body (see figure 50.5).

#### **In amphibians and most reptiles, lungs required a separate circulation.**

Pulmonary circulation pumps blood to the lungs, and systemic circulation pumps blood to the body.

Amphibian hearts have two atria that separate blood flow to the lungs and body, and a single ventricle (figure 50.6). The heart of most reptiles has a septum that partially divides the ventricle, reducing mixing of blood from the atria.

#### **Mammals, birds, and crocodilians have two completely separated circulatory systems.**

The four-chambered heart has two ventricles (see figure 50.7). The extreme similarity between the heart of mammals and birds is an example of convergent evolution.

### 50.4 The Four-Chambered Heart and the Blood Vessels

#### **The cardiac cycle drives the cardiovascular system.**

The unidirectional flow of blood through the heart is maintained by two atrioventricular valves (see figure 50.9). During diastole ventricles relax and atria contract; during systole ventricles contract.

#### **Contraction of heart muscle is initiated by autorhythmic cells.**

Contraction is initiated by the SA node, a natural pacemaker, and impulses then travel to the AV node (see figure 50.10).

#### **Arteries and veins branch to and from all parts of the body.**

Arteries and arterioles carry oxygenated blood to the body; veins and venules return deoxygenated blood to the heart (see figure 50.7).

#### **Arterial blood pressure can be measured.**

A sphygmomanometer measures the peak (systolic) and minimum (diastolic) blood pressure. Blood pressure is expressed as the ratio of systolic to diastolic.

### 50.5 Characteristics of Blood Vessels

#### **Larger vessels are composed of four tissue layers.**

Arteries and veins consist of endothelium, elastic fibers, smooth muscle, and connective tissues (see figure 50.12). Capillaries have only one layer of endothelium.

#### **Arteries and arterioles have evolved to withstand pressure.**

Arteries and arterioles have thicker muscular layer and more elastic fibers to control blood flow and to recoil with changes in blood pressure.

#### **Capillaries form a vast network for exchange of materials.**

Capillaries are the region of the circulatory system where exchange takes place with the body's tissues (see figure 50.13).

#### **Venules and veins have less muscle in their walls.**

The return of blood to the heart through veins is facilitated by skeletal muscle contractions and one-way valves (see figure 50.14).

#### **The lymphatic system handles fluids that leave the cardiovascular system.**

Fluid from plasma filters out of capillaries, then returns via the separate, one-way lymphatic system (see figure 50.15). The lymphatic system connects with the blood circulation at the subclavian veins.

#### **Cardiovascular diseases affect the delivery system.**

Atherosclerosis is an accumulation of fatty materials in arteries; it is one cause of a heart attack, which results from an insufficient supply of blood to heart muscle. Strokes are caused by blockage of the blood supply to the brain.

### 50.6 Regulation of Blood Flow and Blood Pressure

#### **The nervous system may speed up or slow down heart rate.**

Norepinephrine from sympathetic neurons increases heart rate; acetylcholine from parasympathetic neurons decreases the rate.

#### **Cardiac output increases with exertion.**

Both heart rate and stroke volume increase with exertion.

#### **The baroreceptor reflex maintains homeostasis in blood pressure.**

Arterial blood pressure is monitored by baroreceptors in the aortic arch and carotid arteries, which relay impulses to the cardiac center (see figure 50.17).

#### **Blood volume is regulated by hormones.**

Blood volume regulation and arterial resistance involves the effects of four hormones: (1) antidiuretic hormone, (2) aldosterone, (3) atrial natriuretic hormone, and (4) nitric oxide.

## Review Questions

### UNDERSTAND

- An ECG measures
  - changes in electrical potential during the cardiac cycle.
  - $\text{Ca}^{2+}$  concentration of the ventricles in diastole.
  - the force of contraction of the atria during systole.
  - the volume of blood being pumped during the contraction cycle.
- Systole is vitally important to heart function and begins in the heart with the
  - activation of the AV node.
  - activation of the SA node.
  - opening of the voltage-gated potassium gates.
  - opening of the semilunar valves.
- Which of the following is the correct sequence of events in the circulation of blood?
  - Heart  $\rightarrow$  arteries  $\rightarrow$  arterioles  $\rightarrow$  capillaries  $\rightarrow$  venules  $\rightarrow$  lymph  $\rightarrow$  heart
  - Heart  $\rightarrow$  arteries  $\rightarrow$  arterioles  $\rightarrow$  capillaries  $\rightarrow$  veins  $\rightarrow$  venules  $\rightarrow$  heart
  - Heart  $\rightarrow$  arteries  $\rightarrow$  arterioles  $\rightarrow$  capillaries  $\rightarrow$  venules  $\rightarrow$  veins  $\rightarrow$  heart
  - Heart  $\rightarrow$  arterioles  $\rightarrow$  arteries  $\rightarrow$  capillaries  $\rightarrow$  venules  $\rightarrow$  veins  $\rightarrow$  heart
- Which of the following statements is not true?
  - Only arteries carry oxygenated blood.
  - Both arteries and veins have a layer of smooth muscle.
  - Both arteries and veins branch out into capillary beds.
  - Precapillary sphincters regulate blood flow through capillaries.
- The lymphatic system is like the circulatory system in that they both
  - have nodes that filter out pathogens.
  - have a network of arteries.
  - have capillaries.
  - are closed systems.
- Which pairing of structure and function is incorrect?
  - Erythrocytes: oxygen transport
  - Platelets: blood clotting
  - Plasma: waste transport
  - All of these are correct.
- When a sphygmomanometer is used,
  - blood pulses through the vein when systolic pressure is greater than the pressure caused by the cuff.
  - pulsing ceases when blood pressure falls below the systolic pressure.
  - blood does not move through the vein when cuff pressure is greater than maximal blood pressure.
  - cuff pressure stops decreasing when it equals systolic pressure.

### APPLY

- In vertebrate hearts, atria contract from the top, and ventricles contract from the bottom. How is this accomplished?
  - Depolarization from the SA node proceeds across the atria from the top; depolarization from the AV node is carried

- to the bottom of the ventricles before it emanates over ventricular tissue.
  - The depolarization from the SA node is initiated from motor neurons coming down from our brain; depolarization from the AV node is initiated from motor neurons coming up from our spinal cord.
  - Gravity carries the depolarization from the SA node down from the top of the heart; contraction of the diaphragm forces depolarization from the AV node from the bottom up.
  - This statement is false; both contract from the bottom.
- A molecule of  $\text{CO}_2$  that is generated in the cardiac muscle of the left ventricle would *not* pass through which of the following structures before leaving the body?
  - Right atrium
  - Left atrium
  - Right ventricle
  - Left ventricle
- Blood clots are made of
  - fibrin.
  - fibrinogen.
  - prothrombin.
  - all of these.
- The difference between the amphibian and mammal hearts is that
  - in the amphibian heart, oxygenated and deoxygenated blood mix completely in the single ventricle.
  - in the amphibian heart, there are two SA nodes so that contractions occur simultaneously throughout the heart.
  - in the ventricle in the amphibian heart, internal channels reduce mixing of blood.
  - in the amphibian heart, only the left aorta pumps oxygen obtained by diffusion through the skin.
- Contraction of the smooth muscle layers of the arterioles
  - increases the frictional resistance to blood flow.
  - may be a way of increasing heat exchange through the skin.
  - can increase blood flow to an organ.
  - includes all of the above.

### SYNTHESIZE

- Humans have a number of mechanisms that help to maintain blood pressure, particularly when it falls too low. Explain how the kidney and the endocrine systems help to maintain blood pressure.
- What is the difference among blood, lymph, and hemolymph?
- Is the evolution of the four-chambered heart related to the evolution of endothermy?
- What do you think are the clinical symptoms indicating that a person requires the surgical implantation of a mechanical pacemaker?

# Chapter 51

## Osmotic Regulation and the Urinary System

### Chapter Outline

- 51.1 Osmolarity and Osmotic Balance
- 51.2 Osmoregulatory Organs
- 51.3 Evolution of the Vertebrate Kidney
- 51.4 Nitrogenous Wastes: Ammonia, Urea, and Uric Acid
- 51.5 The Mammalian Kidney
- 51.6 Hormonal Control of Osmoregulatory Functions

### Introduction

The majority of your body weight is actually water, but you exist in a very dehydrating environment. The kangaroo rat pictured lives in a desert environment that is even more dehydrating and yet is so parsimonious with water that it never needs to drink; it generates sufficient water as a by-product of oxidizing its food. Fish can exist in both freshwater and marine environments, facing the challenge of either gaining or losing water, respectively. Life in these different environments is possible because elaborate mechanisms enable organisms to control the osmotic strength of their blood and extracellular fluids. The regulation of internal fluid and its composition is an example of homeostasis—the ability of living organisms to maintain internal conditions within an optimal range. In this chapter, we describe the osmoregulatory systems of a number of animals, including the mammalian urinary system. These organ systems maintain the water and ionic balance of fluids in the body.

### 51.1 Osmolarity and Osmotic Balance

#### Learning Outcomes

1. Explain the importance of osmotic balance.
2. Describe how organisms are classified based on their method of osmotic regulation.

Water in a multicellular animal's body is distributed between the intracellular and extracellular compartments (figure 51.1). To maintain osmotic balance, the extracellular compartment of an animal's body (including its blood plasma) must be able to take water from the environment and to excrete excess water into the environment. Inorganic ions must also be exchanged between the extracellular body fluids and the external environment to maintain homeostasis. Exchanges of water and electrolytes between the body and the external environment occur across specialized epithelial cells and, in most vertebrates, through a filtration process in the kidneys.

**Figure 51.1** The interaction between intracellular and extracellular compartments of the body and the external environment. Water can be taken in from the environment or lost to the environment. Exchanges of water and solutes between the extracellular fluids of the body and the environment occur across transport epithelia, and water and solutes can be filtered out of the blood by the kidneys. Overall, the amount of water and solutes that enters and leaves the body must be balanced in order to maintain homeostasis.

Most vertebrates maintain homeostasis for both the total solute concentration of their extracellular fluids and the concentration of specific inorganic ions. Sodium ( $\text{Na}^+$ ) is the major cation in extracellular fluids, and chloride ( $\text{Cl}^-$ ) is the major anion. The divalent cations, calcium ( $\text{Ca}^{2+}$ ) and magnesium ( $\text{Mg}^{2+}$ ), the monovalent cation  $\text{K}^+$ , as well as other ions, also have important functions and are maintained at constant levels.

### Osmotic pressure is a measure of concentration difference

You learned in chapter 5 that osmosis is the diffusion of water across a semipermeable membrane. Osmosis always occurs from a more dilute solution (with a lower solute concentration) to a less dilute solution (with a higher solute concentration). The osmotic pressure of a solution is a measure of its tendency to take in water by osmosis. This is the amount of pressure needed to balance the pressure created by the movement of water.

A solution with a higher concentration of solute exerts more osmotic pressure. This is measured as the **osmolarity** of a solution, the number of osmotically active moles of solute per liter of solution. Notice that osmolarity can differ from molar concentration if a substance dissociates in solution into more than one osmotically active particle. For example, a 1 molar (M) solution of sucrose is also 1 osmolar (Osm), but a 1 M solution of NaCl is 2 Osm as it dissociates into two osmotically active ions.

The **tonicity** of a solution is a measure of the ability of the solution to change the volume of a cell by osmosis. An animal cell

placed in a *hypertonic* solution loses water to the surrounding solution and shrinks. In contrast, an animal cell placed in a *hypotonic* solution gains water and expands. A cell in an *isotonic* solution shows no net water movement. In medical care, isotonic solutions such as normal saline and 5% dextrose are used to bathe exposed tissues and are given as intravenous fluids.

### Osmoconformers live in marine environments

The osmolarity of body fluids in most marine invertebrates is the same as that of seawater (although the concentrations of particular solutes, such as  $\text{Mg}^{2+}$ , are not equal). Because the extracellular fluids are isotonic to seawater, no osmotic gradient exists, and there is no tendency for water to leave or enter the body. Such organisms are termed **osmoconformers**—they are in osmotic equilibrium with their environment.

Among the vertebrates, only the primitive hagfish are strict osmoconformers. The sharks and their relatives in the class Chondrichthyes (cartilaginous fish) are also isotonic to seawater, even though their blood level of NaCl is lower than that of seawater; the difference in total osmolarity is made up by retaining urea, as described later on.

### Osmoregulators control their osmolarity internally

All other vertebrates are **osmoregulators**—that is, animals that maintain a relatively constant blood osmolarity despite

the different concentration in the surrounding environment. The maintenance of a relatively constant body fluid osmolarity has permitted vertebrates to exploit a wide variety of ecological niches. Achieving this constancy, however, requires continuous regulation.

Freshwater vertebrates have a much higher solute concentration in their body fluids than that of the surrounding water. In other words, they are hypertonic to their environment. Because of their cells' higher osmotic pressure, water tends to enter their bodies. Consequently, they have adapted to prevent water from entering their bodies as much as possible and to eliminate the excess water that does enter. In addition, freshwater vertebrates tend to lose inorganic ions to their environment and so must actively transport these ions back into their bodies.

In contrast, most marine vertebrates are hypotonic to their environment; their body fluids have only about one-third the osmolarity of the surrounding seawater. These animals are therefore in danger of losing water by osmosis, and adaptations have evolved to help them retain water to prevent dehydration. They do this by drinking seawater and eliminating the excess ions through kidneys and gills.

The body fluids of terrestrial vertebrates clearly have a higher concentration of water than does the air surrounding them. Therefore, they tend to lose water to the air by evaporation from the skin and lungs. All reptiles, birds, and mammals, as well as amphibians during the time when they live on land, face this problem. Urinary/osmoregulatory systems have evolved in these vertebrates that help them retain water.

### Learning Outcomes Review 51.1

Osmotic balance must be maintained so that tissues can carry out metabolic functions. Physiological mechanisms help most vertebrates keep blood osmolarity and ion concentrations relatively constant. Marine invertebrates are osmoconformers; their body fluids are isotonic to their environment. Most vertebrates are osmoregulators; their body fluids are either hypertonic or hypotonic compared to their environment.

- During osmosis, does water move toward regions of higher or lower osmolarity?

## 51.2 Osmoregulatory Organs

### Learning Outcomes

1. Describe invertebrate osmoregulatory organs.
2. Define reabsorption and secretion.

A variety of mechanisms have evolved in animals to cope with problems of water balance. In many animals, the removal of water or salts from the body is coupled with the removal of metabolic wastes through the excretory system. Single-celled protists employ contractile vacuoles for this purpose, as do sponges. Other multicellular animals have a system of excretory

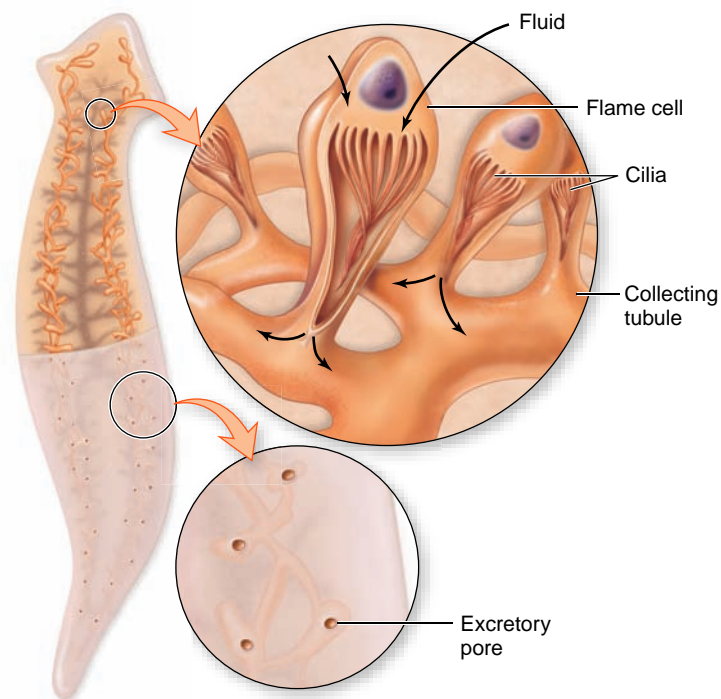

tubules (little tubes) that expel fluid and wastes from the body. In addition, more elaborate systems can be found in invertebrates. In vertebrates, the urinary system is highly complex.

### Invertebrates make use of specialized cells and tubules

In flatworms, tubules called **protonephridia** branch throughout the body into bulblike flame cells (figure 51.2). Although these simple excretory structures open to the outside of the body, they do not open to the inside; rather, the movement of cilia within the flame cells must draw in fluid from the body. Water and metabolites are then reabsorbed, and the substances to be excreted are expelled through excretory pores.

Other invertebrates have a system of tubules that open both to the inside and to the outside of the body. In the earthworm, these tubules are known as nephridia (orange structures in figure 51.3). The nephridia obtain fluid from the body cavity through a process of filtration into funnel-shaped structures called *nephrostomes*. The term *filtration* is used because the fluid is formed under pressure and passes through small openings, so that molecules larger than a certain size are excluded. This filtered fluid is isotonic to the fluid in the coelom, but as it passes through the tubules of the nephridia, NaCl is removed by active transport processes.

The general term for transport out of the tubule and into the surrounding body fluids is **reabsorption**. Because salt is

**Figure 51.2 The protonephridia of flatworms.** A branching system of tubules, bulblike flame cells, and excretory pores make up the protonephridia of flatworms. Cilia inside the flame cells draw in fluids from the body by their beating action. Substances are then expelled through pores that open to the outside of the body.

**Figure 51.3** The nephridia of annelids. Most invertebrates, such as the annelid shown here, have nephridia (orange). These consist of tubules that receive a filtrate of coelomic fluid, which enters the funnel-like nephrostomes. Salt can be reabsorbed from these tubules, and the fluid that remains, urine, is released from pores into the external environment.

reabsorbed from the filtrate, the urine excreted is more dilute than the body fluids—that is, the urine is hypotonic. The kidneys of mollusks and the excretory organs of crustaceans (called *antennal glands*) also produce urine by filtration and reclaim certain ions by reabsorption.

## Insects have a unique osmoregulatory system

The excretory organs in insects are the Malpighian tubules (figure 51.4), extensions of the digestive tract that branch off anterior to the hindgut. Urine is not formed by filtration in these tubules because there is no pressure difference between the blood in the body cavity and the tubule. Instead, waste molecules and potassium ( $K^+$ ) ions are secreted into the tubules by active transport.

**Secretion** is the opposite of reabsorption—ions or molecules are transported from the body fluid into the tubule. The secretion of  $K^+$  creates an osmotic gradient that causes water to enter the tubules by osmosis from the body's open circulatory system. Most of the water and  $K^+$  is then reabsorbed into the circulatory system through the epithelium of the hindgut, leaving only small molecules and waste products to be excreted from the rectum along with feces. Malpighian tubules thus provide a very efficient means of water conservation.

## The vertebrate kidney filters and then reabsorbs

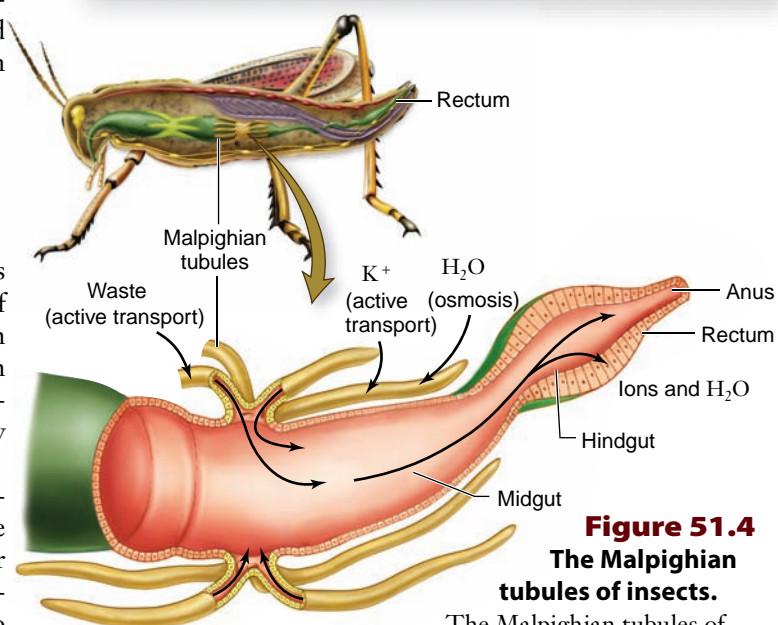

The **kidneys** of vertebrates, unlike the Malpighian tubules of insects, create a tubular fluid by filtering the blood under pressure. In addition to waste products and water, the filtrate contains many small molecules, including glucose, amino acids, and vitamins, that are of value to the animal. These molecules and most of the water are reabsorbed from the tubules into the blood, while wastes remain in the filtrate. Additional wastes may be secreted by the tubules and added to the filtrate, and the final waste product, urine, is eliminated from the body.

It may seem odd that the vertebrate kidney should filter out almost everything from blood plasma (except proteins, which are too large to be filtered) and then spend energy to take back or reabsorb what the body needs. But selective reabsorption provides great flexibility. Various vertebrate groups have evolved the ability to reabsorb molecules that are especially valuable in particular habitats. This flexibility is a key factor underlying the successful colonization of many diverse environments by the vertebrates. In the rest of this chapter, we focus on the vertebrate kidney and its elimination of waste materials, notably nitrogen compounds.

### Learning Outcomes Review 51.2

Many invertebrates filter fluid into a system of tubules and then reabsorb ions and water, leaving waste products for excretion. Insects create an excretory fluid by secreting  $K^+$  and waste products into tubules, which draw water osmotically. The vertebrate kidney produces a filtrate that enters tubules and is modified to become urine.

- How are the function of Malpighian tubules and kidneys similar?

**Figure 51.4** The Malpighian tubules of insects.

The Malpighian tubules of insects are extensions of the digestive tract that collect water and wastes from the body's circulatory system.  $K^+$  is secreted into these tubules, drawing water with it osmotically. Much of this water (arrows) is reabsorbed across the wall of the hindgut.

## 51.3 Evolution of the Vertebrate Kidney

### Learning Outcomes

1. Contrast osmotic adaptations of freshwater fish with those of marine fish.
2. Explain the significance of the loop of Henle in mammalian and avian kidneys.

The kidney is a complex organ made up of thousands of repeating units called **nephrons**, each with the structure of a loop that penetrates deep into the medulla of the kidney (shown schematically in figure 51.5). Blood pressure forces the fluid in blood out of a ball of capillaries called the *glomerulus* into *Bowman's capsule*, the beginning of the tubule system. This process filters the blood forming the tubular filtrate that can then be modified by the rest of the nephron. The glomerulus retains blood cells, proteins, and other useful large molecules in the blood, but it allows the water, and the small molecules

**Figure 51.5** Organization of the vertebrate nephron.

The nephron tubule is a basic design that has been retained in the kidneys of vertebrates. Sugars, amino acids, water, important monovalent ions, and divalent ions are reabsorbed in the proximal arm; water and monovalent ions such as Na<sup>+</sup> and Cl<sup>-</sup> are reabsorbed in the loop of Henle; varying amounts of water and monovalent ions (Na<sup>+</sup> and Cl<sup>-</sup>) can be reabsorbed in the distal arm and the collecting duct, depending on hormonal influences.

and wastes dissolved in it, to pass through and into the tubule system of the nephron. As the filtered fluid passes through the nephron tube, useful nutrients and ions are reabsorbed from it by both active and passive transport mechanisms, leaving the water and metabolic wastes behind in a fluid urine. (The details of this process are described in a later section.)

Although the same basic design has been retained in all vertebrate kidneys, a few modifications have occurred. Because the original glomerular filtrate is isotonic to blood, all vertebrates can produce a urine that is isotonic to blood by reabsorbing ions and water in equal proportions. Or, they can produce a urine that is hypotonic to blood—more dilute than the blood—by reabsorbing relatively less water. Only birds and mammals can reabsorb enough water from their glomerular filtrate to produce a urine that is hypertonic to blood—more concentrated than the blood—by reabsorbing relatively more water.

### Freshwater fishes must retain electrolytes and keep water out

Kidneys are thought to have evolved among the freshwater teleosts, or bony fishes. Because the body fluids of a freshwater fish are hypertonic with respect to the surrounding water, these animals face two serious problems: (1) Water tends to enter the body from the environment; and (2) solutes tend to leave the body and enter the environment.

Freshwater fish address the first problem by *not* drinking water and by excreting a large volume of dilute urine, which is hypotonic to their body fluids. They address the second problem by reabsorbing ions across the nephron tubules, from the glomerular filtrate back into the blood. In addition, they actively transport ions across their gill surfaces from the surrounding water into the blood (figure 51.6, left).

### Marine bony fishes must excrete electrolytes and keep water in

Although most groups of animals seem to have evolved first in the sea, marine bony fish (teleosts) probably evolved from freshwater ancestors. They faced significant new problems in making the transition to the sea because their body fluids were, and are, hypotonic to seawater. Consequently, water tends to leave their bodies by osmosis across their gills, and they also lose water in their urine. To compensate for this continuous water loss, marine fish drink large amounts of seawater (figure 51.6, right).

Many of the divalent cations (principally, Ca<sup>2+</sup> and Mg<sup>2+</sup>) in the seawater that a marine fish drinks remain in the digestive tract and are eliminated through the anus. Some, however, are absorbed into the blood, as are the monovalent ions K<sup>+</sup>, Na<sup>+</sup>, and Cl<sup>-</sup>. Most of the monovalent ions are actively transported out of the blood across the gill surfaces, whereas the divalent ions that enter the blood are secreted into the nephron tubules and excreted in the urine. In these two ways, marine bony fish eliminate the ions they get from the seawater they drink. The urine they excrete is isotonic to their body fluids. It is more concentrated than the urine of freshwater fish, but not as concentrated as that of birds and mammals.

**Figure 51.6 Freshwater and marine teleosts face different osmotic problems.** Whereas the freshwater teleost is hypertonic to its environment, the marine teleost is hypotonic to seawater. To compensate for its tendency to take in water and lose ions, a freshwater fish excretes dilute urine, avoids drinking water, and reabsorbs ions across the nephron tubules. To compensate for its osmotic loss of water, the marine teleost drinks seawater and eliminates the excess ions through active transport across epithelia in the gills and kidneys.

## Cartilaginous fishes pump out electrolytes and retain urea

The elasmobranchs, including sharks and rays, are by far the most common subclass in the class Chondrichthyes (cartilaginous fish). Elasmobranchs have solved the osmotic problem posed by their seawater environment in a different way. Instead of having body fluids that are hypotonic to seawater, so that they have to continuously drink seawater and actively pump out ions, the elasmobranchs reabsorb urea from the nephron tubules and maintain a blood urea concentration that is 100 times higher than that of mammals.

The added urea makes elasmobranchs' blood approximately isotonic to the surrounding sea. Because no net water movement occurs between isotonic solutions, water loss is therefore prevented. As a result, these fishes do not need to drink seawater for osmotic balance, and their kidneys and gills do not have to remove large amounts of ions from their bodies. The enzymes and tissues of the cartilaginous fish have evolved to tolerate the high urea concentrations.

## Amphibians and reptiles have osmotic adaptations to their environments

The first terrestrial vertebrates were the amphibians, and the amphibian kidney is identical to that of freshwater fish. This is not surprising because amphibians spend a significant portion of their time in fresh water, and when on land, they generally stay in wet places. Amphibians produce a very dilute urine and compensate for their loss of  $\text{Na}^+$  by actively transporting  $\text{Na}^+$  across their skin from the surrounding water.

Reptiles, on the other hand, live in diverse habitats. Those living mainly in fresh water occupy a habitat similar to that of the freshwater fish and amphibians, and thus have similar kidneys. Marine reptiles, including some crocodylians, sea turtles, sea snakes, and one lizard, possess kidneys similar to those of their freshwater relatives, but they face opposite problems—they tend to lose water and take in salts. Like marine bony fish, they drink seawater and excrete an isotonic urine. Marine reptiles eliminate excess salt through salt glands located near the nose or the eye.

The kidneys of terrestrial reptiles also reabsorb much of the salt and water in their nephron tubules, helping somewhat to conserve blood volume in dry environments. Like fish and amphibians, they cannot produce urine that is more concentrated than the blood plasma; however, they don't really excrete urine, but instead empty it into a cloaca (the common exit of the digestive and urinary tracts), where additional water can be reabsorbed and the wastes excreted with the feces.

## Mammals and birds are able to excrete concentrated urine and retain water

Mammals and birds are the only vertebrates able to produce urine with a higher osmotic concentration than their body fluids. These vertebrates are therefore able to excrete their waste products in a small volume of water, so that more water can be retained in the body.

Human kidneys can produce urine that is as much as 4.2 times as concentrated as blood plasma, but the kidneys of some other mammals are even more efficient at conserving water. For example, camels, gerbils, and pocket mice of the genus *Perognathus*

**Figure 51.7** How marine birds cope with excess salt.

Marine birds drink seawater and then excrete the salt through salt glands. The extremely salty fluid excreted by these glands can then dribble down the beak.

can excrete urine that is 8, 14, and 22 times as concentrated as their blood plasma, respectively. The kidneys of kangaroo rats (genus *Dipodomys*) are so efficient that they never have to drink water; they can obtain all the water they need from their food and from water produced in aerobic cellular respiration.

The production of hypertonic urine is accomplished by the *loop of Henle* portion of the nephron (see figures 51.5 and 51.11), found only in mammals and birds. The degree of concentration depends on the length of the loop; most mammals have some nephrons with short loops and other nephrons with much longer loops. Birds, however, have relatively few or no nephrons with long loops, so they cannot produce urine that is as concentrated as that of mammals. At most, they can only reabsorb enough water to produce a urine that is about twice the concentration of their blood. Marine birds solve the problem of water loss by drinking salt water and then excreting the excess salt from salt glands near the eyes (figure 51.7).

The moderately hypertonic urine of a bird is delivered to its cloaca, along with the fecal material from its digestive tract. If needed, additional water can be absorbed across the wall of the cloaca to produce a semisolid white paste or pellet, which is excreted.

### Learning Outcomes Review 51.3

The kidneys of freshwater fishes must excrete copious amounts of very dilute urine. Marine bony fishes drink seawater and excrete an isotonic urine; cartilaginous fishes retain urea, which prevents water loss. In mammals and birds, the loop of Henle allows reabsorption of water from the urine, making it hypertonic to their body fluids.

- *Mammals and birds have nephrons with a loop of Henle, but reptiles do not. What are the possible evolutionary explanations for this?*

## 51.4 Nitrogenous Wastes: Ammonia, Urea, and Uric Acid

### Learning Outcome

1. Describe the different kinds of nitrogenous waste and their relative toxicity.

Amino acids and nucleic acids are nitrogen-containing molecules. When animals catabolize these molecules for energy or convert them into carbohydrates or lipids, they produce nitrogen-containing by-products called *nitrogenous wastes* (figure 51.8) that must be eliminated from the body.

### Ammonia is toxic and must be quickly removed

The first step in the metabolism of amino acids and nucleic acids is the deamination, that is, removal of the amino ( $-\text{NH}_2$ ) group, and its combination with  $\text{H}^+$  to form *ammonia* ( $\text{NH}_3$ ) in the liver. Ammonia is quite toxic to cells and therefore is safe only in very dilute concentrations. The excretion of ammonia is not a problem for the bony fishes and amphibian tadpoles, which eliminate most of it by diffusion through the gills and less by excretion in very dilute urine.

### Urea and uric acid are less toxic but have different solubilities

In elasmobranchs, adult amphibians, and mammals, the nitrogenous wastes are eliminated in the far less toxic form of *urea*. Urea is water-soluble and so can be excreted in large amounts in the urine. It is carried in the bloodstream from its place of synthesis in the liver to the kidneys where it is excreted.

Reptiles, birds, and insects excrete nitrogenous wastes in the form of *uric acid*, which is only slightly soluble in water. As a result of its low solubility, uric acid precipitates and thus can be excreted using very little water. Uric acid forms the pasty white material in bird droppings called *guano*. It costs the animal energy to synthesize uric acid, but this is offset by the conservation of water.

The ability to synthesize uric acid in these groups of animals is also important because their eggs are encased within shells, and nitrogenous wastes build up as the embryo grows within the egg. The formation of uric acid, although a lengthy process that requires considerable energy, produces a compound that crystallizes and precipitates. As a solid precipitate, uric acid is unable to affect the embryo's development even though it is still inside the egg.

Mammals also produce some uric acid, but it is a waste product of the degradation of purine nucleotides, not of amino acids. Most mammals have an enzyme called *uricase*, which converts uric acid into a more soluble derivative, *allantoin*. Only humans, apes, and the Dalmatian dog lack this enzyme, and they must excrete the uric acid. In humans, excessive accumulation of uric acid in the joints produces a condition known as *gout*.

### Learning Outcome Review 51.4

Metabolic breakdown of amino acids and nucleic acids produces ammonia as a by-product. Bony fishes and gilled amphibians excrete ammonia; other vertebrates convert nitrogenous wastes into urea (reptiles and birds) and uric acid (mammals and adult amphibians), which are less toxic. Most mammals produce a small amount of uric acid that is broken down by uricase except in humans, apes, and the Dalmatian dog.

- *Why is nitrogenous waste problematic?*

**Figure 51.8**

**Nitrogenous wastes.**

When amino acids and nucleic acids are metabolized, the immediate by-product is ammonia, which is quite toxic but can be eliminated through the gills of teleost fish. Mammals convert ammonia into urea, which is less toxic. Birds and terrestrial reptiles convert it instead into uric acid, which is insoluble in water. Production of uric acid is the most energetically expensive of the three but also saves the most water.

## 51.5 The Mammalian Kidney

### Learning Outcomes

1. Describe the actions of filtration, reabsorption, and secretion.
2. Name the primary components of the kidney.
3. Describe the main parts of a nephron.

In humans, the kidneys are fist-sized organs located in the lower back. Each kidney receives blood from a renal artery, and from this blood, urine is produced. Urine drains from each kidney through a **ureter**, which carries the urine to a **urinary bladder**.

From the bladder, urine is passed out of the body through the **urethra** (figure 51.9).

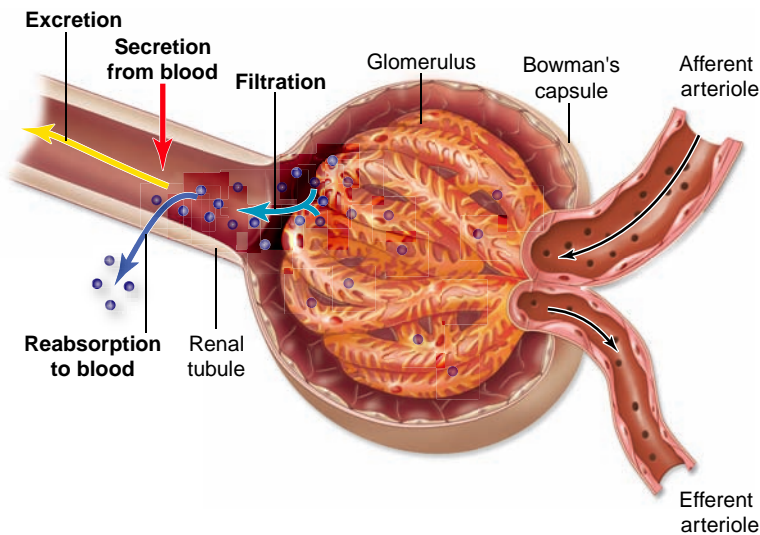

Within the kidney, the mouth of the ureter flares open to form a funnel-like structure, the *renal pelvis*. The renal pelvis, in turn, has cup-shaped extensions that receive urine from the renal tissue. The renal tissue is divided into an outer **renal cortex** and an inner **renal medulla**.

The kidney has three basic functions summarized in figure 51.10:

1. **Filtration:** Fluid in the blood is filtered into the tubule system, leaving cells and large protein in the blood and a filtrate composed of water and all of the blood solutes. This filtrate is modified by the rest of the kidney to produce urine for excretion.

**Figure 51.9 The human renal system.** *a.* The positions of the organs of the urinary system. *b.* A sectioned kidney, revealing the internal structure. *c.* The position of nephrons in the mammalian kidney. Cortical nephrons are located predominantly in the renal cortex; juxtamedullary nephrons have long loops that extend deep into the renal medulla.

**Figure 51.10 Four functions of the kidney.** Molecules enter the urine by filtration out of the glomerulus and by secretion into the tubules from surrounding peritubular capillaries. Molecules that entered the filtrate can be returned to the blood by reabsorption from the tubules into surrounding peritubular capillaries. The fluid exiting the kidney is eliminated from the body by excretion through the tubule to a ureter and then to the bladder.

2. **Reabsorption:** Reabsorption is the selective movement of important solutes such as glucose, amino acids, and a variety of inorganic ions, out of the filtrate in the tubule system to the extracellular fluid, then back into the bloodstream via peritubular capillaries. The process of reabsorption can utilize active or passive processes depending on the solute. Water is also reabsorbed, and this can be controlled to regulate the amount of water loss.
3. **Secretion:** Secretion is the movement of substances from the blood into the extracellular fluid, then into the filtrate in the tubule system. Unlike reabsorption, which preserves substances in the body, this adds to what will be expelled from the body and can be used to remove toxic substances.

### The nephron is the filtering unit of the kidney

On a microscopic level, each kidney contains about a million functioning *nephrons*. Mammalian kidneys contain a mixture of **juxtamedullary nephrons**, which have long loops that dip deeply into the medulla, and **cortical nephrons** with shorter loops. The significance of the length of the loops will be explained a little later.

#### The production of filtrate

Each nephron consists of a long tubule and associated small blood vessels (figure 51.11). First, blood is carried by an *afferent arteriole* to a tuft of capillaries in the renal cortex—the **glomerulus**. Here the blood is filtered as the blood pressure forces fluid through the porous capillary walls. Blood cells

**Figure 51.11**  
**A nephron in a mammalian kidney.**

The nephron tubule is surrounded by peritubular capillaries in the cortex, and their vasa recta extensions surround the loop of Henle in the medulla. This capillary bed carries away molecules and ions that are reabsorbed from the filtrate.

and plasma proteins are too large to enter this glomerular filtrate, but large amounts of the plasma, consisting of water and dissolved molecules, leave the vascular system at this step. The filtrate immediately enters the first region of the nephron tubules. This region, **Bowman's capsule**, envelops the glomerulus much as a large, soft balloon surrounds your hand if you press your fist into it. The capsule has slit openings so that the glomerular filtrate can enter the system of nephron tubules.

Blood components that were not filtered out of the glomerulus drain into an *efferent arteriole*, which then empties into a second bed of capillaries called **peritubular capillaries** that surround the tubules. This is only one of several locations in the body where two capillary beds occur in series. In juxtamedullary nephrons, efferent arteriole and peritubular capillaries also feed the **vasa recta** capillaries that surround the loop of Henle. As described later, the peritubular capillaries are needed for the processes of reabsorption and secretion.

After the filtrate enters Bowman's capsule, it goes into a portion of the nephron called the **proximal convoluted tubule**, located in the cortex. In a cortical nephron, the fluid then flows through the **loop of Henle** that dips only minimally into the medulla before ascending back into the cortex. In juxtamedullary nephrons, the loop of Henle extends much deeper into the medulla before ascending back up into the cortex. More water can be reabsorbed from juxtamedullary nephrons than from cortical nephrons. The fluid then moves deeper into the medulla and back up again into the cortex in a loop of Henle. As mentioned earlier, only the kidneys of mammals and birds have loops of Henle, and this is why only birds and mammals have the ability to concentrate their urine.

### Collection of urine

After leaving the loop, the fluid is delivered to a **distal convoluted tubule** in the cortex that next drains into a **collecting duct**. The collecting duct again descends into the medulla, where it merges

with other collecting ducts to empty its contents, now called urine, into the renal pelvis.

## **Water, some nutrients, and some ions are reabsorbed; other molecules are secreted**

Most of the water and dissolved solutes that enter the glomerular filtrate must be returned to the blood by reabsorption, or the animal would literally urinate to death. In a human, for example, approximately 2000 L of blood passes through the kidneys each day, and 180 L of water leaves the blood and enters the glomerular filtrate.

### **Water**

Because humans have a total blood volume of only about 5 L and produce only 1 to 2 L of urine per day, it is obvious that each liter of blood is filtered many times per day, and most of the filtered water is reabsorbed. Water is reabsorbed from the filtrate by the proximal convoluted tubule, as it passes through the descending loop of Henle and the collecting duct. The selective reabsorption in the collecting duct is driven by an osmotic gradient produced by the loop of Henle, as is described shortly.

### **Glucose and other nutrients**

The reabsorption of glucose, amino acids, and many other molecules needed by the body is driven by active transport and secondary active transport (cotransport) carriers. As in all carrier-mediated transport, a maximum rate of transport is reached whenever the carriers are saturated (see chapter 5).

In the case of the renal glucose carriers in the proximal convoluted tubule, saturation occurs when the concentration of glucose in the blood (and thus in the glomerular filtrate) is about 180 mg/100 mL of blood. If a person has a blood glucose concentration in excess of this amount, as happens in untreated diabetes mellitus, the glucose remaining in the filtrate is expelled in the urine. Indeed, the presence of glucose in the urine is diagnostic of diabetes mellitus.

### **Secretion of wastes**

The secretion of foreign molecules and particular waste products of the body involves the transport of these molecules across the membranes of the blood capillaries and kidney tubules into the filtrate. This process is similar to reabsorption, but it proceeds in the opposite direction.

Some secreted molecules are eliminated in the urine so rapidly that they may be cleared from the blood in a single pass through the kidneys. This rapid elimination explains why penicillin, which is secreted by the nephrons, must be administered in very high doses and several times per day.

## **Excretion of toxins and excess ions maintains homeostasis**

A major function of the kidney is the elimination of a variety of potentially harmful substances that animals eat and drink. In addition, urine contains nitrogenous wastes, described earlier, that are products of the catabolism of amino acids and nucleic

acids. Urine may also contain excess  $K^+$ ,  $H^+$ , and other ions that are removed from the blood.

Urine's generally high  $H^+$  concentration (pH 5 to 7) helps maintain the acid–base balance of the blood within a narrow range (pH 7.35 to 7.45). Moreover, the excretion of water in urine contributes to the maintenance of blood volume and pressure (see chapter 50); the larger the volume of urine excreted, the lower the blood volume.

The purpose of kidney function is therefore homeostasis; the kidneys are critically involved in maintaining the constancy of the internal environment. When disease interferes with kidney function, it causes a rise in the blood concentration of nitrogenous waste products, disturbances in electrolyte and acid–base balance, and a failure in blood pressure regulation. Such potentially fatal changes highlight the central importance of the kidneys in normal body physiology.

## **Each part of the mammalian nephron performs a specific transport function**

As previously described, approximately 180 L of isotonic glomerular filtrate enters the Bowman's capsules of human kidneys each day. After passing through the remainder of the nephron tubules, this volume of fluid would be lost as urine if it were not reabsorbed back into the blood. It is clearly impossible to produce this much urine, yet water is only able to pass through a cell membrane by osmosis, and osmosis is not possible between two isotonic solutions. Therefore, some mechanism is needed to create an osmotic gradient between the glomerular filtrate and the blood, to allow reabsorption of water.

### **Proximal convoluted tubule**

Virtually all the nutrient molecules in the filtrate are reabsorbed back into the systemic blood by the proximal convoluted tubule. In addition, approximately two-thirds of the NaCl and water filtered into Bowman's capsule is immediately reabsorbed across the walls of the proximal convoluted tubule.

This reabsorption is driven by the active transport of  $Na^+$  out of the filtrate and into surrounding peritubular capillaries.  $Cl^-$  follows  $Na^+$  passively because of electrical attraction, and water follows them both because of osmosis. Because NaCl and water are removed from the filtrate in proportionate amounts, the filtrate that remains in the tubule is still isotonic to the blood plasma.

Although only one-third of the initial volume of filtrate remains in the nephron tubule after the initial reabsorption of NaCl and water, it still represents a large volume (60 L out of the original 180 L of filtrate). Obviously, no animal can afford to excrete that much urine, so most of this water must also be reabsorbed. It is reabsorbed primarily across the wall of the collecting duct.

### **Loop of Henle**

The function of the loop of Henle is to create a gradient of increasing osmolarity from the cortex to the medulla. This allows water to be reabsorbed by osmosis in the collecting duct as it runs down into the medulla past the loop of Henle. The

descending and ascending limbs of the loop of Henle differ structurally and in their permeability to ions and water. This produces a gradient of increasing osmolarity from cortex to medulla (figure 51.12). The structure of the loop also forms another example of a countercurrent system, this time acting to increase the osmolarity of interstitial fluid. To understand the functioning of the loop of Henle, it is easiest to start in the ascending limb:

1. The entire ascending limb is impermeable to water. The thick portion of the ascending limb actively transports  $\text{Na}^+$  out of the tubule, with  $\text{Cl}^-$  passively following. The thin ascending limb is permeable to both  $\text{Na}^+$  and  $\text{Cl}^-$ , which move out by diffusion.
2. The descending limb is thin and permeable to water but not to  $\text{NaCl}$ . Because of the  $\text{Na}^+$  and  $\text{Cl}^-$  lost by the ascending limb, the osmolarity of the interstitial fluid is higher than in the descending limb, and water moves out of the descending limb by osmosis. This also increases the osmolarity of the fluid in the tubule such that as it turns at the bottom, it will lose  $\text{NaCl}$  by diffusion in the thin ascending loop as described earlier.

**Figure 51.12 The reabsorption of salt and water in the mammalian kidney.** Active transport of  $\text{Na}^+$  out of the proximal tubules is followed by the passive movement of  $\text{Cl}^-$  and water. Active extrusion of  $\text{NaCl}$  from the ascending limb of the loop of Henle creates the osmotic gradient required for the reabsorption of water from the descending limb of the loop of Henle and the collecting duct. The two limbs of the loop form a countercurrent multiplier system that increases the osmotic gradient. The changes in osmolarity from the cortex to the medulla are indicated to the left of the figure.

3. The loss of water from the descending limb multiplies the concentration that can be achieved at each level of the loop through the active extrusion of  $\text{Na}^+$  (with  $\text{Cl}^-$  following passively) by the ascending limb. The longer the loop of Henle, the longer the region of interaction between the descending and ascending limbs, and the greater the total concentration that can be achieved. In a human kidney, the concentration of filtrate entering the loop is 300 milliosmolar (mOsm), and this concentration is multiplied to more than 1200 mOsm at the bottom of the longest loops of Henle in the renal medulla.
4. The  $\text{NaCl}$  pumped out of the ascending limb of the loop is reabsorbed from the surrounding interstitial fluid into the loops of the *vasa recta*, so that  $\text{NaCl}$  can diffuse from the blood leaving the medulla to the blood entering the medulla. Thus, the *vasa recta* also functions in a countercurrent exchange, similar to that described for the countercurrent flow of blood in the fins of large aquatic vertebrates for heat exchange (see chapter 43), and of water and blood through gills to enhance oxygen exchange (see chapter 49). In the case of the *vasa recta*, this exchange prevents the flow of blood through the capillaries from destroying the osmotic gradient established by the loop of Henle. Thus, blood can be supplied to this region of the kidney without affecting the ability of the collecting duct to selectively reabsorb water.

Because fluid flows in opposite directions in the two limbs of the loop, the action of the loop of Henle in creating a hypertonic renal medulla is known as the countercurrent multiplier system. The osmotic gradient that is established is greater than what would be produced by just active transport of salts out of the tubule system.

The high solute concentration of the renal medulla is primarily the result of  $\text{NaCl}$  accumulation by the countercurrent multiplier system, but urea also contributes to the total osmolarity of the medulla. The descending limb of the loop of Henle and the collecting duct are both permeable to urea, which leaves these regions of the nephron by diffusion.

### Distal convoluted tubule and collecting duct

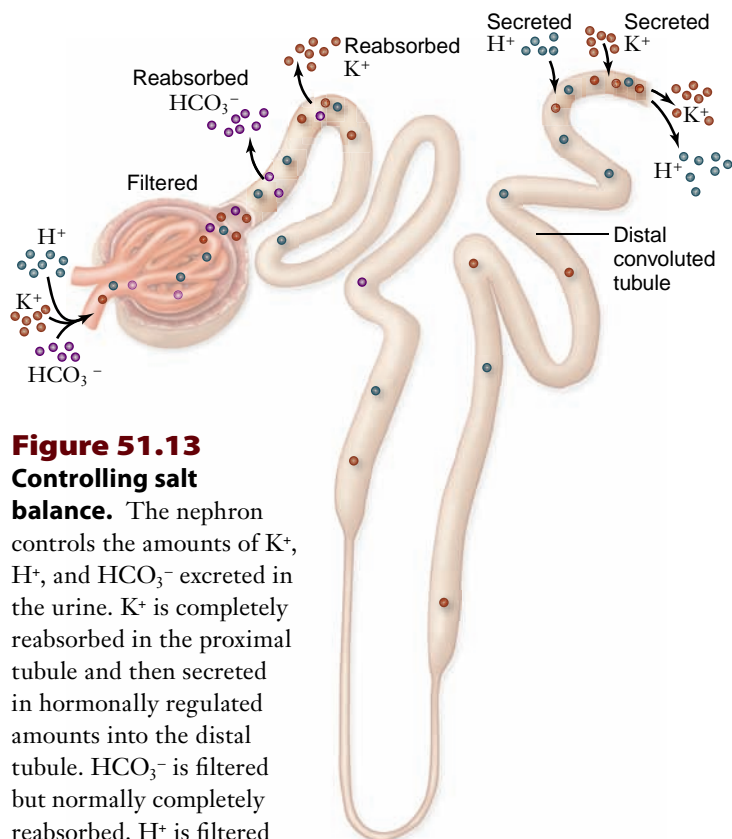

Because  $\text{NaCl}$  was pumped out of the ascending limb, the filtrate that arrives at the distal convoluted tubule and enters the collecting duct in the renal cortex is hypotonic (with a concentration of only 100 mOsm). The collecting duct carrying this dilute fluid now plunges into the medulla. As a result of the hypertonic interstitial fluid of the renal medulla, a strong osmotic gradient pulls water out of the collecting duct and into the surrounding blood vessels.

The osmotic gradient is normally constant, but the permeability of the distal convoluted tubule and the collecting duct to water is adjusted by a hormone, *antidiuretic hormone* (ADH), mentioned in chapters 46 and 50. When an animal needs to conserve water, the posterior pituitary gland secretes more ADH, and this hormone increases the number of water channels in the plasma membranes of the collecting duct cells. This increases the permeability of the collecting ducts to water so that more water is reabsorbed and less is excreted in the urine. The animal thus excretes a hypertonic urine.

## 51.6 Hormonal Control of Osmoregulatory Functions

### Learning Outcomes

1. Explain the actions of ADH, aldosterone, and ANH.
2. Describe the relationship between control of blood osmolarity and blood pressure.

**Figure 51.13**  
**Controlling salt balance.** The nephron controls the amounts of  $K^+$ ,  $H^+$ , and  $HCO_3^-$  excreted in the urine.  $K^+$  is completely reabsorbed in the proximal tubule and then secreted in hormonally regulated amounts into the distal tubule.  $HCO_3^-$  is filtered but normally completely reabsorbed.  $H^+$  is filtered and also secreted into the distal tubule, so that the final urine has an acidic pH.

In addition to regulating water balance, the kidneys regulate the balance of electrolytes in the blood by reabsorption and secretion. For example, the kidneys reabsorb  $K^+$  in the proximal tubule and then secrete an amount of  $K^+$  needed to maintain homeostasis into the distal convoluted tubule (figure 51.13). The kidneys also maintain acid–base balance by excreting  $H^+$  into the urine and reabsorbing  $HCO_3^-$ .

The reabsorption of  $NaCl$  in the distal convoluted tubule and collecting duct depends on the needs of the body and is under the control of the hormone *aldosterone*. Both ADH and aldosterone influence the distal convoluted tubule and collecting duct, although aldosterone is more significant in terms of  $NaCl$ . We present more about hormonal control of excretion in the next section.

### Learning Outcomes Review 51.5

Fluid and certain solutes move out of the blood and into the tubular systems of the kidneys through filtration (passive) and secretion (transported); important solutes and water are returned to the blood through reabsorption. The mammalian kidney is divided into a cortex and a medulla and contains about a million nephrons. The parts of a nephron include the glomerulus and Bowman's capsule, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct.

- The compound mannitol is filtered but cannot be reabsorbed. How would this affect the volume of urine produced?

In mammals and birds, the amount of water excreted in the urine, and thus the concentration of the urine, varies according to the changing needs of the body. Acting through the mechanisms described next, the kidneys excrete a hypertonic urine when the body needs to conserve water. If an animal drinks excess water, the kidneys excrete a hypotonic urine.

As a result, the volume of blood, the blood pressure, and the osmolarity of blood plasma are maintained relatively constant by the kidneys, no matter how much water you drink. The kidneys also regulate the plasma  $K^+$  and  $Na^+$  concentrations and blood pH within very narrow limits. These homeostatic functions of the kidneys are coordinated primarily by hormones.

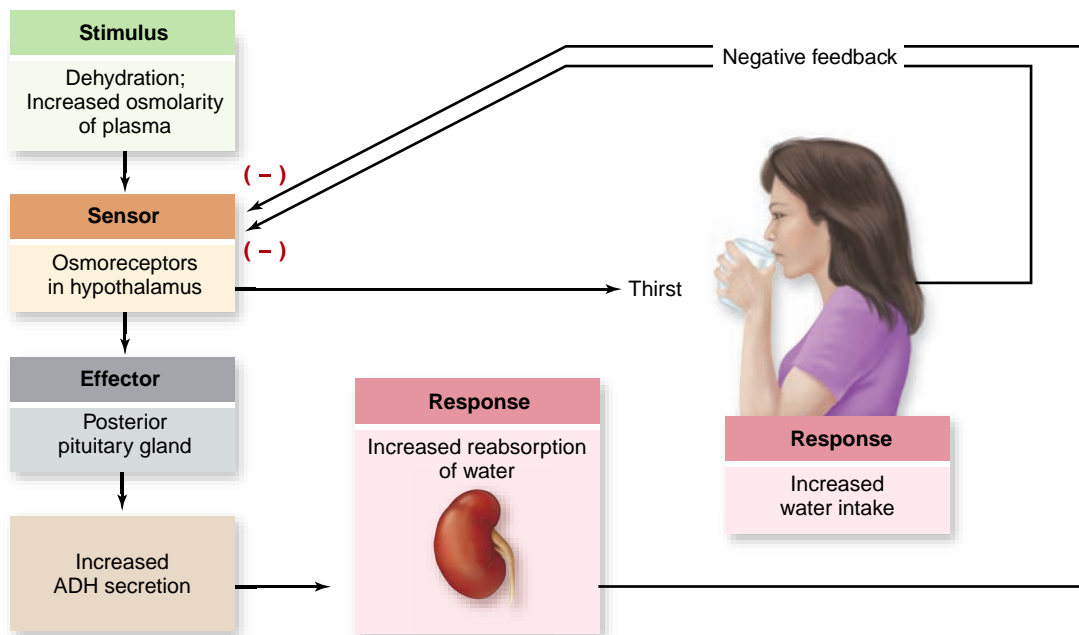

### Antidiuretic hormone causes water to be conserved

*Antidiuretic hormone (ADH)* is produced by the hypothalamus and secreted by the posterior-pituitary gland. The primary stimulus for ADH secretion is an increase in the osmolarity of the blood plasma. When a person is dehydrated or eats salty food, the osmolarity of plasma increases. Osmoreceptors in the hypothalamus respond to the elevated blood osmolarity by sending increasing action potentials to the integration center (also in the hypothalamus). This, in turn, triggers a sensation of thirst and an increase in the secretion of ADH (figure 51.14).

ADH causes the walls of the distal convoluted tubules and collecting ducts in the kidney to become more permeable to water. Water channels called aquaporins (see chapter 5) are contained within the membranes of intracellular vesicles in the epithelium of the distal convoluted tubules and collecting ducts; ADH stimulates the fusion of the vesicle membrane with the plasma membrane, similar to the process of exocytosis. The aquaporins are now in place and allow water to flow out of the tubules and ducts in response to the hypertonic condition of the renal medulla. This water is reabsorbed into the bloodstream.

When secretion of ADH is reduced, the plasma membrane pinches in to form new vesicles that contain aquaporins. This removes the aquaporins from the plasma membrane of the distal convoluted tubule and collecting duct, making them less permeable to water. Thus more water is excreted in urine.

Under conditions of maximal ADH secretion, a person excretes only 600 mL of highly concentrated urine per day. A person who lacks ADH due to pituitary damage has the disorder known as *diabetes insipidus* and constantly excretes a large volume

**Figure 51.14** Antidiuretic hormone stimulates the reabsorption of water by the kidneys. This action completes a negative feedback loop and helps to maintain homeostasis of blood volume and osmolarity.

of dilute urine. Such a person is in danger of becoming severely dehydrated and succumbing to dangerously low blood pressure.

Homeostasis via ADH action is also affected by the common drugs ethanol and caffeine, both of which inhibit secretion of ADH. This is the basis for the dehydration that is the after effect of drinking too much alcohol.

### Aldosterone and atrial natriuretic hormone control sodium ion concentration

Sodium ions are the major solute in the blood plasma. When the blood concentration of  $\text{Na}^+$  falls, therefore, the blood osmolarity also falls. This drop in osmolarity inhibits ADH secretion, causing more water to remain in the collecting duct for excretion in the urine. As a result, the blood volume and blood pressure decrease.

A decrease in extracellular  $\text{Na}^+$  also causes more water to be drawn into cells by osmosis, partially offsetting the drop in plasma osmolarity, but further decreasing blood volume and blood pressure. If  $\text{Na}^+$  deprivation is severe, the blood volume may fall so low that blood pressure is insufficient to sustain life. For this reason, salt is necessary for life. Many animals have a “salt hunger” and actively seek salt, such as when deer gather at “salt licks.”

A drop in blood  $\text{Na}^+$  concentration is normally compensated for by the kidneys under the influence of the hormone *aldosterone*, which is secreted by the adrenal cortex. Aldosterone stimulates the distal convoluted tubules and collecting ducts to reabsorb  $\text{Na}^+$ , decreasing the excretion of  $\text{Na}^+$  in the urine. Indeed, under conditions of maximal aldosterone secretion,  $\text{Na}^+$  may be completely absent from the urine. The reabsorption of  $\text{Na}^+$  is followed by reabsorption of  $\text{Cl}^-$  and water, so aldosterone has the net effect of promoting the retention of both salt

and water. It thereby helps to maintain blood volume, osmolarity, and pressure.

The secretion of aldosterone in response to a decreased blood level of  $\text{Na}^+$  is indirect. Because a fall in blood  $\text{Na}^+$  is accompanied by decreased blood volume, the flow of blood past a group of cells called the juxtaglomerular apparatus is reduced. The juxtaglomerular apparatus is located in the region of the kidney between the distal convoluted tubule and the afferent arteriole (figure 51.15).

When blood flow is reduced, the juxtaglomerular apparatus responds by secreting the enzyme *renin* into the blood (figure 51.16). Renin catalyzes the production of the polypeptide angiotensin I from the protein angiotensinogen. Angiotensin I is then converted by

another enzyme into angiotensin II, which stimulates blood vessels to constrict and the adrenal cortex to secrete aldosterone. Thus, homeostasis of blood volume and pressure can be maintained by the activation of this renin–angiotensin–aldosterone system. In addition to stimulating  $\text{Na}^+$  reabsorption, aldosterone also promotes the secretion of  $\text{K}^+$  into the distal convoluted tubules and collecting ducts. Consequently, aldosterone lowers the blood  $\text{K}^+$  concentration, helping to maintain constant blood  $\text{K}^+$  levels in the face of changing amounts of  $\text{K}^+$  in the diet. People who lack the ability to produce aldosterone will die if untreated because of the excessive loss of salt and water in the urine and the buildup of  $\text{K}^+$  in the blood.

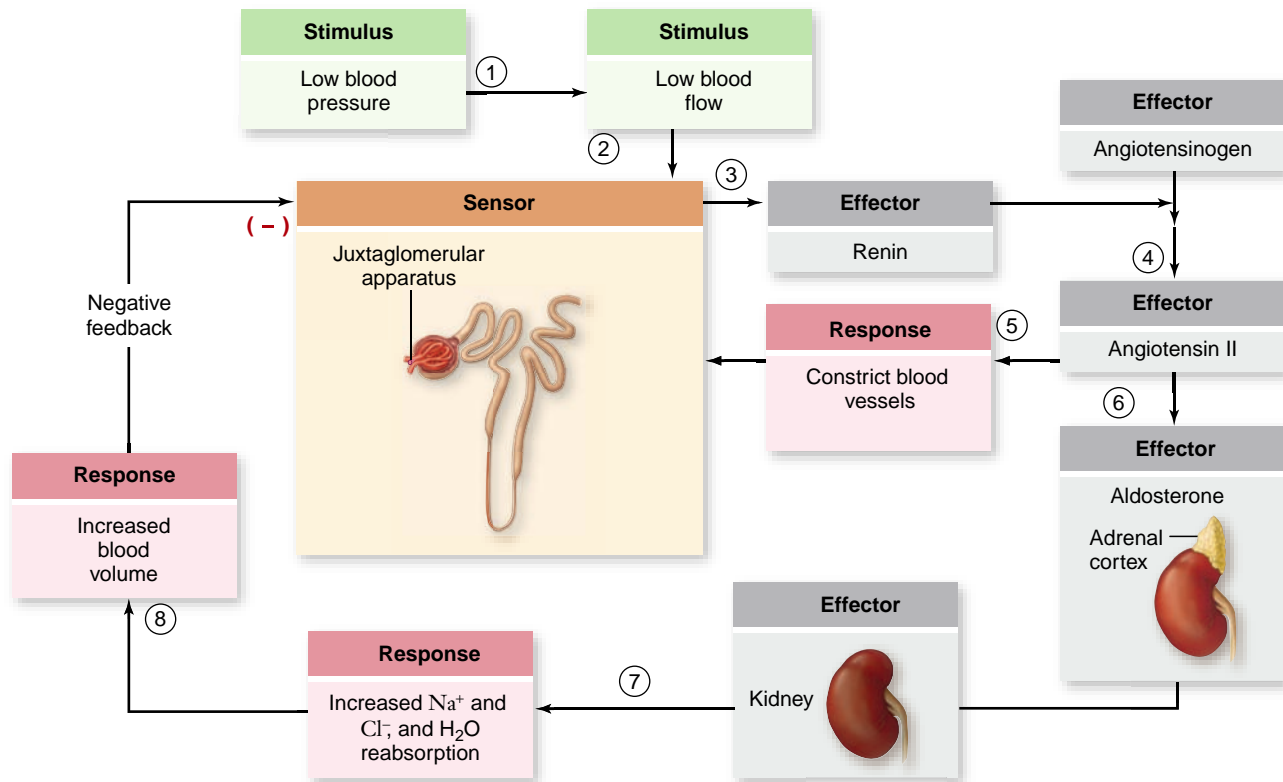

The action of aldosterone in promoting salt and water retention is opposed by another hormone, *atrial natriuretic hormone (ANH)*, mentioned in chapter 50. This hormone is secreted by the right atrium of the heart in response to an increased blood volume, which stretches the atrium. Under these conditions, aldosterone secretion from the adrenal cortex decreases, and ANH secretion increases, thus promoting the excretion of salt and water in the urine and lowering the blood volume.

#### Learning Outcomes Review 51.6

ADH stimulates the insertion of water channels into the cells of the distal convoluted tubule and collecting duct, making them more permeable to water and increasing its reabsorption. Aldosterone promotes reabsorption of  $\text{Na}^+$ ,  $\text{Cl}^-$ , and water across the distal convoluted tubule and collecting duct, as well as the secretion of  $\text{K}^+$  into the tubules. ANH decreases  $\text{Na}^+$  and  $\text{Cl}^-$  reabsorption. When blood osmolarity increases, more water is retained by the release of ADH, and blood pressure increases; if blood osmolarity falls, ADH release is inhibited, less water is retained, and blood pressure drops.

- **What would be the effect of a compound that blocks aquaporin water channels?**

**Figure 51.15** A lowering of blood volume activates the renin–angiotensin–aldosterone system. (1) Low blood volume and a decrease in blood Na<sup>+</sup> levels reduce blood pressure. (2) Reduced blood flow past the juxtaglomerular apparatus triggers (3) the release of renin into the blood, which catalyzes the production of angiotensin I from angiotensinogen. (4) Angiotensin I converts into a more active form, angiotensin II. (5) Angiotensin II stimulates blood vessel constriction and (6) the release of aldosterone from the adrenal cortex. (7) Aldosterone stimulates the reabsorption of Na<sup>+</sup> in the distal convoluted tubules. Increased Na<sup>+</sup> reabsorption is followed by the reabsorption of Cl<sup>-</sup> and water. (8) This increases blood volume. An increase in blood volume may also trigger the release of an atrial natriuretic hormone, which inhibits the release of aldosterone. These two systems work together to maintain homeostasis.

**Figure 51.16** Reduced blood flow to the kidney can cause hypertension.

### SCIENTIFIC THINKING

**Question:** What is the relationship between atherosclerosis and elevated blood pressure?

**Hypothesis:** Atherosclerotic plaques in the renal artery will reduce blood flow to the kidney and consequently filtration pressure. The system will respond by raising blood pressure.

**Prediction:** If blood flow to the renal artery is reduced, this will mimic the effect of plaque deposition and should result in increased blood pressure.

**Test:** Clamp a renal artery to restrict blood flow, and measure blood pressure before, while clamped, and with clamp removed.

**Result:** Clamping the renal artery results in increased blood pressure. This increase is relieved by removing the clamp.

**Conclusion:** Restricting blood flow to the kidney causes a homeostatic response to increase blood pressure.

**Further Experiments:** If this increase in blood pressure involved the renin–angiotensin system, what changes would you expect in the level and function of these proteins?

## Chapter Review

### 51.1 Osmolarity and Osmotic Balance

**Osmotic pressure is a measure of concentration difference.**

Osmotic pressure is a solution's propensity to take in water by osmosis. Osmolarity is defined as moles of solute per liter of solution. Cells in a hypertonic solution lose water, and cells in a hypotonic solution gain water. In an isotonic solution, cells are at equilibrium.

**Osmoconformers live in marine environments.**

Osmoconformers are in osmotic equilibrium with their environment. Most marine invertebrates are osmoconformers.

**Osmoregulators control their osmolarity internally.**

Tissues of freshwater vertebrates are hypertonic to their environment, and those of marine vertebrates are hypotonic; both must maintain their osmolarity. Terrestrial vertebrates are all osmoregulators and have adaptations to retain water.

### 51.2 Osmoregulatory Organs

**Invertebrates make use of specialized cells and tubules.**

Flatworms use tubular protonephridia connected to flame cells that draw fluid from the body (see figure 51.2). Other invertebrates have nephridia open to both the inside and outside of the body for filtering and reabsorption (see figure 51.3).

**Insects have a unique osmoregulatory system.**

Insects have Malpighian tubules through which uric acid and wastes are secreted into the excretory organ, and water and salts are reabsorbed before excretion (see figure 51.4).

**The vertebrate kidney filters then reabsorbs.**

Kidneys of vertebrates produce urine by filtration, secretion, and selective reabsorption of water and important solutes.

### 51.3 Evolution of the Vertebrate Kidney

The kidney is made up of a cortex, a medulla, and thousands of units called nephrons that regulate body fluids (see figure 51.5).

**Freshwater fishes must retain electrolytes and keep water out.**

Freshwater fishes maintain hypertonicity by excreting large quantities dilute, hypotonic urine and reabsorbing ions (see figure 51.6).

**Marine bony fishes must excrete electrolytes and keep water in.**

Saltwater fish maintain hypotonicity by drinking large amounts of seawater and excreting or actively transporting ions out through the gills. Their urine is isotonic to the blood.

**Cartilaginous fishes pump out electrolytes and retain urea.**

Cartilaginous fishes are isotonic to their environment because they retain urea, and actively pump out electrolytes. They also produce isotonic urine.

**Amphibians and reptiles have osmotic adaptations to their environments.**

Freshwater amphibians and reptiles act like freshwater fishes, and the kidneys of marine reptiles function like marine bony fishes. Terrestrial reptiles can't produce hypertonic urine.

**Mammals and birds are able to excrete concentrated urine and retain water.**

Mammals and birds can excrete hypertonic urine and retain water. The degree of concentration of urine depends on the length of the loop of Henle.

### 51.4 Nitrogenous Wastes: Ammonia, Urea, and Uric Acid

**Ammonia is toxic and must be quickly removed.**

When animals catabolize amino acids and nucleic acids they produce toxic nitrogenous wastes (see figure 51.8).

In fishes and gilled amphibians, abundant water is used to flush ammonia quickly from the body, or it is eliminated through gills.

**Urea and uric acid are less toxic but have different solubilities.**

Mammals convert ammonia to urea, which is less toxic. Urea requires less water, but requires energy to manufacture. Birds and terrestrial reptiles convert ammonia to uric acid. Uric acid is the least toxic and requires the least water to eliminate, but is the most energetically expensive.

### 51.5 The Mammalian Kidney (see figure 51.10)

**The nephron is the filtering unit of the kidney.**

Blood is filtered through the capillaries of the glomerulus driven by blood pressure. The filtrate passes through the Bowman's capsule, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct (see figure 51.11). Blood passes from the afferent arteriole to the glomerulus, the efferent arteriole, the peritubular capillaries, and the vasa recta.

**Water, some nutrients, and some ions are reabsorbed; other molecules are secreted.**

Glucose, amino acids, and many other molecules are reabsorbed by active transport. Water is reabsorbed osmotically in the proximal convoluted tubule and the collecting duct. Foreign molecules and some wastes are secreted from the blood capillaries and into the tubules by active transport.

**Excretion of toxins and excess ions maintains homeostasis.**

The kidney eliminates many potentially harmful substances including nitrogenous wastes, excess ions, and toxins. The kidneys therefore are critical to homeostasis.

**Each part of the mammalian nephron performs a specific transport function.**

Reabsorption of nutrients and NaCl occurs in the proximal tubule. The loop of Henle creates a gradient of increasing osmolarity from the cortex to the medulla. The gradient allows selective reabsorption of water from the collecting duct. A longer loop of Henle produces more concentrated urine (see figure 51.12).

### 51.6 Hormonal Control of Osmoregulatory Functions

**Antidiuretic hormone causes water to be conserved.**

ADH, produced by the hypothalamus, increases the permeability of the collecting duct (see figure 51.14), allowing greater reabsorption of water.

**Aldosterone and atrial natriuretic hormone control sodium ion concentration.**

Low Na<sup>+</sup> levels inhibit ADH secretion, and aldosterone stimulates Na<sup>+</sup> uptake by the distal convoluted tubule. ANH antagonizes the action of aldosterone.

## Review Questions

### UNDERSTAND

- Which of the following is *not* an ion homeostatically maintained in vertebrates?
  - $\text{Cl}^-$
  - $\text{Na}^+$
  - $\text{Ca}^{++}$
  - $\text{F}^-$
- Suppose that your research mentor has decided to do a project on the filtering capabilities of Malpighian tubules. Which of the following creatures will you be spending your summer studying?
  - Ants
  - Birds
  - Mammals
  - Earthworms
- A shark's blood is isotonic to the surrounding seawater because of the reabsorption of \_\_\_\_ in its blood.
  - ammonia
  - uric acid
  - urea
  - $\text{NaCl}$
- An important function of the excretory system is to eliminate excess nitrogen produced by metabolic processes. Which of the following organisms is most efficient at packaging nitrogen for excretion?
  - Frog
  - Freshwater fish
  - Iguana
  - Camel
- Which of the following is a function of the kidneys?
  - The kidneys remove harmful substances from the body.
  - The kidneys recapture water for use by the body.
  - The kidneys regulate the levels of salt in the blood.
  - All of these are functions of the kidneys.
- Humans excrete their excess nitrogenous wastes as
  - uric acid crystals.
  - compounds containing protein.
  - ammonia.
  - urea.
- An osmoregulator would maintain its internal fluids at a concentration that is \_\_\_\_ relative to its surroundings.
  - isotonic
  - hypertonic
  - hypotonic
  - hypertonic, hypotonic, or isotonic

### APPLY

- In comparing invertebrate and vertebrate excretory systems, you conclude that
  - both filter body fluids and then reabsorb water and solutes.
  - both use a tubule system to process the filtrate.
  - both reabsorb ions and water to control osmotic balance.
  - only vertebrates filter fluids and reabsorb water and ions.
- A viral infection that specifically interferes with the reabsorption of ions from the glomerular filtrate would attack cells located in the
  - Bowman's capsule.
  - glomerulus.
  - renal tubules.
  - collecting duct.
- Diuretics are drugs that can be used to treat high blood pressure by increasing urinary output. Possible mechanisms of action in the kidney include
  - increasing ADH secretion.
  - inhibition of  $\text{NaCl}$  reabsorption from the loop of Henle or the proximal tubule.
  - increasing permeability of the collecting duct.
  - increasing  $\text{NaCl}$  reabsorption in the proximal tubule.

- Caffeine inhibits the secretion of ADH. Prior to an exam, you have a large coffee. During the exam, you can expect
  - greater water reabsorption from the collecting duct.
  - less water reabsorption from the collecting duct.
  - an increase in reabsorption of glucose from the proximal convoluted tubule.
  - a decrease in reabsorption of glucose from the proximal convoluted tubule.
- You and your study partner want to draw the pathway that controls the reabsorption of sodium ion when blood pressure falls. Which of the following is the correct sequence of events?
  - Aldosterone is released.
  - Kidney tubules reabsorb  $\text{Na}^+$ .
  - Renin is released.
  - Juxtaglomerular apparatus recognizes a drop in blood pressure.
  - Angiotensin II is produced.
  - 1, 3, 5, 2, 4
  - 4, 2, 3, 1, 5
  - 4, 3, 5, 1, 2
  - 2, 4, 3, 1, 5
- You are studying renal function in different species of mammals that are found in very different environments. You look at species from a desert environment and compare them with ones from a tropical environment. The desert species would be expected to have
  - shorter loops of Henle than the tropical species.
  - longer loops of Henle than the tropical species.
  - shorter proximal convoluted tubule than the tropical species.
  - longer distal convoluted tubules than the tropical species.

### SYNTHESIZE

- Indicate the areas of the nephron that the following hormones target, and describe when and how the hormones elicit their actions.
  - Antidiuretic hormone
  - Aldosterone
  - Atrial natriuretic hormone
- John's doctor is concerned that John's kidneys may not be functioning properly due to a circulatory condition. The doctor wants to determine if the blood volume flowing through the kidneys (called renal blood flow rate) is within normal range. Calculate what would be a "normal" renal blood flow rate based on the following information:

John weighs 90 kg. Assume a normal total blood volume is 80 mL/kg of body weight, and a normal heart pumps the total blood volume through the heart once per minute (cardiac output). Also assume that the normal renal blood flow rate is 21% of cardiac output.

Chapter **52****The Immune System****Chapter Outline**

- 52.1** Innate Immunity
- 52.2** Adaptive Immunity
- 52.3** Cell-Mediated Immunity
- 52.4** Humoral Immunity and Antibody Production
- 52.5** Autoimmunity and Hypersensitivity
- 52.6** Antibodies in Medical Treatment and Diagnosis
- 52.7** Pathogens That Evade the Immune System

**Introduction**

When you consider how animals defend themselves, it is natural to think of turtles and armadillos with their obvious external armor. However, armor offers little protection against the greatest dangers vertebrates face—microorganisms and viruses. We live in a world awash with organisms too tiny to see with the naked eye, and no vertebrate could long withstand their onslaught unprotected. We survive because we have evolved a variety of very effective defenses. However, our defenses are far from perfect. Some 40 million people died from influenza in 1918–1919, and more than a million people will die of malaria this year. Attempts to improve our defenses against infectious diseases are being actively researched.

**52.1 Innate Immunity****Learning Outcomes**

1. *Distinguish between innate and adaptive immunity.*
2. *Give examples of pathogen-associated molecular patterns.*
3. *Describe the inflammatory response.*

For many years, the response of vertebrates to microbial invasion was divided into specific and nonspecific forms of defense. It has now become clear that this is not only an oversimplifica-

tion, it is not a productive way to view the body's defenses. We now view the response as much more integrated and consisting of two parts: innate and adaptive immunity.

The innate system involves the *recognition* of molecules that are conserved in particular pathogens, such as lipopolysaccharide in gram-negative bacteria. The molecules that bind to these conserved proteins do not result from genomic rearrangements and are limited in number, but do involve recognition of invading pathogens. The characteristic of this system is a rapid response that brings cells to the site of infection and uses soluble antimicrobial proteins to fight the pathogen.

Innate immunity is evolutionarily ancient, with some of the proteins involved recently being identified in cnidarians. Parts of the complement system (described later) have also been identified in horseshoe crabs, indicating that this system

is also more ancient than previously thought. This also implies that the lack of complement in other protostomes is probably due to loss. Together, this implies that the ancestor to all bilaterians had some form of innate immunity.

Adaptive immunity is characterized by the genetic rearrangements that generate a diverse set of molecules that can recognize virtually any invading pathogen. This is the basis for a slower, but highly specific response to invading pathogens, and for the more rapid response to a second attack that is the basis for vaccines. In this chapter, we will discuss innate and adaptive immunity and how they are interrelated. We will begin with a brief description of the barrier that a pathogen must cross to gain access to the interior of the body.

## The skin is a barrier to infection

The skin is the largest organ of the body, accounting for 15% of an adult human's total weight. The integument not only defends the body by providing a nearly impenetrable barrier, but also reinforces this defense with chemical weapons on the surface. Oil and sweat glands give the skin's surface a pH of 3 to 5, which is acidic enough to inhibit the growth of many pathogenic microorganisms. Sweat also contains the enzyme lysozyme, which digests bacterial cell walls. Epithelial cells also produce a variety of small antimicrobial peptides.

The skin is also home to many normal flora, nonpathogenic bacteria or fungi that are well adapted to the skin conditions in different regions of the body. Pathogenic bacteria that might attempt to colonize the skin generally are unable to compete with the normal flora. The epidermis of skin is approximately 10 to 30 cells thick, about as thick as this page. The outer layer contains cells that are continuously abraded, injured, and worn by friction and stress during the body's many activities. Cells are shed continuously and are replaced by new cells produced in the innermost layer of the epidermis.

## Mucosal epithelial surfaces also prevent entry of pathogens

In addition to the skin, three other potential routes of entry by microorganisms and viruses must be guarded: the digestive tract, the respiratory tract, and the urogenital tract. Recall that each of these tracts opens to the external environment. Each of these tracts is lined by epithelial cells, which are continuously replaced, as are those of the skin.

A layer of mucus, secreted by specialized cells scattered between the epithelial cells, covers all these epithelial surfaces. Pathogens are frequently trapped within this mucus layer and are eliminated by mechanisms specific to the particular tract.

Microbes are present in food, but many are killed by saliva (which contains lysozyme), by the very acidic environment of the stomach, and by digestive enzymes in the intestine. Additionally, the gastrointestinal tract is home to a vast array of nonpathogenic normal flora, whose presence inhibits the growth of pathogenic competitors. These nonpathogenic organisms not only outcompete pathogens, but they also may secrete substances that kill harmful agents.

Microorganisms present in inhaled air are trapped by the mucus within the smaller bronchi and bronchioles before they

can reach the warm, moist lungs, which would provide ideal breeding grounds for them. The epithelial cells lining these passages have cilia that continually sweep the mucus toward the glottis. There the mucus can be swallowed, carrying potential invaders out of the lungs and into the digestive tract. One of the pitfalls of smoking is that nicotine paralyzes the cilia of the respiratory system so that this natural cleaning of the air passages does not take place.

Vaginal secretions are sticky and acidic, and they also promote the growth of normal flora; all of these characteristics help prevent foreign invasion. In both males and females, acidic urine continually washes potential pathogens from the urinary tract. In addition to these physical and chemical barriers to pathogen invasion, the body also uses defense mechanisms such as vomiting, diarrhea, coughing, and sneezing to expel potential pathogens.

## Innate immunity recognizes molecular patterns

Innate immunity is a response to invading pathogens that involves both soluble factors and a variety of different types of blood cells. The innate response to invading pathogens is based on the recognition of molecules that are characteristic of the pathogen. Collectively we call these pathogen-associated molecular patterns (PAMPs), or microbe-associated molecular patterns (MAMPs). Examples include the lipopolysaccharide (LPS) found in gram-negative bacterial cell walls; peptidoglycan, which is found in all bacterial cell walls; and viral DNA and RNA. These PAMPs are recognized by **pattern recognition receptors (PRRs)** that can be either soluble or on the surface of blood cells.

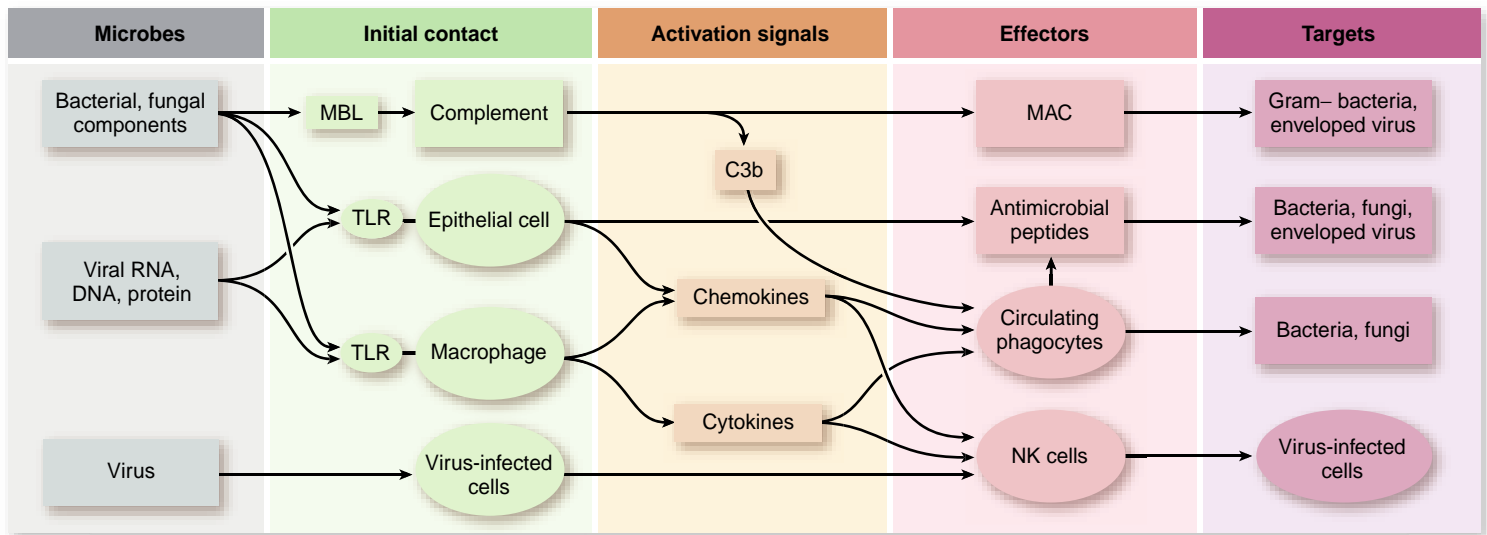

### Toll-like Receptors

The best studied PRR is the Toll receptor in *Drosophila* and the Toll-like receptors (TLR) found in many species. In *Drosophila*, Toll was originally discovered as a part of the dorsal-ventral patterning pathway. Later, the same membrane receptor was found to mediate a response to fungal infection.

In vertebrates 11 TLRs have been found in humans and 13 in mouse. These bind to a variety of specific targets important to pathogen survival, which therefore do not vary greatly. These include gram-negative LPS, bacterial lipoproteins, bacterial peptidoglycan fragments, yeast cell wall components, unmethylated CpG motifs in bacterial DNA, and viral RNA. This represents a wide range of possible invading pathogens that vertebrates have been host to over a long period of evolutionary time.

The structure of TLRs that allows recognition of these PAMPs are repeated leucine-rich regions that fold to form binding pockets. These pockets can bind to a variety of shapes. As these recognize structures that are critical to the pathogen, a single TLR can recognize a range of pathogens that share a feature such as LPS or peptidoglycan.

Activation of TLRs leads to signal transduction pathways that result in the expression of genes encoding products that enhance the response of both innate and adaptive immune responses. Activation of TLRs can lead to induction of the transcription factor NF- $\kappa$ B, which turns on the inflammatory response described later on; to the production of antimicrobial peptides; and to the production of cytokines that attract phagocytic cells as well as B and T cells.

**Figure 52.1 Overview of innate immunity.** Pathogens have critical molecules that adhere to either membrane-bound (TLR), or soluble receptors (MBL). This results in the production of cytokines and chemokines that attract phagocytes, of antimicrobial peptides, the membrane attack complex (MAC) of the complement cascade, and the activation of natural killer cells (NK cells).

### Cytoplasmic receptors

Two newly characterized kinds of receptors are not membrane proteins, rather they are found in the cytoplasm. These are the nucleotide oligomerization domain (NOD)-like receptors (NLRs) and Rig helicase-like receptors (RLRs). These internal receptors can recognize PAMPs in the cytoplasm of cells after phagocytosis. The RLRs also help in responding to viral RNA.

### Soluble receptors

In addition to the surface receptors described earlier, some circulating molecules can respond to molecules derived from pathogens. These include some of the lectin family, such as the mannose-binding lectin (MBL) protein. This protein is found in serum and can bind to mannose-containing carbohydrates on microbial surfaces. MBL is important in activating the complement system described later.

## Innate immunity leads to diverse responses to a pathogen

Binding of a pathogen-associated molecule to any of the innate immune-type receptors activates signal transduction pathways that lead to a rapid response. This includes the production of secreted signaling molecules, release of antimicrobial peptides, and activation of complement. An overview of all of these activities is shown in figure 52.1.

The secretion of antimicrobial peptides normally found in the integument can be increased when TLRs on the surface of epithelial cells and phagocytic cells bind components of invading pathogens. In humans, the major categories of antimicrobial peptides are called defensins and cathelicidin. Defensins are small peptides with 6 disulfide-linked cysteines that expose positively charged amino acids on the surface. The defensins bind to the outer membranes of bacterial species, which tend to be negatively charged. This can both disrupt the outer membrane and enhance phagocytosis. Defensins have also been shown to

work against enveloped viruses (figure 52.2). The antimicrobial enzyme lysozyme can also be induced by TLR activation.

Another class of proteins induced by innate defenses that play a key role in body defense are interferons. Interferons are important secreted signaling molecules with diverse functions.

### SCIENTIFIC THINKING

**Hypothesis:** Defensin peptides have activity against viruses.

**Prediction:** Viruses incubated with the human neutrophil defensin one (HNP-1) *in vitro* will have reduced infectivity.

**Test:** Direct test by incubating different viruses with HNP-1, then using standard infectivity assay expressed as plaque-forming units (PFU)/mL.

Virus	Mean log <sub>10</sub> Reduction in PFU/mL		
	25 µg/mL	50 µg/mL	100 µg/mL
HSV-1	2	2.9	3
HSV-2	0.8	1.2	2
Vesicular stomatitis virus	0.4	0.7	0.9
Influenza virus	0.4	0.5	0.7
Cytomegalovirus	-0.02	0.09	0.3

**Result:** HNP-1 has activity against a variety of viruses as shown in the table.

**Conclusion:** HNP-1 has activity against different enveloped viruses, although this activity is not equally effective against the different viruses.

**Further Experiments:** How could you determine the mechanisms of action?

**Figure 52.2 Activity of defensin against different viruses.**

The three major categories of interferons are alpha, beta, and gamma (IFN- $\alpha$ , IFN- $\beta$ , IFN- $\gamma$ ).

Almost all cells in the body make IFN- $\alpha$  and IFN- $\beta$ . These polypeptides are synthesized when a virus infects a cell and act as messengers that protect normal uninfected cells in the vicinity. Although viruses are still able to penetrate the neighboring cells, IFN- $\alpha$  and IFN- $\beta$  induce the degradation of RNA and block protein production in these cells. Although this leads to the death of the cells, it also prevents virus production and spread.

IFN- $\gamma$  is produced only by particular leukocytes called T lymphocytes (described later) and natural killer cells. The secretion of IFN- $\gamma$  by these cells is part of the immunological defense against infection and cancer.

In addition to these nonspecific defensive molecules, activation of innate immunity leads to two other responses that are important enough to be discussed separately later: activation of the inflammatory response, and activation of the complement pathway. Signaling from both TLR and internal receptors can lead to the secretion of a variety of cytokines, or regulatory signaling molecules. These attract other nonspecific phagocytic cells, cause inflammation, and even signal to the adaptive immune system.

## Phagocytic cells are associated with innate immunity

Among the most important innate defenses are some types of *leukocytes*, or white blood cells, that circulate through the body and nonspecifically attack pathogens within tissues (see chapter 50 for an overview of blood and blood cells). Three basic kinds of defending leukocytes have been identified, and each kills invading microorganisms differently.

### Macrophages

**Macrophages** (“big eaters”) are large, irregularly shaped cells that kill microorganisms by ingesting them through phagocytosis (figure 52.3). Once within the macrophage, the membrane-bound phagosome fuses with a lysosome. Fusion activates lysosomal enzymes that kill and digest the microorganism. Additionally, large quantities of oxygen-containing free radicals are frequently produced within the phagosome; these free radicals are very reactive and degrade the pathogen.

In addition to bacteria, macrophages also engulf viruses, cellular debris, and dust particles in the lungs. Macrophages roam continuously in the extracellular fluid that bathes tissues. In response to an infection, monocytes, which are undifferentiated macrophages found in the blood, squeeze through the endothelial cells of capillaries to enter the connective tissues. There, at the site of the infection, the monocytes mature into active, phagocytic macrophages.

### Neutrophils

**Neutrophils** are the most abundant circulating leukocytes, accounting for 50 to 70% of the peripheral blood leukocytes. They are the first type of cell to appear at the site of tissue damage or infection. Like macrophages, they squeeze between capillary endothelial cells to enter infected tissues, where they

**Figure 52.3 A macrophage in action.** In this scanning electron micrograph, a macrophage is “fishing” with long, sticky cytoplasmic extensions. Bacterial cells that come in contact with the extensions are drawn toward the macrophage and engulfed.

ingest a variety of pathogens by phagocytosis. Their mechanism of pathogen destruction is similar to that of macrophages except that they produce an even greater range of reactive oxygen radicals. Neutrophils also produce defensin peptides.

### Natural killer cells

**Natural killer (NK) cells** do not attack invading microbes directly. Instead, they kill cells of the body that have been infected with viruses. They kill not by phagocytosis, but rather by inducing apoptosis (programmed cell death) of the target cell (see chapter 19). Proteins called *perforins*, released from the NK cells, insert into the membrane of the target cell, polymerizing into a pore. Other NK-produced proteins, *granzymes*, then enter the pores created by the perforin molecules and activate proteins known as *caspases*, found within the target cells, which in turn induce apoptosis (figure 52.4). Macrophages ingest the resulting membrane-bounded vesicular cell debris.

NK cells also attack tumor cells, often before the tumor cells have had a chance to divide sufficiently to be detectable as a tumor. The vigilant surveillance by NK cells is one of the body’s most potent defenses against cancer. Thus, these cells are often said to play a role in **immune surveillance**.

## The inflammatory response is a nonspecific response to infection or tissue injury

The inflammatory response involves several systems of the body, and it may be either localized or systemic. An acute response is one that generally starts rapidly but lasts for only a relatively short while.

**Figure 52.4 How natural killer cells eliminate target cells.** Natural killer cells kill virally infected cells by programmed cell death, or apoptosis. This is accomplished by secreting proteins that form pores in the cell to be killed, along with proteins that diffuse through these pores and induce apoptosis.

### Inquiry question

? What would happen if an NK cell killed a virally infected target cell by simply causing the cell to burst, releasing all the cell contents into the tissues?

Certain infected or injured cells release chemical alarm signals—most notably histamine, along with prostaglandins and bradykinin (see chapter 46). These chemicals promote the dilation of local blood vessels, which increases the flow of blood to the site and causes the area to become red and warm, two of the hallmark signs of inflammation. These chemicals also increase the permeability of capillaries in the area, producing the third hallmark sign of inflammation, the edema (tissue swelling) often associated with infection. Swelling puts pressure on nerve endings in the region, and this, in combination with the release of other mediators, leads to pain and potential loss of function, the final two hallmark signs of inflammation.

Increased capillary permeability initially promotes the migration of phagocytic neutrophils from the blood to the extracellular fluid bathing the tissues, where the neutrophils can ingest and degrade pathogens; the pus associated with some infections is a mixture of dead or dying pathogens, tissue cells, and neutrophils. The neutrophils also secrete signaling molecules that attract monocytes several hours later; as the monocytes differentiate into macrophages, they too engulf pathogens and the remains of the dead cells (figure 52.5).

The inflammatory response is accompanied by an *acute-phase response*. One manifestation of this response is an elevation of body temperature, or fever (see chapter 43). When a macrophage with a TLR on its surface binds to a PAMP, the cytokine called **interleukin-1 (IL-1)** is released and is carried by the blood to the brain. IL-1 causes neurons in the

hypothalamus to raise the body's temperature several degrees above the normal value of 37°C (98.6°F). This increase in body temperature promotes the activity of phagocytic cells and impedes the growth of some microorganisms.

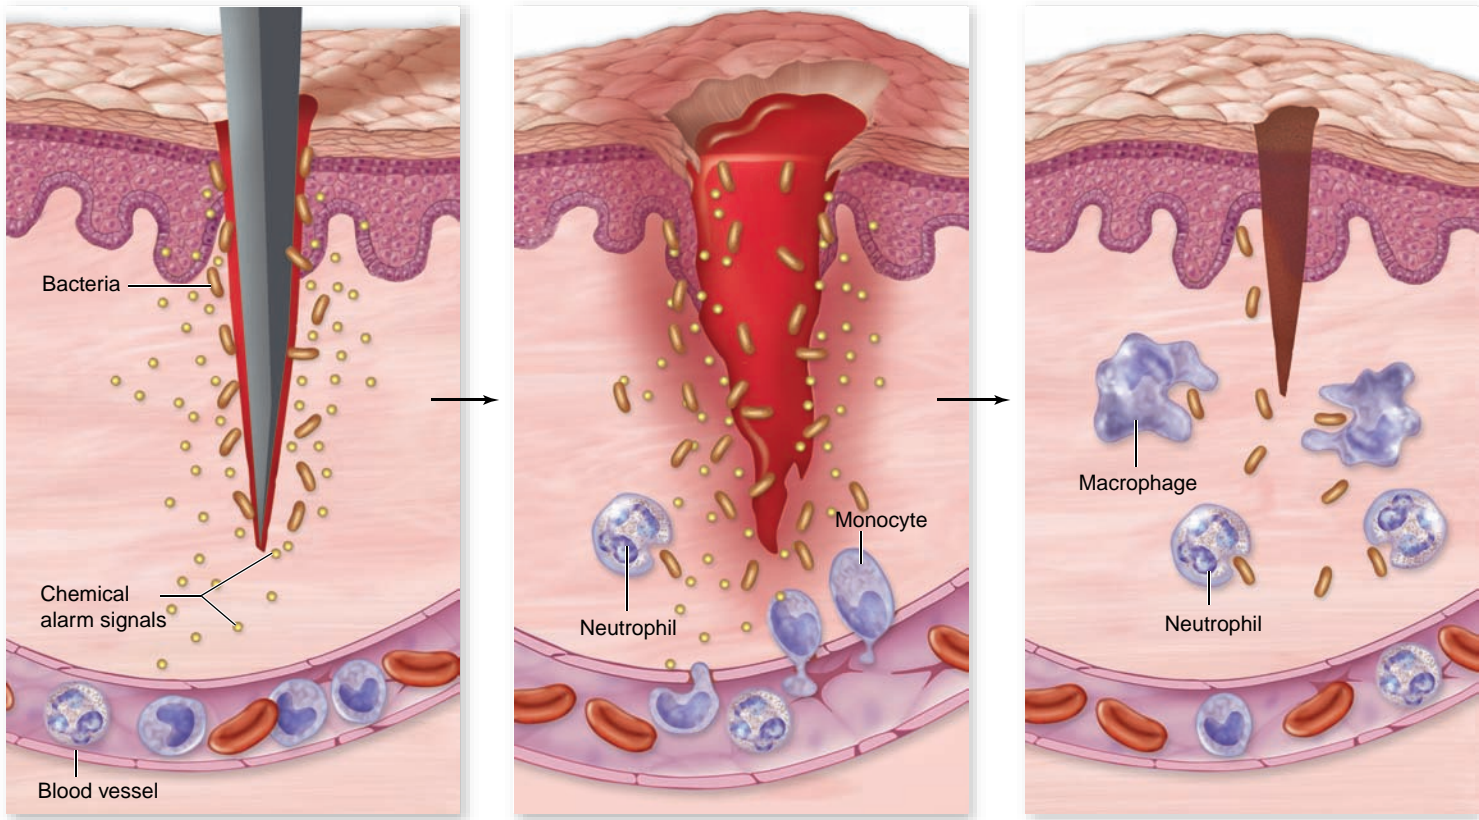

Fever contributes to the body's defense by stimulating phagocytosis and causing the liver and spleen to store iron. This storage reduces blood levels of iron, which bacteria need in large amounts to grow. Very high fevers are hazardous, however, because excessive heat may denature critical enzymes. In general, temperatures greater than 39.4°C (103°F) are considered dangerous for humans, and those greater than 40.6°C (105°F) are often fatal.

A group of proteins collectively referred to as *acute-phase proteins* are also released from cells of the liver during an inflammatory response, sometimes at levels 1000-fold above the normal serum concentration. These proteins bind to a variety of microorganisms and promote their ingestion by phagocytic cells—the neutrophils and macrophages.

### Complement can form a membrane attack complex

The cellular defenses of vertebrates are enhanced by a very effective chemical defense called the **complement system**—a group of approximately 30 different proteins that circulate freely in the blood plasma. Usually they occur in an inactive form, which can enter the tissues during an inflammatory

**Figure 52.5 The events in local inflammation.** When invading pathogens have penetrated an epithelial surface, chemical alarm signals, such as histamine and prostaglandins, released from damaged cells, cause nearby blood vessels to dilate and increase in permeability. Increased blood flow causes swelling and promotes the accumulation of phagocytic cells, specifically neutrophils followed by macrophages, which attack and engulf invading the pathogens.

response. Complement can be activated by mannose-binding lectin protein (MBL), one of the soluble sensors of innate immunity, or can be activated by a complex series of reactions involving charged species on the surface of pathogens.

When the complement system is activated, complement proteins aggregate to form a **membrane attack complex (MAC)** that inserts itself into the pathogen's plasma membrane (or the lipid membrane around an enveloped virus), forming a pore. Extracellular fluid enters the pathogen through this pore, causing the pathogen to swell and burst. Activation of the complement proteins is also triggered in a specific fashion when antibodies (which are secreted by B lymphocytes) are bound to invading pathogens, as we describe in a later section.

Other complement proteins, particularly one known as *C3b*, may coat the surface of invading pathogens. Phagocytic neutrophils and macrophages, which have receptors for *C3b*, may thus be “directed” to bind to the pathogens, promoting their phagocytosis and destruction. This is a particularly efficient way of eliminating those pathogens that do not have an outer lipid membrane into which a MAC may insert itself. Some complement proteins stimulate the release of histamine and other mediators by cells known as mast cells and basophils, promoting the dilation and increased permeability of capillaries; other complement proteins attract more phagocytes, especially neutrophils, to the area of infection through the more-permeable blood vessels.

### Learning Outcomes Review 52.1

Innate immunity is ancient and recognizes molecular patterns; adaptive immunity involves genetic rearrangements to attack specific pathogens. The molecular patterns that innate immunity recognizes include bacterial lipopolysaccharide and peptidoglycan, as well as viral RNA and DNA. The inflammatory response begins with histamine release and involves a variety of molecules and signals that attract neutrophils, increase permeability, activate the complement system, and trigger fever.

■ *Is innate immunity nonspecific?*

## 52.2 Adaptive Immunity

### Learning Outcomes

1. Define the characteristics of adaptive immunity.
2. Describe how lymphocytes acquire receptors.
3. Distinguish between humoral and cellular forms of immunity.

Few of us pass through childhood without contracting a variety of infectious illnesses. Prior to the advent of an effective vaccine in about 1991, most children contracted chicken pox before reaching their teens. Chicken pox and some other such diseases were considered diseases of childhood because most people, once recovered, never experienced them again. They developed immunity to the chicken pox-causing *varicella-zoster* virus and maintained this immunity as long as their immune systems remained intact. Similarly, immunization today with a nonpathogenic form of *varicella* virus can also confer protection. This immunity is produced by adaptive immune defense mechanisms, also called acquired immunity.

### Immunity had long been observed, but the mechanisms have only recently been understood

Societies have known for over 2000 years that an individual who experiences an infectious disease is often protected against a subsequent occurrence of the same disease. The scientific study of immunity, however, did not begin until 1796, when an English country doctor, Edward Jenner, carried out an experiment to protect people against smallpox.

#### Jenner and the smallpox virus

Smallpox, caused by the *variola* virus, was a common and deadly disease in the 1700s and earlier centuries. As with chicken pox, those who survived smallpox rarely caught the disease again, and people had been known to deliberately infect themselves through inoculation hoping to survive a mild case and become immune. Jenner observed, however, that milkmaids who had caught a much milder form of “the pox” called cowpox (presumably from cows) rarely experienced smallpox.

Jenner set out to test the idea that cowpox could confer protection against smallpox. He inoculated a healthy child with fluid from a cowpox vesicle and later deliberately infected him with fluid from a smallpox vesicle; as he had predicted, the child did not become ill. (Jenner’s experiment would be considered unethical today.) Subsequently, many people were protected from smallpox by immunization with fluid from cowpox vesicles, a much less risky proposition (figure 52.6).

We now know that smallpox and cowpox are caused by two different viruses that have similar surfaces. Jenner’s patients who were injected with the cowpox virus mounted a defense that was also effective against a later infection of the smallpox virus.

Jenner’s procedure of injecting a harmless agent to confer resistance to a dangerous one is called *vaccination*. Modern attempts to develop resistance to malaria, herpes, and other diseases often involve delivering antigens via a harmless *vaccinia* virus related to the cowpox virus (see chapter 17).

#### Pasteur and avian cholera

Many years passed before anyone learned how exposure to an infectious agent could confer resistance to a disease. A key step toward answering this question was taken more than a half-century later by the famous French scientist Louis Pasteur. Pasteur was studying avian cholera, a form that infects birds. He isolated a culture of bacteria from diseased chickens that would produce the disease if injected into healthy birds.

It is reported that before departing on a two-week vacation, he accidentally left his bacterial culture out on a shelf. When he returned, he injected this old culture into healthy birds and found that it had apparently been weakened; the injected birds became only slightly ill and then recovered. Surprisingly, however, those birds did not get sick when subsequently infected with fresh cholera bacteria that did produce the disease in control chickens. Clearly, something about the bacteria could elicit immunity, as long as the bacteria did not kill the animals first. We now know that molecules protruding from the surfaces of the bacteria evoked active immunity in the chickens.

#### Antigens stimulate specific immune responses

An **antigen** is a molecule that provokes a specific immune response. The most effective antigens are large, complex molecules such as proteins. The greater their “foreignness,” or put another way, their phylogenetic distance from the host, the greater will be the immune response they elicit.

Antigens may be components of a microorganism or a virus, but they may also be proteins or glycoproteins on the surface of transfused red blood cells or on transplanted tissue.

**Figure 52.6**  
**The birth of immunology.**

This painting shows Edward Jenner inoculating patients with cowpox in the 1790s and thus protecting them from smallpox.

**Figure 52.7** Many different epitopes are exhibited by any one antigen. *a.* A single protein, with associated carbohydrate, may have many different antigenic determinants called epitopes, each of which can stimulate a distinct immune response. *b.* A pathogen such as a bacterium has many proteins on its surface, and there are likely to be multiple copies of each. Note that the protein and bacterium are not drawn to scale with respect to each other.

They may also be components of foods or pollens. A large antigen is likely to have many different parts, known as *antigenic determinants*, or *epitopes* (figure 52.7), each of which can stimulate a distinct immune response.

## Hematopoiesis gives rise to the cells of the immune system

All the cells that are found in the blood are derived from the division and differentiation of hematopoietic stem cells, a process called hematopoiesis (see chapter 50). Embryologically, these stem cells are initially found in the yolk sac, then migrate to the fetal liver and spleen and finally to the bone marrow. Stem cells give rise to lymphoid progenitors and myeloid progenitors. A lymphoid progenitor, in turn, gives rise to both the B and T lymphocytes as well as to natural killer cells. A myeloid progenitor gives rise to all the other cells of the immune system as well as to erythrocytes and platelets (see figure 50.2).

Although the lymphocytes are responsible for adaptive immunity, all the other leukocytes illustrated in figure 50.2 play supporting roles in this specific response or are part of innate immunity. **Monocytes** give rise to the macrophages, and these along with the **neutrophils** are phagocytic cells. **Eosinophils** are important in the elimination of helminths (flatworms; see chapter 33), either via secretion of digestive enzymes through perforin pores inserted in the plasma membrane of the helminths or occasionally by phagocytosis. They also play a role in exacerbating chronic inflammatory diseases such as asthma or inflammatory bowel disease.

**Basophils** and **mast cells** are not phagocytic but rather secrete inflammatory mediators such as histamine and prostaglandin in response to the binding of complement proteins during the elimination of pathogens. These cells, and mast cells in particular, are also activated during an allergic response, and the inflammatory mediators they release cause the symptoms of allergy.

**Dendritic cells** are important in the activation of T cells, as will be described further. Dendritic cells also form a link

TABLE 52.1		Cells of the Immune System
Cell Type		Function
Helper T cell		Specifically recognizes foreign peptides on antigen-presenting cells, inducing the release of cytokines that activate B cells or macrophages
Cytotoxic T cell		Specifically recognizes and kills "altered-self" cells: virally infected, or tumor cells
B cell		Binds specific soluble antigens with its membrane-bound antibody; serves as an antigen-presenting cell to T <sub>H</sub> cells; on activation differentiates into plasma and memory B cells
Plasma cell		Derived from activated B cell; is a biochemical factory devoted to the secretion of antibodies directed against specific antigens
Natural killer cell		Rapidly recognizes and kills virally infected or tumor cells
Monocyte		Precursor of macrophage; located in blood
Macrophage		Phagocytic tissue cell that is a component of the body's first cellular line of defense; also serves as an antigen-presenting cell to T <sub>H</sub> cells
Neutrophil		A phagocytic cell that is a component of the body's first cellular line of defense; found in the blood in large numbers until attracted to tissues during inflammation
Eosinophil		Important to the elimination of parasites and involved in chronic inflammatory diseases
Basophil		Circulating cell that releases mediators such as histamine that promote inflammation
Mast cell		Located primarily under mucosal surfaces and releases mediators such as histamine that promote inflammation; triggered both during inflammatory and allergic responses
Dendritic cell		Important antigen-presenting cell to naive T <sub>H</sub> cells; also helps in the activation of naive T <sub>C</sub> cells

between innate and adaptive immunity. Dendritic cells have a variety of TLRs that recognize pathogens and stimulate secretion of cytokines and the inflammatory response. Thus they can present antigens and recognize pathogen patterns via innate receptors as well. The roles of these cells are summarized in table 52.1.

## Lymphocytes carry out the adaptive immune responses

The adaptive immune system is characterized by

1. Specificity of recognition of antigen
2. Wide diversity of antigens can be specifically recognized
3. Memory, whereby the immune system responds more quickly and more intensely to an antigen it encountered previously than to one it is meeting for the first time
4. Ability to distinguish self-antigens from nonself

The cells in the blood involved in the adaptive immune response are leukocytes derived from a stem cell line called lymphoid progenitor cells (see figure 50.2). These **lymphocytes** have receptor proteins on their surfaces that recognize specific epitopes on an antigen and direct an immune response against either the antigen in solution or on the cell surface (figure 52.8). This response is also affected by signals derived from the innate system described earlier. The innate system dominates early in infection by a new pathogen, and the adaptive response dominates in later stages of infection.

### Lymphocytes and antigen recognition

Although all the receptor proteins on any one lymphocyte have the same epitope specificity, it is rare that any two lymphocytes

**Figure 52.8 B- and T-cell receptors bind antigens.**

B-cell receptors are immunoglobulin (Ig) molecules with a characteristic Y-shaped structure. Every B cell has a single kind of Ig on its surface that binds to a single antigenic determinant. T-cell receptors are simpler than Ig molecules, but also bind to specific antigenic determinants. T cells only bind to antigens bound to another cell.

have identical specificities. This feature produces the diversity of immune responses that ensures that at least some epitopes of any antigen that might be encountered are recognized.

A lymphocyte that has never before encountered antigen is referred to as a *naive lymphocyte*. When a naive lymphocyte binds to a foreign antigen, the lymphocyte is activated, causing it to divide producing a clone of cells with identical antigen specificity, a process called **clonal selection**. Some of these cells respond immediately to the antigen, and others become memory cells, which can remain in our bodies for years and perhaps for the remainder of our lives. Memory cells are easily and rapidly activated on subsequent encounters with the same antigen.

### B cells

Lymphocytes called **B lymphocytes**, or **B cells**, respond to antigens by secreting proteins called **antibodies**, or **immunoglobulins (Ig)**. Antigen recognition occurs when an antigen binds to immunoglobulins on the B cell's membrane. Binding to antigen, in conjunction with other signals to be described later, initiates a signaling pathway that leads to the production of plasma cell's that secrete antibodies specific for the epitope recognized by the antibody in the B-cell membrane. This B-cell-mediated response producing secreted antibodies is called **humoral immunity**.

### T cells

Other lymphocytes, called **T lymphocytes**, or **T cells**, do not secrete antibodies but instead regulate the immune responses of other cells or directly attack the cells that carry the specific antigens. These cells participate in the other arm of adaptive immunity called **cell-mediated immunity**. Both cell-mediated and humoral immunity processes are described in detail in later sections.

### Inquiry question

? Jenner used cowpox virus to elicit an immune response against smallpox. What does this tell us about the antigenic properties of the two viruses?

## Adaptive immunity can be active or passive

Immunity can be acquired in different ways. First, an individual can gain immunity when infected by a pathogen and perhaps developing the disease it causes. Alternatively, an individual can be immunized with portions of a pathogen or with a less virulent form of the pathogen. Both of these situations result in *active immunity*, associated with the activation of specific lymphocytes and the generation of memory cells by the individual. Second, an individual can gain immunity by obtaining antibodies from another individual. This happened to you before you were born, as some antibodies made by your mother were transferred to your body across the placenta. Immunity gained in this way is called *passive immunity*, and it does not result in the generation of memory cells. The immunity is only effective as long as the antibodies remain in your body. Like any other proteins, they will degrade in time.

## The immune system is supported by two classes of organs

The organs of the immune system consist of the **primary lymphoid organs**—the bone marrow and the thymus—as well as the **secondary lymphoid organs**—the lymph nodes, spleen, and mucosa-associated lymphoid tissue, or MALT (figure 52.9).

**Figure 52.9** Organs of the specific immune system.

There are two types of immune system organs: primary lymphoid organs (red boxes), in which B and T lymphocytes mature and acquire their specific receptors, and secondary lymphoid organs (labeled in black) in which antigen is collected and through which the mature naive lymphocytes circulate in order to meet and be stimulated by antigen.

## The primary lymphoid organs

The **bone marrow** is not only the source of stem cells, it is where B cells mature. After hematopoiesis gives rise to the most immature B cells, progenitor B cells, these cells complete their maturation in the bone marrow. It is here that DNA rearrangements of the immunoglobulin genes, to be discussed later, dictate the specificity of each B cell. Every B cell has about  $10^5$  Ig molecules on its surface, all with identical specificity of epitope binding and all different from cell to cell.

Any lymphocytes that are likely to bind to self-antigens undergo apoptosis (figure 52.10a). The remainder are released to circulate in the blood and lymph and pass through the secondary lymphoid organs, where they may encounter antigen.

After their origin in the bone marrow, progenitor T cells migrate to the **thymus**, a primary lymphoid organ located just above the heart. The thymus is very large in infants; it starts to shrink in the teenage years, which it continues to do throughout life.

The antigen receptor on T cells is designated the **T-cell receptor**, or **TCR**. The TCR is produced by gene rearrangements as T cells mature in the thymus, similar to those that occur for Ig genes of progenitor B cells. Thus, T cells may express about  $10^5$  identical TCRs per T cell, all likely to be different from one T cell to the next.

B cells recognize an epitope of an intact antigen that may or may not be a protein. In contrast, T cells recognize only a peptide fragment of a protein antigen, and this peptide fragment must be bound to one of a series of self-proteins that are present on the surface of almost all of the body's cells. These proteins are encoded by genes in the **major histocompatibility complex**, or **MHC**. The MHC is discussed in detail in subsequent sections.

During selection in the thymus, T cells are exposed to many thymic cells, all expressing self-MHC proteins with bound self-peptides on their surfaces. If a T cell's TCRs bind too strongly to these self-MHC protein complexes, that T cell becomes "self-reactive" and undergoes apoptosis (figure 52.10b). Conversely, if the T cell's TCR does not bind MHC complexes at all, it is also eliminated. Only about 5% of the progenitor T cells that enter the thymus pass this rigorous two-step selection and avoid apoptosis.

## The secondary lymphoid organs

The locations of the secondary lymphoid organs promote the filtering of antigens that enter any part of an individual's body. Bacteria attached to a thorn stuck in the skin, for example, enter the lymph that bathes the tissues. Lymph is eventually returned to the blood circulation through a series of vessels referred to as the lymphatics (see chapter 50). On its way, the lymph is filtered in the thousands of lymph nodes, which are located at the junction of lymphatic vessels (see figure 52.9).

The many mature but naive B and T lymphocytes that have entered a lymph node on exiting the primary lymphoid organs, or the memory cells that are located here, become activated on meeting with antigen. Antibodies secreted on activation of B cells in the lymph nodes, as well as the clonal progeny of the activated B and T cells, then leave the lymph node and enter the blood circulation when the lymph is returned to blood vessels near the heart.

**Figure 52.10 Selection against self-reactive lymphocytes in primary lymphoid organs.** After B and T lymphocytes acquire their specific receptors, self-reactive cells are eliminated by apoptosis. **a.** If Igs on the surface of a maturing B cell bind to an epitope on a bone marrow stromal cell, that cell will undergo apoptosis. The small percentage (10%) of B cells whose Igs do not recognize stromal cell epitopes will be released from the bone marrow. **b.** If TCRs on a maturing T cell bind too tightly to self-MHC/self-peptide complexes on dendritic cells in the thymus, that T cell will undergo apoptosis. Cells that don't bind MHC complexes at all are also eliminated. The very small percentage (2–5%) of maturing T cells that bind MHC peptide complexes with intermediate affinity are released from the thymus. These cells bind self-MHC/foreign peptide complexes with high affinity.

Lymphocytes responding to antigens in a lymph node may pass out of capillaries supplying blood to the lymph node and enter the node's tissues. This is the cause of the “swollen glands” that sometimes accompany infection. The local lymph nodes enlarge due to the vast influx of lymphocytes.

Some antigens are found primarily in the blood, or in the blood as well as in the tissues. One example is the bacterium *Neisseria meningitidis*, a cause of a potentially fatal meningitis (infection of the meninges, layers of membranes covering the brain). Immune responses to such antigens occur in the spleen.

The splenic artery carries blood to the spleen where it then subdivides into arterioles. Antigens released into the ground tissue of the spleen are recognized by B and T cells present in the white pulp, regions of the spleen immediately surrounding the arterioles. Lymphocytes in the white pulp may be activated, as in the lymph node. Antibodies along with some of the activated lymphocytes exit via the splenic vein.

The final important secondary lymphoid organ is the **mucosa-associated lymphoid tissue (MALT)**, which includes the tonsils, the appendix, and a large number of follicles located in the connective tissue under mucosal surfaces. These follicles are composed of lymphocytes, primarily B cells but also some T cells, and some macrophages. Any antigens that pass through the mucosa immediately encounter lymphocytes in these follicles and their entry further into the body may be stopped at this point.

If invading organisms manage to escape or evade innate defenses of mucosal surfaces as well as the specific responses of the lymphocytes in the MALT, then they still face a further

chance of being stopped by responses in the other secondary lymphoid organs.

## Two forms of adaptive immunity have evolved

Adaptive immunity, involving the ability to distinguish between self and nonself, was long thought to have evolved once in vertebrates. The type of adaptive immunity described in this chapter first arose in the cartilaginous fish that evolved some 450 MYA (see chapter 35).

Sharks and rays possess a thymus and a spleen, as well as a rather diffuse MALT. These animals mount cell-mediated responses with T cells bearing TCRs, and humoral responses with B cells that secrete Ig. Bone marrow in which hematopoiesis occurs appeared first in amphibians, although its exact role appears to vary in different species. Lymph nodes appeared first in birds, and their immune system differs little from that of mammals.

Recently, a second form of adaptive immunity has been described in jawless fish. This system does not involve B and T cells with their characteristic receptors. Instead, lymphocytes have receptor proteins composed of variable repeats rich in the amino acid leucine. These proteins appear to function much like Ig, but with a completely different protein architecture. The number of different receptor proteins produced by this system appears similar to the number of potential Ig. The generation of diversity in the two systems appears to have some similarity as the different lymphocyte receptors in jawless fish

are also assembled by DNA rearrangements. The makeup of the genes involved and the mechanism of these rearrangements is currently unknown.

It is unclear whether this newly described form of adaptive immunity was present in the ancestor to all chordates, or if it evolved in the lineage that gave rise to jawless fish. Given the differences in the two systems, it is likely that they represent independent events. If this other form of adaptive immunity was present in the ancestor to all chordates, some vestige may remain in modern vertebrates, including humans.

### Learning Outcomes Review 52.2

Adaptive immunity is able to recognize individual pathogens and mount a specific response. Lymphocytes, produced in bone marrow, must acquire their specific receptors and undergo selection for self-reactivity in primary lymphoid organs. These mature but naive lymphocytes circulate to secondary lymphoid organs, where they may encounter foreign antigens. B cells produce circulating antibodies (humoral immunity); T cells kill pathogens or help other cells respond to them (cell-mediated immunity).

- What type of adult stem cells are found in the immune system?

## 52.3 Cell-Mediated Immunity

### Learning Outcomes

1. Describe the function of cytotoxic T cells.
2. Explain the role of helper T cells.

T cells may be characterized as either **cytotoxic T cells** ( $T_C$ ) or **helper T cells** ( $T_H$ ). These cells can also be identified based on cell surface markers.  $T_C$  cells have CD8 protein on their cell surface, making them CD8<sup>+</sup> cells.  $T_H$  cells have CD4 protein on their cell surface, making them CD4<sup>+</sup> cells.

To be activated, both of these T cell types must recognize peptide fragments bound to MHC proteins, but the two cell types may be distinguished by (1) recognition of different classes of MHC proteins, which have distinct cell distributions, and (2) differing roles of the T cells after they are activated.

## The MHC carries self and nonself information

As discussed earlier, the surfaces of most vertebrate cells exhibit glycoproteins encoded by the MHC. In humans, the name given to the proteins encoded by the MHC complex is **human leukocyte antigens (HLAs)**. The genes encoding the MHC proteins are highly polymorphic (have many alleles). For example, the HLA proteins are specified by genes that are the most polymorphic known, with nearly 500 alleles detected for some of the proteins. Only rarely will two individuals have the same combination of alleles, and the HLAs are thus different for each individual, much as fingerprints are.

MHC proteins on the tissue cells serve as self markers that enable an individual's immune system, specifically its T cells, to distinguish its own cells from foreign cells, an ability called *self versus nonself recognition*.

There are two classes of MHC proteins. **MHC class I proteins** are present on every nucleated cell of the body. **MHC class II proteins**, however, are found only on **antigen-presenting cells** (in addition to MHC class I); these cells include macrophages, B cells, and dendritic cells (table 52.2).  $T_C$  cells respond to peptides bound to MHC class I proteins, and  $T_H$  cells respond to peptides bound to MHC class II proteins.

Most of the time, the peptides bound to MHC proteins are derived from self-proteins from the individual's own cells. For this reason, it is important that T cells undergo selection in the thymus so that those that bind too strongly to peptides of self-proteins on self-MHC are eliminated. In this way, T cells normally are activated only outside the primary lymphoid organs in which they mature, when they encounter peptides of foreign proteins on self-MHC—for example, in the case of viral infection or cancer.

## Cytotoxic T cells eliminate virally infected cells and tumor cells

Activated cytotoxic T cells recognize “altered-self” cells, particularly those that are virally infected or tumor cells. The TCRs of cytotoxic T lymphocytes recognize peptides of endogenous antigens bound to MHC class I proteins. Peptides of endogenous antigens are generated in a cell's cytosol and then are pumped by special transport proteins into the rough endoplasmic reticulum where they become bound to MHC class I proteins. These proteins continue on their way through the endomembrane system to the cell surface.

**TABLE 52.2** Lymphocyte Recognition of Antigen

	Recognize epitopes of soluble or particulate antigen	Recognize peptides bound to self-MHC proteins	Class of MHC proteins recognized	Cell types on which recognized MHC is expressed
B cells	Yes	No	None	NA
$T_H$ (CD4 <sup>+</sup> ) cells	No	Yes	Class II	Antigen-presenting cells: dendritic cells, B cells, and macrophages
$T_C$ (CD8 <sup>+</sup> ) cells	No	Yes	Class I	All nucleated cells

**Figure 52.11 Cytotoxic T cells induce apoptosis of “altered-self” cells.** Naive cytotoxic T cells are initially activated on TCR recognition of foreign peptide displayed on self-MHC class I proteins on dendritic cells in a secondary lymphoid organ. Activation results in clonal expansion and differentiation into memory cells and activated cells. Activated progeny of the  $T_C$  cell can induce apoptosis of any cell in the periphery (outside the secondary lymphoid organ) that displays the same self-MHC class I–peptide combination on its surface. This will most likely be a virally infected cell or a tumor cell.

An endogenous antigen may be a self-protein, or it may be a viral protein produced within a virally infected cell or an unusual protein produced by a cancerous cell.  $T_C$  cells respond only to the peptides of these unusual proteins bound to self-MHC class I. T-cell activation occurs in a secondary lymphoid organ, as described earlier. In a lymph node, for example, T cells encounter antigen-presenting cells. Dendritic cells in particular often present antigens that activate  $T_C$  cells.

Because not all viruses can infect dendritic cells, the dendritic cells must ingest viruses or tumor cells and then, through a mechanism referred to as cross-presentation, place the viral or tumor peptides on MHC class I proteins. Binding of the  $T_C$  cell through its TCR and its CD8 site to the dendritic cell induces clonal expansion of the  $T_C$  cell, generating many activated  $T_C$  cells as well as memory  $T_C$  cells (figure 52.11). The activated  $T_C$  cells then circulate around the body where they bind to “target” host cells that express the same combination of foreign peptide on self-MHC class I (figure 52.12).

Apoptosis of the target cell is induced in a very similar fashion to that used by NK cells; a  $T_C$  cell secretes perforin monomers that create pores in the target’s membrane; granzymes enter and activate caspases, which in turn cause apoptosis of the target.

## Helper T cells secrete proteins that direct immune responses

Activated helper T cells,  $T_H$  cells, secrete low-molecular-weight proteins known as **cytokines**. A vast array of cytokines is known, many but not all of which are secreted by  $T_H$  cells. These cytokines bind to specific receptors on the membranes of many other cells, particularly but not exclusively those of the immune system. On binding, they initiate signaling cascades in these cells that promote their activation or differentiation.

**Figure 52.12 Cytotoxic T cells destroy tumor cells.** *a.* The cytotoxic T cell (orange) comes into contact with a tumor cell (purple). *b.* The T cell recognizes that the tumor cell is “altered-self” and induces the apoptosis of the tumor cell.

Because cytokines are quite potent, they are generally secreted at very low concentrations so that, with a few exceptions, they bind only to nearby cells. IL-1 is an exception in that it travels to the hypothalamus to induce the fever response. Different subsets of  $T_H$  cells secrete cytokines specific for different cell receptors, so it is largely the  $T_H$  cells and the cytokines they secrete that determine whether an immune response will be humoral or cell-mediated in nature.

$T_H$  cells respond to exogenous antigen that has been brought into an antigen-presenting cell. Macrophages or dendritic cells acquire these antigens by phagocytosis or endocytosis, and B cells gain them through receptor-mediated endocytosis. Once inside these cells, the antigen is gradually degraded in increasingly acidic endosomes or lysosomes. Peptides of the antigen join with MHC class II proteins in certain of these endosomes, and the MHC class II-peptide complexes are then transported to and displayed on the cell surface of the antigen-presenting cell.  $T_H$  cells encounter these cells within the secondary lymphoid organs and bind to the complexes. The CD4 protein of the  $T_H$  cells additionally bind to conserved regions of MHC class II.

A naive  $T_H$  cell expresses a protein called CD28 that must bind to a protein called B7 if that T cell is to be activated. B7 is found only on antigen-presenting cells and is at highest levels on dendritic cells. This requirement ensures that  $T_H$  cells are activated only when needed; this careful regulation is necessary due to the potency of the cytokines these cells release.

As with  $T_C$  cells, an activated  $T_H$  cell gives rise to a clone of  $T_H$  cells including both effector  $T_H$  cells and memory  $T_H$  cells, with identical TCR specificity. Most of the effector cells will leave the lymphoid organ and circulate around the body.

## T cells are the primary cells that mediate transplant rejection

When T cells encounter the nonself MHC-peptide complexes present on transplanted tissue, such as a kidney, the TCRs on many of the T cells can weakly bind to these complexes. This is simply a case of cross-reactivity: The structure of a nonself MHC-peptide complex sufficiently resembles that of the self-MHC-foreign-peptide complex. The result is that the T cell binds to the foreign tissue cell.

Although the interactions between TCRs and nonself MHC-peptide complexes are relatively weak, many interactions occur between any one T cell and any one transplanted cell because a high density of MHC proteins is present on the surface of all cells. This activates the T cells and initiates the attack on the foreign tissues.

Because of the genetic basis of MHC proteins, the more closely two individuals are related, the less their MHC proteins vary, and thus the more likely they will be to tolerate each other's tissues. As a result, relatives are often sought as donors for patients in need of an organ transplant, and HLA typing is done to find matching alleles.

A variety of drugs are used to suppress immune system rejection of a transplant; most individuals with a non-MHC-matched transplant continue to take some of these drugs for the

remainder of their lives. One very effective drug is cyclosporin, which blocks the activation of lymphocytes.

## Cells of the innate immune system release cytokines

Many cells in addition to  $T_H$  cells release cytokines, always in a carefully regulated fashion. For example, macrophages that have been activated by phagocytosis of antigen, or by the binding of PAMP molecules to TLRs on their surface, release cytokines such as interleukin-12 (IL-12) that can, in turn, bind to  $T_H$  cells to increase their level of activation. Macrophages with TLRs bound to PAMP also release other cytokines, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ). These cytokines bind to blood vessels to induce a local or even systemic increase in vascular permeability. This links the innate response to the adaptive response.

### Learning Outcomes Review 52.3

T cells respond to peptides of foreign antigens displayed on self-MHC proteins. Activated  $T_C$  cells induce apoptosis of altered self cells—those that are virally infected or are tumor cells.  $T_H$  cells secrete cytokines that promote either cell-mediated or humoral immune responses.

- How are T-cell receptors different from Toll-like receptors?

## 52.4 Humoral Immunity and Antibody Production

### Learning Outcomes

1. Explain how antibody diversity is generated.
2. List the five classes of immunoglobulins.
3. Explain how vaccination prevents disease.

The B-cell receptors for antigen are the immunoglobulin molecules present as integral proteins in the plasma membrane. As noted earlier, each B cell exhibits about  $10^5$  immunoglobulin molecules of identical specificity for a particular epitope of an antigen. Naive B cells in secondary lymph organs encounter antigens. When immunoglobulin molecules on a B cell bind to a specific epitope on an antigen, and the B cell receives additional required signals, particularly cytokines secreted by  $T_H$  cells, then that B cell becomes activated, proliferating into plasma cells and memory cells (figure 52.13).

Each plasma B cell is a miniature factory producing soluble antibodies of the same specificity as the membrane-bound antibodies of the parent B cell. These antibodies enter the lymph and blood circulation as well as the extracellular fluid, and they bind to the appropriate epitopes of antigen encountered anywhere in the body. Any one antigen may present a variety of epitopes, so that different B cells might recognize different epitopes of a single antigen.

Once immunoglobulins coat an antigen, many other cells and processes may be activated to eliminate the antigen. The immunity to avian cholera that Pasteur observed in his chickens resulted from such antibodies and from the continued presence of the progeny of the B cells that produced them.

## Immunoglobulin structure reveals variable and constant regions

Each immunoglobulin molecule consists of two identical short polypeptides called *light chains* and two identical longer polypeptides called **heavy chains** (figure 52.14). The four chains in an immunoglobulin molecule are held together by disulfide

bonds, forming a Y-shaped molecule (figure 52.14a). Each “arm” of the molecule is referred to as an Fab region, and the “stem” is the Fc region (figure 52.14b).

### Antibody specificity: The variable region

Comparison of the amino acid sequences of many different immunoglobulin molecules has demonstrated that the specificity of immunoglobulins for antigen epitopes resides in the amino-terminal half of each Fab region. This half of the Fab has an amino acid sequence that varies from one immunoglobulin to the next and is thus designated the *variable region*. Both the light chain and the heavy chain have a variable region.

**Figure 52.13** Helper T cells secrete cytokines promoting either cell-mediated or humoral immune responses. Naive helper T cells are initially activated by TCR bound to a foreign peptide displayed on self-MHC class II proteins on dendritic cells. Activation results in clonal expansion and differentiation into memory cells and activated cells.  $T_H$  cells promote the humoral response when they recognize the same antigen displayed by a B cell. Cytokines such as interleukin-4 (IL-4) released from the  $T_H$  cell then activate the B cell, producing memory cells and plasma that secrete antibodies against the antigen.  $T_H$  cells also secrete interferon- $\gamma$  (IFN- $\gamma$ ), which stimulates cells involved in the cellular response such as the macrophage shown here. Macrophages secrete other cytokines that stimulate  $T_H$  cells.

### Figure 52.14 The structure of an

**immunoglobulin molecule.** *a.* In this model of an immunoglobulin (Ig) molecule, amino acids in the peptide chains are represented by small spheres. The molecule consists of two heavy chains (*brown*) and two light chains (*yellow*). The four chains form a Y shape, with two identical antigen-binding sites at the arms of the Y, the Fab regions, and a stem, or Fc region. The two Fab regions are joined to the Fc region by a flexible hinge. *b.* A more schematic depiction showing heavy chains (*brown*) and light chains (*yellow*) as rods. The two identical halves of the molecule are joined by disulfide bonds (*red*) as are the heavy and light chains of each half. *c.* Ig molecule shown as a membrane protein. This depiction highlights the domain structure of heavy and light chains. Each chain contains a series of domains, each about 110 amino acids, which include an immunoglobulin fold motif. These are represented as loops with globular structure maintained by disulfide bonds (*red*). The amino-terminal half of each Fab is a variable region (*blue*) that binds to an epitope and the remainder of the molecule is the constant region.

*a.*

*b.*

*c.*

The amino acid sequence of the remainder of the immunoglobulin is relatively constant from one immunoglobulin to the next and is thus designated the *constant region* (figure 52.14c). Both light and heavy chains also exhibit constant regions. Careful analysis shows that light-chain constant regions of mammalian immunoglobulins consist of two different sequences, designated  $\kappa$  (kappa) and  $\lambda$  (lambda), which have apparently equivalent function. The heavy-chain constant regions consist of five different sequences:  $\mu$  (mu),  $\delta$  (delta),  $\gamma$  (gamma),  $\alpha$  (alpha), and  $\epsilon$  (epsilon). When each of these heavy chains is bound to either type of light chain, they give rise to a particular class of immunoglobulin: IgM, IgD, IgG, IgA, and IgE.

### Binding of antibody with antigen

The variable regions of the heavy and light chains fold together to form a sort of cleft, the *antigen-binding site* (see figure 52.14). The size and shape of the antigen-binding site, as well as which amino acids line its surface, determine the specificity of each immunoglobulin for an antigen epitope.

Because each immunoglobulin is composed of two identical halves, they can each bind with two identical epitopes,

although not generally on the same antigen because of steric (shape) constraints. This ability to bind with two epitopes allows the formation of antigen–antibody complexes containing multiple antibody and antigen molecules (figure 52.15a).

### Function of antibody classes: The constant region

Although the specificity of each immunoglobulin is determined by its variable region, the function of the immunoglobulin depends on its class, as determined by the heavy-chain constant region, and particularly the Fc portion of the constant region.

Many cells have Fc receptors that can bind the Fc region of a particular class of immunoglobulin. Therefore, when an immunoglobulin binds to an antigen through its antigen-binding site, another cell, such as a phagocytic cell, may be brought close to the antigen by binding to the Fc region of the immunoglobulin (figure 52.15c). This binding of antigen–antibody complex to Fc receptors can also activate these cells. In this way, specific immunoglobulins can promote the interaction of nonspecific cells with the antigen, generally resulting in the elimination of the antigen.

## The five classes of immunoglobulins have different functions

The five classes of antibodies are based on the sequence and structure of the constant regions of their heavy chains. These five classes have different functions in the protection of an individual. Characteristics of the different classes are summarized in table 52.3 and are described in the following sections.

Keep in mind that antibodies don't kill invading pathogens directly; rather, they cause destruction of pathogens by targeting them for attack by other, nonspecific cells or by activating the complement system.

**IgM** is a receptor on the surface of all mature, naive B cells and is the first type of antibody to be secreted during an immune response. Although IgM in the membrane of a B cell is monomeric in form, it is secreted as a pentamer (five units) of about 900,000 kDa. Its large size restricts it to the circulation, but its pentameric form means that it very efficiently promotes agglutination of larger antigens (figure 52.15*a*) and precipitation

*a.*

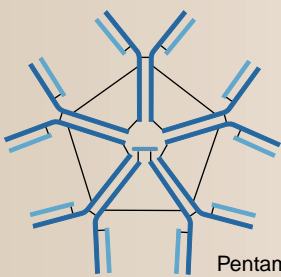

*b.*

*c.*

**Figure 52.15** Binding of antibody to antigens can cause agglutination, precipitation, or neutralization of the antigens. *a.* Binding of secreted IgM to larger particulate antigens leads to the clumping, or agglutination, of the antigens. *b.* Binding of secreted IgM to small soluble antigens can lead to their precipitation. Secreted IgG, due to its high concentration (75% of plasma Ig), can also agglutinate and precipitate antigens. IgG does not precipitate as efficiently as IgM because of the pentameric nature of secreted IgM. *c.* Secreted IgG can coat or neutralize an antigen by blocking its ability to bind to a host. Macrophages and neutrophils that have Fc receptors for IgG can thus attach to an antigen–antibody complex, which they will then phagocytose and destroy.

TABLE 52.3		Five Classes of Immunoglobulins
Class		Function
IgM	 Pentamer	First antibody secreted during the primary immune response; promotes agglutination and precipitation reactions and activates complement
IgD	 Monomer	Present only on surfaces of B cells; serves as antigen receptor
IgG	 Monomer	Major antibody secreted during the secondary response; neutralizes antigens and promotes their phagocytosis and activates complement
IgA	 Dimer	Most abundant form of antibody in body secretions; high density of IgA-secreting plasma cells in the MALT
IgE	 Monomer	Fc binds to mast cells and basophils; allergen binding to V regions promotes the release of mediators, which triggers allergic reactions

of soluble antigens (figure 52.15*b*). IgM bound to an antigen also activates a complement protein cascade, triggered by the binding of certain complement proteins to the exposed Fc ends.

**IgD** is also present, along with IgM, on mature naive B cells. The B cells can be activated by cross-linking of two IgD molecules, although under normal circumstances this class of immunoglobulin is not secreted by the cells. On B-cell activation, IgD is no longer displayed on the cell surface. Other roles for IgD remain elusive.

**IgG** is the major form of antibody in the blood plasma and in most tissues, making up about 75% of plasma antibodies. It is the most common form of antibody produced in a secondary immune response (any response triggered on a subsequent exposure to an antigen). IgG can bind to an antigen in such quantity that the antigen—a virus, bacterium, or bacterially derived toxin—is said to be neutralized, meaning that it can no longer bind to the host. Macrophages and neutrophils have Fc receptors that bind to IgGs bound to antigens, and in this way IgG binding or coating of antigens facilitates their elimination by phagocytosis (figure 52.15*c*). IgG is also important in providing passive immunity to a fetus; it readily crosses the placenta from the mother. Finally, IgG can also activate complement, although not as efficiently as IgM, leading to pathogen elimination.

**IgA** is the major form of antibody in external secretions, such as saliva, tears, and the mucus that coats the gastrointestinal tract, bronchi, and genitourinary tract. IgA plays a major role in protection of these surfaces; it is usually secreted as a dimer. The many plasma cells present in the MALT, under the mucosal surfaces, secrete IgA that crosses the epithelial cells to the lumen of these tracts; here it can bind and neutralize antigens. Additionally, any pathogen that passes through a mucosal surface becomes bound to IgA because it is secreted by cells in follicles under that surface. The bound IgA crosses the epithelial cells into the lumen, taking the pathogen with it. The pathogen can then be eliminated by innate defenses. IgA also provides passive immunity to a nursing infant since it is present in mother's milk.

**IgE** is present at very low concentration in the plasma. On secretion, most becomes bound to mast cells and basophils that recognize the Fc portion of IgE. As described later, binding of certain normally harmless antigens to IgE molecules bound to mast cells and basophils produces the symptoms of allergy, such as the runny nose and itchy eyes of hay fever. IgE is also often secreted in response to an infection by helminth worms. In this instance, secreted IgE binds to epitopes on the worms and is then recognized by Fc receptors on eosinophils. The eosinophils generally kill the worms by secreting digestive enzymes through perforin pores into the worms.

## Immunoglobulin diversity is generated through DNA rearrangement

The vertebrate immune system is capable of recognizing as foreign virtually any nonself molecule presented to it. It is estimated that human or mouse B cells can generate antibodies with over  $10^{10}$  different antigen-binding sites. Although an

individual probably does not have antibodies specific to all epitopes of an antigen, it is fairly certain that antibodies will recognize some of the epitopes, which is all that is required to generate an effective immune response. How do vertebrates generate such diversity of antigen recognition?

The answer lies in the unusual genetics of the variable region. This region in each chain of an immunoglobulin is not encoded by one single stretch of DNA but rather is assembled by joining two or three separate DNA segments together to produce the variable region. This process is called DNA rearrangement and is similar to the crossing over that occurs during meiosis (see chapter 11) with two key differences: It occurs between loci on the same chromosome and it is site-specific.

DNA rearrangement occurs as a progenitor B cell matures in the bone marrow. After DNA rearrangement, RNA transcription produces an mRNA that can be translated into either a heavy- or a light-chain immunoglobulin polypeptide, depending on the locus transcribed.

Cells contain homologous pairs of chromosomes, but DNA rearrangement occurs for the heavy-chain and light-chain loci on only one homologue, a process referred to as *allelic exclusion*. Thus, each B cell makes immunoglobulins of only one specificity.

### Variable region DNA rearrangements

Sequencing of human immunoglobulin heavy-chain gene loci from several different individuals shows that the locus contains a cluster of approximately 50 sequential DNA segments, termed V segments, followed by a cluster of approximately 30 smaller segments, D segments, and finally by another cluster of 6 smaller segments, J segments. Each V segment is approximately the same size as any other, but they are all of different nucleotide sequence and thus encode different amino acids; the situation is similar for the D and the J segments.

The first DNA rearrangement during B-cell maturation is a site-specific recombination event joining one of the D segments to one of the J segments (figure 52.16). Recombination between two sites on the same chromosome results in the deletion of the intervening DNA, which is subsequently degraded.

This is followed by another site-specific recombination joining a V segment to the rearranged DJ, with the deletion of all the intervening DNA. Which V, which D, and which J are chosen by any cell appears to be completely random.

Because of the many combinations of V, D, and J that can be formed, one can calculate the generation of about 9000 different heavy-chain variable-region sequences. A similar situation occurs for light-chain variable region formation, except that each light-chain variable region is encoded by only a V segment and a J segment.

Other processes contribute even further to the diversity of variable region sequence. As the DNA segments are joined to each other, a few nucleotides may be added to or deleted from the ends of each segment, and this is generally followed by somewhat imprecise joining of the segments to each other, resulting in a shift of the reading frame. B cells may end up expressing any heavy-chain variable region with any light-chain variable region during its maturation. Lastly, these genes show

an elevated mutation rate, termed somatic hyper-mutation. Taking all these processes into account has allowed the estimate of more than  $10^{10}$  possible variable regions.

### Transcription and translation

After the DNA rearrangements that encode the variable region are complete, pre-mRNA transcripts are formed with 5' ends that begin at the rearranged variable region-encoding segments and continue through constant region exons. More specifically, heavy-chain-encoding pre-mRNA transcripts start at the rearranged VDJ and continue through exons encoding  $\mu$  and  $\delta$  constant regions (see figure 52.16).

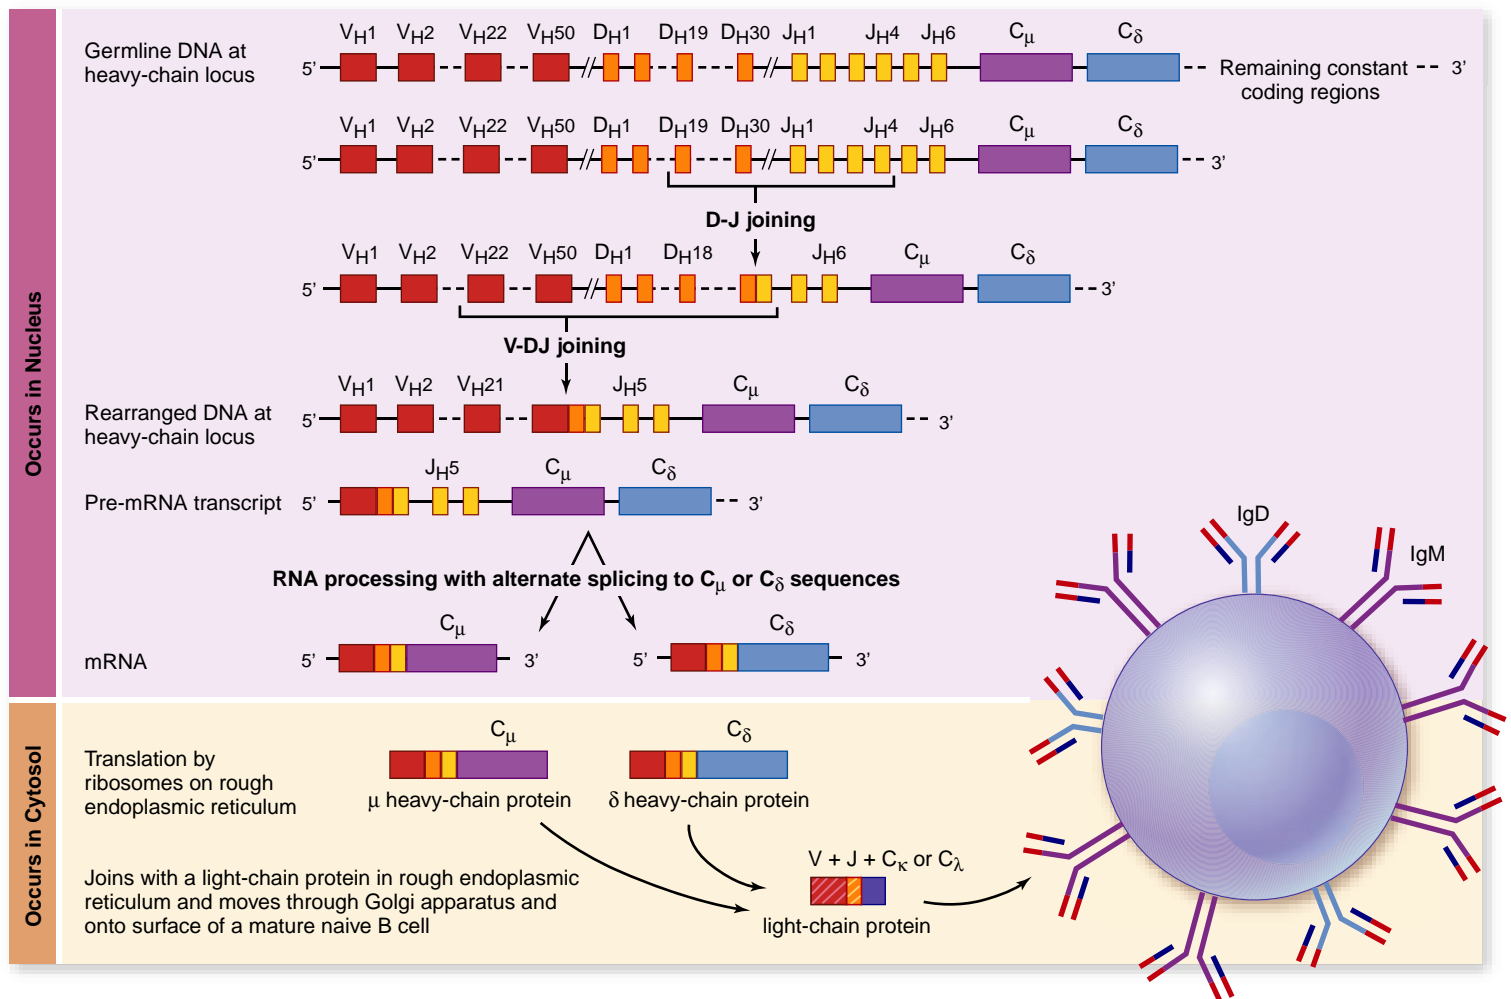

Alternative splicing of these RNA transcripts removes any extra J segments that remain 3' to the rearranged VDJ, as well as either  $\delta$  or  $\mu$  sequences, resulting in transcripts that all encode the same variable region but either  $\mu$  or  $\delta$  constant region exons, respectively. Translation results in a  $\mu$  or  $\delta$  heavy-chain

polypeptide, which associates with a light-chain polypeptide in the rough endoplasmic reticulum. Thus, the mature naive B cell expresses both IgM and IgD on its surface, both having the same antigen-binding specificity (see figure 52.16).

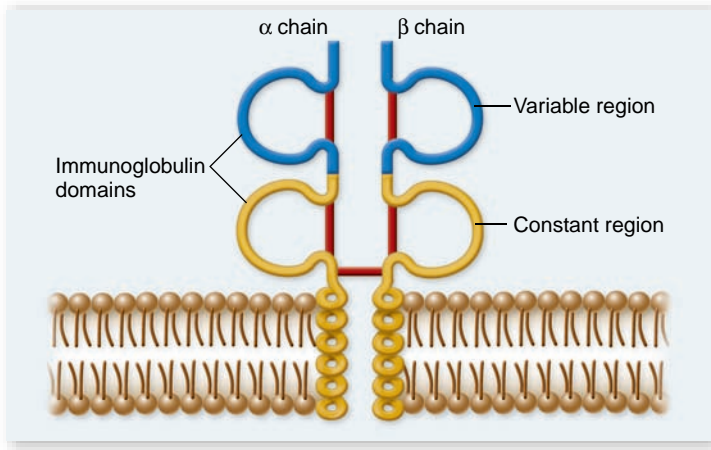

### T-cell receptors

At this point, we must briefly return to T-cell receptors and examine their similarity to the immunoglobulins of B cells. The structure of a TCR is essentially like a single Fab region of an immunoglobulin molecule (figure 52.17).

The TCR is a dimeric (two-chain) protein, with about 95% of TCRs composed of an  $\alpha$  chain and a  $\beta$  chain. The amino terminal halves of the two polypeptides are the variable domains that bind to self-MHC plus peptide, and the membrane-proximal halves are the constant domains of each polypeptide. The TCR variable-region gene loci also contain multiple DNA segments—V, D, and J, or only V and J—that

**Figure 52.16 Immunoglobulin diversity is generated by rearrangement of segments of DNA.** An immunoglobulin (Ig) protein is encoded by different segments of DNA: a V (variable), a D (diversity), and a J (joining) segment, plus a constant region. These are joined by a precise sequence of DNA rearrangements during maturation in the bone marrow. This first joins a D to a J segment, then this combined DJ joins to a V segment. Other cells will select other V, D, and J segments, contributing to Ig diversity. Transcription starts at the rearranged VDJ and continues through constant-region exons. Pre-mRNA splicing joins the variable region to either a  $\mu$  or a  $\delta$  constant region. These transcripts are translated by ribosomes on the RER to produce heavy-chain polypeptides that join with light chains (encoded by a V, a J, and a C). These proteins are transported to the cell surface, resulting in a mature naive B cell that expresses both IgM ( $\mu$  constant region) and IgD ( $\delta$  constant region), with the same variable region and thus the same antigen specificity.

**Figure 52.17** The structure of a TCR is similar to an immunoglobulin Fab. TCRs are composed of two chains—generally  $\alpha$  and  $\beta$ —joined by a disulfide bond (red). Each also includes two immunoglobulin domains as in an Ig Fab. The amino-terminal domain of each chain is the variable region that binds to an MHC–peptide complex, and the membrane-proximal domain is the constant region. Unlike Igs, TCRs are not secreted.

### Inquiry question

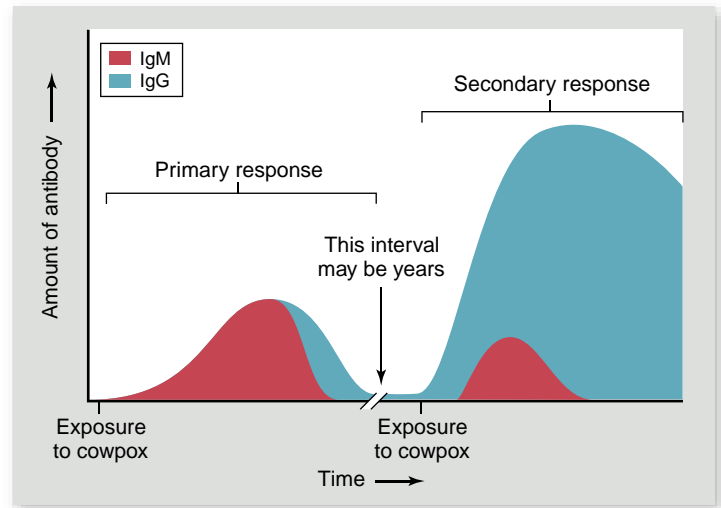

? What does the common structure and mechanism of formation of Igs and TCRs suggest about the evolution of B and T lymphocytes and these proteins?

are joined by the same enzymes and in a similar fashion to the immunoglobulin gene segments. This similarity in structure and DNA rearrangements produces similar diversity of TCRs as immunoglobulins.

## The secondary response to an antigen is more effective than the primary response

When a particular antigen enters the body, it must, by chance, encounter naive lymphocytes with the appropriate receptors to provoke an immune response. The first time a pathogen invades the body only a few B or T cells may exist with receptors able to recognize the pathogen's epitopes or, for infected or otherwise abnormal cells, foreign peptides bound to self-MHC. Thus, in this first encounter, a person develops symptoms of illness because only a few cells are present that can mount an immune response. Clonal expansion of T and B cells occurs, as well as secretion of IgM antibodies, but this takes several days (figure 52.18).

Because a clone of many memory cells develops during the primary response, the next time the body is invaded by the same pathogen, the immune system is ready. Memory cells are more rapidly activated than are naive lymphocytes, so a secondary immune response both initiates and peaks much more rapidly than a primary response. Further clonal expansion takes place, along with the secretion of large amounts of antibodies that are generally of the IgG class, although IgA and IgE are also possible (see figure 52.18). The class of immunoglobulin produced is dictated by the identity of the cytokines, derived from activated  $T_H$  memory cells, that bind to the B cells during their secondary response.

**Figure 52.18** The development of active immunity.

Immunity to smallpox in Jenner's patients occurred because their inoculation with cowpox stimulated the development of lymphocyte clones, including memory cells, with receptors that could bind not only to cowpox but also to smallpox antigens. A second exposure stimulates the memory cells to produce large amounts of antibody of the same specificity and much more rapidly than during the primary immunization. The first antibodies produced during the primary response are IgM in class (red), although IgG (blue) is secreted near the end of the primary response. The majority of the antibody secreted during a secondary response is IgG, although IgA could be secreted if the antigen has activated B cells in the MALT, or in some circumstances, such as allergies, IgE is secreted.

It is advantageous for an individual to produce immunoglobulins of different classes during an immune response because each class has a different function. During a second exposure to the same antigen, while memory cells are activated and secrete isotypes other than IgM, other naive B cells also recognize the antigen for the first time, become activated, and secrete IgM.

Memory cells can survive for several decades, which is why people rarely contract chicken pox a second time after they have had it once or been vaccinated against it. The vaccine triggers a primary response, so that if the actual pathogen is encountered later, a large and rapid secondary response occurs and stops the infection before disease symptoms are even detected. The viruses causing childhood diseases have surface antigens that change little from year to year, so the same antibody is effective for decades.

### Learning Outcomes Review 52.4

Antibodies have variable regions by which they recognize and bind to an antigen. Variable regions are encoded by joining distinct DNA segments, providing recognition diversity. Each antibody also has one of five kinds of constant region that determines its function; these five classes are IgA, IgD, IgE, IgG, and IgM. Vaccination artificially presents an antigen to elicit the primary response; when encountered later, a pathogen with this antigen is eliminated quickly by the secondary response.

■ How do Ig receptors differ from TLR innate receptors?

## 52.5 Autoimmunity and Hypersensitivity

### Learning Outcomes

1. Define autoimmune diseases.
2. Explain the cellular basis of the allergic reaction.

Sometimes the immune system is the cause of disease rather than the cure. Inappropriate responses to self-antigens may occur, as well as inappropriate or greatly heightened responses to foreign antigens, which, in turn, causes tissue damage.

A mature animal's immune system normally does not respond to that animal's own tissue. This acceptance of self cells is known as **immunological tolerance**. The immune system of a fetus undergoes the process of tolerance to lose the ability to respond to self-molecules as its development proceeds.

We now know that not all self-reactive T and B lymphocytes undergo apoptosis during selection in primary lymphoid organs. Normal healthy individuals are known to possess mature, potentially self-reactive lymphocytes. The activity of these cells, however, is regulated or suppressed so that they do not respond to the self-antigens they encounter. When this regulation or suppression breaks down, then humoral or cell-mediated responses can occur against self-antigens, causing serious and sometimes fatal disease.

Additionally, an immune response against a foreign antigen may be a greater one than is actually required to eliminate the antigen, or the response may be seemingly inappropriate to the antigen. Thus, instead of eliminating the antigen with only a localized inflammatory response, extensive tissue damage and occasionally death occurs.

### Autoimmune diseases result from immune system attack on the body's own tissues

Autoimmune diseases are produced by the failure of immunological tolerance. Autoreactive T cells become activated, and autoreactive B cells produce autoantibodies, causing inflammation and organ damage. More than 40 known or suspected autoimmune diseases exist, affecting 5 to 7% of the population. For reasons that are not understood, two-thirds of the people with autoimmune diseases are women.

Autoimmune diseases can result from a variety of mechanisms. For example, the self-antigen may normally be hidden from the immune system; if later it is exposed, the immune system may treat it as foreign. This happens, for example, when a protein normally trapped in the thyroid follicles triggers autoimmune destruction of the thyroid (Hashimoto thyroiditis). It also occurs in sympathetic ophthalmia in which antigens are released from the eye.

Because the immune attack triggers inflammation, and inflammation causes tissue and organ damage, the immune system must be suppressed to alleviate the symptoms of au-

toimmune diseases. Immune suppression is generally accomplished by administering corticosteroids and nonsteroidal anti-inflammatory drugs, including aspirin.

### Allergies are caused by IgE secretion in response to antigens

The most common form of allergy is known as immediate hypersensitivity. It is the result of excessive IgE production in response to antigens, generally referred to as allergens in this context. Allergens that provoke immediate hypersensitivity include various foods, the venom in insect stings, molds, animal danders, and pollen grains. The most common allergy of this type is seasonal hay fever, which may be provoked by the pollen from ragweed (*Ambrosia* spp.) or other plants. Allergies have earned the designation "immediate" because a response to an allergen occurs within seconds or minutes.

The first time or even the first few times that one encounters an allergen, the allergen binds to and activates B cells, which start to secrete allergen-specific immunoglobulins. Activated T<sub>H</sub> cells release cytokines such as IL-4, which bind to the B cells and dictate that the antibodies secreted should be IgE. The B cells rapidly switch from the more common IgG secretion to IgE secretion.

Unlike IgG, IgE rapidly binds to mast cells and basophils. When the individual is again exposed to the same allergen, the allergen now specifically binds to the exposed variable regions of identical IgE molecules attached to mast cells and basophils. This binding triggers these cells to secrete histamine, prostaglandins, and other chemical mediators, which produce the symptoms of allergy (figure 52.19).

In *systemic anaphylaxis*, the allergic reaction is severe and potentially life-threatening because of the rapid inflammatory response and release of chemical mediators. The individual experiences a tremendous drop in blood pressure; swelling of the epiglottis can block the trachea, and bronchial constriction can prevent the exit of air from the lungs. This combination of effects is referred to as *anaphylactic shock*. Death can result within 20 to 30 min without prompt medical treatment.

Fortunately, most people with allergies only experience *local anaphylaxis*, such as the itchy welts from hives, or the respiratory constriction of mild asthma. Diarrhea from response to food allergens is another form of local anaphylaxis.

Allergies have traditionally been treated with antihistamines that prevent histamine released by mast cells from binding to its receptor. More recently, a variety of drugs have been developed that block the activation of mast cells and basophils, so that they do not release their mediators. Hyposensitization treatment is another alternative; it consists of the injection, over several months, of an increasing concentration of the allergens to which one is allergic. In some individuals, particularly those with allergic rhinitis (runny nose and eyes) or asthma, this treatment seems to cause a preferential secretion of IgG rather than IgE, and allergy symptoms diminish over time.

**Figure 52.19 An allergic response.** On initial exposure to an allergen, B cells are activated to secrete antibodies of the IgE class. These antibodies are in very low levels in the plasma but rapidly bind to Fc receptors on mast cells or basophils. On subsequent exposure to allergen, the allergen cross-links variable regions of two neighboring IgEs with the same epitope specificity on mast cells and basophils. This induces the cells to release histamine and other mediators of inflammation that will cause the symptoms of allergy.

## Delayed-type hypersensitivity is mediated by $T_H$ cells and macrophages

Delayed-type hypersensitivity, which is mediated by  $T_H$  cells and macrophages, produces symptoms within about 48 hr after a second exposure to an antigen. (A first exposure causes a much slower primary response, such as described earlier, frequently without the manifestation of any symptoms.) A form of delayed-type hypersensitivity is contact dermatitis, caused by such varied materials as poison ivy, nickel in jewelry, and some cosmetics. After contact with poison ivy, oils that enter the skin complex with skin proteins, causing the proteins to appear foreign. A delayed-type hypersensitivity response requires that antigen entering the body travel to a secondary lymphoid organ, generally lymph nodes, where  $T_H$  cells can be activated. These activated  $T_H$  cells then recirculate around the body, and on encountering macrophages that have

ingested the antigen, they release cytokines that activate the macrophages. This induces the macrophages to release other cytokines, and in the case of poison ivy, itchy welts on the skin erupt. The time required for the activation of  $T_H$  cells and then of macrophages is the reason for the “delayed” response to the antigens.

### Learning Outcomes Review 52.5

Autoimmunity, allergies (immediate hypersensitivity), and delayed hypersensitivity are all examples of inappropriate or heightened immune responses. Autoimmunity results from a loss of self-tolerance. Allergies are associated with a rapid response from mast cells when an allergen binds to IgE on these cells' membrane. Delayed hypersensitivity to pathogens or irritants such as poison ivy is mediated by  $T_H$  cells and macrophages.

- How are allergies different from autoimmune diseases?

## 52.6 Antibodies in Medical Treatment and Diagnosis

### Learning Outcomes

1. Explain antigen–antibody reactions in the ABO blood group system.
2. Define monoclonal antibodies.
3. Describe the use of monoclonal antibodies in diagnosis.

The vertebrate immune system can have a range of effects on medical treatment of disease. As two examples, we discuss blood type and its effect on transfusion, as well as the use of monoclonal antibodies for diagnosis and treatment.

### Blood type indicates the antigens present on an individual's red blood cells

A person's blood type is determined by certain antigens found on the red blood cell surface. These antigens are clinically important because they must be matched between donor and recipient during a blood transfusion.

#### ABO groups

In chapter 12, you learned about the genetic basis of the human *ABO blood groups*. The protein–sugar complex on the surface of the red blood cells acts as an antigen, and these antigens differ with regard to the sugar present (or absent, in the case of type O). The immune system is tolerant to its own red blood cell antigens but makes antibodies that bind to those that differ, causing agglutination (clumping) and lysis of foreign red blood cells. Apparently, IgM antibodies made in response to carbohydrates on bacteria that are part of our normal flora also recognize the monosaccharide differences on red blood cells. Such antibodies are not made against carbohydrate patterns that are also present on our own cells.

#### Rh factor

Another important blood-borne antigen is the Rh antigen or *Rh factor*. This protein is either present (Rh positive) or absent (Rh negative) on the surface of red blood cells. An Rh-negative person who receives an Rh-positive blood transfusion produces antibodies to the foreign Rh protein on the transfused cells.

An additional complication occurs when Rh-negative mothers carry Rh-positive fetuses, which may result in the infant exhibiting a condition called hemolytic disease of newborns (HDN). A first child is usually not harmed; however, at the time of the first birth, the Rh-negative mother's immune system may be exposed to fetal blood. As a result, the woman may become sensitized and produce antibodies and memory B cells against the Rh antigen. If any exposure to fetal blood occurs during a subsequent pregnancy, IgG antibodies, secreted on activation of these memory cells, can cross the placenta and cause destruction of the red blood cells of the fetus.

Blood typing is done by taking advantage of the circulating IgM antibodies, which are produced against foreign blood antigens but not against self. If type A blood is mixed with serum from a person with type B or type O blood, the anti-A antibodies in the serum cause the type A red blood cells to agglutinate. This does not happen if type A blood is mixed with serum from another type A individual or from a type AB individual.

Similarly, if serum from an Rh-negative individual is added to red blood cells, agglutination of the red blood cells indicates that they came from an Rh-positive individual. This individual's blood would not be an appropriate match for transfusion.

Typing of blood prior to transfusions prevents destruction of mismatched cells by a transfusion recipient, as described next. Over 20 blood groups, including the ABO and Rh groups, have been identified; most variants of these other blood groups are rare, but individuals at risk for mismatch may need to “stockpile” their own blood before elective surgery—a practice termed *autologous blood donation*.

### Transfusion reactions result from mismatched blood transfusions

Prior to the advent of blood typing in the early 20th century, transfusion of blood was a last resort because of the danger of death from transfusion reaction. An immediate transfusion reaction occurs when an individual receives blood that is not correctly ABO matched. Typically, within 5 to 8 hr of the start of the transfusion, tremendous intravascular hemolysis (rupture) of the transfused red blood cells is detected. This rupture is a result of IgM binding to foreign antigens and activating the complement system. The result is the formation of MACs in the red blood cell membranes and rapid osmotic lysis of the cells.

The hemoglobin released from the red blood cells is converted to a molecule called *bilirubin*, which is particularly toxic to cells and can cause severe organ damage, especially to the kidneys. The major treatment in such situations is to stop the transfusion immediately and to administer large amounts of intravenous fluids to “wash” the bilirubin from the body.

### Monoclonal antibodies are a valuable tool for diagnosis and treatment

Antibodies to a known antigen may be obtained by chemically purifying an antigen and then injecting it into a laboratory animal (vertebrate). Periodic bleeding of the animal after a few immunizations allows the isolation of serum antibodies against the antigen. But because an antigen typically has many different epitopes, the antibodies obtained by this method are *polyclonal*, that is, they are secreted by B-cell clones with many different specificities. Their polyclonal nature decreases their sensitivity to any one particular epitope, and it may result in some degree of cross-reactivity with closely related epitopes of different antigens.

*Monoclonal antibodies*, by contrast, exhibit specificity for one epitope only. In the preparation of monoclonal antibodies, an animal, generally a mouse, is immunized several times with an antigen and is subsequently killed. B lymphocytes, many of

**Figure 52.20 The production of monoclonal antibodies.** These antibodies are of a single specificity and are produced by “hybridoma” cells. These result from the fusion of B cells, specific for a particular antigenic determinant, with myeloma cells, a B-cell tumor that no longer secretes Ig but provides immortality to the fusion. After hybridoma production, the antibody produced by each hybridoma is tested to see whether it produces specific antibodies against the desired antigen. Selected hybridomas are grown in mass culture for antibody production and are frozen for future use.

which should now be specific for epitopes of the antigen, are collected from the animal’s spleen. These B cells would soon die in culture, but utilizing a technique first described in 1975, they are fused with cancerous multiple myeloma cells. These myeloma cells have all the characteristics of plasma cells, except for the secretion of immunoglobulins—but more importantly, they are immortal, meaning they will divide indefinitely. The outcome of a B-cell/myeloma cell fusion is a *hybridoma cell*, that can divide indefinitely and that continues to secrete a large quantity of identical, monoclonal antibodies of the specificity produced by a single B cell (figure 52.20).

### Monoclonal antibodies and diagnostic testing

The availability of large quantities of pure monoclonal antibodies has allowed the development of much more sensitive clinical laboratory tests. Some pregnancy tests, for example, use a monoclonal antibody produced against the hormone human chorionic gonadotrophin (hCG, secreted early in pregnancy). The test uses hCG-coated latex particles that are exposed to a urine sample and anti-hCG antibody. If the urine contains hCG, it will block binding of the antibody to the hCG-coated particles and prevent their agglutination, indicating pregnancy based on the presence of hCG (figure 52.21).

**Figure 52.21 Using monoclonal antibodies to detect an antigen.** Many clinical tests, such as pregnancy testing, use monoclonal antibodies. A specific antigen is attached to latex beads that are mixed with the test sample and a monoclonal antibody specific for the antigen. If no antigen is present in the sample, the antibody will cause agglutination of the beads. If the sample contains the antigen, it will bind to the antibodies and prevent agglutination of the beads by the antibody.

### Inquiry question

? How would a high level of HCG present in a urine sample be indicated in this agglutination test?

**Acquired immunodeficiency syndrome (AIDS)** is characterized in part by destruction of  $T_H$  cells. The progression of this disease can be monitored by examining the reactivity of a patient's leukocytes with a monoclonal antibody against CD4, a marker of  $T_H$  cells, to track a decrease in the number of these cells.

### Learning Outcomes Review 52.6

Blood group antibodies in plasma made blood transfusion risky and often fatal in the past. Type O RBCs have no surface antigen, but serum from a type O person has both anti-A and anti-B antibodies; someone with type A produces anti-B, and someone with B produces anti-A. Type AB serum lacks A or B antibodies, but RBCs have both surface antigens. Monoclonal antibodies are specific for only a single epitope (antigenic determinant). Hybridoma technology has allowed production of monoclonal antibodies for use in diagnostic tests and elimination of tumors.

- Why do diagnostic kits use monoclonal rather than polyclonal antibodies?

## 52.7 Pathogens That Evade the Immune System

### Learning Outcomes

1. Explain how pathogens can change antigenic specificity.
2. Describe how the immune system has affected the evolution of pathogens.

For any pathogen to establish itself in a host and to cause a productive infection in which the pathogen successfully reproduces, the pathogen must evade both the nonspecific and specific immune systems. In response to the selective pressure caused by the development of previous immunity against specific epitopes on the pathogen, many pathogens can alter the structure of their surface antigens so that they are no longer recognized. This is a form of natural selection that allows pathogens with altered surface antigens to survive and continue to cause infection. Other pathogens have simply evolved ways to evade destruction. Infection by still other pathogens can actually cause the death of cells of the immune system.

### Many pathogens change surface antigens to avoid immune system detection

Influenza virus is perhaps the most universally known example of an organism or virus altering its surface antigens and thus avoiding immune system recognition and destruction. Because of this tendency of the virus to change, yearly immunizations against influenza virus are recommended.

The two viral proteins expressed on the influenza virus' envelope, as well as on the surface of cells infected by influenza virus, are hemagglutinin (HA) and neuraminidase (NA). Because this virus has an RNA genome, it is replicated by a

viral RNA polymerase that lacks proofreading ability. As a result, mutations are likely to accumulate over time, including point mutations to the HA and NA genes. This is referred to as **antigen drift**.

Even more dramatically but less frequently, the HA and NA proteins may also undergo **antigen shift**, referring to the sudden appearance of a new subtype of influenza virus in which the expressed HA or NA proteins (or both) are completely different. Such a change makes the population particularly susceptible to infection. Immunization with a new vaccine created every year using the most common strains of the virus attempts to establish immunity in the population prior to infection by the strains circulating.

Antigen shifting and the resulting lack of immunity is the reason for the recent interest in "bird flu." The subtype of influenza that causes bird flu is characterized as H5N1, a primarily avian form of influenza to which people have no immunity. There is no evidence as of this writing, however, that the H5N1 virus can infect people except through contact with infected birds. This strain has been a source of concern due to the high mortality rates seen in human infections. Even more recently, a flu strain with the subtype H1N1 has jumped from pigs to humans and is proving to be very infectious. Current evidence is that the mortality rate is not higher than most strains of influenza, but the World Health Organization has now declared that this particular strain has reached pandemic levels in the population (see chapter 27).

Many other pathogens can alter or shift their surface antigens in order to avoid immune system destruction. As another example, every year, more than 1 million people, the vast majority of whom are African children under the age of 5, die from malaria. This disease, as described in chapter 29, is caused by the protozoan parasite *Plasmodium* and contracted when humans are bitten by an infected *Anopheles* mosquito. These protozoans have several life-cycle stages and are hidden from the immune system alternately within host hepatocytes or red blood cells. In addition, they can alter some of the proteins expressed during certain life cycle stages. Continued use of certain anti-*Plasmodium* drugs has also selected for the emergence of multi-drug-resistant organisms. Work is ongoing to develop a vaccine that would induce effective immunity to specific life cycle stages and that would thus promote immune system elimination of the *Plasmodium*.

### Inquiry question

Why were we able to eliminate smallpox virus using a vaccine but cannot eliminate influenza?

### Many mechanisms have evolved in bacteria to evade immune system attack

*Salmonella typhimurium*, a common cause of food poisoning, can alternate between expression of two different flagellar proteins, so that antibodies made to one protein do not recognize the other protein and therefore cannot be used to promote phagocytosis of the bacteria.

*Mycobacterium tuberculosis* bacteria, once phagocytosed into macrophages, inhibit fusion of the phagosome with

lysosomes. These organisms can then multiply quite successfully within the macrophages.

Other bacteria that invade mucosal surfaces, such as *Neisseria meningitidis* or *Neisseria gonorrhoeae*, secrete proteases that degrade the IgA antibodies that protect the mucosal surface. External capsules on many particularly pathogenic strains of bacteria block binding of the phagocytosis-inducing complement protein C3b, slowing the phagocytosis response. Because bacteria utilizing any of these mechanisms are better able to survive, the immune response acts as selective pressure favoring the evolution of such mechanisms.

## HIV infection kills $T_H$ cells and causes immunosuppression

One mechanism for defeating vertebrate defenses is to attack the adaptive immune system itself.  $CD4^+$   $T_H$  cells play a central role in the activity of the immune system: The cytokines they secrete directly or indirectly affect the activity of all other cells of the immune system.

**HIV, human immunodeficiency virus**, mounts a direct attack on  $T_H$  cells (see chapter 27). It binds to the CD4 proteins present on these cells and utilizes these proteins to promote endocytosis into the cells. (The virus infects monocytes as well because they too express CD4.) HIV-infected cells die only after releasing replicated viruses that infect other  $CD4^+$  cells (figure 52.22). Over time, the number of  $T_H$  cells in an infected individual decreases.

An individual is considered to have AIDS when his or her  $T_H$  cell levels have dropped dramatically, leading to an increase in infections due to opportunistic organisms as well as other diseases.

### The progression of HIV infection

The immune system initially controls an HIV infection by the production of antibodies to the virus and by the elimination of virally infected cells by cytotoxic T cells. For a time, the level of HIV in the serum does not increase beyond a steady state, and the number of  $T_H$  cells does not significantly decrease.

As the virus reproduces in the  $T_H$  cells, it rapidly kills some of them, but many others continue to divide on antigen stimulation. Eventually, however, HIV kills  $T_H$  cells more rapidly than they can proliferate. HIV-encoded proteins also cause a decrease in the expression of MHC class I on the infected cells, so that these cells are less likely to be recognized and killed by  $T_C$  cells.

Finally, because HIV is a retrovirus (see chapter 27), it can integrate itself into the genome of infected cells and hide in a “latent” form. When any of these cells divides, the HIV genome is present in the progeny cells and thus these progeny can start to produce HIV at any point in time.

The combined effect of these responses to HIV infection is to ravage the human immune system. With little defense against infection, any of a variety of otherwise commonplace infections may prove fatal. Death by cancer also becomes far more likely. In fact, AIDS was first recognized as a disease when a cluster of previously healthy young men all died of *Pneumocystis jiroveci*-induced pneumonia, a disease that gener-

**Figure 52.22 HIV, the virus that causes AIDS.** Viruses released from infected  $CD4^+$   $T_H$  cells soon spread to neighboring  $T_H$  cells, infecting them in turn. The individual viruses, colored red in this scanning electron micrograph, are extremely small; over 200 million would fit on the period at the end of this sentence.

ally affects the immunosuppressed, or of Kaposi's sarcoma, a rare form of cancer.

### The human effect of HIV

Although HIV became a human disease only recently, AIDS is already clearly one of the most serious diseases in human history. The WHO estimates that for the year 2007 between 30 and 36 million people are living with AIDS, with the greatest number in sub-Saharan Africa (about 22 million), followed by south and southeast Asia (4.2 million). For 2007, the WHO estimates there were 2.5 million people newly infected, and an estimated 2.1 million deaths worldwide.

The fatality rate of untreated AIDS is close to 100%. No patient exhibiting the symptoms of AIDS has been known to survive more than a few years without treatment. The disease is not highly contagious, however; it is transmitted from one individual to another through the transfer of internal body fluids, typically semen and blood.

### Learning Outcomes Review 52.7

Pathogens such as influenza virus frequently alter epitopes on their surfaces and thus evade specific immune-system recognition. Other pathogens, such as HIV, infect and destroy  $T_H$  cells, simply disabling the immune system. The diseases associated with AIDS often result from destruction of the immune system.

- *Polio is a viral disease against which vaccines have been very successful. How would you say this virus differs from influenza virus?*

## Chapter Review

### 52.1 Innate Immunity

#### *The skin is a barrier to infection.*

In addition to being a physical barrier, skin has a low surface pH, lysozyme secreted in sweat, and a population of nonpathogenic organisms, all of which deter pathogens.

#### *Mucosal epithelial surfaces also prevent entry of pathogens.*

The epithelia of the digestive, respiratory, and urogenital tracts produce mucus to trap microorganisms.

#### *Innate immunity recognizes molecular patterns.*

Toll-like receptors have leucine-rich regions that recognize molecules such as LPS and peptidoglycan.

#### *Innate immunity leads to diverse responses to a pathogen.*

Binding of pathogen-associated molecular patterns (PAMPs) leads to production of antimicrobial peptides and cytokines, and activation of complement, among other actions.

#### *Phagocytic cells are associated with innate immunity.*

Macrophages and neutrophils are associated with phagocytosis (see figure 52.4). Natural killer (NK) cells induce apoptosis.

#### *The inflammatory response is a nonspecific response to infection or tissue injury.*

Histamines increase blood flow and permeability of capillaries (see figure 52.5). Acute-phase fever promotes phagocytic activity and impedes growth of microbes.

#### *Complement can form a membrane attack complex.*

Complement forms pores in invading cells, coats pathogens with C3b proteins, and targets cells for destruction.

### 52.2 Adaptive Immunity

#### *Immunity had long been observed, but the mechanisms have only recently been understood.*

Jenner's and Pasteur's work on cowpox and avian cholera indicated that prior exposure to a disease prevented subsequent infections

#### *Antigens stimulate specific immune responses.*

Surface receptors on lymphocytes recognize antigens and direct a specific immune response (see figure 52.8).

#### *Hematopoiesis gives rise to the cells of the immune system (see table 52.1).*

#### *Lymphocytes carry out the adaptive immune responses.*

A naive lymphocyte binds to a foreign antigen and divides, producing a clone of activated cells and memory cells.

Humoral immunity is the production of Ig by B cells. Cell-mediated immunity involves T cells that regulate the immune responses of other cells or directly attack cells.

#### *Adaptive immunity can be active or passive.*

#### *The immune system is supported by two classes of organs.*

Immune system organs include the primary lymphoid organs and secondary lymphoid organs (see figure 52.9).

#### *Two forms of adaptive immunity have evolved.*

An immune system based on proteins with variable repeats has been found in jawless fishes, in contrast to the immunoglobulin system of other vertebrates.

### 52.3 Cell-Mediated Immunity

#### *The MHC carries self and nonself information.*

Most cells exhibit glycoproteins encoded by the MHC. In humans these proteins are called human leukocyte antigens (HLAs). MHC class I proteins, found on every nucleated cell, present antigen brought into the cell by phagocytosis; MHC class II proteins are found only on antigen-presenting cells.

#### *Cytotoxic T cells eliminate virally infected cells and tumor cells.*

T<sub>C</sub> cells recognize virally infected cells and tumor cells. They destroy cells in a fashion similar to NK cells (see figure 52.11).

#### *Helper T cells secrete proteins that direct immune responses.*

T<sub>H</sub> cells secrete cytokines in response to foreign antigens and promote both cell-mediated and humoral immune responses. Activated T<sub>C</sub> and T<sub>H</sub> produce both effector and memory cells.

#### *T cells are the primary cells that mediate transplant rejection.*

#### *Cells of the innate immune system release cytokines.*

Macrophages release interleukin-12 and tumor necrosis factor- $\alpha$ .

### 52.4 Humoral Immunity and Antibody Production

#### *Immunoglobulin structure reveals variable and constant regions.*

B cells are activated by membrane Ig molecules binding to a specific epitope on an antigen. Activated B cells produce antibody secreting plasma cells and memory cells.

Immunoglobulins consists of two light chain and two longer heavy-chain polypeptides, with the binding site in the Fab region (see figure 52.14). Antibodies can agglutinate, precipitate, or neutralize antigens (see figure 52.15).

#### *The five classes of immunoglobulins have different functions (see table 52.3).*

#### *Immunoglobulin diversity is generated through DNA rearrangement.*

Ig diversity is generated by DNA rearrangements (see figure 52.16). T cell receptors (TCRs) are similar to a single Fab region of an Ig. Their diversity also results from DNA rearrangements.

#### *The secondary response to an antigen is more effective than the primary response.*

On second exposure to a pathogen, a rapid secondary immune response is launched due to memory cells (see figure 52.18).

### 52.5 Autoimmunity and Hypersensitivity

#### *Autoimmune diseases result from immune system attack on the body's own tissues.*

The acceptance of self-cells is called immunological tolerance. Autoimmunity is a failure of immunological tolerance.

#### *Allergies are caused by IgE secretion in response to antigens.*

Immediate hypersensitivity is caused by allergens' binding to IgE, triggering the release of histamine (see figure 51.19). Anaphylaxis is a severe reaction with rapid inflammation and release of chemical mediators.

#### *Delayed-type hypersensitivity is mediated by T<sub>H</sub> cells and macrophages.*

Symptoms appear about 48 hr after second exposure.

## 52.6 Antibodies in Medical Treatment and Diagnosis

**Blood type indicates the antigens present on an individual's red blood cells.**

The ABO blood group antigens, Rh factor antigens, and many others constitute the blood type.

HLA antigens can be used to match tissues between donors and recipients in transplants.

**Transfusion reactions result from mismatched blood transfusions.**

Before blood type was understood, many died from mismatched blood transfusions.

**Monoclonal antibodies are a valuable tool for diagnosis and treatment.**

Monoclonal antibodies are specific to a single epitope and can be used in testing and manufacture of immunotoxins.

## 52.7 Pathogens That Evade the Immune System

**Many pathogens change surface antigens to avoid immune system detection.**

Antigen drift and antigen shift, such as exhibited in influenza viruses, allow alteration of surface antigens to avoid immune detection.

**Many mechanisms have evolved in bacteria to evade immune system attack.**

Some bacteria have evolved mechanisms to inhibit normal immune system processes, such as slowing phagocytosis.

**HIV infection kills  $T_H$  cells and causes immunosuppression.**

Destruction of  $T_H$  cells lowers the body's ability to fend off infections, leading to the characteristic illnesses of AIDS.

### Review Questions

#### UNDERSTAND

- Cells that target and kill body cells infected by viruses are
  - macrophages.
  - natural killer cells.
  - monocytes.
  - neutrophils.
- Structures on invading cells recognized by the adaptive immune system are known as
  - antigens.
  - interleukins.
  - antibodies.
  - lymphocytes.
- Which one of the following acts as the “alarm signal” to activate the body's adaptive immune system by stimulating helper T cells?
  - B cells
  - Interleukin-1
  - Complement
  - Histamines
- Cytotoxic T cells are called into action by the
  - presence of histamine.
  - presence of interleukin-1.
  - presence of interleukin-2.
  - interferon.
- Receptors that trigger innate immune responses
  - are antibodies recognizing specific antigens.
  - are T-cell receptors recognizing specific antigens.
  - recognize pathogen-associated molecular patterns.
  - are not specific at all.
- Diseases in which the person's immune system no longer recognizes its own MHC proteins are called
  - allergies.
  - autoimmune diseases.
  - immediate hypersensitivity.
  - delayed hypersensitivity.

- Suppose that a new disease is discovered that suppresses the immune system. Which of the following would indicate that the disease specifically affects the B cells rather than the helper or cytotoxic T cells?
  - A decrease in the production of interleukin-2
  - A decrease in interferon production
  - A decrease in the number of plasma cells
  - A decrease in the production of interleukin-1

#### APPLY

- You start a new job in a research lab. The lab protocols state that you should check your hands for any breaks in the skin before handling infectious agents. This is because the epidermis fights microbial infections by
  - making the surface of the skin acidic.
  - excreting lysozyme to attack bacteria.
  - producing mucus to trap microorganisms.
  - all of these.
- In comparing T-cell receptors and immunoglobulins
  - the proteins have unrelated structures, but diversity is generated by a similar mechanism.
  - the proteins have related structures, but diversity is generated by different mechanisms.
  - the proteins have related structures, and diversity is generated by a similar mechanism.
  - the proteins have unrelated structures, and diversity is generated by different mechanisms.
- If you have type AB blood, which of the following results would be expected?
  - Your blood agglutinates with anti-A antibodies only.
  - Your blood agglutinates with anti-B antibodies only.

- c. Your blood agglutinates with both anti-A and anti-B antibodies.
  - d. Your blood would not agglutinate with either anti-A or anti-B antibodies.
4. Suppose that you get a paper cut while studying. Arrange the following into the correct order in time.
    - a. Injured epidermal cells release histamine.
    - b. Bacteria enter the cut.
    - c. Helper T cells are activated.
    - d. Macrophages engulf bacteria.
  5. If you wanted to cure allergies by bioengineering an antibody that would bind and disable the antibody responsible for allergic reactions, which of the following would you target?
 

a. IgG	c. IgE
b. IgA	d. IgD
  6. Why do we need to be repeatedly vaccinated for influenza viruses?
    - a. Because they attack only the helper T cells, thereby suppressing the immune system
    - b. Because they alter their surface proteins and thus avoid immune recognition
    - c. Because they don't actually generate an immune response, the "flu" is actually an inflammatory response
    - d. Because they are too small to serve as good antigens
  7. If you wanted to design an artificial cell that could safely carry drugs inside the body, which of the following molecules would you need to mimic to deter the immune system?
 

a. MHC-1	c. Antigen
b. Interleukin-1	d. Complement

## SYNTHESIZE

1. Suppose you take a job in the marketing department of a cosmetics company. Always seeking a competitive advantage, the vice president of marketing has decided to advertise the new skin lotion as having immune-enhancing effects. The lotion is produced from secretions of a plant that releases extremely watery, alkaline fluid. Explain how you will market this product as an immune-enhancer.
2. Your new kitten scratches your roommate. Her skin is reddened and feels warm and sore to the touch; she thinks she has contracted some kind of fatal infection. In order to deflect her anger (she is definitely not a cat person!), you try telling her about the activities of the innate defense system. Explain what is actually happening to her skin.
3. Some people claim that they never catch colds. How could you show that this is due to a difference in receptors on their respective cell surfaces?
4. Toll-like receptors have been found in a wide variety of organisms, including both protostomes and deuterostomes, and now in cnidarians. In addition, parts of the signaling system have been found in a wide variety of organisms as have parts of the complement system. What does this say about the evolution of innate immunity?

# The Reproductive System

## Chapter Outline

- 53.1** Animal Reproductive Strategies
- 53.2** Vertebrate Fertilization and Development
- 53.3** Structure and Function of the Human Male Reproductive System
- 53.4** Structure and Function of the Human Female Reproductive System
- 53.5** Contraception and Infertility Treatments

## Introduction

Bird song in the spring, insects chirping outside the window, frogs croaking in swamps, and wolves howling in a frozen northern forest are all sounds of evolution's essential act, reproduction. These distinctive noises, as well as the bright coloration of some animals, function to attract mates. Few subjects pervade our everyday thinking more than sex, and few urges are more insistent. This chapter deals with sex and reproduction among the vertebrates, including humans.

### 53.1 Animal Reproductive Strategies

#### Learning Outcomes

1. Distinguish between sexual and asexual methods of reproduction.
2. Describe the different types of hermaphroditism.
3. Explain factors that influence sex determination.

Most animals, including humans, reproduce sexually. As described in chapter 11, sexual reproduction requires a spe-

cialized form of cell division, meiosis, to produce haploid gametes, each of which has a single complete set of chromosomes. These gametes, including sperm and eggs (or *ova*; singular *ovum*), are united by fertilization to restore the diploid complement of chromosomes. The diploid fertilized egg, or zygote, develops by mitotic division into a new multicellular organism.

Bacteria, archaea, protists, and multicellular animals including cnidarians and tunicates, as well as many other types of animals, reproduce asexually. In asexual reproduction, genetically identical cells are produced from a single parent cell through mitosis. In single-celled organisms, an individual organism divides, a process called fission, and then each part becomes a separate but identical organism. Cnidarians

commonly reproduce by budding, whereby a part of the parent's body becomes separated from the rest and differentiates into a new individual (figure 53.1). The new individual may become an independent animal or may remain attached to the parent, forming a colony.

### Some species have developed novel reproductive methods

Another form of asexual reproduction, **parthenogenesis**, is common in many species of arthropods. In parthenogenesis, females produce offspring from unfertilized eggs. Some species are exclusively parthenogenic (and all female), whereas others switch between sexual reproduction and parthenogenesis, producing progeny that are both diploid and haploid, respectively. In honeybees, for example, a queen bee mates only once and stores the sperm. She then can control the release of the sperm. If no sperm are released, the eggs develop parthenogenetically into haploid drones, which are males. If sperm are allowed to fertilize the eggs, the fertilized eggs develop into diploid worker bees, which are female. However, when fertilized eggs are exposed to the appropriate hormone, they will develop into queens.

In 1958, the Russian biologist Ilya Darevsky reported one of the first cases of unusual modes of reproduction among vertebrates. He observed that some populations of small lizards of the genus *Lacerta* were exclusively female, and he suggested that these lizards could lay eggs that were viable even if they were not fertilized. In other words, they were capable of asexual reproduction in the absence of sperm, a type of parthenogenesis. Further work has shown that parthenogenesis has evolved a number of times in lizards, as well as in fish and salamanders.

Another variation in reproductive strategies is hermaphroditism, in which one individual has both testes and ovaries, and so can produce both sperm and eggs. A tape-

**Figure 53.1 Cnidarian budding.** This cnidarian reproduces asexually by budding. The new individual can be seen in the lower right of the micrograph.

**Figure 53.2 Hermaphroditism and protogyny.** The bluehead wrasse, *Thalassoma bifasciatum*, is protogynous—females sometimes turn into males. Here, a large male, which had been a female before changing sex, is seen among females, which are typically much smaller.

#### Inquiry question

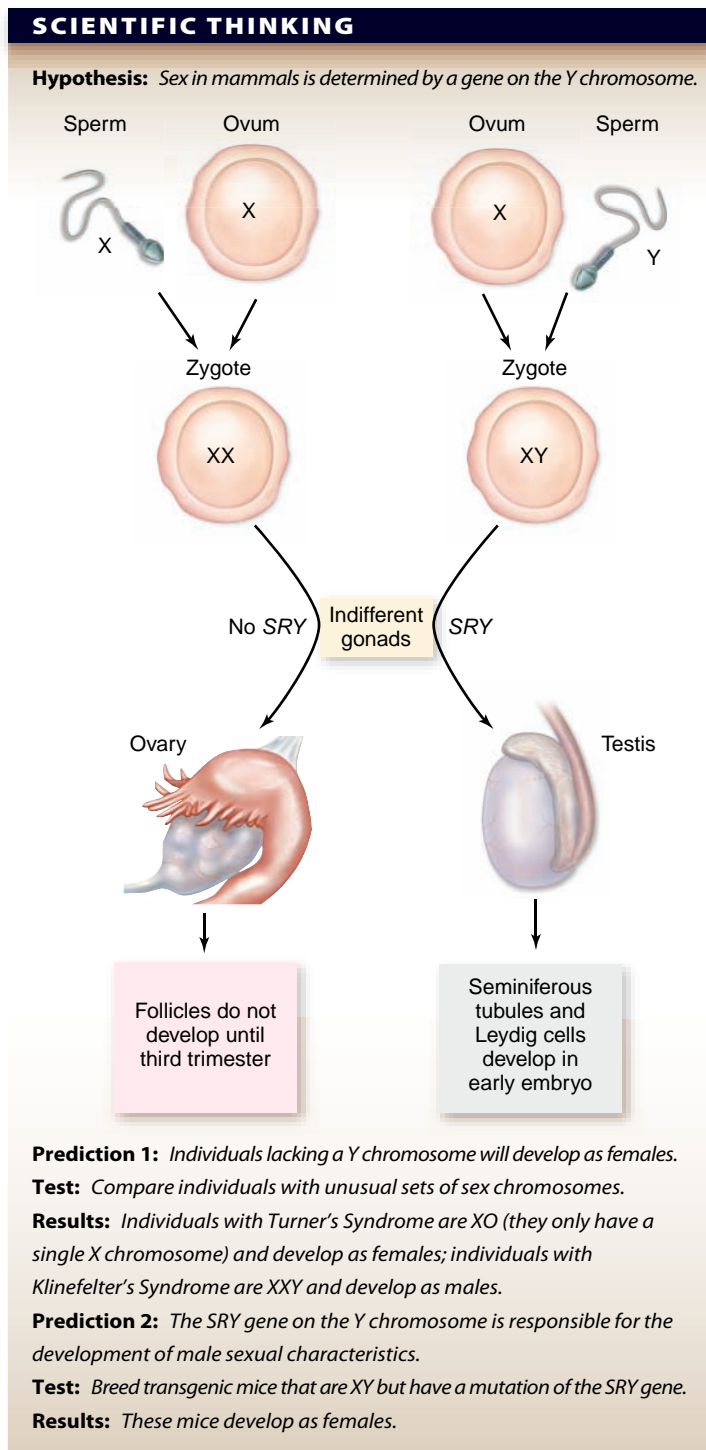

Why might it be adaptive for an individual to be female at small size and become male when very large? Under what circumstances might the opposite condition, protandry, evolve?

worm is hermaphroditic and can fertilize itself, a useful strategy because it is unlikely to encounter another tapeworm. Most hermaphroditic animals, however, require another individual in order to reproduce. Two earthworms, for example, are required for reproduction—each functions as both male and female during copulation, and each leaves the encounter with fertilized eggs.

Numerous fish genera include species whose individuals can change their sex, a process called *sequential hermaphroditism*. Among coral reef fish, for example, both protogyny (“first female,” a change from female to male) and protandry (“first male,” a change from male to female) occur. In fish that practice protogyny (figure 53.2), the sex change appears to be under social control. These fish commonly live in large groups, or schools, where successful reproduction is typically limited to one or a few large, dominant males. If those males are removed, the largest female rapidly changes sex and becomes a dominant male.

## Sex can be determined genetically or by environmental conditions

An individual's sex is determined during development as an embryo, but the way in which it occurs varies among species.

**Figure 53.3 Sex determination in mammals.** The sex-determining region of the mammalian Y chromosome is designated SRY. Testes are formed when the Y chromosome and SRY are present; ovaries are formed when they are absent.

## Temperature-sensitive sex determination

In many fish and reptiles, an individual's sex is determined by the temperature it experiences during development. In some species, cold temperatures produce males and warm temperatures produce females, but in others, the opposite occurs. In still others, males are produced at both high and low temperatures, and females at temperatures in-between.

Phylogenetic analyses indicate that temperature-sensitive sex determination has evolved many times from ancestors in which sex was genetically determined. The molecular mechanisms that determine sex in this species are now being discovered, but why this trait has evolved so often is not well understood. One possibility is that sometimes it may be advantageous for a female to be able to determine the sex of her offspring by laying eggs in appropriate locations. Currently, the jury is still out on this hypothesis.

## Genetic sex determination

In all birds and mammals and many other vertebrates, the sex is determined by an individual's genes. In mammals and some other animals, individuals with an X and a Y chromosome are males, whereas individuals with two X chromosomes are females. However, in other animals, such as birds, it is females that are the heterozygous sex.

## Sexual differentiation in humans

The reproductive systems of human males and females appear similar for the first 40 days after conception. During this time, the cells that will give rise to ova or sperm migrate from the yolk sac to the embryonic gonads, which have the potential to become either ovaries in females or testes in males (figure 53.3). For this reason, the embryonic gonads are said to be "indifferent."

If the embryo is a male, a gene on the Y chromosome converts the indifferent gonads into testes. In females, which lack a Y chromosome, this gene and the protein it encodes are absent, and the gonads become ovaries. An important gene involved in sex determination is known as SRY (for "sex-determining region of the Y chromosome").

Once testes have formed in the embryo, the testes secrete testosterone and other hormones that promote the development of the male external genitalia and accessory reproductive organs.

If the embryo lacks the SRY gene, the embryo develops female external genitalia and accessory organs. In other words, all mammalian embryos will develop into females unless a functional SRY gene is present.

## Learning Outcomes Review 53.1

Sexual reproduction involves fusion of gametes derived from different individuals of a species. Asexual reproduction in some species may be accomplished by fission, budding, or parthenogenesis. In hermaphroditic species, an individual may have both testes and ovaries; in sequential hermaphroditism, an individual may change from one sex to the other. Sex can be determined either by genes or by environmental conditions such as temperature experienced while an embryo.

- **Why might natural selection favor genetic sex determination?**

## 53.2 Vertebrate Fertilization and Development

### Learning Outcomes

1. Distinguish among viviparity, oviparity, and ovoviviparity.
2. Describe the advantages of internal fertilization.

Vertebrate sexual reproduction evolved in the ocean before vertebrates colonized the land. The females of most species of marine bony fish produce eggs in batches and release them into the water. The males generally release their sperm into the water containing the eggs, where the union of the free gametes occurs. This process is known as external fertilization.

Although seawater is not a hostile environment for gametes, it does cause the gametes to disperse rapidly, so their release by females and males must be almost simultaneous. Thus, most marine fish restrict the release of their eggs and sperm to a few brief and well-defined periods. Some reproduce just once a year, but others do so more frequently. The ocean has few seasonal clues that organisms can use as signals for synchronizing reproduction, but one all-pervasive signal is the cycle of the Moon. Once each month, the Moon approaches closer to the Earth than usual, and when it does, its increased gravitational attraction causes somewhat higher tides. Many marine organisms sense the tidal changes and link the production and release of their gametes to the lunar cycle.

Once vertebrates began living on land, they encountered a new danger—desiccation, a problem that can be especially severe for the small and vulnerable gametes. On land, the gametes could not simply be released near each other because they would soon dry up and perish. Consequently, intense selective pressure resulted in the evolution of internal fertilization in terrestrial vertebrates (as well as some groups of fish)—that is, the introduction of male gametes directly into the female reproductive tract. By this means, fertilization still occurs in a nondesiccating environment, even when the adult animals are fully terrestrial.

### Internal fertilization has led to three strategies for development of offspring

The vertebrates that practice internal fertilization exhibit three strategies for embryonic and fetal development, namely *oviparity*, *ovoviviparity*, and *viviparity*.

1. **Oviparity** is found in some bony fish, most reptiles, some cartilaginous fish, some amphibians, a few mammals, and all birds. The eggs, after being fertilized internally, are deposited outside the mother's body to complete their development.
2. **Ovoviviparity** is found in some bony fish (including mollies, guppies, and mosquito fish), some cartilaginous fish, and many reptiles. The fertilized eggs are retained within the mother to complete their development, but

**Figure 53.4 Viviparous fish carry live, mobile young within their bodies.** The young complete their development within the body of the mother and are then released as small but competent adults. Here, a lemon shark has just given birth to a young shark, which is still attached by the umbilical cord.

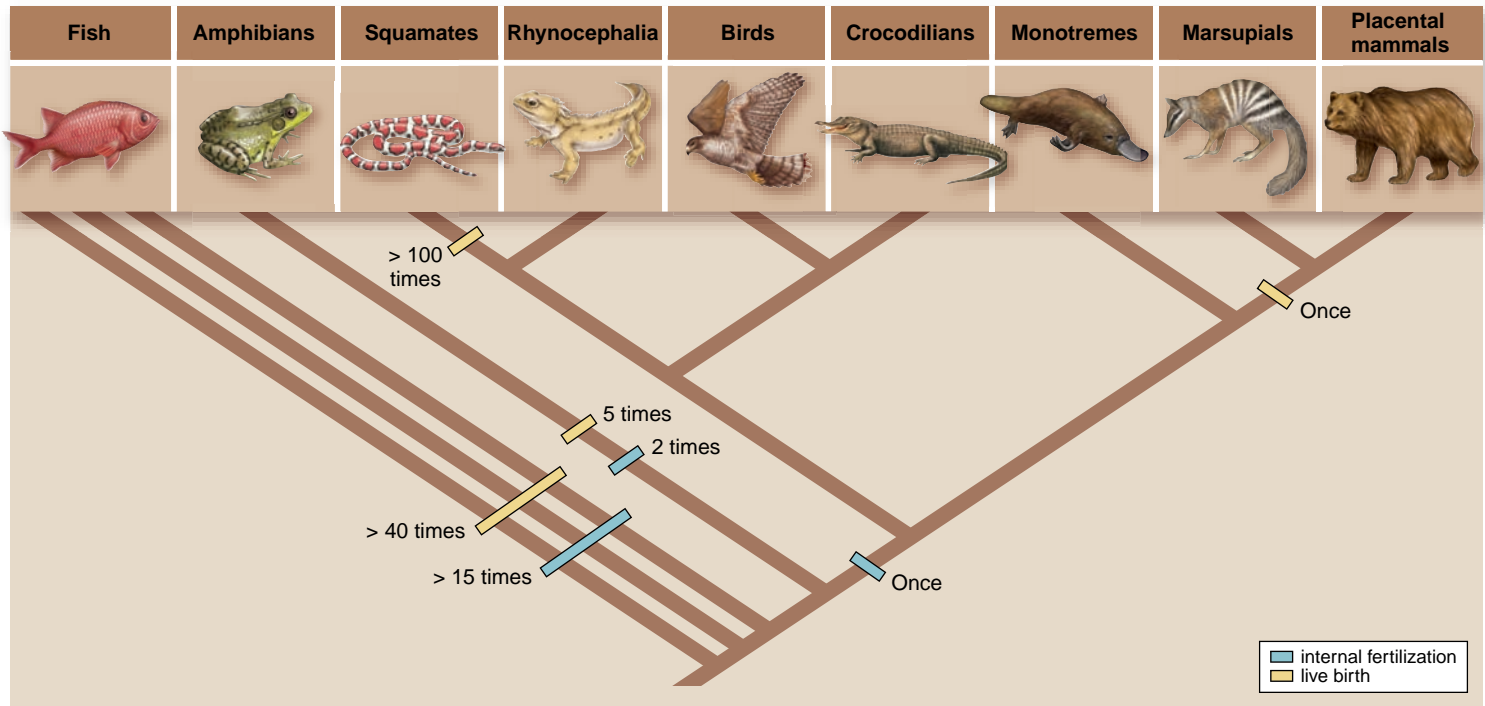

the embryos still obtain all of their nourishment from the egg yolk. The young are fully developed when they are hatched and released from the mother.

3. **Viviparity** is found in most cartilaginous fish, some amphibians, a few reptiles, and almost all mammals (figure 53.4). The young develop within the mother and obtain nourishment directly from their mother's blood, rather than from the egg yolk. A placenta, the structure through which blood and gas exchange occurs, has not evolved only in mammals (see next chapter), but also several times in fishes and lizards.

### Evolution of reproductive systems

Live birth—either viviparity or ovoviviparity—has evolved many times in vertebrates: once in mammals, but many times independently in fishes, amphibians, and reptiles (figure 53.5). The evolution of live birth appears to be a one-way evolutionary street: once it evolves, it is almost never lost. Live birth requires internal fertilization so that the eggs can develop within the body of the female; internal fertilization has evolved only once in amniotes (the clade composed of reptiles, birds, and mammals), but multiple times within fishes and amphibians.

Internal fertilization requires some means of transferring the sperm from the male to the female. Salamanders evolved one way: males deposit their sperm on top of a mass of eggs and then the female positions her cloaca above them and then lowers her body, picking up the fertilized eggs. All other vertebrates have taken a different approach, evolving an intromittent organ that the male uses to transfer the sperm directly into the female's body. The variety of structures that has evolved to accomplish this includes a modified pelvic fin in cartilaginous fishes; a modification of the cloaca (the common opening through which waste and reproductive products exit the body) in some frogs, caecilians, and birds; penises derived from different embryological structures in turtles, crocodiles, and mammals; and a pair of hemipenises—one on

**Figure 53.5 Evolution of internal fertilization and live birth in vertebrates.** Although live birth has evolved many times in fishes and squamate reptiles, most species in both groups lay eggs. Evolutionary reversal from live birth to egg-laying has occurred very rarely, if at all. Estimates of the number of origins in fishes and squamates is based on detailed phylogenetic analyses within each group; uncertainty in numbers is a result of incomplete information in some groups.

### Inquiry question

? Why do you think that egg-laying rarely evolves from live-bearing?

each side—in snakes and lizards. Moreover, intromittent organs have been lost entirely in birds and rhyngocephalians; to achieve internal fertilization, males and females of these species simply align their cloacae and pass the sperm from male to female.

## Most fishes and amphibians have external fertilization

Most fishes and amphibians, unlike other vertebrates, reproduce by means of external fertilization, although internal fertilization has arisen many times.

### Fishes

Fertilization in most species of bony fish (teleosts) is external, and the eggs contain only enough yolk to sustain the developing embryo for a short time. After the initial supply of yolk has been exhausted, the young fish must seek its food from the waters around it. Development is speedy, and the young that survive mature rapidly. Although thousands or even millions of eggs are fertilized in a single mating, many of the resulting individuals succumb to microbial infection or predation, and few grow to maturity.

In marked contrast to the bony fish, fertilization in most cartilaginous fish is internal. Development of the young is generally viviparous, and the female usually gives birth to few, well-developed offspring.

### Amphibians

The life cycle of amphibians is still tied to the water. Fertilization is external in most amphibians. Gametes from both males and females are released through the cloaca. Among the frogs and toads, the male grasps the female and discharges fluid containing the sperm onto the eggs as the female releases them into the water (figure 53.6).

Although the eggs of most amphibians develop in the water, there are some interesting exceptions (figure 53.7). In some frogs, for example, the eggs develop in the back of the parents; in others, males carry around the tadpoles in their vocal sacs, and the young frogs leave through their parents' mouths.

## Reptiles and birds have internal fertilization

All birds and about 80% of reptile species are oviparous. After the eggs are fertilized internally, they are deposited outside the mother's body to complete their development.

**Figure 53.6** The eggs of frogs are fertilized externally.

When frogs mate, the clasp of the male induces the female to release a large mass of mature eggs, over which the male discharges his sperm.

### Reptiles

Most oviparous reptiles lay eggs and then abandon them. These eggs are surrounded by a leathery shell that is deposited as the egg passes through the oviduct, the part of the female reproductive tract leading from the ovary. Other species of reptiles are ovoviviparous, forming eggs that develop into embryos within the body of the mother, and some species are viviparous.

### Birds

All birds practice internal fertilization, though most male birds lack a penis (some, including swans, geese, and ostriches, have modified the wall of the cloaca wall to serve as an intromittent organ).

**Figure 53.8** Crested penguins incubating their egg.

This nesting pair is changing the parental guard in a stylized ritual.

As the egg passes along the oviduct, glands secrete albumin proteins (the egg white) and the hard, calcareous shell that distinguishes bird eggs from reptilian eggs. Although modern reptiles are ectotherms, birds are endotherms (see chapter 43); therefore, most birds incubate their eggs after laying them to keep them warm (figure 53.8). The young that hatch from the eggs of most bird species are unable to survive unaided because their development is still incomplete. These young birds are fed and nurtured by their parents, and they grow to maturity gradually.

The shelled eggs of reptiles and birds constitute one of the most important adaptations of these vertebrates to life on land. As described in chapter 35, these eggs are known as *amniotic eggs* because the embryo develops within a fluid-filled cavity surrounded by a membrane called the *amnion*. Other extraembryonic membranes in amniotic eggs include the *chorion*, which lines the inside of the eggshell, the *yolk sac*, and the *allantois*. Together, these extraembryonic membranes in combination with the external calcareous shell help form a desiccation-resistant egg that can be laid in dry places. In

contrast, the eggs of fish and amphibians contain only one extraembryonic membrane, the yolk sac, and must be deposited in an aquatic habitat to keep from drying out.

The viviparous mammals, including humans, also have extraembryonic membranes, as described in the following chapter.

## Mammals generally do not lay eggs, but give birth to their young

Some mammals are seasonal breeders, reproducing only once a year, while others have more frequent reproductive cycles. Among the latter, the females generally undergo the reproductive cycles, and the males are more constant in their reproductive capability.

### Female reproductive cycles

Cycling in females involves the periodic release of a mature ovum from the ovary in a process known as *ovulation*. Most female mammals are “in heat,” or sexually receptive to males, only around the time of ovulation. This period of sexual receptivity is called **estrus**, and the reproductive cycle is therefore called an estrous cycle. Reproductive cycles continue in females until they become pregnant.

In the estrous cycle of most mammals, changes in the secretion by the anterior pituitary gland of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) cause changes in egg cell development and hormone secretion in the ovaries (see chapter 46). Humans and apes have menstrual cycles that are similar to the estrous cycles of other mammals in their pattern of hormone secretion and ovulation. Unlike mammals with estrous cycles, however, human and ape females bleed when they shed the inner lining of their uterus, a process called **menstruation**, and they may engage in copulation at any time during the cycle.

Rabbits and cats differ from most other mammals in that they are induced ovulators. Instead of ovulating in a cyclic fashion regardless of sexual activity, the females ovulate only after copulation, as a result of a reflex stimulation of LH secretion.

## Monotremes, marsupials, and placental mammals

The most primitive mammals, the **monotremes** (consisting solely of the duck-billed platypus and the echidna), are oviparous, like the reptiles from which they evolved. They incubate their eggs in a nest (figure 53.9*a*) or specialized pouch, and the young hatchlings obtain milk from their mother’s mammary glands by licking her skin (because monotremes lack nipples).

All other mammals are viviparous and are divided into two subcategories based on how they nourish their young. The **marsupials**, a group that includes opossums and kangaroos, give birth to small, fetuslike offspring that are incompletely developed. The young complete their development in a pouch of their mother’s skin, where they can obtain nourishment from nipples of the mammary glands (figure 53.9*b*).

The placental mammals (figure 53.9*c*) retain their young for a much longer period of development within the mother’s uterus. The fetuses are nourished by a structure known as the placenta, which is derived from both an extraembryonic membrane (the chorion) and the mother’s uterine lining. Because the fetal and maternal blood vessels are in very close proximity in the placenta, the fetus can obtain nutrients by diffusion from the mother’s blood. The functioning of the placenta is discussed in more detail in chapter 54.

### Learning Outcomes Review 53.2

Oviparous species lay eggs; the amniotic eggs of reptiles and birds protect the embryo from desiccation. Females of ovoviparous species retain fertilized eggs inside their bodies and release fully developed young when eggs hatch. Most mammals are viviparous, giving birth to young that have been nourished by the mother’s body. Internal fertilization allows embryos to develop inside the female’s body, leading to greater reproductive success.

- Under what circumstances would an estrous cycle be advantageous?

### Figure 53.9 Reproduction in mammals.

**a.** Monotremes lay eggs in a nest, such as the duck-billed platypus (*Ornithorhynchus anatinus*) shown here with newly hatched offspring. **b.** Marsupials, such as this red kangaroo (*Macropus rufus*), give birth to small offspring that complete their development in a pouch. **c.** In placental mammals, such as this spotted deer doe (*Axis axis*) nursing her fawn, the young remain inside the mother’s uterus for a longer period of time and are born relatively more developed.

## 53.3 Structure and Function of the Human Male Reproductive System

### Learning Outcomes

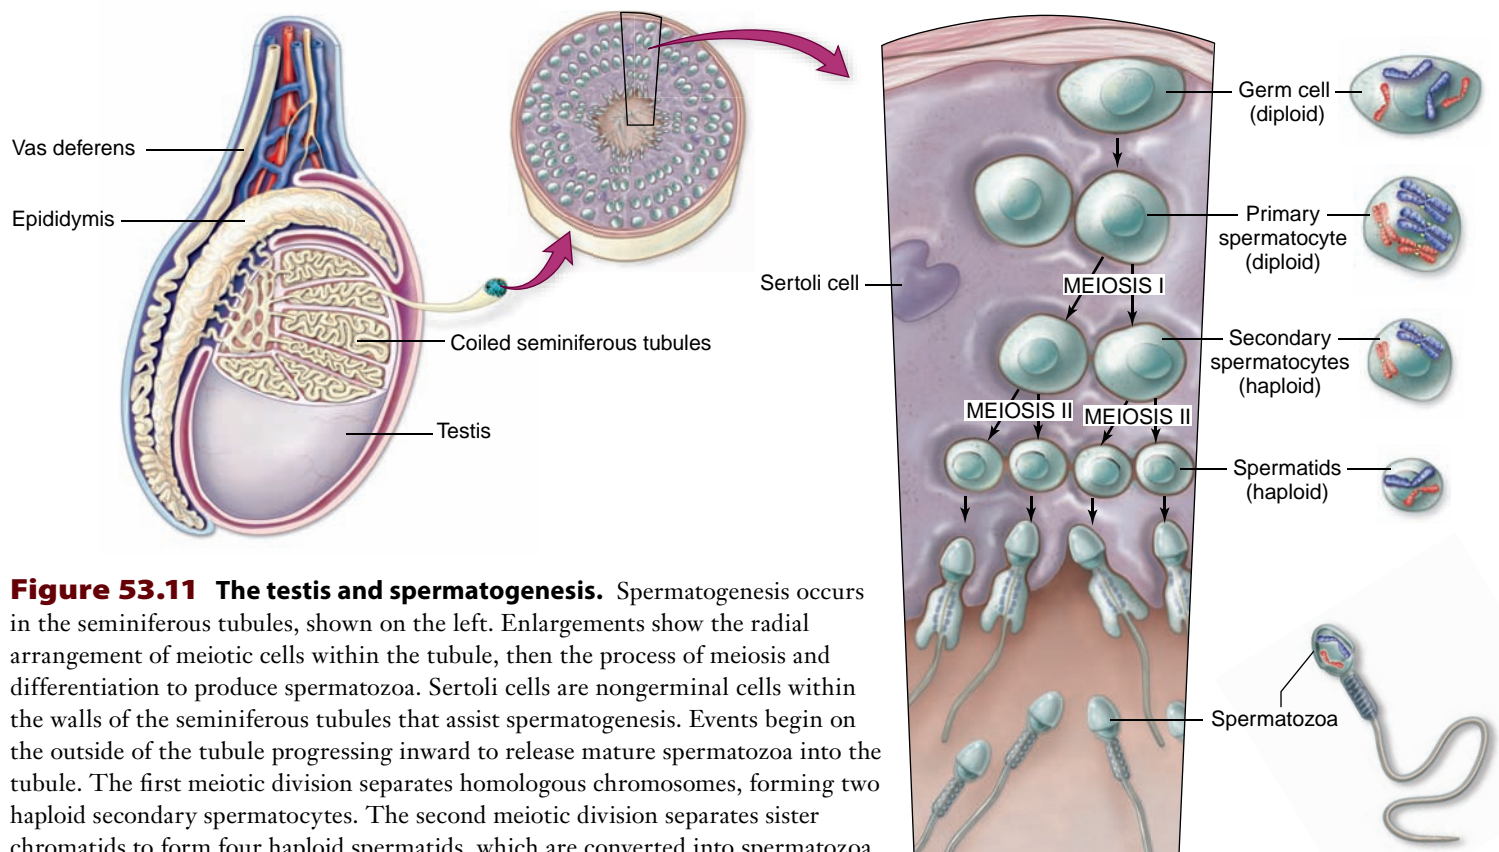

1. Describe the sequence of events in spermatogenesis.
2. Describe semen and explain how it is released during mating.
3. Explain how hormones regulate male reproductive function.

The structures of the human male reproductive system, typical of male mammals, are illustrated in figure 53.10. When testes form in the human embryo, they develop seminiferous tubules, the sites of sperm production, beginning around 43 to 50 days after conception. At about 9 to 10 weeks, the Leydig cells, located in the interstitial tissue between the seminiferous tubules, begin to secrete testosterone (the major male sex hormone, or androgen). Testosterone secretion during embryonic development converts indifferent structures into the male external genitalia, the *penis* and the *scrotum*, the latter being a sac that contains the testes. In the absence of testosterone, these structures develop into the female external genitalia. Testosterone is also responsible at puberty for male secondary sex characteristics, such as development of the beard, a deeper voice, and body hair.

**Figure 53.10 Organization of the human male reproductive system.** The penis and scrotum are the external genitalia, the testes are the gonads, and the other organs are accessory sex organs, aiding the production and ejaculation of semen.

In an adult, each testis is composed primarily of the highly convoluted seminiferous tubules (figure 53.11, left). Although the testes are actually formed within the abdominal cavity, shortly before birth they descend through an opening called the inguinal canal into the scrotum, which suspends them outside the abdominal cavity. The scrotum maintains the testes at around 34°C, slightly lower than the core body temperature (37°C). This lower temperature is required for normal sperm development in humans.

**Figure 53.11 The testis and spermatogenesis.** Spermatogenesis occurs in the seminiferous tubules, shown on the left. Enlargements show the radial arrangement of meiotic cells within the tubule, then the process of meiosis and differentiation to produce spermatozoa. Sertoli cells are nongerminal cells within the walls of the seminiferous tubules that assist spermatogenesis. Events begin on the outside of the tubule progressing inward to release mature spermatozoa into the tubule. The first meiotic division separates homologous chromosomes, forming two haploid secondary spermatocytes. The second meiotic division separates sister chromatids to form four haploid spermatids, which are converted into spermatozoa.

## Sperm cells are produced by the millions

The wall of the seminiferous tubule consists of spermatogonia, or *germ cells*, and supporting Sertoli cells. The germ cells near the outer surface of the seminiferous tubule are diploid and are the only cells that will undergo meiosis to produce gametes (see chapter 11). The developing gamete cells, located closer to the lumen of the tubule, are haploid.

### Cell divisions leading to sperm

A spermatogonium cell divides by mitosis to produce two diploid cells. One of these two cells then undergoes meiotic division to produce four haploid cells that will become sperm while the other remains as a spermatogonium. In that way, the male never runs out of spermatogonia to produce sperm. Adult males produce an average of 100 to 200 million sperm each day and can continue to do so throughout most of the rest of their lives.

The diploid daughter cell that begins meiosis is called a primary spermatocyte. In humans it has 23 pairs of chromosomes (46 chromosomes total), and each chromosome is duplicated, with two chromatids. The first meiotic division separates the homologous chromosome pairs, producing two haploid secondary spermatocytes. However, each chromosome still consists of two duplicate chromatids.

Each of these cells then undergoes the second meiotic division to separate the chromatids and produce two haploid cells, the **spermatids**. Therefore, a total of four haploid spermatids are produced from each primary spermatocyte (see figure 53.11, right). All of these cells constitute the germinal epithelium of the seminiferous tubules because they “germinate” the gametes.

### Supporting tissues

In addition to the germinal epithelium, the walls of the seminiferous tubules contain nongerminal cells such as the Sertoli cells mentioned earlier. These cells nurse the developing sperm and secrete products required for spermatogenesis. They also help convert the spermatids into **spermatozoa (sperm)** by engulfing their extra cytoplasm.

*a.*

**Figure 53.12 Human sperm.** *a.* A scanning electron micrograph with sperm digitally colored yellow. *b.* A diagram of the main components of a sperm cell.

### Sperm structure

Spermatozoa are relatively simple cells, consisting of a head, body, and flagellum (tail) (figure 53.12). The head encloses a compact nucleus and is capped by a vesicle called an acrosome, which is derived from the Golgi complex. The acrosome contains enzymes that aid in the penetration of the protective layers surrounding the egg. The body and tail provide a propulsive mechanism: Within the tail is a flagellum, and inside the body are a centriole, which acts as a basal body for the flagellum, and mitochondria, which generate the energy needed for flagellar movement.

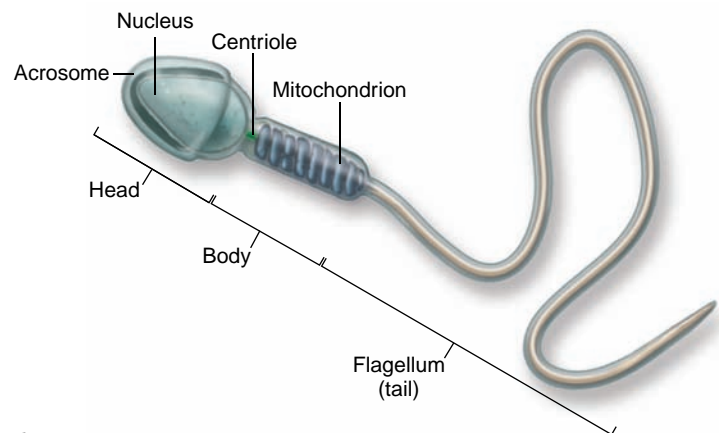

## Male accessory sex organs aid in sperm delivery

After the sperm are produced within the seminiferous tubules, they are delivered into a long, coiled tube called the **epididymis**. The sperm are not motile when they arrive in the epididymis, and they must remain there for at least 18 hours before their motility develops. From the epididymis, the sperm enter another long tube, the **vas deferens**, which passes into the abdominal cavity via the inguinal canal.

### Semen production

Semen is a complex mixture of fluids and sperm. The vas deferens from each testis joins with one of the ducts from a pair of glands called the seminal vesicles (see figure 53.10), which produce a fructose-rich fluid constituting about 60% of semen volume. From this point, the vas deferens continues as the ejaculatory duct and enters the prostate gland at the base of the urinary bladder.

In humans, the **prostate gland** is about the size of a golf ball and is spongy in texture. It contributes up to 30% of the bulk of the semen. Within the prostate gland, the ejaculatory duct merges with the urethra from the urinary bladder. The urethra carries the semen out of the body through the tip of the penis. A pair of pea-sized bulbourethral glands add secretions to make up the last 10% of semen, also secreting a fluid that lines the urethra and lubricates the tip of the penis prior to coitus (sexual intercourse).

*b.*

### Structure of the penis and erection

In addition to the urethra, the penis has two columns of erectile tissue, the corpora cavernosa, along its dorsal side and one column, the corpus spongiosum, along the ventral side (figure 53.13). Penile erection is produced by neurons in the parasympathetic division of the autonomic nervous system, which release nitric oxide (NO), causing arterioles in the penis to dilate. The erectile tissue becomes turgid as it engorges with blood. This increased pressure in the erectile tissue compresses the veins, so blood flows into the penis but cannot flow out.

Most mammals have a bone in the penis, called a “*baculum*,” that contributes to its stiffness during erection, but humans do not.

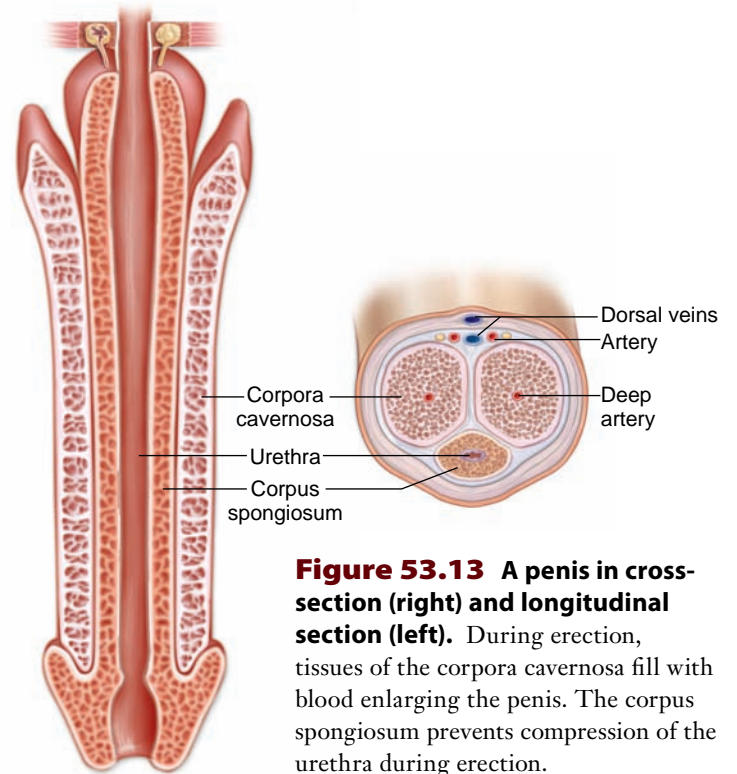

### Ejaculation

The result of erection and continued sexual stimulation is ejaculation, the ejection from the penis of about 2 to 5 mL of semen containing an average of 300 million sperm. Successful fertilization requires such a high sperm count because the odds against any one sperm cell completing the journey to the egg and fertilizing it are extraordinarily high, and the acrosomes of many sperm need to interact with the egg before a single sperm can penetrate the egg (fertilization is described in chapter 54). Males with fewer than 20 million sperm per milliliter are generally considered sterile. Despite their large numbers, sperm constitute only about 1% of the volume of the semen ejaculated.

### Hormones regulate male reproductive function

As you saw in chapter 46, the anterior pituitary gland secretes two gonadotropic hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Although these hormones are named for their actions in the female, they are also involved in regulating male reproductive function (table 53.1). In males, FSH stimulates the Sertoli cells to facilitate sperm development, and LH stimulates the Leydig cells to secrete testosterone.

The principle of negative feedback inhibition applies to the control of FSH and LH secretion (figure 53.14). The hypo-

**Figure 53.13** A penis in cross-section (right) and longitudinal section (left). During erection, tissues of the corpora cavernosa fill with blood enlarging the penis. The corpus spongiosum prevents compression of the urethra during erection.

thalamic hormone gonadotropin-releasing hormone (GnRH) stimulates the anterior pituitary gland to secrete both FSH and LH. FSH causes the Sertoli cells to release a peptide hormone called inhibin, which specifically inhibits FSH secretion. Similarly, LH stimulates testosterone secretion, and testosterone feeds back to inhibit the release of LH, both directly at the anterior pituitary gland and indirectly by reducing GnRH release from the hypothalamus.

The importance of negative feedback inhibition can be demonstrated by removing the testes; in the absence of testosterone and inhibin, the secretion of FSH and LH from the anterior pituitary is greatly increased.

**TABLE 53.1**

**Mammalian Reproductive Hormones**

#### M A L E

Follicle-stimulating hormone (FSH)	Stimulates spermatogenesis via Sertoli cells
Luteinizing hormone (LH)	Stimulates secretion of testosterone by Leydig cells
Testosterone	Stimulates development and maintenance of male secondary sexual characteristics, accessory sex organs, and spermatogenesis

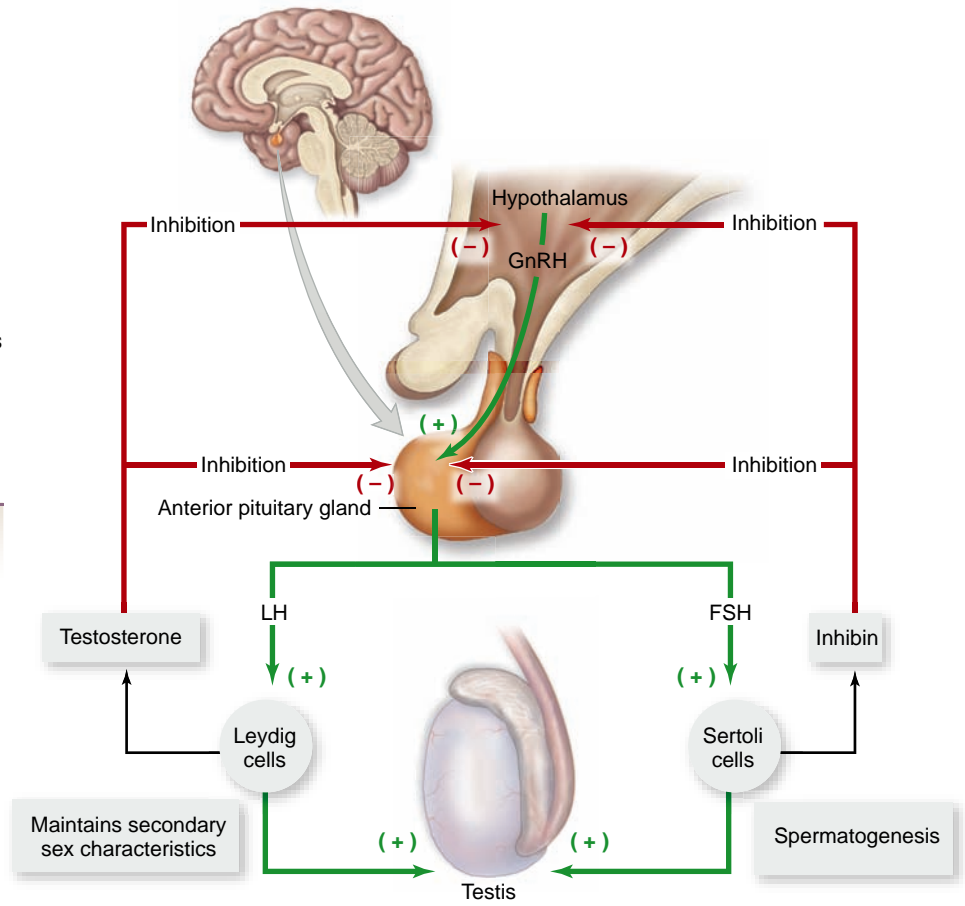

#### F E M A L E

Follicle-stimulating hormone (FSH)	Stimulates growth of ovarian follicles and secretion of estradiol
Luteinizing hormone (LH)	Stimulates ovulation, conversion of ovarian follicles into corpus luteum, and secretion of estradiol and progesterone by corpus luteum
Estradiol (estrogen)	Stimulates development and maintenance of female secondary sexual characteristics; prompts monthly preparation of uterus for pregnancy
Progesterone	Completes preparation of uterus for pregnancy; helps maintain female secondary sexual characteristics
Oxytocin	Stimulates contraction of uterus and milk-ejection reflex
Prolactin	Stimulates milk production

**Figure 53.14 Hormonal interactions between the testes and anterior pituitary.**

The hypothalamus secretes GnRH, which stimulates the anterior pituitary to produce LH and FSH. LH stimulates the Leydig cells to secrete testosterone, which is involved in development and maintenance of secondary sexual characteristics, and stimulates spermatogenesis. FSH stimulates the Sertoli cells of the seminiferous tubules, which facilitate spermatogenesis. FSH also stimulates Sertoli cells to secrete inhibin. Testosterone and inhibin exert negative feedback inhibition on the secretion of LH and FSH, respectively.

**Inquiry question**  
 ? Why do you think the brain is affected when the testes are surgically removed (termed *castration*)?

**Learning Outcomes Review 53.3**

Each of the spermatogonia lining the seminiferous tubules of the testes undergoes mitosis; one of the two daughter cells then undergoes meiosis to produce four haploid sperm cells. Semen consists of sperm from the testes and fluid from the seminal vesicles and prostate gland. Sexual stimulation causes erection of the penis, and continued stimulation leads to ejaculation of semen. Production of sperm and secretion of testosterone from the testes are controlled by FSH and LH from the anterior pituitary.

- Would natural selection favor those males that produce more sperm? Explain your answer.

The structures of the reproductive system in a human female are shown in figure 53.15. In contrast to the testes, the ovaries develop much more slowly. In the absence of testosterone, the female embryo develops a **clitoris** and labia majora from the same embryonic structures that produce a penis and a scrotum in males. Thus, the clitoris and penis, and the labia majora and scrotum, are said to be homologous structures.

**53.4 Structure and Function of the Human Female Reproductive System**

**Learning Outcomes**

1. Describe the sequence of events in production of an oocyte.
2. Explain ovulation and the female reproductive cycle.
3. Explain how hormones regulate female reproductive function.

**Figure 53.15 Organization of the human female reproductive system.** The ovaries are the gonads, the Fallopian tubes receive the ovulated ova, and the uterus is the womb, the site of development of an embryo if the egg cell becomes fertilized.

The clitoris, like the penis, contains corpora cavernosa and is therefore erectile.

The ovaries contain microscopic structures called ovarian follicles, which each contain a potential egg cell called a primary oocyte and smaller **granulosa cells**.

At puberty, the granulosa cells begin to secrete the major female sex hormone, estradiol (also called estrogen), triggering *menarche*, the onset of menstrual cycling. Estradiol also stimulates the formation of the female secondary sexual characteristics, including breast development and the production of pubic hair. In addition, estradiol and another steroid hormone, progesterone, help maintain the female accessory sex organs: the fallopian tubes, uterus, and vagina.

## Usually only one egg is produced per menstrual cycle

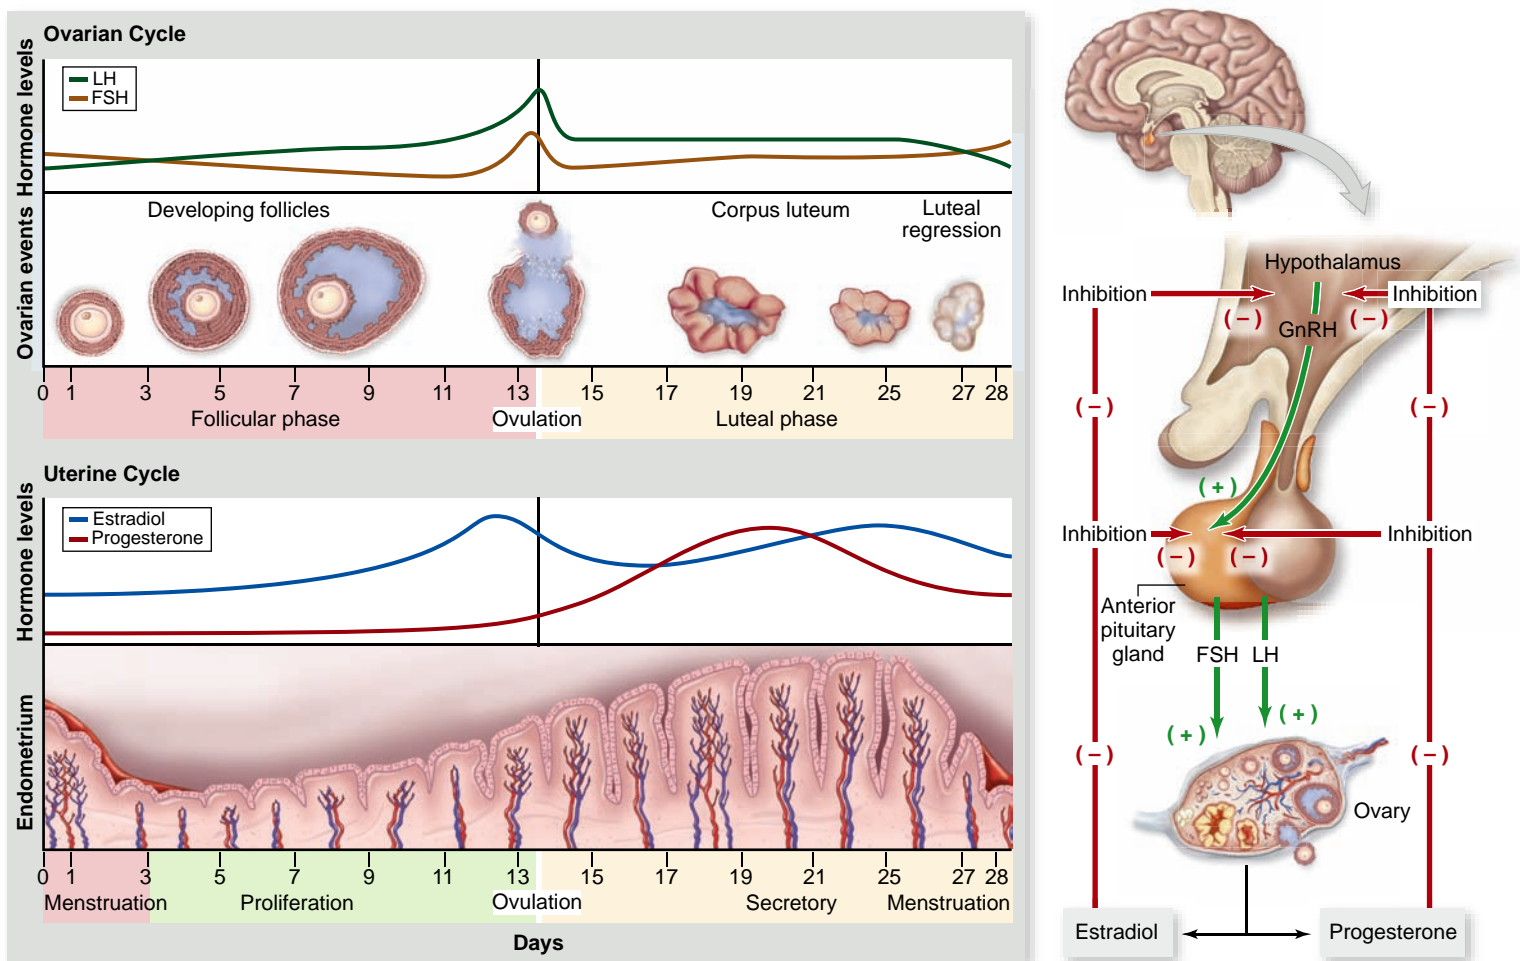

At birth, a female's ovaries contain about 1 million follicles, each containing a **primary oocyte** that has begun meiosis but is arrested in prophase of the first meiotic division. Some of these

primary oocyte-containing follicles are stimulated to develop during each cycle. The human menstrual cycle lasts approximately one month (28 days on the average) and can be divided in terms of ovarian activity into a follicular phase and luteal phase, with the two phases separated by the event of ovulation (figure 53.16).

### Follicular phase

During each *follicular phase*, several follicles in the ovaries are stimulated to grow under FSH stimulation, but only one achieves full maturity as a **tertiary**, or **Graafian, follicle** by ovulation. This follicle forms a thin-walled blister on the surface of the ovary. The uterus is lined with a simple columnar epithelial membrane called the endometrium, and during the follicular phase estradiol causes growth of the endometrium. This phase is therefore also known as the **proliferative phase** of the endometrium (see figure 53.16).

The primary oocyte within the Graafian follicle completes the first meiotic division during the follicular phase. Instead of forming two equally large daughter cells,

**Figure 53.16 The human menstrual cycle.** Left: Hormone levels during the cycle are correlated with ovulation and the growth of the endometrial lining of the uterus. Growth and thickening of the endometrium is stimulated by estradiol during the proliferative phase. Estradiol and progesterone maintain and regulate the endometrium during the secretory phase. Decline in the levels of these two hormones triggers menstruation. Right: Production of estradiol and progesterone by the anterior pituitary is controlled by negative feedback.

**Figure 53.17** A mature Graafian follicle in a cat ovary. Note the ring of granulosa cells that surrounds the secondary oocyte. This ring will remain around the egg cell when it is ovulated, and sperm must tunnel through the ring in order to reach the plasma membrane of the secondary oocyte.

however, it produces one large daughter cell, the secondary oocyte (figure 53.17), and one tiny daughter cell, called a **polar body**. Thus, the secondary oocyte acquires almost all of the cytoplasm from the primary oocyte (unequal cytokinesis), increasing its chances of sustaining the early embryo should the oocyte be fertilized. The polar body, on the other hand, disintegrates.

The secondary oocyte then begins the second meiotic division, but its progress is arrested at metaphase II. It is in this form that the potential egg cell is discharged from the ovary at ovulation, and it does not complete the second meiotic division unless it becomes fertilized in the Fallopian tube.

### Ovulation

The increasing level of estradiol in the blood during the follicular phase stimulates the anterior pituitary gland to secrete LH about midcycle. This sudden secretion of LH causes the fully developed Graafian follicle to burst in the process of ovulation, releasing its secondary oocyte.

The released oocyte enters the abdominal cavity near the fimbriae, the feathery projections surrounding the opening to the Fallopian tube. The ciliated epithelial cells lining the Fallopian tube draw in the oocyte and propel it through the Fallopian tube toward the uterus.

If it is not fertilized, the oocyte disintegrates within a day following ovulation. If it is fertilized, the stimulus of fertilization allows it to complete the second meiotic division, forming a fully mature ovum and a second polar body (figure 53.18). Fusion of the nuclei from the ovum and the sperm produces a diploid zygote. Fertilization normally occurs in the upper one-third of the Fallopian tube, and in humans the zygote takes

**Figure 53.18** The meiotic events of oogenesis in humans. A primary oocyte is diploid. At the completion of the first meiotic division, one division product is eliminated as a polar body, and the other, the secondary oocyte, is released during ovulation. The secondary oocyte does not complete the second meiotic division until after fertilization; that division yields a second polar body and a single haploid egg, or ovum. Fusion of the haploid egg nucleus with a haploid sperm nucleus produces a diploid zygote.

approximately 3 days to reach the uterus and then another 2 to 3 days to implant in the endometrium (figure 53.19).

### Luteal phase

After ovulation, LH stimulation completes the development of the Graafian follicle into a structure called the **corpus luteum**. For this reason, the second half of the menstrual cycle is referred to as the **luteal phase**. The corpus luteum secretes both estradiol and another steroid hormone, progesterone. The high blood levels of estradiol and progesterone during the luteal phase now exert negative feedback inhibition of FSH and LH secretion by the anterior pituitary gland (see figure 53.16). This inhibition during the luteal phase is in contrast to the stimulation exerted by estradiol on LH secretion at midcycle, which caused ovulation. The inhibitory effect of estradiol and progesterone after ovulation acts as a natural contraceptive mechanism, preventing both the development of additional follicles and continued ovulation.

During the luteal phase of the cycle, the combination of estradiol and progesterone cause the endometrium to become more vascular, glandular, and enriched with glycogen deposits. Because of the endometrium's glandular appearance and function, this portion of the cycle is known as the **secretory phase** of the endometrium. These changes prepare the uterine lining for embryo implantation.

In the absence of fertilization, the corpus luteum degenerates due to the decreasing levels of LH and FSH near the end of the luteal phase. Estradiol and progesterone, which the corpus luteum produces, inhibit the secretion of LH, the hormone needed for its survival. The disappearance of the corpus luteum results in an abrupt decline in the blood concentration

of estradiol and progesterone at the end of the luteal phase, causing the built-up endometrium to be sloughed off with accompanying bleeding. This is menstruation; the portion of the cycle in which it occurs is known as the *menstrual phase* of the endometrium.

If the ovulated oocyte is fertilized, however, the tiny embryo prevents regression of the corpus luteum and subsequent menstruation by secreting *human chorionic gonadotropin (hCG)*, an LH-like hormone produced by the chorionic membrane of the embryo. By maintaining the corpus luteum, hCG keeps the levels of estradiol and progesterone high and thereby prevents menstruation, which would terminate the pregnancy. Because hCG comes from the embryonic chorion and not from the mother, it is the hormone tested for in all pregnancy tests.

### Mammals with estrous cycles

Menstruation is absent in mammals with an estrous cycle. Although such mammals do cyclically shed cells from the endometrium, they don't bleed in the process. The estrous cycle is divided into four phases: proestrus, estrus, metestrus, and diestrus, which correspond to the proliferative, midcycle, secretory, and menstrual phases of the endometrium in the menstrual cycle.

### Female accessory sex organs receive sperm and provide nourishment and protection to the embryo

The Fallopian tubes (also called uterine tubes or oviducts) transport ova from the ovaries to the uterus. In humans, the

**Figure 53.19 The journey of an egg.** Produced within a follicle and released at ovulation, the secondary oocyte is swept into a Fallopian tube and carried along by waves of ciliary motion in the tube walls. Sperm journeying upward from the vagina penetrate the secondary oocyte, meiosis is completed and fertilization of the resulting ovum occurs within the Fallopian tube. The resulting zygote undergoes several mitotic divisions while still in the tube. By the time it enters the uterus, it is a hollow sphere of cells called a blastocyst. The blastocyst implants within the wall of the uterus, where it continues its development. (The egg and its subsequent stages have been enlarged for clarification.)

**Figure 53.20**  
A comparison  
of mammalian  
uteruses.

*a.* Humans and other primates; *(b)* cats, dogs, and cows; and *(c)* marsupials.

**uterus** is a muscular, pear-shaped organ that narrows to form a neck, the cervix, which leads to the vagina (figure 53.20*a*).

The entrance to the vagina is initially covered by a membrane called the *hymen*. This will eventually be disrupted by vigorous activity or actual sexual intercourse. In the latter case, this can make the first experience painful when the hymen is ruptured.

During sexual arousal, the labia minora, clitoris, and vagina all become engorged with blood, much like the male erectile tissues. The clitoris has many sensory nerve endings and is one of the most sensitive and responsive areas for female arousal. During sexual arousal, glands located near the vaginal opening called Bartholin's glands, secrete a lubricating fluid that facilitates penetration by the penis. Ejaculation by the male introduces sperm cells that must then make the long swim out of the vagina and up the Fallopian tubes to encounter a secondary oocyte for fertilization to occur.

Mammals other than primates have more complex female reproductive tracts, in which part of the uterus divides to form uterine "horns," each of which leads to an oviduct (figure 53.20*b, c*). Cats, dogs, and cows, for example, have one cervix but two uterine horns separated by a septum, or wall. Marsupials, such as opossums, carry the split even further, with two unconnected uterine horns, two cervixes, and two vaginas. A male marsupial has a forked penis that can enter both vaginas simultaneously.

### Learning Outcomes Review 53.4

Primary oocytes reside in follicles in the ovaries. At puberty, some oocytes are triggered by FSH to develop with every menstrual cycle. Unequal cytokinesis produces a single egg and three polar bodies from each primary oocyte. During the follicular phase, one follicle matures; ovulation is the release of this follicle's secondary oocyte triggered by LH. This oocyte completes division only if fertilization occurs. During the luteal phase, development of additional oocytes is inhibited. If fertilization does not occur, the endometrium is sloughed off as menstrual bleeding.

- **Would more than one offspring per pregnancy be favored by natural selection? Under what conditions?**

## 53.5 Contraception and Infertility Treatments

### Learning Outcomes

1. Compare the different types of birth control.
2. Describe causes of infertility.

In most vertebrates, copulation is associated solely with reproduction. Reflexive behavior that is deeply ingrained in the female limits sexual receptivity to those periods of the sexual cycle when she is fertile. In humans and a few species of apes, the female can be sexually receptive throughout her reproductive cycle, and this extended receptivity to sexual intercourse serves a second important function—it reinforces pair-bonding, the emotional relationship between two individuals.

Sexual intercourse may be a necessary and important part of humans' emotional lives—and yet not all couples desire to initiate a pregnancy every time they engage in sex. Throughout history, people and cultures have attempted to control reproduction while still being able to engage in sexual intercourse. The prevention of pregnancy or giving birth is known as birth control. Physiologically, pregnancy begins not at fertilization but approximately a week later with successful implantation. Methods of birth control that act prior to implantation are usually termed contraception.

In contrast, some couples desire to have children, but find for a variety of reasons that pregnancy is not occurring—a condition termed infertility. Technologies have also been developed to assist these couples in having children.

### Contraception is aimed at preventing fertilization or implantation

A variety of approaches, differing in effectiveness and in their acceptability to different couples, religions, and cultures, are commonly taken to prevent pregnancy (figure 53.21 and table 53.2).

a.

b.

c.

d.

**Figure 53.21** Four common methods of birth control. *a.* Condom; *(b)* diaphragm and spermicidal jelly; *(c)* oral contraceptives; *(d)* medroxyprogesterone acetate (Depo-Provera).

Device	Action	Failure Rate*	Advantages	Disadvantages
Oral contraceptive	Hormones (progesterone analogue alone or in combination with other hormones) primarily prevent ovulation	1–5, depending on type	Convenient; highly effective; provides significant noncontraceptive health benefits such as protection against ovarian and endometrial cancers	Must be taken regularly; possible minor side effects, which new formulations have reduced; not for women with cardiovascular risks (mostly smokers over age 35)
Condom	Thin sheath for penis collects semen; “female condoms” sheath vaginal walls	3–15	Easy to use, effective, inexpensive, protects against some sexually transmitted diseases	Requires male cooperation, may diminish spontaneity, may deteriorate on the shelf
Diaphragm	Soft rubber cup covers entrance to uterus; prevents sperm from reaching egg, holds spermicide	4–25	No dangerous side effects; reliable if used properly; provides some protection against sexually transmitted diseases and cervical cancer	Requires careful fitting, some inconvenience associated with insertion and removal; may be dislodged during intercourse
Intrauterine device (IUD)	Small plastic or metal device placed in the uterus, prevents implantation; some contain copper, others release hormones	1–5	Convenient, highly effective; infrequent replacement	Can cause excess menstrual bleeding and pain; risk of perforation, infection, expulsion, pelvic inflammatory disease, and infertility; not recommended for those who eventually intend to conceive or are not monogamous; dangerous in pregnancy
Cervical cap	Miniature diaphragm covers cervix closely, prevents sperm from reaching egg, holds spermicide	Probably similar to that of diaphragm	No dangerous side effects; fairly effective; can remain in place longer than diaphragm	Problems with fitting and insertion; comes in limited number of sizes
Foams, creams, jellies, vaginal suppositories	Chemical spermicides inserted in vagina before intercourse prevent sperm from entering uterus	10–25	Can be used by anyone who is not allergic; protect against some sexually transmitted diseases; no known side effects	Relatively unreliable; sometimes messy; must be used 5–10 minutes before each act of intercourse
Implant (levonorgestrel; Norplant)	Capsules surgically implanted under skin slowly release hormone that blocks ovulation	0.03	Very safe, convenient, and effective; very long-lasting (5 years); may have nonreproductive health benefits like those of oral contraceptives	Irregular or absent periods; minor surgical procedure needed for insertion and removal; some scarring may occur
Injectable contraceptive (medroxyprogesterone; Depo-Provera)	Injection every 3 months of a hormone that is slowly released and prevents ovulation	1	Convenient and highly effective; no serious side effects other than occasional heavy menstrual bleeding	Animal studies suggest it may cause cancer, though new studies in humans are mostly encouraging; occasional heavy menstrual bleeding

\*Failure rate is expressed as pregnancies per 100 actual users per year.

Source: Data from American College of Obstetricians and Gynecologists: Contraception, Patient Education Pamphlet No. AP005. ACOG, Washington, D.C., 1990.

## **Abstinence**

The most reliable way to avoid pregnancy is to not have sexual intercourse at all, which is called *abstinence*. Of all the methods of contraception, this is the most certain. It is also the most limiting and the most difficult method to sustain. The drive to engage in sexual intercourse is compelling, and many unwanted pregnancies result when a couple who desire each other and are attempting to adhere to abstinence fail in the attempt.

## **Sperm blockage**

If sperm cannot reach the uterus, fertilization cannot occur. One way to prevent the delivery of sperm is to encase the penis within a thin sheath, or condom. Some males do not favor the use of condoms, which tend to decrease males' sensory pleasure during intercourse. In principle, this method is easy to apply and foolproof, but in practice it has a failure rate of 3 to 15% per year because of incorrect or inconsistent use or condom failure. Nevertheless, condom use is the most commonly employed form of contraception in the United States. Condoms are also widely used to prevent the transmission of AIDS and other sexually transmitted diseases (STDs). Over a billion condoms are sold in the United States each year.

A second way to prevent the entry of sperm into the uterus is to place a cover over the cervix. The cover may be a relatively tight-fitting cervical cap, which is worn for days at a time, or a rubber dome called a diaphragm, which is inserted before intercourse. Because the dimensions of individual cervixes vary, a cervical cap or diaphragm must be initially fitted by a physician. Pregnancy rates average 4 to 25% per year for women using diaphragms. Failure rates for cervical caps are somewhat lower.

## **Sperm destruction**

A third general approach to pregnancy prevention is to eliminate the sperm after ejaculation. This can be achieved in principle by washing out the vagina immediately after intercourse, before the sperm have a chance to enter the uterus. Such a procedure is called a douche. The douche method is difficult to apply well, because it involves a rapid dash to the bathroom immediately after ejaculation and a very thorough washing. Douching can, in fact, increase the possibility of conception by forcing sperm farther up into the vagina and uterus, thereby accounting for its high failure rate (40%).

Alternatively, sperm delivered to the vagina can be destroyed there with spermicidal agents, jellies, or foams. These treatments generally require application immediately before intercourse. Their failure rates vary from 10 to 25%. The use of a spermicide with a condom or diaphragm increases the effectiveness over each method used independently.

## **Prevention of ovulation**

Since about 1960, a widespread form of contraception in the United States has been the daily ingestion of birth control pills, or oral contraceptives, by women. These pills contain analogues of progesterone, sometimes in combination with estrogens. As described earlier, progesterone and estradiol act by negative feedback to inhibit the secretion of FSH and LH during the luteal phase of the ovarian cycle, thereby preventing follicle development and

ovulation. They also cause a buildup of the endometrium. The hormones in birth control pills have the same effects. Because the pills block ovulation, no ovum is available to be fertilized.

A woman generally takes the hormone-containing pills for 3 weeks; during the fourth week, she takes pills without hormones, allowing the levels of those hormones in her blood to fall, which causes menstruation.

Oral contraceptives provide a very effective means of birth control, with a failure rate of only 1 to 5% per year. In a variation of the oral contraceptive, hormone-containing capsules are implanted beneath the skin. These implanted capsules have failure rates below 1%.

A small number of women using birth control pills or implants experience undesirable side effects, such as blood clotting and nausea. These side effects have been reduced in newer generations of birth control pills, which contain less estrogen and different analogues of progesterone. Moreover, these new oral contraceptives provide a number of benefits, including reduced risks of endometrial and ovarian cancer, cardiovascular disease, and osteoporosis (for older women). However, they may increase the risk of developing breast cancer and cervical cancer.

The risks involved with birth control pills increase in women who smoke and increase greatly in women over 35 who smoke. The current consensus is that, for many women, the health benefits of oral contraceptives outweigh their risks, although a physician must help each woman determine the relative risks and benefits.

## **Prevention of embryo implantation**

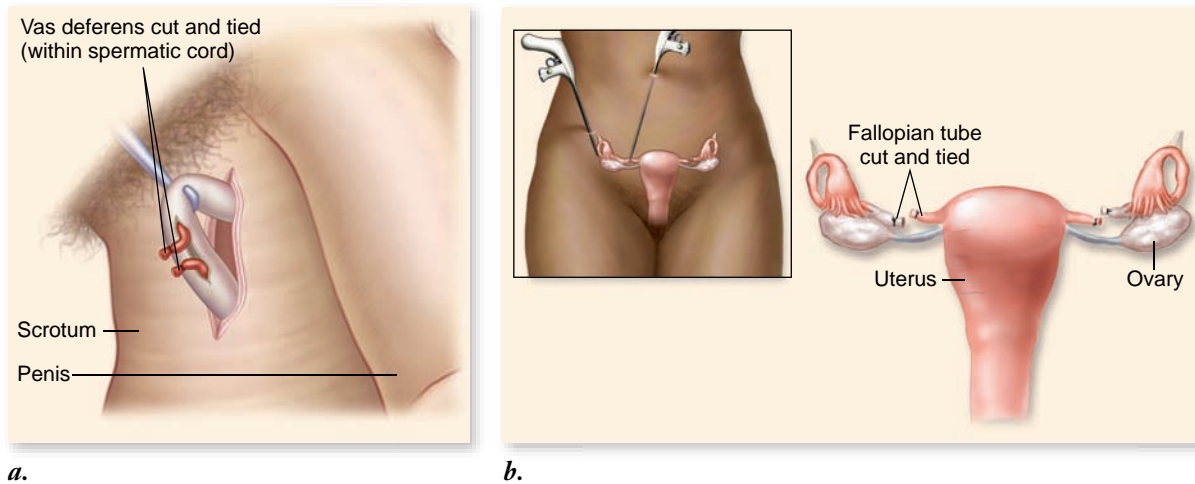

The insertion of an intrauterine device (IUD), such as a coil or other irregularly shaped object, is an effective means of contraception because the irritation it produces prevents the implantation of an embryo. IUDs have a failure rate of only 1 to 5%. Their high degree of effectiveness probably reflects their convenience; once they are inserted, they can be forgotten. The great disadvantage of this method is that almost a third of the women who attempt to use IUDs experience cramps, pain, and sometimes bleeding and therefore must discontinue using them. There is also a risk of uterine infection with insertion of the IUD.

Another method of preventing embryo implantation is the "morning-after pill," or Plan B, which contains 50 times the dose of estrogen present in birth control pills. The pill works by temporarily stopping ovum development, by preventing fertilization, or by stopping the implantation of a fertilized ovum. Its failure rate is 1 to 10% per use.

Many women are uneasy about taking such high hormone doses because side effects can be severe. This pill is not designed as a regular method of pregnancy prevention, but rather as a method of emergency contraception.

## **Sterilization**

Sterilization is usually accomplished by the surgical removal of portions of the tubes that transport the gametes from the gonads (figure 53.22). It is an almost 100% effective means of contraception. Sterilization may be performed on either males or females, preventing sperm from entering the semen in males and preventing an ovulated oocyte from reaching the uterus in females.

**Figure 53.22**  
**Birth control**  
**through**  
**sterilization.**  
*a.* Vasectomy;  
*b.* tubal ligation.

In males, sterilization involves a vasectomy, the removal and tying off of a portion of the vas deferens from each testis. In females, the comparable operation, called tubal ligation, involves the removal of a section of each Fallopian tube and tying off the tube. In very rare cases, it is possible for the tubes to grow back together, restoring fertility. This is more common in vasectomy but does occur in both at a very low level. This accounts for the less than 100% effectiveness statistically. Both methods can also be reversed surgically, though for vasectomy the surgery is both expensive and frequently unsuccessful.

### Infertility occurs in both males and females

Infertility is defined as the inability to conceive after 12 months of contraception-free sexual intercourse. In about 40% of cases, the failure to conceive is due to problems on the male side with about 45% due to problems on the female side, leaving another 15% unexplained (idiopathic infertility). Given these background statistics, it is clear that we still have a lot to learn about human fertility, despite a significant amount of study.

#### Female infertility

Infertility in females can occur due to a failure at any stage from the production of an oocyte, to the implantation of the zygote. The most common problems arise from failure to ovulate, and from some kind of mechanical blockage preventing either fertilization or implantation.

The leading cause of infertility worldwide is pelvic inflammatory disease (PID). This can be caused by infection with a number of different bacteria that all lead to blockage of the Fallopian tubes. This blockage then causes problems in sperm passage, and of transfer of fertilized eggs to the uterus.

Endometriosis, the presence of ectopic endometrial tissue, can lead to infertility by a mechanism similar to PID. The body responds to the ectopic tissue by trying to wall it off with scar tissue. The buildup of scar tissue can then prevent the transfer of eggs to the uterus.

Another common cause of infertility in females is age, or premature ovarian failure (POF). Fertility declines significantly in females with age, and the incidence of some genetic abnor-

malities caused by nondisjunction of chromosomes increases (see chapter 13). If a woman younger than 40 has a diminished supply of eggs, this is considered diagnostic of POF.

Disruption of the normal hormonal control of ovulation discussed earlier is also a common cause of infertility in females. Decreased levels of GnRH will disrupt ovulation, a condition referred to as hypogonadotropic hypogonadism. This can arise from damage to the hypothalamus or pituitary, or by any disorder that affects normal levels of hypothalamic hormones. For example, diabetes, thyroid disease, and excessive adrenal androgen production all affect hormonal feedback to the hypothalamus and can disrupt its normal function, leading to decreased levels of GnRH and infertility. Excessive exercise and anorexia can also lead to reduced GnRH levels and produce infertility.

Hormonal imbalances can occur during the luteal phase as well. Inadequate levels of progesterone during the luteal phase reduce the thickening of the uterine wall. If the uterine wall is inadequately prepared, implantation may not occur or can lead to an increased likelihood of spontaneous abortion.

#### Male infertility

Infertility in males can be due to a reduced number, viability, or motility of sperm in the ejaculate. These can be due to a variety of factors from infection to hormonal imbalances. Analysis on the male side is easier since sperm collection is noninvasive. Sperm can be easily analyzed for number, viability, morphology, and motility.

Infertility can arise from autoimmunity to sperm, leading to sperm loss, as well as due to abnormalities of all of the glands that contribute to the production of semen. Damage to the vas deferens or to the seminiferous tubules can also result in infertility. Anything that disrupts the maturation process of sperm can result in possible infertility.

After all possible causes have been ruled out, up to 5% of infertile men suffer from idiopathic, or unexplained, infertility. This may be due to genetic causes as the numbers seem to be similar worldwide despite different environments. It has been estimated in studies of *Drosophila* that up to 1500 recessive genes contribute to male fertility. Work is ongoing to examine the human genome for evidence of similar genes.

## Treatment of infertility often involves assisted reproductive technologies

There are two basic possibilities for treating infertility: hormonal treatment and **assisted reproductive technologies (ART)**. The number and variety of assisted technologies available today is large and growing.

### Hormone treatment

In the case of female infertility due to ovulatory defects, treatment is designed to produce high levels of FSH and LH at a single point during the normal menstrual cycle. Given the complexity of the hormonal control of the cycle, it is not surprising that this can be achieved in a number of ways. The most common drug currently used is clomiphene (Clomid), which is a competitive inhibitor of the estrogen receptor. This interferes with the negative feedback loop controlling estradiol production by the ovaries and consequently increases FSH and LH levels. If this is not successful, gonadotropins can be injected to stimulate ovulation.

### Assistive reproductive technology

The simplest method to assist reproduction is to use artificial insemination, a process by which sperm are introduced into the female reproductive tract artificially. This is widely used in reproduction of domestic animals and is also used in humans. This has also been extended in cases of infertility in which both sperm and egg are introduced artificially by a technique called *gametic intrafallopian transfer*, or *GIFT*.

The birth of the first “test tube baby” in 1978 was heralded as the beginning of a new age of reproductive technology. Even the early pioneers may not have envisioned how far this technology would proceed. The basic technique of external

fertilization is called *in vitro fertilization (IVF)*, and transfer of the developing embryo is called simply *embryo transfer (ET)*. When the sperm are unable to successfully fertilize an egg in vitro, they can be directly injected into an egg by *intracytoplasmic sperm injection (ICSI)*.

One of the downsides of much of this assisted technology is multiple births. This is due to the common practice of transferring more than one embryo to ensure that at least one implants and develops normally. With advances in understanding of human development, it is possible to monitor early embryo growth to select the “best” embryos for transfer and to therefore transfer fewer embryos to reduce multiple births.

It is also possible to freeze sperm, eggs, and even human embryos to reduce the number of invasive techniques such as harvesting oocytes. Live births have been achieved using all combinations of frozen eggs, sperm, and embryos. This allows the transfer of a single embryo while freezing others produced by in vitro fertilization. If the first embryo transferred does not implant, then the others can be thawed and transferred later.

### Learning Outcomes Review 53.5

Pregnancy can be prevented by a variety of contraception methods, including abstinence, barrier contraceptives, hormonal inhibition, and sterilization surgery. Some methods are more susceptible to human error than others and thus have a lower success rate. Infertility can be treated by hormonal manipulation to induce ovulation or by the use of assisted reproductive technologies. These assisted technologies include in vitro fertilization and intracytoplasmic sperm injection.

- *Why isn't there a male birth control pill?*

## Chapter Review

### 53.1 Animal Reproductive Strategies

**Some species have developed novel reproductive methods.**

Sexual reproduction involves production by meiosis of haploid gametes (eggs and sperm). These join at fertilization to produce a diploid zygote.

Asexual reproduction produces offspring with the same genes as the parent organism.

In budding, a part of an individual becomes separated and develops into a new, identical individual. In parthenogenesis, females produce offspring from unfertilized eggs. In hermaphroditism, an individual has both testes and ovaries (simultaneous) or may change sex (sequential).

**Sex can be determined genetically or by environmental conditions.**

In some animals, the temperature an individual experiences as an embryo determines its sex. In mammals, sex is genetically determined by the presence of a Y chromosome (see figure 53.3).

### 53.2 Vertebrate Fertilization and Development

**Internal fertilization has led to three strategies for development of offspring.**

Vertebrates with internal fertilization exhibit three strategies for development: oviparity, ovoviviparity, and viviparity. Both internal fertilization and live birth have evolved many times.

**Most fishes and amphibians have external fertilization.**

Most fish and amphibians release eggs and sperm into the water, where the gametes unite by chance. Few fertilized eggs grow to maturity.

**Reptiles and birds have internal fertilization.**

The embryos of reptiles and birds develop in a fluid-filled cavity surrounded by the amnion and extraembryonic membranes and a shell to help prevent desiccation.

**Mammals generally do not lay eggs, but give birth to their young.**

Mammals are also amniotic, but most species are viviparous. Most mammals have an estrus cycle, but primates have a menstrual cycle.

### 53.3 Structure and Function of the Human Male Reproductive System

**Sperm cells are produced by the millions.**

Haploid sperm are produced by meiosis of spermatogonia with the aid of Sertoli cells (see figure 53.11). Each spermatogonium produces four sperm cells. A sperm cell has three parts: a head with an acrosome, a body containing mitochondria, and a flagellar tail.

**Male accessory sex organs aid in sperm delivery.**

Semen is a complex mixture of sperm and fluids from the seminal vesicles, prostate gland, and bulbourethral glands.

The urethra of the penis transports both sperm and urine and contains two columns of erectile tissue, blood vessels, and nerves (see figure 53.13). Ejaculation is the ejection of semen from the penis by smooth muscle contraction.

**Hormones regulate male reproductive function.**

Male reproductive function is controlled by the hormones FSH and LH and negative feedback loops (see figure 53.14, table 53.1).

### 53.4 Structure and Function of the Human Female Reproductive System

**Usually only one egg is produced per menstrual cycle.**

The female clitoris and labial lips have the same embryonic origin as the penis and scrotum. They develop in the absence of testosterone.

In adult females, FSH stimulates follicular development, which in turn produces estrogen. LH stimulates ovulation and corpus luteum development, which produces progesterone and more estrogen. Estrogen and progesterone are necessary to develop and maintain the uterine lining (see figure 53.16).

The ovarian cycle has three phases: follicular phase, ovulation, and luteal phase. The uterine cycle has three stages that mirror the ovarian cycle: menstruation, proliferation, and secretion.

At birth, all primary oocytes are arrested in the first meiotic division. Each oocyte is capable of producing one ovum and three polar bodies. Each month, one oocyte completes meiosis I. This secondary oocyte begins the second meiotic division and arrests until the egg is fertilized (see figure 53.18).

A fertilized egg, or zygote, develops into a blastocyst and implants in the wall of the uterus. Here it produces hCG, which maintains the corpus luteum and prevents menstruation.

If fertilization and implantation do not occur, the production of hormones declines, causing the built-up endometrium in the uterus to be sloughed off during menstruation.

**Female accessory organs receive sperm and provide nourishment and protection to the embryo.**

The Fallopian tubes transport ova from the ovaries to the uterus. The vagina receives sperm, which enters the uterus via the cervix (see figure 53.20). Other female organs are involved in sexual response.

### 53.5 Contraception and Infertility Treatments

**Contraception is aimed at preventing fertilization or implantation.**

Pregnancy can be avoided by abstinence, by blocking sperm from reaching the ovum, by destroying sperm after ejaculation, by preventing ovulation or embryo implantation, or by sterilization. Some methods are more successful in practice than others.

**Infertility occurs in both males and females.**

Female infertility ranges from failure of oocyte production to failure of zygote implantation. Male infertility is usually due to reduction in sperm number, viability, or motility; hormonal imbalance; or damage to the sperm delivery system.

**Treatment of infertility often involves assisted reproductive technologies.**

Hormonal treatment may be used to correct ovulatory defects or sperm production defects. Assistive reproduction technologies involve artificial insemination, in vitro fertilization and embryo transfer, or intracytoplasmic sperm injection.

## Review Questions

### UNDERSTAND

- You have discovered a new organism living in tide pools at your favorite beach. Every so often, one of the creature's appendages will break off and gradually grow into a whole new organism, identical to the first. This is an example of
  - sexual reproduction.
  - fission.
  - budding.
  - parthenogenesis.
- If you decided that the organism you discovered in question 1 used parthenogenesis, what would you also know about this species?
  - It is asexual.
  - All the individuals are female.
  - Each individual develops from an unfertilized egg.
  - All of these would be true.
- Which of the following terms describes your first stage as a diploid organism?
  - Sperm
  - Egg
  - Gamete
  - Zygote
- Which of the following structures is the site of spermatogenesis?
  - Prostate
  - Bulbourethral gland
  - Urethra
  - Seminiferous tubule
- FSH and LH are produced by the
  - ovaries.
  - testes.
  - anterior pituitary.
  - adrenal glands.
- Gametogenesis requires the conclusion of meiosis II. When does this occur in females?
  - During fetal development
  - At the onset of puberty
  - After fertilization
  - After implantation
- Mutations that affect proteins in the acrosome would impede which of the following functions?
  - Fertilization
  - Locomotion
  - Meiosis
  - Semen production

8. In humans, fertilization occurs in the\_\_\_\_, and implantation of the zygote occurs in the\_\_\_\_.
  - a. seminiferous tubules; uterus
  - b. vagina; oviduct
  - c. oviduct; uterus
  - d. urethra; uterus
9. The testicles of male mammals are suspended in the scrotum because
  - a. the optimum temperature for sperm production is less than the normal core body temperature of the organism.
  - b. the optimum temperature for sperm production is higher than the normal core body temperature of the organism.
  - c. there is not enough room in the pelvic area for the testicles to be housed internally.
  - d. it is easier for the body to expel sperm during ejaculation.
3. In species with environmental sex determination
  - a. sex is determined during development as an embryo.
  - b. environmental conditions determine the sex of an individual.
  - c. hermaphroditism always occurs.
  - d. a and b are correct.
4. Internal and external fertilization differ in that all species that
  - a. produce an amniotic egg have internal fertilization.
  - b. do not produce an amniotic egg have external fertilization.
  - c. produce live young have a penis or other intromittent organ.
  - d. lay eggs are external fertilizers.

## APPLY

1. The major difference between an estrous cycle and a menstrual cycle is that
  - a. sexual receptivity occurs only around ovulation in the estrous cycle, but it can occur during any time of the menstrual cycle.
  - b. estrous cycles occur in reptiles, but menstrual cycles occur in mammals.
  - c. estrous cycles are determined by FSH, but menstrual cycles are determined by LH.
  - d. estrous cycles occur monthly, but menstrual cycles occur sporadically.
2. Which of the following is a major difference between spermatogenesis and oogenesis?
  - a. Spermatogenesis involves meiosis, and oogenesis involves mitosis.
  - b. Spermatogenesis is continuous, but oogenesis is variable.
  - c. Spermatogenesis produces fewer gametes per precursor cell than oogenesis.
  - d. All of these are significant differences between oogenesis and spermatogenesis.

## SYNTHESIZE

1. Suppose that the *SRY* gene mutated such that a male embryo could not produce functional protein. What kinds of changes would you expect to see in the embryo?
2. Why do you think that amphibians and many fish have external fertilization, whereas lizards, birds, and mammals rely on internal fertilization?
3. How are the functions of FSH and LH similar in male and female mammals? How do they differ?
4. You are interested in developing a contraceptive that blocks hCG receptors. Will it work? Why or why not?
5. Why are all parthenogenic parents female?

# Chapter 54

## *Animal Development*

### Chapter Outline

---

- 54.1** Fertilization
- 54.2** Cleavage and the Blastula Stage
- 54.3** Gastrulation
- 54.4** Organogenesis
- 54.5** Vertebrate Axis Formation
- 54.6** Human Development

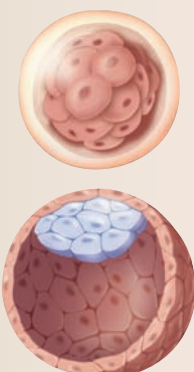

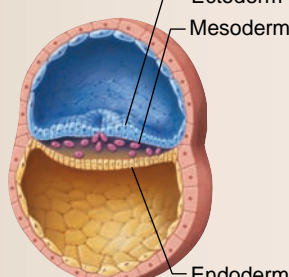

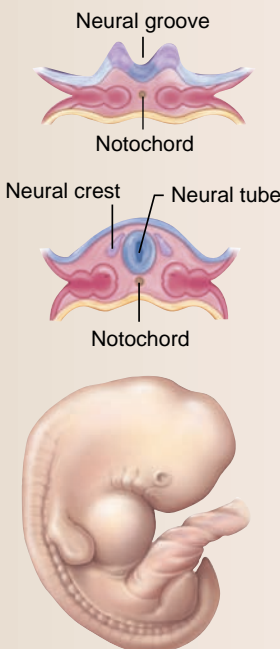

### Introduction

---

**S**exual reproduction in all but a few animals unites two haploid gametes to form a single diploid cell called a zygote. The zygote develops by a process of cell division and differentiation into a complex multicellular organism, composed of many different tissues and organs, as the picture illustrates. At the same time, a group of cells that constitute the germ line are set aside to enable the developing organism to engage in sexual reproduction as an adult. In this chapter, we focus on the stages that all coelomate animals pass through during embryogenesis: fertilization, cleavage, gastrulation, and organogenesis (table 54.1). Development is a dynamic process, and so the boundaries between these stages are somewhat artificial. Although differences can be found in the details, developmental genes and cellular pathways have been greatly conserved, and they create similar structures in different organisms.

**TABLE**  
**54.1**

**Stages of Animal Development  
(Using a Mammal as an Example)**

Fertilization	The haploid male and female gametes fuse to form a diploid zygote.	
Cleavage	The zygote rapidly divides into many cells, with no overall increase in size. In many animals, these divisions affect future development because different cells receive different portions of the egg cytoplasm and, hence, different cytoplasmic determinants. Cleavage ends with formation of a blastula (called a blastocyst in mammals), which varies in structure among animal embryos.	 Blastocyst
Gastrulation	The cells of the embryo move, forming the three primary germ layers: ectoderm, mesoderm, and endoderm.	
Organogenesis	Cells from the three primary germ layers interact in various ways to produce the organs of the body. In chordates, organogenesis begins with formation of the notochord and the hollow dorsal nerve cord in the process of neurulation.	

**54.1 Fertilization**

**Learning Outcomes**

1. Describe the events necessary for fertilization to occur.
2. List different ways that polyspermy is blocked.

In all sexually reproducing animals, the first step in development is the union of male and female gametes, a process called *fertilization*. As you learned in the preceding chapter, fertilization is typically external in aquatic animals. In contrast, internal fertilization is used by most terrestrial animals to provide a nondessicating environment for the gametes.

One physical challenge of sexual reproduction is for gametes to get together. Many elaborate strategies have evolved to enhance the likelihood of such encounters. For example, most marine invertebrates release hundreds of millions of eggs and sperm into the surrounding sea water on spawning; others use lunar cycles to time gamete release. Elaborate courtship behaviors are typical of many animals that utilize internal fertilization (see chapter 53). Fertilization itself consists of three events: sperm penetration and membrane fusion, egg activation, and fusion of nuclei.

**A sperm must penetrate to the plasma membrane of the egg for membrane fusion to occur**

Embryonic development begins with the fusion of the sperm and egg plasma membranes. But the unfertilized egg presents a challenge to this process, since it is enveloped by one or more protective coats. These protective coats include the *chorion* of insect eggs, the *jelly layer* and *vitelline envelope* of sea urchin and frog eggs, and the *zona pellucida* of mammalian eggs. Mammalian oocytes are also surrounded by a layer of supporting granulosa cells (figure 54.1). Thus, the first challenge of fertilization is that sperm have to penetrate these external layers to reach the plasma membrane of the egg.

A saclike organelle named the **acrosome** is positioned between the plasma membrane and the nucleus of the sperm head. The acrosome contains digestive enzymes, which are released by the process of exocytosis when a sperm reaches the outer layers of the egg. These enzymes create a hole in the protective layers, enabling the sperm to tunnel its way through to the egg's plasma membrane.

In sea urchin sperm, actin monomers assemble into cytoskeletal filaments just under the plasma membrane to create a long narrow offshoot—the *acrosomal process*. The acrosomal process extends through the vitelline envelope to the egg's plasma membrane, and the sperm nucleus then passes through the acrosomal process to enter the egg.

In mice, an acrosomal process is not formed, and the entire sperm head burrows through the zona pellucida to the egg. Membrane fusion of the sperm and egg then allows the sperm nucleus to pass directly into the egg cytoplasm. In many species, egg cytoplasm bulges out at membrane fusion to engulf the head of the sperm (figure 54.2).

**Figure 54.1 Animal reproductive cells.** *a.* The structure of a sea urchin egg at fertilization. This diagram also shows the relative sizes of the sperm and egg. *b.* A mammalian sperm must penetrate a layer of granulosa cells and then a glycoprotein layer called the zona pellucida before it reaches the oocyte membrane. The scanning electron micrographs show (*c*) a human oocyte surrounded by numerous granulosa cells and (*d*) a human sperm on an egg.

**Figure 54.2 Sperm penetration and fusion.** The sperm must penetrate the outer layers around the egg before fusion of sperm and egg plasma membranes can occur. Fusion activates the egg and leads to a series of events that prevent polyspermy.

## Membrane fusion activates the egg

After ovulation, the egg remains in a quiescent state until fusion of the sperm and egg membranes triggers reactivation of the egg's metabolism. In most species, there is a dramatic increase in the levels of free intracellular  $\text{Ca}^{2+}$  ions in the egg shortly after the sperm makes contact with the egg's plasma membrane. This increase is due to release of  $\text{Ca}^{2+}$  from internal, membrane-bounded organelles, starting at the point of sperm entry and traversing across the egg.

Scientists have been able to watch this wave of  $\text{Ca}^{2+}$  release by preloading unfertilized eggs with a dye that fluoresces when bound to free  $\text{Ca}^{2+}$ , and then fertilizing the eggs (figure 54.3). The released  $\text{Ca}^{2+}$  act as second messengers in the cytoplasm of the egg, to initiate a host of changes in protein activity. These many events initiated by membrane fusion are collectively called *egg activation*.

### Blocking of additional fertilization events

Because large numbers of sperm are released during spawning or ejaculation, many more than one sperm is likely to reach, and try to fertilize, a single egg. Multiple fertilization would result in a zygote that has three or more sets of chromosomes, a condition known as *polyploidy*. Polyploidy is incompatible with animal development, although it is frequently found in plants. As a result, an early response to sperm fusion in many animal eggs is to prevent fusion of additional sperm—in other words, to initiate a block to *polyspermy*.

In sea urchins, membrane contact by the first sperm results in a rapid, transient change in membrane potential of the egg, which prevents other sperm from fusing to the egg's plasma membrane. The importance of this event was shown by experiments where sea urchin eggs are fertilized in low-sodium, artificial seawater. The change in membrane potential is mostly due to an influx of  $\text{Na}^+$ , so fertilization in low-sodium water prevents this. Under these conditions polyspermy is much more frequent than in normal seawater.

Many animals use additional mechanisms to permanently alter the composition of the exterior egg coats, preventing any further sperm from penetrating through these layers. In sea urchins and mammals, specialized vesicles called **cortical granules**, located just beneath the plasma membrane of the egg, release their contents by exocytosis into the space between the plasma membrane and the vitelline envelope or zona pellucida, respectively. In each case, cortical granule enzymes remove critical sperm receptors from the outer coat of the egg.

Finally, the vitelline envelopes in many sea urchin species “lift off” the surfaces of the eggs via the combined action of different cortical granule enzymes and hyalin release. The enzymes digest connections between the vitelline envelope and the plasma membrane to allow separation. *Hyalin* is a sugar-rich macromolecule that attracts water by osmosis into the space between the vitelline envelope and the egg surface, thus separating the two. Additional sperm cannot penetrate through the hardened, elevated vitelline envelope, which is now called a *fertilization envelope*.

Many animals do not utilize any specific mechanisms to prevent multiple sperm from entering an egg. In these species, all but one of the sperm nuclei is degraded or subsequently extruded from the egg to prevent polyplody.

**Figure 54.3** Calcium ions are released in a wave across two sea urchin eggs following sperm contact. The bright white dots are dye molecules that fluoresce when they are bound to  $\text{Ca}^{2+}$ . The  $\text{Ca}^{2+}$  wave moves from left to right in these two eggs (a–d). The egg on the right was fertilized a few seconds before the egg on the left. The wave takes about 30 sec to cross the entire egg.

**Figure 54.4** Stage of egg maturation at time of sperm binding in representative animals.

### Other effects of sperm penetration

In addition to the previously mentioned surface changes, sperm penetration can have three other effects on the egg. First, in many animals, the nucleus of the unfertilized egg is not yet haploid because it had not entered or completed meiosis prior to ovulation (figure 54.4). Fusion of the sperm plasma membrane then triggers the eggs of these animals to complete meiosis. In mammals, a single large egg with a haploid nucleus and one or more small polar bodies, which contain the other nuclei, are produced (see chapter 53).

Second, sperm penetration in many animals triggers movements of the egg cytoplasm. In chapter 19, we discussed the cytoplasmic rearrangements of newly fertilized tunicate eggs, which result in the asymmetrical localization of pigment granules that determine muscle development. In amphibian embryos, the point of sperm entry is the focal point of cytoplasmic movements in the egg, and these movements ultimately establish the bilateral symmetry of the developing animal.

In some frogs, for example, sperm penetration causes an outer pigmented cap of egg cytoplasm to rotate toward the point of entry, uncovering a gray crescent of interior cytoplasm opposite the point of penetration (figure 54.5). The position of this gray crescent determines the orientation of the first cell division.

**Figure 54.5** Gray crescent formation in frog eggs.

The gray crescent forms on the side of the egg opposite the point of penetration by the sperm.

A line drawn between the point of sperm entry and the gray crescent would bisect the right and left halves of the future adult.

Third, activation is characterized by a sharp increase in protein synthesis and an increase in metabolic activity in general. Experiments demonstrate that the burst of protein synthesis in an activated egg uses mRNAs that were deposited into the cytoplasm of the egg during oogenesis.

In some animals, it is possible to artificially activate an egg without the entry of a sperm, simply by pricking the egg membrane. An egg that is activated in this way may go on to develop parthenogenetically. A few kinds of amphibians, fish, and reptiles rely entirely on parthenogenetic reproduction in nature, as we mentioned in chapter 53.

### The fusion of nuclei restores the diploid state

In the third and final stage of fertilization, the haploid sperm nucleus fuses with the haploid egg nucleus to form the diploid nucleus of the zygote. The process involves migration of the two nuclei toward each other along a microtubule-based aster. A centriole that enters the egg cell with the sperm nucleus organizes the microtubule array, which is made from stored tubulin proteins in the egg's cytoplasm.

In mammals, including humans, the nuclei do not actually fuse. Instead sperm and egg nuclear membranes each break down prior to the formation of a new diploid nucleus. A new nuclear membrane forms around the two sets of chromosomes.

### Learning Outcomes Review 54.1

Following penetration, fusion of sperm with the egg membrane initiates a series of events including egg activation, blocks to polyspermy, and major rearrangements of cytoplasm. Polyspermy is blocked by changes in membrane polarity, release of enzymes that remove sperm receptors, and release of hyalin that lifts the vitelline envelope from the cell membrane. Egg and sperm nuclei then fuse to create a diploid zygote.

- **What is the role of  $Ca^{2+}$  in egg activation?**

## 54.2 Cleavage and the Blastula Stage

### Learning Outcomes

1. Define the terms *cleavage* and *blastula*.
2. Describe the different patterns of cleavage.
3. Explain what is meant by *regulative development*.

Following fertilization, the second major event in animal development is the rapid division of the zygote into a larger and larger number of smaller and smaller cells (see table 54.1). This period of division, called *cleavage*, is not accompanied by an increase in the overall size of the embryo. Each individual cell in the resulting tightly packed mass of cells is referred to as a *blastomere*. In many animals, the two ends of the egg and subsequent embryo are traditionally referred to as the **animal pole** and the **vegetal pole**. In general, the blastomeres of the animal pole go on to form the external tissues of the body, and those of the vegetal pole form the internal tissues.

### The blastula is a hollow mass of cells

In many animal embryos, the outermost blastomeres in the ball of cells produced during cleavage become joined to one another by tight junctions, belts of protein that encircle a cell and weld it to its neighbors (see chapter 4). These tight junctions create a seal that isolates the interior of the cell mass from the surrounding medium.

Subsequently, cells in the interior of the mass begin to pump  $\text{Na}^+$  from their cytoplasm into the spaces between cells. The resulting osmotic gradient causes water to be drawn into the center of the embryo, enlarging the intercellular spaces. Eventually, the spaces coalesce to form a single large cavity within the embryo. The resulting hollow ball of cells is called a *blastula* (or *blastocyst* in mammals), and the fluid-filled cavity within the blastula is known as the **blastocoel** (see table 54.1).

## Cleavage patterns are highly diverse and distinctive

Cleavage divisions are quite rapid in most species, and chapter 19 provides an overview of the conserved set of proteins that control the cell cycle in animal embryos. Cleavage patterns are quite diverse, and there are about as many ways to divide up the cytoplasm of an animal egg during cleavage as there are phyla of animals! Nonetheless, we can make some generalizations.

First, the relative amount of nutritive yolk in the egg is the characteristic that most affects the cleavage pattern of an animal embryo (figure 54.6). Vertebrates exhibit a variety of developmental strategies involving different patterns of yolk utilization.

### Cleavage in insects

Insects have yolk-rich eggs, and in chapter 19 we discussed the *syncytial blastoderm* of insects, in which multiple mitotic divisions of the nucleus occur in the absence of cytokinesis. Because there are no membranes separating the early embryonic nuclei of insects, gradients of diffusible proteins termed *morphogens* within the egg's cytoplasm can directly and differentially affect the activity of these embryonic nuclei, and thus the pattern of the early embryo. The nuclei eventually migrate to the periphery of the egg, where cell membranes form around each nucleus. The resulting *cellular blastoderm* of an insect has a single layer of cells surrounding a central mass of yolk (see figure 19.12 and table 54.2).

### Cleavage of eggs with moderate or little yolk

In eggs that contain moderate to little yolk, cleavage occurs throughout the whole egg, a pattern called **holoblastic cleavage** (figure 54.7). This pattern of cleavage is characteristic of invertebrates such as mollusks, annelids, echinoderms, and tunicates, and also of amphibians and mammals (described shortly).

In sea urchins, holoblastic cleavage results in the formation of a symmetrical blastula composed of a single layer of cells of approximately equal size surrounding a spherical blastocoel. In contrast, amphibian eggs contain much more cytoplasmic yolk in the vegetal hemisphere than in the animal hemisphere. Because yolk-rich regions divide much more

**Figure 54.6** Yolk distribution in three kinds of eggs. *a.* In a sea urchin egg, the cytoplasm contains a small amount of evenly distributed yolk and a centrally located nucleus. *b.* In a frog egg, there is much more yolk, and the nucleus is displaced toward one pole. *c.* Bird eggs are complex, with the nucleus contained in a small disc of cytoplasm that sits on top of a large, central yolk mass.

**TABLE 54.2**

**The Major Cleavage Patterns of Animal Embryos**

**HOLOBLASTIC (COMPLETE) CLEAVAGE**

**Isolecithal (Sparse, evenly distributed yolk)**

**Mesolecithal (Moderate vegetal yolk disposition)**

**MEROBLASTIC (INCOMPLETE) CLEAVAGE**

**Telolecithal (Dense yolk throughout most of cell)**

**Centrolecithal (Yolk in center of egg)**

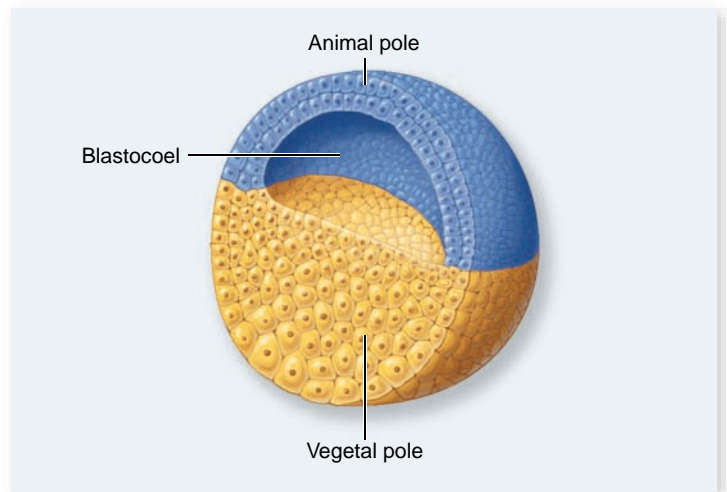

3.3 μm

**Figure 54.7 Holoblastic cleavage.** In this type of cleavage, which is characteristic of eggs with relatively small amounts of yolk, cell division occurs throughout the entire egg.

a.

333.3 μm

b.

**Figure 54.8 Frog cleavage and blastula formation.**

a. The closest cells in this photo (those near the animal pole) divide faster and are smaller than those near the vegetal pole (below cells of the animal pole). b. A cross-section of a frog blastula, showing an eccentric blastocoel, larger yolk-filled cells at the vegetal pole, and smaller cells with little yolk at the animal pole.

slowly than areas with little yolk, horizontal cleavage furrows are displaced toward the animal pole (figure 54.8a). Thus, holoblastic cleavage in frog eggs results in an asymmetrical blastula, with a displaced blastocoel. The blastula consists of large cells containing a lot of yolk at the vegetal pole, and smaller, more numerous cells containing little yolk at the animal pole (figure 54.8b).

**Cleavage of eggs with large amounts of yolk**

The eggs of reptiles, birds, and some fishes are composed almost entirely of yolk, with a small amount of clear cytoplasm concentrated at one pole called the **blastodisc**. Cleavage in these eggs is restricted to the blastodisc. The yolk is essentially an inert mass. This type of cleavage pattern is called **meroblastic**

**Figure 54.9 Meroblastic cleavage.** Only a portion of the egg actively divides to form a mass of cells in this type of cleavage, which occurs in eggs with relatively large amounts of yolk.

**cleavage** (figure 54.9). The resulting embryo is not spherical, but rather has the form of a thin cap perched on the yolk.

### Cleavage in mammals

Mammalian eggs contain very little yolk; however, mammalian embryogenesis has many similarities to development of their reptilian and avian relatives.

Because cleavage is not impeded by yolk in mammalian eggs, it is holoblastic, forming a structure called a *blastocyst*, in which a single layer of cells surrounds a central fluid-filled blastocoel. In addition, an **inner cell mass (ICM)** is located at one pole of the blastocoel cavity (figure 54.10). The ICM is similar to the blastodisc of reptiles and birds, and it goes on to form the developing embryo.

The outer layer of cells, called the **trophoblast**, is similar to the cells that form the membranes underlying the tough outer shell of the reptilian egg. These cells have changed during the course of mammalian evolution to carry out a very different function: Part of the trophoblast enters the maternal endometrium (the epithelial lining of the uterus) and contributes to the *placenta*, the organ that permits exchanges between the fetal and maternal blood supplies. The placenta will be discussed in more detail in a later section.

The major cleavage patterns of animal embryos are summarized in table 54.2.

### Blastomeres may or may not be committed to developmental paths

Viewed from the outside, cleavage-stage embryos often look like a simple ball or disc of similar cells. In many animals, this

**Figure 54.10 The embryos of mammals and birds are more similar than they seem.** A mammalian blastula (*left*), called a blastocyst, is composed of a sphere of cells, the trophoblast, surrounding a cavity, the blastocoel, and an inner cell mass (ICM). An avian (bird) blastula consists of a cap of cells, the blastodisc, resting atop a large yolk mass (*right*). The blastodisc will form an upper and a lower layer with a compressed blastocoel in between.

appearance is misleading; for example, the unequal segregation of cytoplasmic determinants into specific blastomeres of tunicate embryos (described in chapter 19) commits those cells to different developmental paths. The experimental destruction or removal of these committed cells results in embryos deficient in the tissues that would have developed from those cells.

In contrast, mammals exhibit highly *regulative development*, in which early blastomeres do not appear to be committed to a particular fate. For example, if a blastomere is removed from an early eight-cell stage human embryo (as is done in the process of preimplantation genetic diagnosis), the remaining seven cells of the embryo will “regulate” and develop into a complete individual if implanted into the uterus of a woman. Similarly, embryos that are split into two (either naturally or experimentally) form identical twins. It therefore appears that inheritance of maternally encoded determinants is not an important mechanism in mammalian development, and body form is determined primarily by cell–cell interactions.

The earliest patterning events in mammalian embryos occur during the preimplantation stages that lead to formation of the blastocyst. At the eight-cell stage, the outer surfaces of many mammalian blastomeres flatten against each other in a process called *compaction*, which serves to polarize the blastomeres. The polarized blastomeres then undergo asymmetrical cell divisions. Cell lineage studies have shown that cells that are in the interior of the embryo most often become ICM cells of the mammalian blastocyst, whereas cells on the exterior of the embryo usually become trophoblast cells.

### Learning Outcomes Review 54.2

Cleavage is a series of rapid cell divisions that transforms the zygote into the blastula—a hollow ball of cells. The amount of yolk is the major determinant of cleavage pattern. Eggs with little yolk cleave completely (holoblastic cleavage); eggs with a large yolk cannot cleave completely (meroblastic cleavage). In many animals, each blastomere is committed to a developmental path; in mammals, blastomeres are not committed but can regulate as needed to produce a complete individual.

- *If the cells of a mammalian embryo were separated at the four-cell stage, would they develop normally? What about a frog embryo at the four-cell stage?*

## 54.3 Gastrulation

### Learning Outcomes

1. Define gastrulation.
2. Compare gastrulation in different animals.
3. Name the extraembryonic membranes in amniotes.

In a complex series of cell shape changes and cell movements, the cells of the blastula rearrange themselves to form the basic body plan of the embryo. This process, called *gastrulation*, forms the three primary germ layers and converts the blastula

<b>TABLE 54.3</b> <b>Developmental Fates of the Primary Germ Layers in Vertebrates</b>	
<b>Ectoderm</b>	Epidermis of skin, nervous system, sense organs
<b>Mesoderm</b>	Skeleton, muscles, blood vessels, heart, blood, gonads, kidneys, dermis of skin
<b>Endoderm</b>	Lining of digestive and respiratory tracts, liver, pancreas, thymus, thyroid

into a bilaterally symmetrical embryo with a central progenitor gut and visible anterior–posterior and dorsal–ventral axes.

### Gastrulation produces the three germ layers

Gastrulation creates the three primary *germ layers*: endoderm, ectoderm, and mesoderm. The cells in each germ layer have very different developmental fates. The cells that move into the embryo to form the tube of the primitive gut are *endoderm*; they give rise to the lining of the gut and its derivatives (pancreas, lungs, liver, etc.). The cells that remain on the exterior are *ectoderm*, and their derivatives include the epidermis on the outside of the body and the nervous system. The cells that move into the space between the endoderm and ectoderm are *mesoderm*; they eventually form the notochord, bones, blood vessels, connective tissues, muscles and internal organs such as the kidneys and gonads (table 54.3).

Cells move during gastrulation using a variety of cell shape changes. Some cells use broad, actin-filled extensions called *lamellipodia* to crawl over neighboring cells. Other cells send out narrow extensions called *filopodia*, which are used to “feel out” the surfaces of other cells or the extracellular matrix. Once a satisfactory attachment is made, the filopodia retract to pull the cell forward. Contractions of actin filament bundles are responsible for many of these cell shape changes. Cells that are

tightly attached to one another via desmosomes or adherens junctions will move as cell sheets.

In embryos with little yolk and a hollow blastula, the cell sheet at the vegetal pole of the blastula **invaginates** (dents inward) to form the primitive gut tube. In embryos with large yolk cells that are hard to move, sheets of smaller cells **involute** (roll inward) from the surface of the blastula and move over the basal surfaces of the outer cells. Other cells break away from cell sheets and migrate as individual cells during **ingression**.

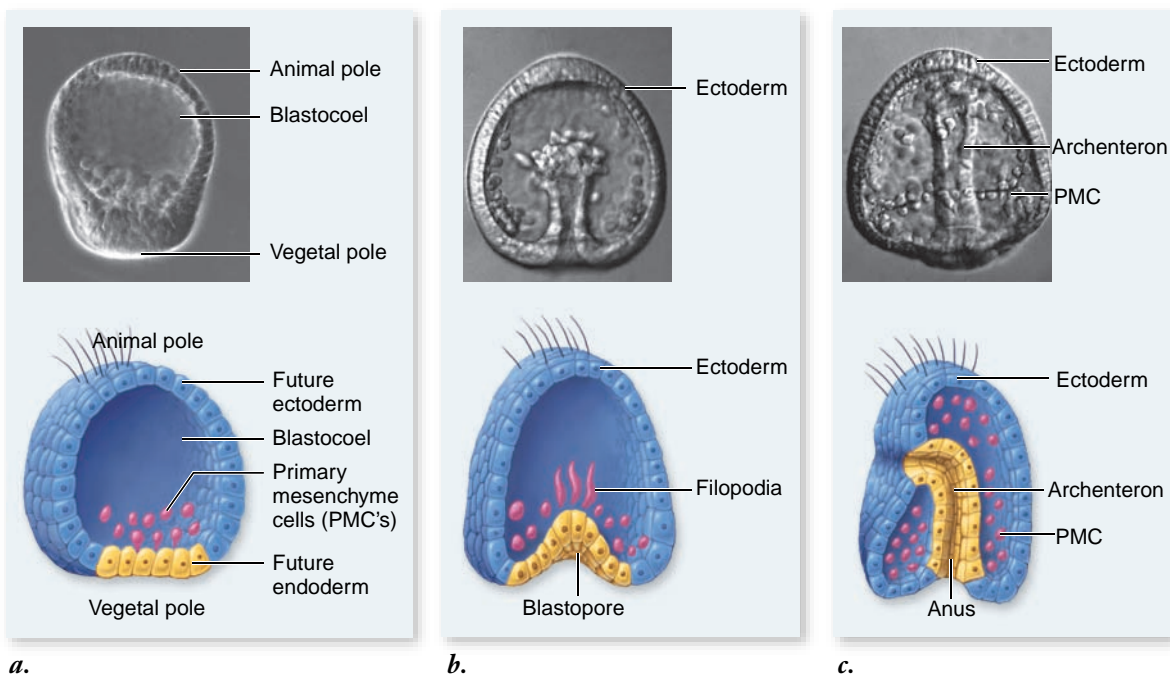

Avian and mammalian gastrulation begins with **delamination**, in which one sheet of cells splits into two sheets. Each migrating cell possesses particular cell-surface glycoproteins, which adhere to specific molecules on the surfaces of other cells or in the extracellular matrix. Changes in cell adhesiveness, as described in chapter 19, are key events in gastrulation. The extracellular matrix protein fibronectin and the corresponding integrin receptors of cells are essential molecules of gastrulation in many animals.

### Gastrulation patterns also vary according to the amount of yolk

Just as in cleavage patterns, yolk quantity also affects the types of cell movements that occur during gastrulation. Here, we examine gastrulation in four representative classes of embryos with differing quantities of yolk.

#### Gastrulation in sea urchins

Echinoderms such as sea urchins develop from relatively yolk-poor eggs and form hollow, symmetrical blastulas. Gastrulation begins when cells at the vegetal surface of the blastula change their shape to form a flattened **vegetal plate**. In an example of ingression, a subset of cells in the vegetal plate breaks away from the blastula wall and moves into the blastocoel cavity. These **primary mesenchyme cells** are future mesoderm cells, and they use *filopodia* to migrate through the blastocoel cavity (figure 54.11).

**Figure 54.11**  
**Gastrulation in a sea urchin.** *a.* Gastrulation begins with formation of the vegetal plate and ingression of primary mesenchyme cells (prospective mesoderm cells) into the blastocoel cavity. *b.* The endoderm is then formed by invagination of the remaining vegetal plate cells and extension of a cellular tube to produce the primitive gut, or archenteron. *c.* Cells that remain on the surface form the ectoderm.

Eventually, they become localized in the ventrolateral corners of the blastocoel, where they form the larval skeleton.

The remaining cells of the vegetal plate then invaginate into the blastocoel to form the endoderm layer, creating a structure that looks something like an indented tennis ball. Eventually, the inward-moving tube of cells contacts the opposite side of the gastrula and stops moving. The hollow structure resulting from the invagination is called the *archenteron*, and it is the progenitor of the digestive tube. The opening of the archenteron, the future anus, is known as the *blastopore*. A secondary opening develops at the point where the archenteron contacts the opposite side of the gastrula, forming the mouth (see figure 54.11). Animals in which the anus develops first and the mouth second are termed *deuterostomes*, as was discussed in chapter 32.

### Gastrulation in frogs

The blastula of an amphibian has an asymmetrical yolk distribution, and the yolk-laden cells of the vegetal pole are less numerous but much larger than the yolk-free cells of the animal pole. Consequently, gastrulation is more complex than it is in sea urchins. In frogs, a layer of surface cells first invaginates to form a small, crescent-shaped slit, which initiates formation of

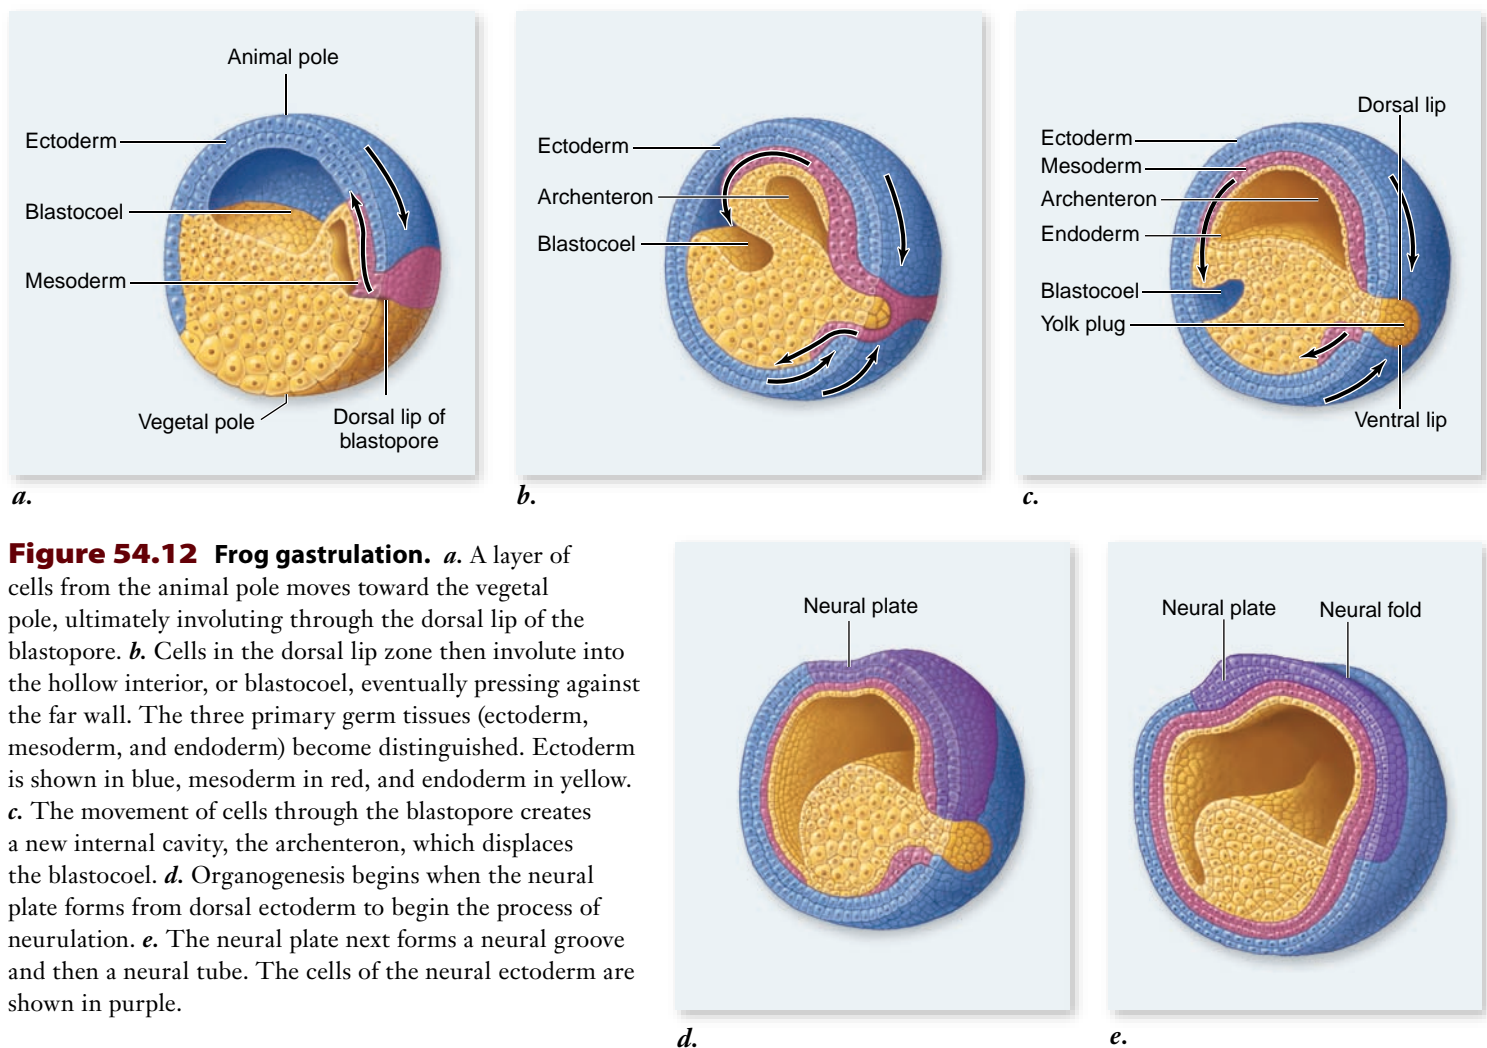

the blastopore. Next, cells from the animal pole involute over the dorsal lip of the blastopore (see figure 54.12*a*), which forms at the same location as the gray crescent of the fertilized egg (see figure 54.5).

The involuting cell layer eventually presses against the inner surface of the opposite side of the embryo, eliminating the blastocoel and producing an archenteron with a blastopore. In this case, however, the blastopore is filled with yolk-rich cells, forming the **yolk plug** (figure 54.12*b, c*). The outer layer of cells resulting from these movements is the ectoderm, and the inner layer is the endoderm. Other cells that involute over the dorsal lip and ventral lip (the two lips of the blastopore that are separated by the yolk plug) migrate between the ectoderm and endoderm to form the third germ layer—the mesoderm (figure 54.12*c–e*).

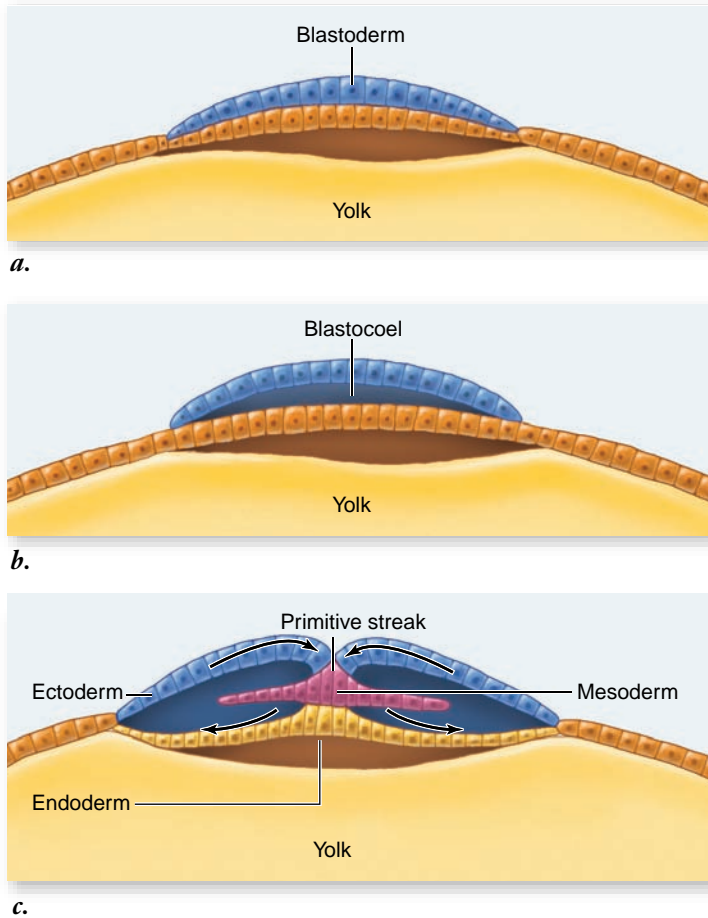

### Gastrulation in birds

At the end of cleavage in a bird or reptile, the developing embryo is a small cap of cells called the **blastoderm**, which sits on top of the large ball of yolk (figure 54.13*a*). As a result, gastrulation proceeds somewhat differently.

In birds, the blastoderm first separates into two layers, and a blastocoel cavity forms between them (figure 54.13*b*).

**Figure 54.12** Frog gastrulation. *a.* A layer of cells from the animal pole moves toward the vegetal pole, ultimately involuting through the dorsal lip of the blastopore. *b.* Cells in the dorsal lip zone then involute into the hollow interior, or blastocoel, eventually pressing against the far wall. The three primary germ tissues (ectoderm, mesoderm, and endoderm) become distinguished. Ectoderm is shown in blue, mesoderm in red, and endoderm in yellow. *c.* The movement of cells through the blastopore creates a new internal cavity, the archenteron, which displaces the blastocoel. *d.* Organogenesis begins when the neural plate forms from dorsal ectoderm to begin the process of neurulation. *e.* The neural plate next forms a neural groove and then a neural tube. The cells of the neural ectoderm are shown in purple.

**Figure 54.13 Gastrulation in birds.** *a.* The avian blastula is made up of a disc of cells sitting atop the large yolk mass. *b.* Gastrulation commences with the delamination of the blastoderm into two layers. All three germ layers are derived from the upper layer of the blastoderm. *c.* Cells that migrate through the primitive streak into the interior of the embryo are future endoderm or mesoderm cells. Cells that remain in the upper layer form the ectoderm.

The deep, internal layer of the bilayered blastoderm gives rise to extraembryonic tissues only (described later on), whereas all cells of the embryo proper are derived from the upper layer of cells. Thus, the upper layer of the blastoderm gives rise to all three germ layers.

Some of the surface cells begin moving to the midline, where they break away from the surface sheet of cells and ingress into the blastocoel cavity. A furrow along the longitudinal midline marks the site of this ingression (figure 54.13*c*). This furrow, analogous to an elongated blastopore, is called the **primitive streak**. Some cells migrate through the primitive streak and across the blastocoel cavity to displace cells in the lower layer. These deep-migrating cells form the endoderm. Other cells that move through the primitive streak migrate laterally into intermediate regions and form a new layer—the mesoderm. Cells that remain on the surface and do not enter the primitive streak form the ectoderm.

### Gastrulation in mammals

Mammalian gastrulation proceeds much the same as it does in birds. In both types of animals, the embryo develops from a flattened collection of cells—the blastoderm in birds or the inner cell mass in mammals. Although the blastoderm of a bird is flattened because it is pressed against a mass of yolk, the inner cell mass of a mammal is flat despite the absence of a yolk mass.

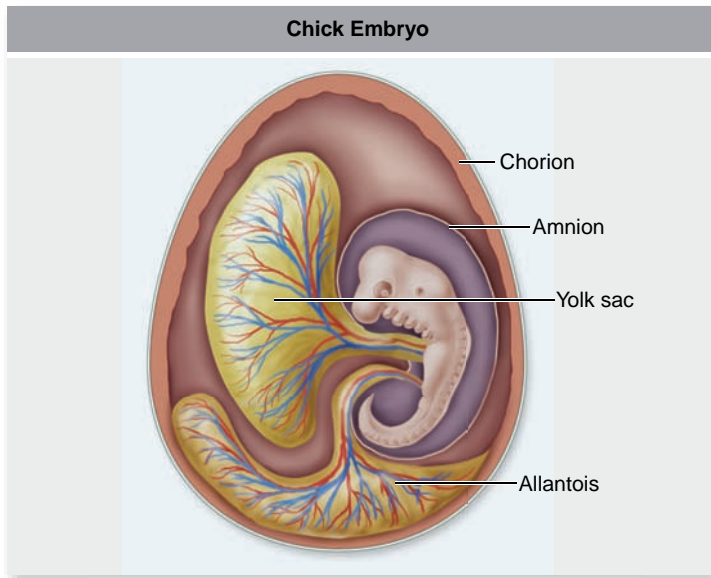

In mammals, the placenta has made yolk dispensable; the embryo obtains nutrients from its mother following implantation into the uterine wall. However, the embryo still gastrulates as though it were sitting on top of a ball of yolk.

In mammals, a primitive streak forms, and cell movements through the primitive streak give rise to the three primary germ layers, much the same as in birds (figure 54.14). Similarly, mammalian embryos envelop their “missing” yolk by forming a yolk sac from extraembryonic cells that migrate away from the lower layer of the blastoderm and line the blastocoel cavity.

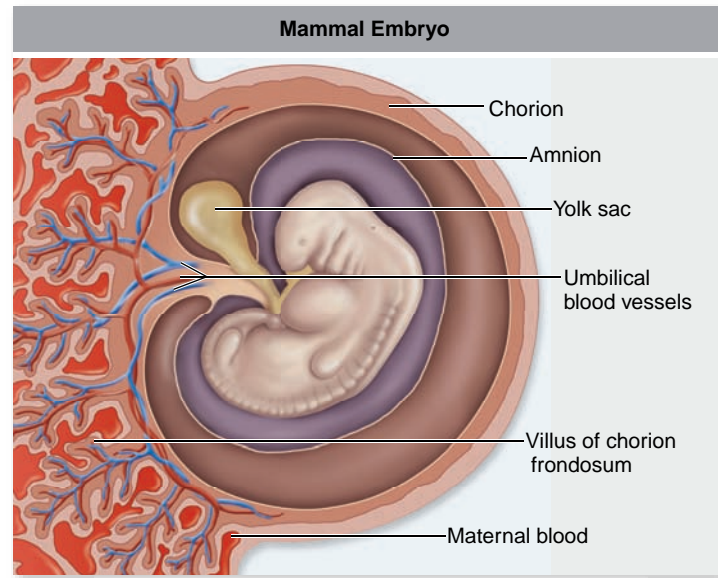

**Figure 54.14 Mammalian gastrulation.** *a.* Cross section of the mammalian blastocyst at the end of cleavage. *b.* The amniotic cavity forms between the inner cell mass (ICM) and the pole of the embryo. Meanwhile, the ICM flattens and delaminates into two layers that will become ectoderm and endoderm. *b.* and *c.* Cells of the lower layer migrate out to line the blastocoel cavity to form the yolk sac. *d.* A primitive streak forms the ectoderm layer, and cells destined to become mesoderm migrate into the interior, similar to gastrulation in birds.

a.

**Figure 54.15 The extraembryonic membranes.** The extraembryonic membranes in (a) a chick embryo and (b) a mammalian embryo share some of the same characteristics. However, in the chick, the allantois continues to grow until it eventually unites with the chorion just under the eggshell, where it is involved in gas exchange. In the mammalian embryo, the allantois contributes blood vessels to the developing umbilical cord.

b.

## Extraembryonic membranes are an adaptation to life on dry land

As an adaptation to terrestrial life, the embryos of reptiles, birds, and mammals develop within a fluid-filled *amniotic membrane*, or *amnion* (chapter 35). The amniotic membrane and several other membranes form from embryonic cells, but they are located outside of the body of the embryo. For this reason, they are known as **extraembryonic membranes**. The extraembryonic membranes include the amnion, chorion, yolk sac, and allantois.

In birds, the amnion and chorion arise from two folds that grow to completely surround the embryo (figure 54.15a). The amnion is the inner membrane that surrounds the embryo and suspends it in *amniotic fluid*, thereby mimicking the aquatic environments of fish and amphibian embryos. The chorion is located next to the eggshell and is separated from the other membranes by a cavity—the *extraembryonic coelom*.

The *yolk sac* plays a critical role in the nutrition of bird and reptile embryos; it is also present in mammals, although it does not nourish the embryo. The *allantois* is derived as an out-pouching of the gut and serves to store the uric acid excreted in the urine of birds. During development, the allantois of a bird embryo expands to form a sac that eventually fuses with the overlying chorion, just under the eggshell. The fusion of the allantois and chorion form a functioning unit, the chorio-allantoic membrane, in which embryonic blood vessels, carried in the allantois, are brought close to the porous eggshell for gas exchange. The chorioallantoic membrane is thus the respiratory membrane of a bird embryo.

In mammals, the trophoblast cells of the blastocyst implant into the endometrial lining of the mother's uterus and become the chorionic membrane (figure 54.15b). The part of the chorion in contact with endometrial tissue contributes to the placenta.

The other part of the placenta is composed of modified endometrial tissue of the mother's uterus, as is described in more detail in a later section. The allantois in mammals contributes blood vessels to the structure that will become the umbilical cord, so that fetal blood can be delivered to the placenta for gas exchange.

### Learning Outcomes Review 54.3

Gastrulation involves cell rearrangement and migration to produce ectoderm, mesoderm, and endoderm. In sea urchins, endoderm forms by invagination of the blastula; mesodermal cells form from other surface cells. In vertebrates with moderate to extensive amounts of yolk, surface cells move through a blastopore or a primitive streak, respectively. Mammalian gastrulation is similar to gastrulation in birds. Extraembryonic membranes of amniote species form from embryonic cells outside the embryo's body and include the yolk sac, amnion, chorion, and allantois.

- What kind of cellular behaviors are necessary for gastrulation?

## 54.4 Organogenesis

### Learning Outcomes

1. Describe examples of organogenesis.
2. Describe neurulation and somitogenesis.
3. Explain the migration and role of neural crest cells.

Gastrulation establishes the basic body plan and creates the three primary germ layers of animal embryos. The stage is now

set for *organogenesis*—the formation of the organs in their proper locations—which occurs by interactions of cells within and between the three germ layers. Thus, organogenesis follows rapidly on the heels of gastrulation, and in many animals begins before gastrulation is complete. Over the course of subsequent development, tissues develop into organs and animal embryos assume their unique body form (see table 54.1).

## Changes in gene expression lead to cell determination

All of the cells in an animal's body, with the exception of a few specialized ones that have lost their nuclei, have the same complement of genetic information. Despite the fact that all of its cells are genetically identical, an adult animal contains dozens to hundreds of cell types, each expressing some unique aspect of the total genetic information for that individual. The information for other cell types is not lost, but most cells within a developing organism progressively lose the capacity to express ever-larger portions of their genomes. What factors determine which genes are to be expressed in a particular cell?

To a large degree, a cell's location in the developing embryo determines its fate. By changing a cell's location, an experimenter can often alter its developmental destiny, as mentioned in chapter 19. But this is only true up to a certain point in the cell's development. At some stage, every cell's ultimate fate becomes fixed, a process referred to as *cell determination*.

A cell's fate can be established by inheritance of cytoplasmic determinants or by interactions with neighboring cells. The process by which a cell or group of cells instructs neighboring cells to adopt a particular fate is called *induction*. If a nonporous barrier, such as a layer of cellophane, is imposed between the inducer and the target tissue, no induction takes place. In contrast, a porous filter, through which proteins can pass, does permit induction to occur.

In these experiments, researchers concluded that the inducing cells secrete a paracrine signal molecule that binds to the cells of the target tissue. Such signal molecules are capable of producing changes in the patterns of gene transcription in the target cells. You will learn more about the origin of embryonic induction a little later in this chapter.

## Development of selected systems in *Drosophila* illustrates organogenesis

In chapter 19, you saw how the creation of morphogen gradients in a fruit fly embryo leads to hierarchies of gene expression that direct cell fate decisions along both the anterior–posterior and dorsal–ventral axes. These two axes form a coordinate system to specify the position of tissues and organs within the *Drosophila* embryo. In this section we look at development of three different organs: salivary glands, the heart, and the tracheae of the respiratory system.

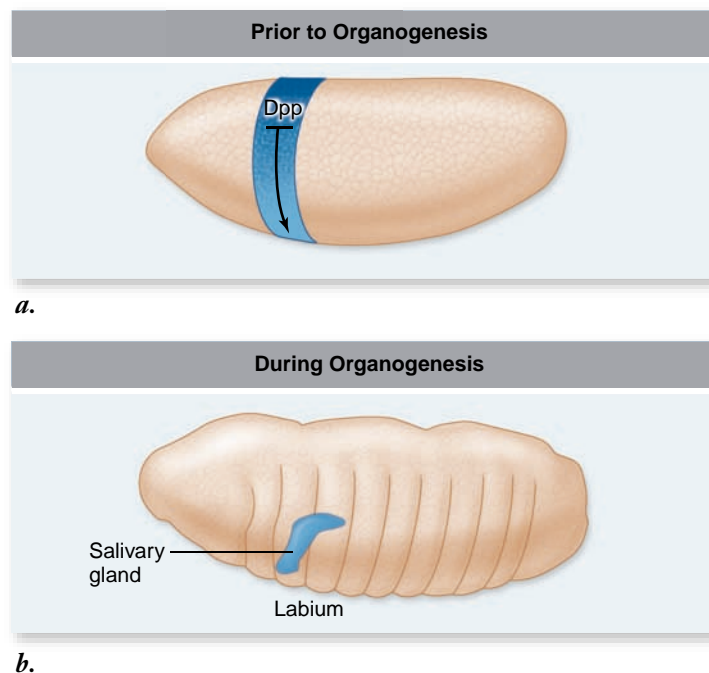

### Salivary gland development

The fruit fly larva is a mobile eating machine, and thus it has very active salivary glands. The primordia of the salivary glands develop as simple tubular invaginations of ectodermal cells on the ventral surface of the third head segment.

Salivary glands develop only from an anterior strip of cells that express the *sex combs reduced* (*scr*) gene. No salivary glands form in *scr*-deficient embryos, whereas experimental expansion of *scr* expression along the anterior–posterior axis results in the formation of additional salivary gland primordia along the length of the embryo.

The *scr* gene is one of the homeotic genes in the Antennapedia complex, which encode transcription factors that bind to DNA via their homeodomains to regulate gene expression (see chapter 19). One downstream target of the *scr* gene is the *fork head* (*fhb*) gene, which has Scr-binding sites in its enhancer. The *fhb* gene is required for secretory cell development in salivary gland rudiments, and it encodes a transcription factor that directly activates expression of salivary gland-specific genes. Thus, action of the *scr* gene activates *fhb* expression at the proper anterior location for salivary gland formation.

The inhibitory action of a dorsally expressed protein, Decapentaplegic (Dpp), determines the ventral position of the salivary glands. Activation of the Dpp-signaling pathway represses salivary gland specification in neighboring cells. This restricts development of salivary gland rudiments to their specific ventral patch of ectoderm cells (figure 54.16). In mutant embryos deficient for Dpp or any of the downstream Dpp-signaling proteins,

**Figure 54.16** Salivary gland formation in *Drosophila*.

Prospective salivary gland cells are determined by the intersection of the anterior–posterior and dorsal–ventral axes. **a.** Prior to organogenesis, the *sex combs reduced* (*scr*) gene is expressed in an anterior band of cells (shaded blue). At the same time, Decapentaplegic protein (Dpp) is released by cells on the dorsal side of the embryo, forming a gradient in the dorsal–ventral direction. Dpp specifies dorsal cell fates and inhibits formation of salivary gland rudiments. **b.** During organogenesis, the salivary glands develop in areas where Scr is expressed but Dpp is absent. Each salivary gland rudiment forms as a ventral invagination of the surface ectoderm on either side of the third head segment (the labium).

salivary gland rudiments are not restricted to this ventral patch, and they form from the entire ectoderm of the third segment.

### Heart development

The heart is a mesoderm-derived structure in all animals, and it is the first organ to become functional during embryonic development. The dorsal vessel is the heart-equivalent structure in *Drosophila melanogaster*. The homeobox-containing gene *tinman* is expressed in the prospective heart mesoderm and in the developing dorsal vessel, and its activity is required for dorsal vessel development in *Drosophila* (figure 54.17).

Dorsal vessel development in *Drosophila* is also dependent on two other types of transcription factors (known as GATA and T-box factors). In an illuminating case of evolutionary conservation, scientists have discovered gene families similar to each of these three *Drosophila* genes in vertebrates. Moreover, members of these gene families play important roles in vertebrate heart specification.

This evolutionary conservation includes not just the structure of these genes, but their function as well. Research-

ers have discovered that specification of cardiac mesoderm is subject to inductive signals from adjoining germ layers in both *Drosophila* and vertebrates. In vertebrates, the heart develops in an internal location, and the inductive signals come from the underlying anterior endoderm. In *Drosophila*, the dorsal vessel forms in a more superficial location, and the signals come from the overlying ectoderm.

Despite the different sources, the signals that regulate the expression of these three key types of transcription factors are themselves conserved between *Drosophila* and vertebrates. Given the critical and conserved circulatory function of the heart, it is perhaps not surprising that similar gene families mediate the specification of heart mesoderm in both *Drosophila* and vertebrates.

### Tracheae: Branching morphogenesis

As you learned in chapters 34 and 49, insects exchange gases via a branching system of finer and finer tubes called *tracheae*. The repeated branching of simple epithelial tubes that leads to formation of the tracheal system is an example of **branching morphogenesis**.

Mutations in the *branchless* gene in *Drosophila* result in embryos with greatly reduced tracheal systems. The *branchless* gene encodes a member of the large family of **fibroblast growth factors (FGF)**, which bind to receptor tyrosine kinase proteins (see chapter 9) to stimulate proliferation of target cells. In another interesting case of evolutionary conservation, the mammalian FGF homologue of the *branchless* gene is required for branching morphogenesis that creates the alveolar passageways in the mammalian lung.

In both animals, loose clusters of mesenchymal cells adjacent to distal regions of the epithelial tube secrete FGF. The FGF binds to a specific FGF receptor in the membrane of the epithelial cells, stimulating them to proliferate and to grow out into a new tube bud.

### In vertebrates, organogenesis begins with neurulation and somitogenesis

The process of organogenesis in vertebrates begins with the formation of two morphological features found only in chordates: the *notochord* and the hollow **dorsal nerve cord** (see chapter 35). The development of the dorsal nerve cord is called *neurulation*.

#### Development of the neural tube

The notochord forms from mesoderm and is first visible soon after gastrulation is complete. It is a flexible rod located along the dorsal midline in the embryos of all chordates, although its function as a supporting structure is supplanted by the subsequent development of the vertebral column in the vertebrates. After the notochord has been laid down, the region of dorsal ectodermal cells situated above the notochord begins to thicken to form the *neural plate*.

The thickening is produced by the elongation of the dorsal ectoderm cells. Those cells then assume a wedge shape because of contracting bundles of actin filaments at their apical end. This change in shape causes the neural tissue to roll up into a **neural groove** running down the long axis of the embryo. The edges of the neural groove then move toward each

### SCIENTIFIC THINKING

**Hypothesis:** The *tinman* gene is required for proper development of the dorsal vessel in *Drosophila*.

**Prediction:** The *tinman* gene must be expressed in precursor cells for the dorsal vessel. Loss of *tinman* function should result in loss of dorsal vessel.

**Test:** Analyze expression of *tinman* in whole mount embryos in wild type (top) and mutant (bottom) embryos.

**Result:** In the wild type embryo, *tinman* is expressed in a line of cells where the dorsal vessel forms. In mutant embryos with no expression, no dorsal vessel forms.

**Conclusion:** The function of *tinman* is necessary for dorsal vessel formation.

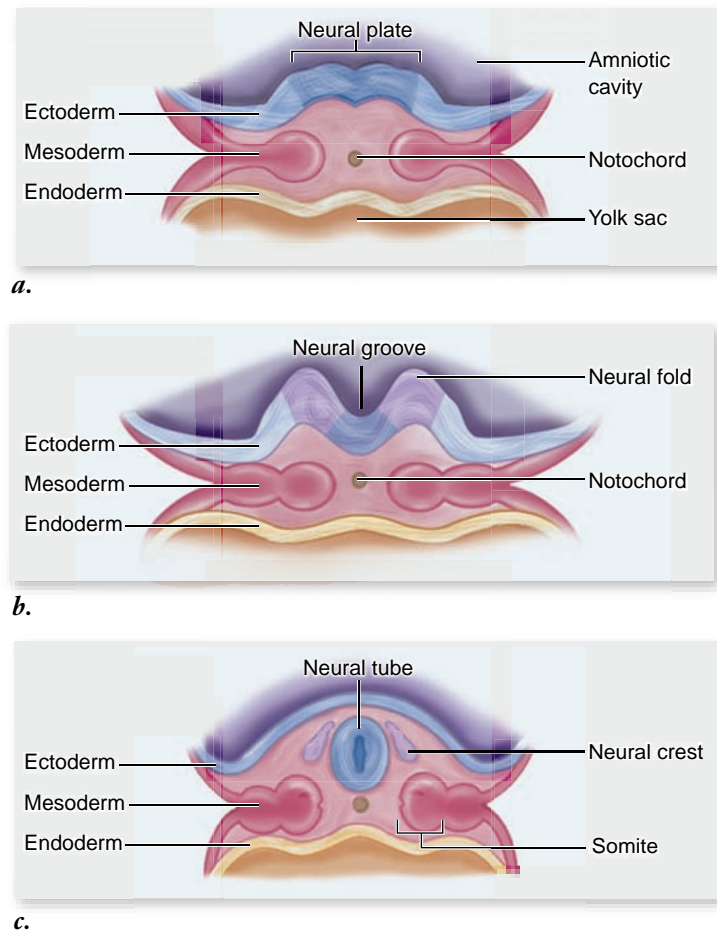

**Further Experiments:** *Tinman* is a homeobox containing gene. What does this suggest about its function? How could you follow up on this?

**Figure 54.17** A gene necessary for heart formation in *Drosophila*.

other and fuse, creating a long hollow cylinder, the **neural tube** (figure 54.18). The neural tube eventually pinches off from the surface ectoderm to end up beneath the surface of the embryo's back. Regional changes, which are under control of the *Hox* gene complexes (see chapter 19), then occur in the neural tube as it differentiates into the spinal cord and brain.

### Generation of somites

While the neural tube is forming from dorsal ectoderm, the rest of the basic architecture of the body is being rapidly established by changes in the mesoderm. The sheets of mesoderm on either side of the developing notochord separate into a series of rounded regions called **somitomeres**. The somitomeres then separate into segmented blocks called **somites** (see figure 54.18). The mesoderm in the head region does not separate into discrete somites but remains connected as somitomeres, which form the skeletal muscles of the face, jaws, and throat.

**Figure 54.18** Mammalian neural tube formation.

**a.** The neural plate forms from ectoderm above the notochord. **b.** The cells of the neural plate fold together to form the neural groove. **c.** The neural groove eventually closes to form a hollow tube called the neural tube, which will become the brain and spinal cord. As the tube closes, some of the cells from the dorsal margin of the neural tube differentiate into the neural crest, migratory cells that form a variety of structures and are characteristic of vertebrates.

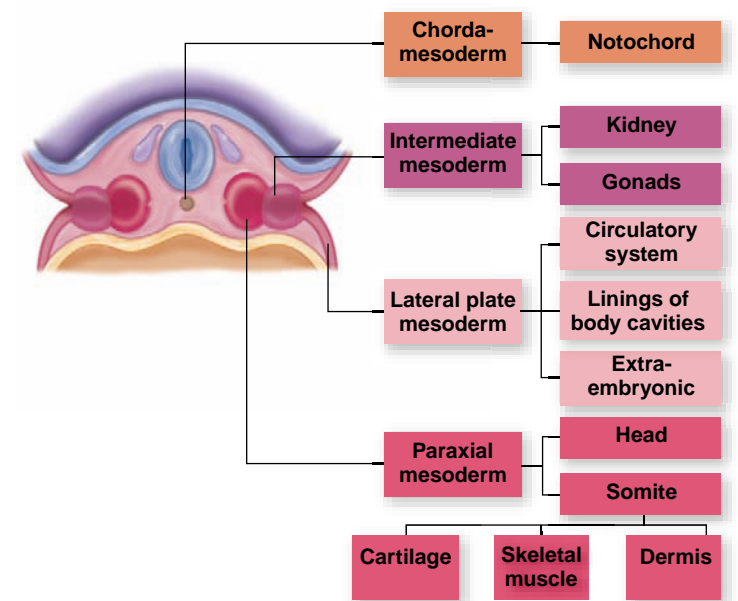

Somites form in an anterior–posterior wave with a regular periodicity that can be easily timed—for example, by using a vital dye, which marks cells without killing them, to mark each somite as it forms in a chick embryo. Cells at the presumptive boundary regions in the presomitic mesoderm instruct cells anterior to them to condense and separate into somites at specific times (for example, every 90 min in a chick embryo). This “clock” appears to be regulated by contact-mediated cell signaling between neighboring cells.

Somites themselves are transient embryonic structures, and soon after their formation, cells disperse and start differentiating along different pathways to ultimately form the skeleton, skeletal musculature, and associated connective tissues. The total number of somites formed is species-specific; for example, chickens form 50 somites, whereas some species of snakes form as many as 400 somites.

Some body organs, including the kidneys, adrenal glands, and gonads, develop within a strip of mesoderm that runs lateral to each row of somites. The remainder of the mesoderm, which is most ventrally located, moves out and around the endoderm and eventually surrounds it completely. As a result of this movement, the mesoderm becomes separated into two layers. The outer layer is associated with the inner body wall, and the inner layer is associated with the outer lining of the gut tube. Between these two layers of mesoderm is the *coelom* (see chapter 32), which becomes the body cavity of the adult. Figure 54.19 shows the major mesoderm lineages of amniote embryos.

### Migratory neural crest cells differentiate into many cell types

Neurulation occurs in all chordates, and the process in the simple lancelet, a nonvertebrate chordate, is much the same as it is in a human. However, neurulation is accompanied by an additional step in vertebrates. Just before the neural groove closes

**Figure 54.19** Mesoderm-derived structures of birds and mammals.

to form the neural tube, its edges pinch off, forming a small cluster of cells—the *neural crest*—between the roof of the neural tube and the surface ectoderm (figure 54.18c).

In another example of extensive cell movements during animal development, the neural crest cells then migrate away from the neural tube to colonize many different regions of the developing embryo. The appearance of the neural crest was a key event in the evolution of the vertebrates because neural crest cells, after reaching their final destinations, ultimately develop into many structures characteristic of the vertebrate body.

The differentiation of neural crest cells depends on their migration pathway and final location. Neural crest cells migrate along one of three pathways in the embryo. Cranial neural crest cells are anterior cells that migrate into the head and neck; trunk neural crest cells migrate along one of two different pathways (to be described shortly). Each population of neural crest cells develops into a variety of cell types.

### Cranial neural crest cells' migration

Cranial neural crest cells contribute significantly to development of the skeletal and connective tissues of the face and skull, as well as differentiating into nerve and glial cells of the nervous system, and melanocyte pigment cells. Changes in the placement of cranial neural crest cells during development have led to the evolution of the great complexity and variety of vertebrate heads.

There are two waves of cranial neural crest cell migration. The first produces both dorsal and ventral structures, and the second produces only dorsal structures and makes much less cartilage and bone. Transplantation experiments indicate that the developmental potential of the cells in these two waves is identical. The differences in cell fate are due to the environment the migrating cells encounter and not due to prior determination of cell fate.

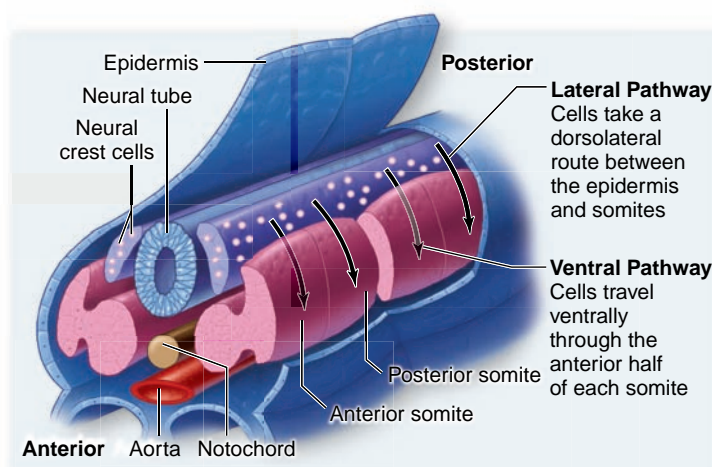

### Trunk neural crest cells: Ventral pathway

Neural crest cells located in more posterior positions have very different developmental fates depending on their migration pathway. The first trunk neural crest cells that migrate away from the neural tube pass through the anterior half of each adjoining somite to ventral locations (figure 54.20a).

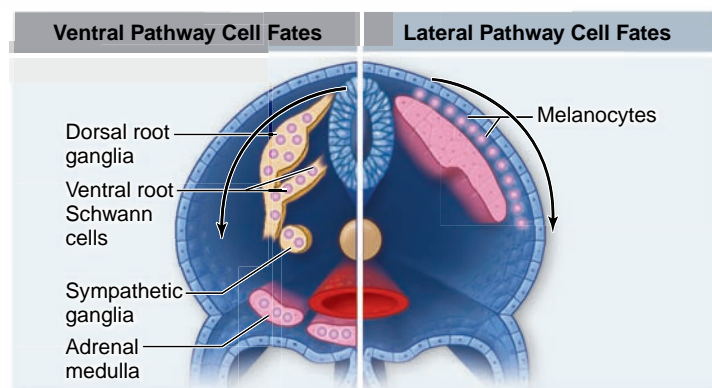

Some of these cells form the sensory neurons of the dorsal root ganglia, which send out projections to connect the periphery of the animal with the spinal cord (see chapter 44). Others become specialized as Schwann cells, which insulate nerve fibers to facilitate the rapid conduction of impulses along peripheral nerves. Still others form nerves of the autonomic ganglia, which regulate the activity of internal organs, and endocrine cells of the adrenal medulla (figure 54.20b). The chemical similarity of the hormone epinephrine and the neurotransmitter norepinephrine, which are released by sympathetic neurons of the autonomic nervous systems, may result because both adrenal medullary cells and sympathetic neurons derive from the neural crest.

### Trunk neural crest cells: Lateral pathway

The second group of trunk neural crest cells migrate away from the neural tube in the space just under the surface ectoderm, to occupy this space around the entire body of the embryo. There, they will differentiate into the pigment cells of the skin

a.

b.

c.

**Figure 54.20 Migration pathways and cell fates of trunk neural crest cells.** a. The first wave of trunk neural crest cells migrates ventrally through the anterior half of each somite, whereas the second wave of cells leaves dorsally and migrates through the space between the epidermis and the somites. b. Ventral pathway neural crest cells differentiate into a variety of specialized cell types, but lateral pathway cells develop into the melanocytes (pigment cells) of the skin. c. A mutation in a gene that promotes survival of neural crest cells in all mammals leads to white spotting on the bellies and foreheads of both human babies and mice! Each individual is heterozygous for this mutation and thus has only half as much of the survival factor as unaffected individuals.

(figure 54.20*a, b*). Mutations in genes that affect the survival and migration of neural crest cells lead to white spotting in the skin on ventral surfaces, as well as internal problems in other neural crest-derived tissues (figure 54.20*c*).

Because the fate of a neural crest cell is dictated by its migration pathway, many studies have been done to identify the molecules that control the migration pathways of neural crest cells. Cell adhesion molecules on cell surfaces and in the extracellular matrix are expected to play prominent roles. For example, prospective neural crest cells down-regulate the expression of *N*-cadherin on their surfaces, which enables them to break away from the neural tube. Then, soon after leaving the neural tube, integrin receptors appear on the surfaces of neural crest cells, allowing them to interact with proteins in the extracellular matrix pathways along which they will migrate.

## Neural crest derivatives are important in vertebrate evolution

Primitive chordates such as lancelets are filter feeders, using the rapid beating of cilia to draw water into their mouths, which then exits through slits in their pharynx. These pharyngeal slits evolved into the vertebrate gill chamber, a structure that provides a greatly improved means of gas exchange. Thus, evolution of the gill chamber was certainly a key event in the transition from filter feeding to active predation, which requires a much higher metabolic rate.

In the development of the gill chamber, some of the cranial neural crest cells form cartilaginous bars between the em-

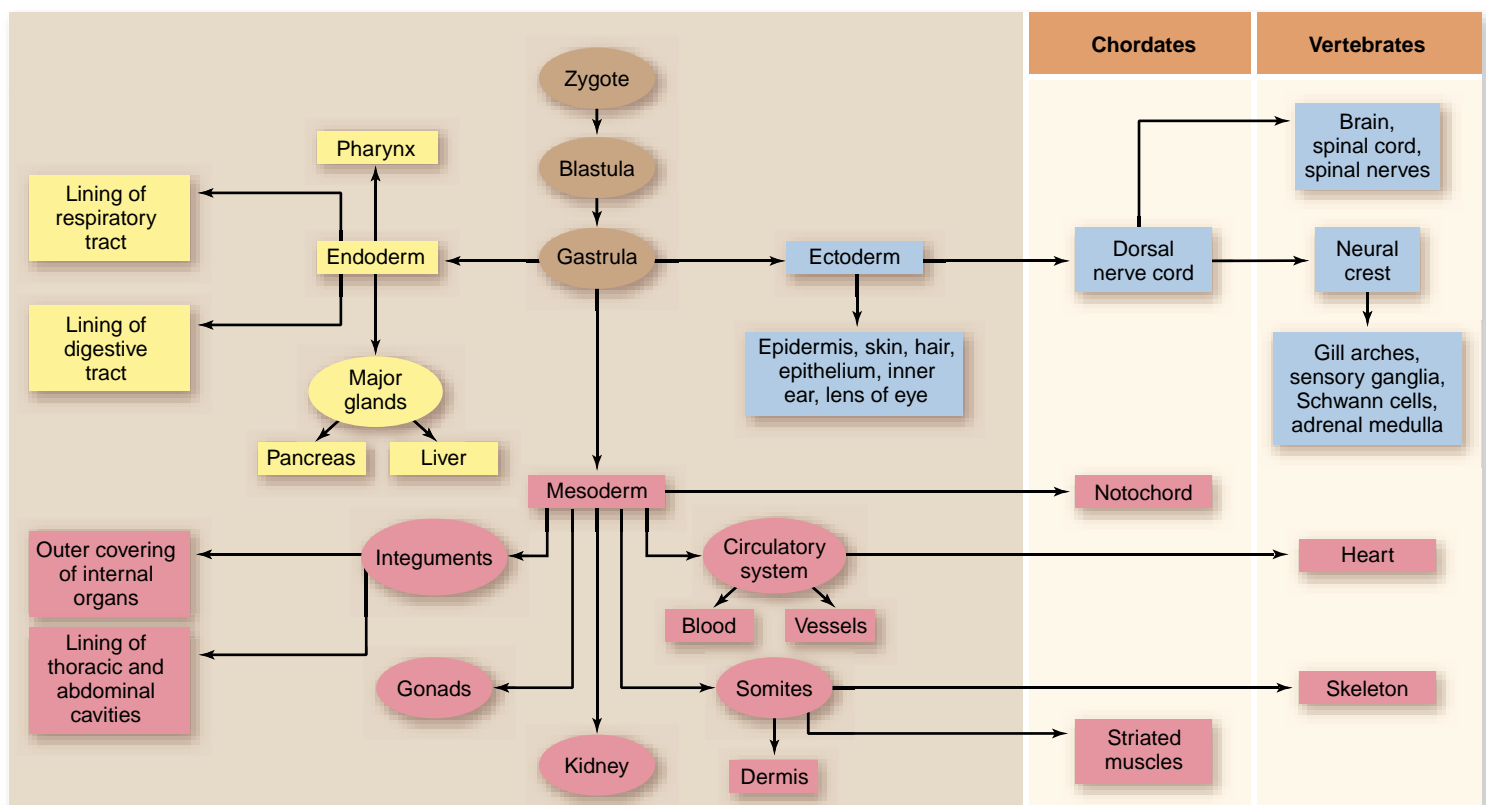

bryonic pharyngeal slits. Other cranial neural crest cells induce portions of the mesoderm to form muscles along the cartilage, and still others to form neurons that carry impulses between the central nervous system and these muscles.

Many of the unique vertebrate adaptations that contribute to their varied ecological roles involve structures that arise from neural crest cells. The vertebrates became fast-swimming predators with much higher metabolic rates. This accelerated metabolism permitted a greater level of activity than was possible among the more primitive chordates. Other evolutionary changes associated with the derivatives of the neural crest provided better detection of prey, a greatly improved ability to orient spatially during prey capture, and the means to respond quickly to sensory information. The evolution of the neural crest and of the structures derived from it were thus crucial steps in the evolution of the vertebrates (figure 54.21).

### Learning Outcomes Review 54.4

Genetic control of organogenesis relies on conserved families of cell-signaling molecules and transcription factors. The control of heart development in *Drosophila* and mammals uses some of the same proteins. The process of neurulation forms the basic nervous system in vertebrates. Somitogenesis is the division of mesoderm into somites. Neural crest cells arise from the neural tube and migrate to many sites to form a variety of cell types. The evolution of the neural crest led to the appearance of many vertebrate-specific adaptations.

- Are neural crest cells determined prior to migration?

**Figure 54.21 Germ-layer derivation of the major tissue types in animals.** The three germ layers that form during gastrulation give rise to all the organs and tissues in the body, but the neural crest cells that form from ectodermal tissue give rise to structures that are prevalent in vertebrates, such as gill arches and bones of the face and skull.

## 54.5 Vertebrate Axis Formation

### Learning Outcomes

1. Describe the Spemann-Mangold experiment.
2. Explain the function of the organizer.
3. Distinguish between primary and secondary inductive events.

In animal development, the relative position of cells in particular germ layers determines, to a large extent, the organs that develop from them. In *Drosophila*, you have seen that formation of morphogen gradients in the syncytial blastoderm establishes the anterior–posterior and dorsal–ventral axes of the embryo. The *Hox* gene complexes in vertebrates function similarly to the homeotic genes of *Drosophila* to specify the position of organs along the anterior–posterior axis. But how is cell fate selection along the dorsal–ventral axis accomplished in vertebrate embryos? Put another way, how do cells of the dorsal ectoderm “know” they are above the mesoderm-derived notochord, and thus fated to develop into the neural tube? The solution to this puzzle is one of the outstanding accomplishments of experimental embryology.

### The Spemann organizer determines dorsal–ventral axis

The renowned German biologist Hans Spemann and his student Hilde Mangold solved this puzzle early in the 20th century. Normally, cells derived from the dorsal lip of the blastopore of a gastrulating amphibian embryo give rise to the notochord. Spemann and Mangold removed cells of the dorsal lip from one embryo and transplanted them to a different location on another embryo (figure 54.22). The new location corresponded to that of the animal’s future belly. They found that some of the embryos developed two notochords: a normal dorsal one, and a second one along the belly. Moreover, a complete set of dorsal axial structures (e.g., notochord, neural

tube, and somites) formed at the ventral transplantation site in most of these embryos.

By using genetically different donor and host blastulas, Spemann and Mangold were able to show that the second notochord produced by transplanting dorsal lip cells contained host cells as well as transplanted ones. The transplanted dorsal lip cells had thus acted as *organizers*, stimulating cells that would normally form skin and belly structures to develop into dorsal axial structures. The belly cells must clearly contain the genetic information for dorsal axial developmental program, but they do not express it in the normal course of their development. Signals from the transplanted dorsal lip cells, however, must have caused them to do so.

### How the organizer works

An organizer is a cluster of cells that release diffusible signal molecules, which then convey positional information to other cells. As seen earlier, organizers can have a profound influence on the development of surrounding tissues. Working as signal beacons, they inform surrounding cells of their distance from the organizer. The closer a particular cell is to an organizer, the higher the concentration of the signal molecule (*morphogen*) it experiences. Organizers and the diffusible morphogens that they release are thought to be part of a widespread mechanism for determining relative position and cell fates during vertebrate development.

### The action of morphogens

The action of morphogens can be studied by using isolated portions of the blastula. The blastula can be bisected into an animal half (the animal cap) and vegetal half (the vegetal cap). If animal caps are removed from a frog blastula and cultured alone, they will form only ectoderm-derived epidermal cells. Similarly, cultured vegetal caps will form only endodermal cells. However, if animal caps are cultured combined with vegetal caps, the animal caps will form mesodermal structures.

The molecules involved in this induction have not been unambiguously identified. Members of the transforming growth factor beta (TGF- $\beta$ ) family have been implicated. These include activin, and *Xenopus* nodal-related proteins (Xnrs). Evidence for the inducing action of these molecules ranges from indirect: the

**Figure 54.22 Spemann and Mangold’s dorsal lip transplant experiment.** Tissue from the dorsal lip of a donor embryo induced the formation of a second axis in the future belly region of a second, recipient embryo.

timing and pattern of expression correlates with inducing tissue, to depleting developing embryos of these proteins with specific reagents that block gene expression.

### The origin of the organizer

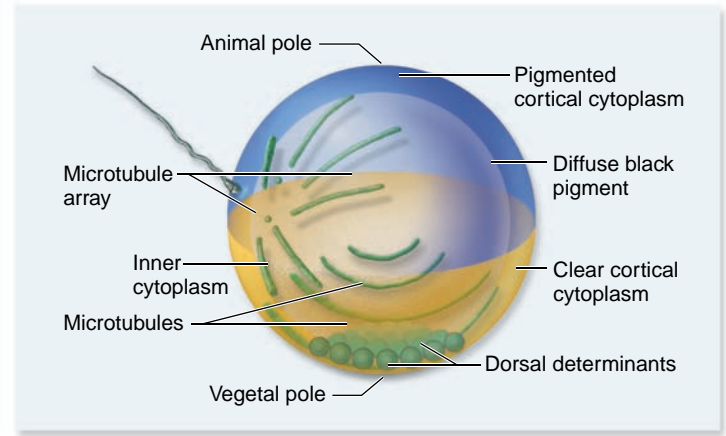

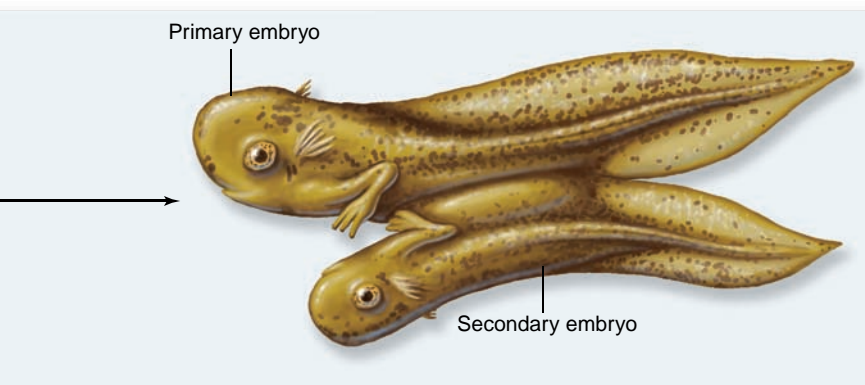

How do cells of the frog blastopore's dorsal lip become the Spemann organizer and how do they acquire their ability to specify cell fate along the dorsal-ventral axis? In frogs, as in fruit flies, this process starts during oogenesis in the mother. At that time, maternally encoded dorsal determinants are put into the developing oocyte, one of which accumulates at the vegetal pole of the unfertilized egg. At fertilization, cytoplasmic rearrangements cause this determinant to shift to the future dorsal side of the egg.

First, a signal from the point of sperm entry initiates the assembly of a microtubule array, which enables the egg's plasma membrane and the underlying cortical cytoplasm to rotate over the surface of the deeper cytoplasm. This physical rotation shifts this maternally encoded dorsal determinant to the opposite side of the egg from the point of sperm entry (figure 54.23*a, b*). In some frogs, a gray crescent forms opposite the sperm entry point, as mentioned earlier, and this crescent marks the future site of the dorsal lip.

Cells that form in this area during cleavage (called the Nieuwkoop center for the scientist who did the previously mentioned animal cap studies) receive the dorsal determinants that moved during cortical rotation. The dorsal determinants cause a change in gene expression in these cells, producing a signaling molecule that induces the cells above them to develop into the dorsal lip of the blastopore (figure 54.23*c*).

### Maternally encoded dorsal determinants activate Wnt signaling

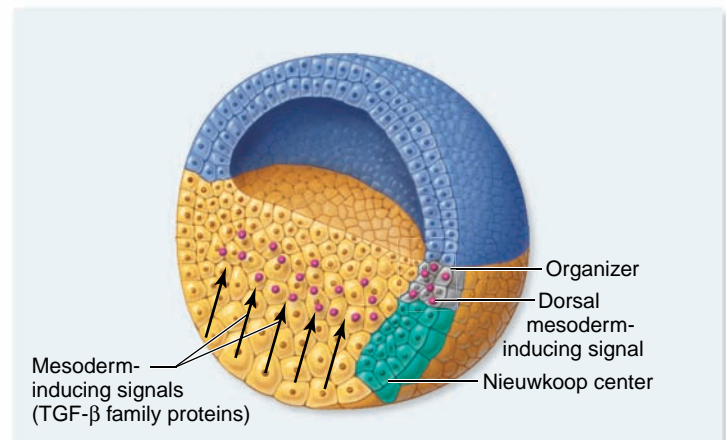

Experiments carried out over the last 15 years suggest that the maternally encoded dorsal determinants in *Xenopus* are mRNAs for proteins that function in the intracellular **Wnt** signaling pathway. *Wnt* genes encode a large family of cell-signaling proteins that affect the development of a number of structures in both vertebrates and invertebrates. Turning on the Wnt pathway in the dorsal vegetal cells of the Nieuwkoop center leads ultimately to activation of a transcription factor, which moves into the nucleus to activate the expression of genes necessary for organizer specification.

*a.*

*b.*

*c.*

### Figure 54.23 Creation of the Spemann organizer.

*a.* Dorsal determinants are localized at the vegetal pole of the unfertilized frog egg. At fertilization, a microtubule array forms at the site of sperm entry. These microtubules organize parallel microtubules to line the vegetal half of the egg between the cortex and cytoplasm. *b.* The cortical cytoplasm and dorsal determinants ride on this parallel array of microtubules, shifting to a site opposite sperm entry. *c.* Cells that inherit these shifted dorsal determinants form the Nieuwkoop center, which releases diffusible signaling molecules that specify the cells in the overlying dorsal marginal zone to become the organizer. The organizer forms at the area of the gray crescent, visible following the cytoplasmic rearrangements at fertilization.

## Signaling molecules from the Spemann organizer inhibit ventral development

It has taken decades to establish the identity and function of the molecules that are synthesized by cells of the Spemann organizer to subsequently specify dorsal mesoderm cell fates in frogs. A surprising finding of recent experiments indicates that dorsal lip cells do not directly *activate* dorsal development. Instead, dorsal mesoderm development is a result of the *inhibition* of ventral development.

A protein called **bone morphogenetic protein 4 (BMP4)** is expressed in all marginal zone cells (the prospective mesoderm) of a frog embryo. Cells with receptors for BMP4 have the potential to develop into mesodermal derivatives. The specific mesodermal fate depends on how many receptors bind BMP4: More BMP4 binding induces a more ventral mesodermal fate.

The organizer functions by secreting a host of *inhibitory* molecules that can bind to BMP4 and prevent its binding to receptor. Such molecules are referred to as BMP4 antagonists. Up to 13 different proteins have been identified in the Spemann organizer, most of which appear to function as BMP4 antagonists. These include the proteins Noggin, Chordin, Dickkopf, and Cerebrus. Noggin and BMP4 are also involved in toe and finger joint formation, so humans homozygous for a *Noggin* mutation have fused joints.

Thus, the gradient of *inhibitory* molecules that emanates from the Spemann organizer leads to a declining level of BMP4 *function* in the ventral-to-dorsal direction. Cells farthest from the organizer bind the highest levels of BMP4 and differentiate into ventral mesoderm structures such as blood and connective tissues. Cells that are midway from the organizer bind intermediate amounts of BMP4, differentiate into intermediate mesoderm, and form organs such as the kidneys and gonads. BMP4 binding is completely inhibited by the high levels of antagonists in the organizer itself. Thus, these cells adopt the most dorsal of mesoderm fates and develop into somites. The influence of the organizer also extends to ectoderm as inhibition of BMP4 in ectoderm leads to formation of neural tissue instead of epidermis (figure 54.24).

## Evidence indicates that organizers are present in all vertebrates

In chicks, a group of cells at the anterior limit of the primitive streak called *Hensen's node* functions similarly to the dorsal lip of the blastopore: Hensen's node induces a second axis when transplanted to another area of a chick embryo. Recent studies have shown that cells of Hensen's node act like the Spemann organizer, secreting molecules that inhibit ventral development. These molecules are the same as those found in frog embryos. Therefore, these experiments once again illustrate the evolutionary conservation of particular genes in animal development.

In addition, notochord signaling acts to pattern the neural tube. The notochord produces the signaling molecule sonic hedgehog (Shh), which is related to a signaling molecule in

**Figure 54.24** Function of the Spemann organizer.

The organizer is a hotbed of secreted molecules that bind to and antagonize the action of BMP4, a morphogen that at high levels specifies ventral mesoderm cell fates.

*Drosophila* called hedgehog. Signaling by Shh specifies ventral cell fate with dose-related effects similar to those described for the TGF- $\beta$  family proteins discussed earlier. In this way, induction by the notochord causes somites to form vertebrae, ribs, muscle, and skin, depending on the levels of Shh cells are exposed to.

## Induction can be primary or secondary

The process of induction that Spemann initially discovered appears to be a fundamental mode of development in vertebrates. Inductions between the three primary germ layers—ectoderm, mesoderm, and endoderm—are referred to as **primary inductions**. The differentiation of the central nervous system during neurulation by the interaction of dorsal ectoderm and dorsal mesoderm to form the neural tube is an example of primary induction.

Inductions between tissues that have already been specified to develop along a particular developmental pathway are called **secondary inductions**. An example of secondary induction is the development of the lens of the vertebrate eye. The eye develops as an extension of the forebrain, a stalk that grows outward until it comes into contact with the surface ectoderm (figure 54.25). At a point directly above the growing stalk, a layer of the surface ectoderm pinches off, forming a transparent lens. The formation of lens from the surface ectoderm requires induction by the underlying neural ectoderm.

This was shown by transplantation experiments performed by Spemann. When the optic stalks of the two eyes have just started to project from the brain prior to lens

**Figure 54.25 Development of the vertebrate eye by induction.** An extension of the optic stalk grows until it contacts the surface ectoderm, where it induces a section of the ectoderm to pinch off and form the lens. Other structures of the eye develop from the optic stalk, with lens cells reciprocally inducing the formation of photoreceptors in the optic cup.

formation, one of the budding stalks can be removed and transplanted underneath surface ectoderm in a region that would normally develop into the epidermis of the skin (such as that of the belly). When this is done, a lens forms from belly ectoderm cells in the region above where the budding stalk was transplanted. This lens forms due to inductive signals from the underlying optic stalk.

### Learning Outcomes Review 54.5

The Spemann-Mangold experiment showed that transplanted cells of the dorsal lip of the blastopore act as organizers stimulating development of a notochord. Hensen's node plays an equivalent role in vertebrates. By inhibiting BMP4, the organizer induces ectoderm to form neural tissue and mesoderm to form dorsal mesoderm. Primary inductions between germ layers lead to development of the vertebrate nervous system, whereas secondary inductions result in formation of structures such as the lens of the eye.

- How can the organizer function by inhibiting the action of other molecules?

## 54.6 Human Development

### Learning Outcomes

1. Describe the major developmental events in first trimester.
2. Explain the role of the placenta.
3. Describe the hormonal control of the birth process.

Human development from fertilization to birth takes an average of 266 days, or about 9 months. This time is commonly divided into three periods called *trimesters*. We describe here the development of the embryo as it takes place during these trimesters. Later, we summarize the process of birth, nursing of the infant, and postnatal development.

### During the first trimester, the zygote undergoes rapid development and differentiation

About 30 hr after fertilization, the zygote undergoes its first cleavage; the second cleavage occurs about 30 hr after that. By the time the embryo reaches the uterus, 6 to 7 days after fertilization, it has differentiated into a blastocyst. As mentioned earlier, the blastocyst consists of an inner cell mass, which will become the body of the embryo, and a surrounding layer of trophoblast cells (see figure 54.10).

The trophoblast cells of the blastocyst digest their way into the endometrial lining of the uterus in the process known as **implantation**. The blastocyst begins to grow rapidly and initiates the formation of the amnion and the chorion.

### Development in the first month

During the second week after fertilization, the developing chorion and the endometrial tissues of the mother engage to form the placenta (figure 54.26). Within the placenta, the mother's blood and the blood of the embryo come into close proximity but do not mix. Gases are exchanged, however, and the placenta provides nourishment for the embryo, detoxifies certain molecules that may pass into the embryonic circulation, and secretes hormones. Certain substances, such as alcohol, drugs, and antibiotics, are not stopped by the placenta and pass from the mother's bloodstream into the embryo.

One of the hormones released by the placenta is human chorionic gonadotropin (hCG), which was discussed in chapter 53. This hormone is secreted by the trophoblast cells even before they become the chorion, and it is the hormone assayed in pregnancy tests. Human chorionic gonadotropin maintains the mother's corpus luteum. The corpus luteum, in turn, continues to secrete estradiol and progesterone, thereby preventing menstruation and further ovulations.

Gastrulation also takes place in the second week after fertilization, and the three germ layers are formed. Neurulation occurs in the third week. The first somites appear, which give rise to the muscles, vertebrae, and connective tissues. By the end of the third week, over a dozen somites are evident, and the blood vessels and gut have begun to develop. At this point, the embryo is about 2 mm long.

*a.*

**Figure 54.26 Structure of the placenta.** *a.* The placenta contains a fetal component, the chorionic frondosum, and a maternal component, the decidua basalis. Deoxygenated fetal blood from the umbilical arteries (shown in blue) enters the placenta, where it picks up oxygen and nutrients from the mother's blood. Oxygenated fetal blood returns in the umbilical vein (shown in red) to the fetus. *b.* Note that the 7-week embryo is surrounded by a fluid-filled amniotic sac.

*b.*

Organogenesis begins during the fourth week (figure 54.27*a*). The eyes form. The tubular heart develops its four chambers and starts to pulsate rhythmically, as it will for the rest of the individual's life. At 70 beats per minute, the heart is destined to beat more than 2.5 billion times during a lifetime of 70 years. Over 30 pairs of somites are visible by the end of the fourth week, and the arm and leg buds have begun to form. The embryo has increased in length to about 5 mm. Although the developmental scenario is now far advanced, many women are still unaware they are pregnant at this stage. Most spontaneous abortions (miscarriages), which frequently occur in the case of a defective embryo, occur during this period.

### The second month

Organogenesis continues during the second month (figure 54.27*b*). The miniature limbs of the embryo assume their adult shapes. The arms, legs, knees, elbows, fingers, and toes can all be seen—as well as a short bony tail. The bones of the embryonic tail, an evolutionary reminder of our past, later fuse to form the coccyx.

Within the abdominal cavity, the major organs, including the liver, pancreas, and gallbladder, become evident. By the end of the second month, the embryo has grown to about 25 mm in length, weighs about 1 g, and begins to look distinctly human. The ninth week marks the transition from embryo to fetus. At this time, all of the major organs of the body have been established in their proper locations.

### The third month

The nervous system develops during the third month, and the arms and legs start to move (figure 54.27*c*). The embryo begins to show facial expressions and carries out primitive reflexes such as the startle reflex and sucking.

At around 10 weeks, the secretion of hCG by the placenta declines, and the corpus luteum regresses as a result. However, menstruation does not occur because the placenta itself secretes estradiol and progesterone (figure 54.28).

The high levels of estradiol and progesterone in the blood during pregnancy continue to inhibit the release of FSH and LH, thereby preventing ovulation. They also help maintain the uterus and eventually prepare it for labor and delivery, and they stimulate the development of the mammary glands in preparation for lactation after delivery.

## During the second trimester, the basic body plan develops further

Bones actively enlarge during the fourth month (figure 54.27*d*), and by the end of the month, the mother can feel the baby kicking. By the end of the fifth month, the rapid heartbeat of the fetus can be heard with a stethoscope, although it can also be detected as early as 10 weeks with a fetal monitor.

Growth begins in earnest in the sixth month; by the end of that month, the fetus weighs 600 g (1.3 lb) and is over 300 mm (1 ft) long. Most of its prebirth growth is still to come, however. The fetus cannot yet survive outside the uterus without special medical intervention.

## During the third trimester, organs mature to the point at which the baby can survive outside the womb

The third trimester is predominantly a period of growth and maturation of organs. The weight of the fetus doubles several

a.

b.

c.

d.

**Figure 54.27** The developing human. (a) 4 weeks, (b) end of 5th week, (c) 3 months, and (d) 4 months.

times, but this increase in bulk is not the only kind of growth that occurs. Most of the major nerve tracts in the brain, as well as many new neurons (nerve cells), are formed during this period. Neurological growth is far from complete when birth takes place, however. If the fetus remained in the uterus until its neurological development was complete, it would grow too large for safe delivery through the pelvis. Instead, the infant

**Figure 54.28** Hormonal secretion by the placenta.

The placenta secretes human chorionic gonadotropin (hCG), which peaks in the second month and then declines. After 5 weeks, it secretes increasing amounts of estrogen and progesterone.

**Inquiry question**

? The high levels of estradiol and progesterone secreted by the placenta prevent ovulation and thus formation of any additional embryos during pregnancy. What would be the expected effect of these high hormone levels in the absence of pregnancy?

is born as soon as the probability of its survival is high, and its brain continues to develop and produce new neurons for months after birth.

## Critical changes in hormones bring on birth

In some mammals, changing hormone levels in the developing fetus initiate the process of birth. The fetuses of these mammals have an extra layer of cells in their adrenal cortex, which secrete corticosteroids that induce the uterus of the mother to manufacture prostaglandins. Prostaglandins trigger powerful contractions of the uterine smooth muscles.

In humans, fetal secretion of cortisol increases during late pregnancy, which appears to stimulate estradiol secretion by the placenta. The mother's uterus releases prostaglandins, possibly as a result of the high levels of estradiol secreted by the placenta. Estradiol also stimulates the uterus to produce more oxytocin receptors, and as a result, the uterus becomes increasingly sensitive to oxytocin.

Prostaglandins begin the uterine contractions, but then sensory feedback from the uterus stimulates the release of oxytocin from the mother's posterior-pituitary gland. Working together, oxytocin and prostaglandins further stimulate uterine contractions, forcing the fetus downward (figure 54.29). This positive feedback mechanism accelerates during labor. Initially, only a few contractions occur each hour, but the rate eventually increases to one contraction every 2 to 3 min. Finally, strong contractions, aided by the mother's voluntary pushing, expel the fetus, which is now a newborn baby, or *neonate*.

After birth, continuing uterine contractions expel the placenta and associated membranes, collectively called the *afterbirth*. The

**Figure 54.29** Position of the fetus just before birth.

A developing fetus causes major changes in a woman's anatomy. The stomach and intestines are pushed far up, and considerable discomfort often results from pressure on the lower back. In a normal vaginal delivery, the fetus exits through the cervix, which must dilate (expand) considerably to permit passage.

umbilical cord is still attached to the baby, and to free the newborn, a doctor or midwife clamps and cuts the cord. Blood clotting and contraction of muscles in the cord prevent excessive bleeding.

## Nursing of young is a distinguishing feature of mammals

Milk production, or *lactation*, occurs in the alveoli of mammary glands when they are stimulated by the anterior-pituitary hormone prolactin. Milk from the alveoli is secreted into a series of alveolar ducts, which are surrounded by smooth muscle and lead to the nipple.

During pregnancy, high levels of progesterone stimulate the development of the mammary alveoli, and high levels of estradiol stimulate the development of the alveolar ducts. However, estradiol blocks the actions of prolactin on the mammary glands, and it inhibits prolactin secretion by promoting the release of prolactin-inhibiting hormone from the hypothalamus. During pregnancy, therefore, the mammary glands are prepared for, but prevented from, lactating. The growth of mammary glands is also stimulated by the placental hormones human chorionic somatomammotropin, a prolactin-like hormone, and human somatotropin, a growth hormone-like hormone.

When the placenta is discharged after birth, the concentrations of estradiol and progesterone in the mother's blood decline rapidly. This decline allows the anterior-pituitary gland to secrete prolactin, which stimulates the mammary alveoli to produce milk. Sensory impulses associated with the baby's suckling trigger the posterior-pituitary gland to release oxytocin. Oxytocin stimulates contraction of the smooth muscle surrounding the alveolar ducts, thus causing milk to be ejected by the breast. This pathway is known as the *milk let-down reflex*, and it is found in other mammals as well. The secretion of oxytocin during lactation also causes some uterine contractions, as it did during labor. These contractions help restore the tone of uterine muscles in mothers who are breast-feeding.

The first milk produced after birth is a yellowish fluid called colostrum, which is both nutritious and rich in maternal antibodies. Milk synthesis begins about 3 days following the birth and is referred to as the milk "coming in." Many mothers nurse for a year or longer. When nursing stops, the accumulation of milk in the breasts signals the brain to stop secreting prolactin, and milk production ceases.

## Postnatal development in humans continues for years

Growth of the infant continues rapidly after birth. Babies typically double their birth weight within 2 months. Because different organs grow at different rates and cease growing at different times, the body proportions of infants are different from those of adults. The head, for example, is disproportionately large in newborns, but after birth it grows more slowly than the rest of the body. Such a pattern of growth, in which different components grow at different rates, is referred to as **allometric growth**.

In most mammals, brain growth is mainly a fetal phenomenon. In chimpanzees, for instance, the brain and the cerebral

portion of the skull grow very little after birth, whereas the bones of the jaw continue to grow. As a result, the head of an adult chimpanzee looks very different from that of a fetal or infant chimpanzee. In human infants, by contrast, the brain and cerebral skull grow at the same rate as the jaw. Therefore, the jaw–skull proportions do not change after birth, and the head of a human adult looks very similar to that of a human fetus or infant.

The fact that the human brain continues to grow significantly for the first few years of postnatal life means that adequate nutrition and a safe environment are particularly crucial during this period for the full development of a person's intellectual potential.

## Learning Outcomes Review 54.6

The critical stages of human development occur in the first trimester of gestation; the subsequent 6 months involve growth and maturation. Growth of the brain is not complete at birth and must be completed postnatally. Hormones in the mother's blood maintain the nutritive uterine environment for the developing fetus; changes in hormone secretion and levels stimulate birth (prostaglandins and oxytocin) and lactation (oxytocin and prolactin).

- **Why are teratogens (agents that cause birth defects) most potent in the first trimester?**

## Chapter Review

### 54.1 Fertilization

**A sperm must penetrate to the plasma membrane of the egg for membrane fusion to occur.**

The sperm's acrosome releases digestive enzymes to penetrate the egg's external layers (see figure 54.1). Fusion with the egg's membrane allows the sperm nucleus to pass into the egg's cytoplasm.

**Membrane fusion activates the egg.**

Fusion of membranes triggers egg activation by the release of calcium (see figure 54.2). Blocks to polyspermy include changes in membrane potential and alterations to the external coat of the egg. Upon egg activation, meiosis is completed (see figures 54.4 and 54.5).

**The fusion of nuclei restores the diploid state.**

Fertilization is complete when the haploid sperm nucleus fuses with the haploid egg nucleus.

### 54.2 Cleavage and the Blastula Stage

**The blastula is a hollow mass of cells.**

Cleavage is a rapid series of cell divisions that produces blastomeres, which form a hollow ball of cells called a blastula.

**Cleavage patterns are highly diverse and distinctive.**

Cleavage patterns are primarily influenced by the amount of yolk (see table 54.2). With little or no yolk, cleavage is holoblastic (involving the whole egg); where more yolk is present, cleavage is meroblastic (involving the blastodisc only). Cleavage in mammals is holoblastic.

**Blastomeres may or may not be committed to developmental paths.**

In many animals, unequal segregation of cytoplasmic determinants commits each blastomere to a different path. Mammals exhibit regulative development in which the fate of early blastomeres is not predetermined.

### 54.3 Gastrulation

**Gastrulation produces the three germ layers.**

During gastrulation the three germ layers differentiate: endoderm, ectoderm, and mesoderm (see table 54.3). Cells move during gastrulation using a variety of cell shape changes.

**Gastrulation patterns also vary according to the amount of yolk.**

The amount of yolk also influences cell movement. In frogs, a layer of cells involutes through the dorsal lip of the blastopore. In birds, surface cells migrate through the primitive streak. Mammalian gastrulation is similar to that of birds.

**Extraembryonic membranes are an adaptation to life on dry land.**

The yolk sac, amnion, chorion, and allantois prevent desiccation and nourish and protect the developing embryo (see figure 54.15).

### 54.4 Organogenesis

**Changes in gene expression lead to cell determination.**

A cell's location in the developing embryo often determines its fate. Differentiation can be established by inheritance of cytoplasmic determinants and by interactions with other cells (induction).

**Development of selected systems in *Drosophila* illustrates organogenesis.**

The development of salivary glands, the dorsal vessel, and tracheae all demonstrate the action of gene expression on development.

**In vertebrates, organogenesis begins with neurulation and somitogenesis (see figures 55.18–55.20).**

Neurulation is the formation of the neural tube from ectoderm near the notochord; somitogenesis is the establishment of mesoderm into units called somites.

**Migratory neural crest cells differentiate into many cell types.**

Neural crest cells migrate widely to become connective tissue, nerve and glial cells, melanocytes, sensory neurons, and other cells.

**Neural crest derivatives are important in vertebrate evolution.**

Many of the unique adaptations of vertebrates have arisen from neural crest cells (see figure 54.21).

### 54.5 Vertebrate Axis Formation

**The Spemann organizer determines dorsal–ventral axis.**

Organizers are a cluster of cells that produce gradients of diffusible signal molecules, conveying positional information to other cells.

**Maternally encoded dorsal determinants activate Wnt signaling.**  
Turning on the Wnt pathway activates organizer specification.

**Signaling molecules from the Spemann organizer inhibit ventral development.**

Morphogens can either activate or inhibit development along a certain path. The Spemann organizer induces formation of the dorsum by inhibiting ventral development (see figure 54.24).

**Evidence indicates that organizers are present in all vertebrates.**

Cells at the anterior edge of the primitive streak, termed Hensen's node, function similarly to the Spemann organizer.

**Induction can be primary or secondary.**

Primary induction occurs between the three germ layers; secondary induction occurs between already determined tissues.

## 54.6 Human Development

**During the first trimester, the zygote undergoes rapid development and differentiation.**

Implantation of the blastocyst occurs at the end of the first week of pregnancy. During the second week, the embryonic chorion and

the mother's endometrial tissues form the placenta, and gastrulation occurs. Organogenesis begins during the fourth week. The eighth week marks the transition from embryo to fetus.

**During the second trimester, the basic body plan develops further.**

**During the third trimester, organs mature to the point at which the baby can survive outside the womb.**

**Critical changes in hormones bring on birth.**

Birth is initiated by secretions of steroids from the fetal adrenal cortex that induce prostaglandins, which cause contractions.

**Nursing of young is a distinguishing feature of mammals.**

Nursing involves a neuroendocrine reflex, causing the release of oxytocin and the milk let-down response.

**Postnatal development in humans continues for years.**

Postnatal development continues with different organs growing at different rates—called allometric growth.

## Review Questions

### UNDERSTAND

- Which of the following events occur immediately after fertilization?
  - Egg activation
  - Polyspermy defense
  - Cytoplasm changes
  - All of these occur after fertilization
- Which of the following plays the greatest role in determining how cytoplasmic division occurs during cleavage?
  - Number of chromosomes
  - Amount of yolk
  - Orientation of the vegetal pole
  - Sex of the zygote
- Gastrulation is a critical event during development. Why?
  - Gastrulation converts a hollow ball of cells into a bilaterally symmetrical structure.
  - Gastrulation causes the formation of a primitive digestive tract.
  - Gastrulation causes the blastula to develop a dorsal–ventral axis.
  - All of these are significant events that occur during gastrulation.
- Gastrulation in a mammal would be most similar to gastrulation in
  - a gecko.
  - a tuna.
  - an eagle.
  - no other species; mammalian gastrulation is unique.

- Somites
  - begin forming at the tail end of the embryo and then move forward in a wavelike fashion.
  - are derived from endoderm.
  - develop into only one type of tissue per somite.
  - may vary in number from one species to the next.
- Of the following processes, which occurs last?
  - Cleavage
  - Neurulation
  - Gastrulation
  - Fertilization

### APPLY

- Your cousin just had twins. She tells you that twinning occurs when two sperm fertilize the same egg. You reply that
  - yes, she is right, that is the most common source of twinning.
  - no, only one sperm survives passage through the uterine cervix, so two sperm are never present at fertilization.
  - no, cortical granules are used to prevent additional sperm penetration.
  - no, twinning occurs when unfertilized eggs divide spontaneously and thus is parthenogenic in nature.
- In the Spemann experiment, when the dorsal lip is transplanted, the recipient embryo then has a second source of molecules that
  - specifies ventral fate.
  - inhibits the molecules that specify ventral fate.
  - specifies dorsal fate.
  - inhibits the molecules that specify dorsal fate.

3. Suppose that a burst of electromagnetic radiation were to strike the blastomeres of only the animal pole of a frog embryo. Which of the following would be most likely to occur?
  - a. A change or mutation relevant to the epidermis or skin
  - b. A switching of the internal organs so that reverse orientation (left/right) occurs along the midline of the body
  - c. The migration of the nervous system to form outside of the body
  - d. Failure of the reproductive system to develop
4. Which of the following would qualify as a secondary induction?
  - a. The formation of the lens of the eye due to induction by the neural ectoderm
  - b. Differentiation during neurulation by the dorsal ectoderm and mesoderm
  - c. Both of these
  - d. Neither of these
5. Your Aunt Ida thinks that babies can stimulate the onset of their own labor. You tell her that
  - a. among mammals the onset of labor has been most closely linked to a change in the phases of the Moon.
  - b. it is the mother's circadian clock that determines the onset of labor.
  - c. body weight determines the onset of labor.
  - d. changes in fetal hormone levels can affect the onset of labor.
6. Drug or alcohol exposure during which of the following stages is most likely to have a profound effect on the neural development of the fetus?
 

a. Preimplantation	c. Second trimester
b. First trimester	d. Third trimester

7. Axis formation in amniotic embryos could be affected by
  - a. mutations in cells in the dorsal lip of the blastopore.
  - b. mutations in cells in the primitive streak.
  - c. both of these.
  - d. neither of these.

### SYNTHESIZE

1. Suppose you discover a new species whose development mechanisms have not been documented before. How could you determine at what stage the cell fate is determined?
2. You look up from your studying to see your dog, Fifi, acting silly again. Using this as a teachable moment, compare and contrast the homeoboxes in your dog and the fruit fly she just ate.
3. Why doesn't a woman menstruate while she is pregnant?
4. Spemann and Mangold were able to demonstrate that some cells act as "organizers" during development. What types of cells did they use? How did they determine that these cells were organizers?

**Introduction**

*The study of behavior is at the center of many disciplines of biology. Observing behavior provides important insights into the workings of the brain and nervous system, the influences of genes and the environment, when and how animals reproduce, and how they adapt to their environment. Behavior is shaped by natural selection and is controlled by internal mechanisms involving genes, hormones, neurotransmitters, and neural circuits. In this chapter, we explore how behavioral biology integrates approaches from several branches of biological science to provide a detailed understanding of the mechanisms that underscore behavior and its evolution.*

## Learning Outcomes

1. Contrast the proximate and ultimate causation of behavior.
2. Explain instinct theory.
3. Describe the physiological factors that might be the basis for innate behaviors.

Observing animal behavior and making inferences about what one sees is at once simple and profound. Behavior is what an animal does. It is the most immediate way an animal responds adaptively to its environment by tracking environmental cues and signals such as odors, sounds, or visual signals associated with food, predators, or mates. Behavior also concerns thinking and cognition, monitoring one's social environment, and making decisions as to whether or not to cooperate or act altruistically. Behavior allows animals to survive and reproduce and is thus critical to the evolutionary process. The work of behavioral biologists has provided important insights into animal behavior, including the very meaning of human behavior.

### Behavior can be analyzed in terms of mechanisms (cause) and evolutionary origin (adaptive nature)

Why does an animal behave in a particular way? Consider hearing a bird sing. We could ask how it vocalizes or determine the time of the year it sings most frequently. We could also ask about the function of the song, that is, ask why it sings. Answers to questions about how birds sing consider the role of internal factors such as hormones and nerve cells and other physiological processes. Such questions concern proximate causation: the mechanisms that are the reason for behavior. To analyze the proximate cause of bird song, we could measure hormone levels or study the development of brain regions and neural circuits associated with singing. For example, a male songbird may sing during the breeding season because of an increased level of the steroid sex hormone testosterone, which binds to receptors in the brain and triggers the production of song. Additionally, neural connections between the brain and the syrinx (the bird's

vocal organ) must develop to allow songs to be produced. These explanations describe the proximate cause of bird song.

Asking about the function of a behavior (once again, bird song) is to ask why it evolved. To answer this question, we would determine how it influenced survival or reproductive success. A male bird sings to defend a territory from other males and to attract a female with which to reproduce. This is the ultimate, or evolutionary, explanation for the male's vocalization. Now we can understand its ultimate causation, or adaptive value. Researchers often study behavior from both perspectives to fully appreciate its mechanisms and ecological function, and thus its role in evolution. Behavior can be analyzed at four levels: (1) physiology (how it is influenced by hormones, nerve cells, and other internal factors); (2) ontogeny (how it develops in an individual), (3) phylogeny (its origin in groups of related species), and (4) adaptive significance (its role in survival and fitness). We'll begin by tracing the history of the study of mechanisms of behavior by focusing on the work of ethologists—biologists who first began to study behavior at the turn of the 20th century.

### Ethology emphasizes the study of instinct and its origins

*Ethology* is the study of the natural history of behavior, with an emphasis on behaviors that form an animal's instincts, or programmed behaviors. Ethologists observed that individuals of a given species behaved in stereotyped ways, showing the same pattern of behavior in response to a particular stimulus. Because their behavior seemed reflexive, they considered it to be instinctive, or *innate*. Behaviors were thought to be programmed by the nervous system, which in turn was designed by genes, and responses would occur without experience. Ethologists based their instinct model on observations and experiments of simple behaviors such as egg retrieval by geese. Geese incubate their eggs in a nest. If an egg falls out of the nest, the goose will roll the egg back into the nest with a side-to-side motion of its neck while the egg is tucked beneath its bill (figure 55.1). Even if the egg is removed during retrieval, the goose will still complete the egg-retrieval sequence, as if driven by a program activated by the initial sight of the egg outside the nest.

This example is one paradigm of instinct theory and illustrates the way ethologists conceptualized the mechanisms of behavior. Egg retrieval behavior is triggered by a *key stimulus* (sometimes called a *sign stimulus*); this is the egg out of the nest. Early ethologists thought the nervous system regulated behavior via the *innate releasing mechanism*, a neural circuit involved

**Figure 55.1** Innate egg-rolling response in geese. The series of movements used by a goose to retrieve an egg is a fixed action pattern. Once it detects the sign stimulus (in this case, an egg outside the nest), the goose goes through the entire set of movements: It will extend its neck toward the egg, get up, and roll the egg back into the nest with a side-to-side motion of its neck while the egg is tucked beneath its bill.

in the perception of the key stimulus and the triggering of a motor program, the *fixed action pattern*, in this case the act of guiding the egg back to the nest. Ethologists generalized that the key stimulus is a cue or signal in the environment that initiates neural events that cause behavior. The innate releasing mechanism involves the sensory apparatus that detects the signal and the neural circuit controlling muscles to generate the fixed action pattern.

### Learning Outcomes Review 55.1

Proximate causation of behavior involves the immediate mechanisms that bring about an action; ultimate causation refers to the adaptive value of a behavior. Ethology is the study of the nature of behavior, emphasizing instinct and the regulation of behavior by internal factors such as genes, nerve cells, and hormones. Ethologists are also interested in the origins of behavior.

- *Why is it important to understand the phylogeny (evolutionary origins) of behavior?*

## 55.2 Nerve Cells, Neurotransmitters, Hormones, and Behavior

### Learning Outcomes

1. *Relate the structure of neural circuits to their function.*
2. *Describe the role of hormones and neurotransmitters in behavior.*

Although early ethologists had little understanding of neurobiology, they hypothesized elements of the nervous system (the innate releasing mechanism) controlled behavior. Today, neuroethologists—researchers who examine the neurobiology of behavior—can describe in detail how information in the environment is processed by sensory cells and how nerve impulses are transmitted to other neurons and muscles to form neural circuits that regulate behaviors important to survival. Behavior reflects the organization of the peripheral and central nervous system, and studying behavior can help us understand how neurons function individually and in combination with other neurons in circuits (see chapters 44 and 45).

Behaviors that must occur rapidly, like those used to capture prey or flee predators, involve neural mechanisms that enable such functions. Some moths have an earlike sensory organ equipped with sensory neurons designed to detect the ultrasonic cries of bats, the first step in evading predation. Specialized cells in the frog's retina detect moving objects like insects and release the tongue in fractions of a second once suitable prey is sighted. Likewise, the jaws of a predatory ant snap shut when prey trigger sensory hairs between the mandibles. Rapid responses to predators or prey often involve large nerve cell axons that can quickly transmit impulses to muscles. In the example of “trap jaw” ants, large axons of the mandibular motor neuron—the fastest neuron yet identified—fire nerve impulses

**Figure 55.2**  
**Functional Magnetic Resonance Imaging (fMRI).** MRIs reveal neural activity in specific regions of the brain. In this case, activity in part of the brain called the nucleus accumbens is associated with viewing images of food.

that close the jaws in only 33 msec. Neural circuits that enable quick responses often are made up of few sensory and motor neurons, and their connecting nerve cells.

Behavioral biologists examine the relationship of hormones to behavior to understand the endocrine mechanisms that are the foundation of reproduction, parental care, aggression, and stress (see chapter 46). In this way, the effects of the steroid sex hormones estrogen and testosterone on behavior have been determined. Testosterone in the male, for example, regulates territorial behavior and courtship, whereas estrogen in the female controls her mating behavior. Glucocorticoid hormones are involved in stress.

Neuroscientists may measure levels of neurotransmitters such as serotonin and dopamine in the nervous system or blood and associate these chemicals with behavior (see chapter 44). These chemicals are released by nerve cells and can affect activity in different brain regions. Serotonin has been shown to influence aggression in an incredibly wide range of animals including lobsters, mice, and humans. Researchers may inject a neurotransmitter or pharmacologically change its level in the brain to examine how it affects behavior.

The techniques of neuroethology include identifying and mapping individual neurons, their dendrites and connections to other neurons, and how their impulses and neurochemicals regulate behavior. Today, techniques such as functional magnetic resonance imaging (fMRI) are generating exciting data on the specialized functions of different regions of the human brain. One striking example concerns how the brain responds to images of food (figure 55.2). In contrast to expectation, the brain's response does not occur in the visual cortex, the region associated with object recognition, but in a circuit in the nucleus accumbens in the forebrain, normally involved in reward and pleasure.

### Learning Outcomes Review 55.2

Instinctive behaviors appear to involve programmed circuits in the nervous system that are likely to be genetically controlled. Research in neuroethology supports the instinct concept of behavior by describing the organization of neural circuits governing behavior. Chemical signals provided by hormones and by neurotransmitters such as serotonin and dopamine cause behaviors to occur.

- *If a male songbird is injected with testosterone two weeks earlier than when these birds normally start to sing in the spring, what would you expect to happen?*

## 55.3 Behavioral Genetics

### Learning Outcomes

1. Discuss the types of studies that have provided evidence to link genes and behavior.
2. Explain how single genes can influence behavior.
3. Describe the role of genes in complex behaviors such as aggression, parental care, and pair bonding.

Instinct theory assumed that genes play a role in behavior, but ethologists did not conclusively demonstrate the role genes can play. The study of genes and behavior has often been highly controversial, as ethologists and social scientists engaged in a seemingly endless debate over whether behavior is determined more by an individual's genes (nature) or by its learning and experience (nurture). One problem with this nature/nurture controversy is that the question is framed as an "either/or" proposition, which fails to consider that both instinct and experience can have significant roles, often interacting in complex ways to shape behavior.

**Behavioral genetics** deals with the contribution that heredity makes to behavior. It is obvious that genes, the units of heredity, are passed from one generation to the next and guide the development of the nervous system and potentially the behavioral responses it regulates. But animals may also develop in a rich social environment and have experiences that guide behavior. The importance of "nature" and "nurture" to behavior can be seen by first reviewing the history of studies in behavioral genetics and next examining the importance of experience and development. We'll then consider their interaction.

### Artificial selection and hybrid studies link genes and behavior

Pioneering research indicated that behavioral differences among individuals result from genetic differences. Research on

a variety of animals demonstrated that hybrids showed behaviors involved in nest building and courtship that were intermediate between those of parents. These early efforts to define the role of genes in behavior demonstrated that behavior can have a heritable component, but fell short of identifying the genes involved. With the development of molecular biology, far greater precision was added to the analysis of the genetics of behavior.

Learning itself can be influenced by genes. In one classic study, rats had to find their way through a maze of blind alleys and only one exit, where a reward of food awaited them. Some rats quickly learned to zip through the maze to the food, making few mistakes, but other rats made more errors in learning the correct path. Researchers bred rats that made few errors with one another to establish a "maze-bright" group, and error-prone rats were interbred, forming a "maze-dull" group. Offspring in each group were then tested for their maze-learning ability. The offspring of maze-bright rats learned to negotiate the maze with fewer errors than their parents, while the offspring of maze-dull parents performed more poorly. Repeating this artificial selection method for several generations led to two behaviorally distinct types of rat with very different maze-learning abilities (figure 55.3). This type of study suggests the ways in which natural selection could shape behavior over time, making genes for certain abilities more prevalent.

### Inquiry question

What would happen if, after the seventh generation, rats were randomly assigned mates regardless of their ability to learn the maze?

### Some behaviors appear to be controlled by a single gene

Artificial selection and hybrid studies only suggested a role for genes in behavior. Subsequent research took advantage of advances in molecular biology and identified the genes involved. Fruit flies, *Drosophila*, have traditionally provided a useful model system in which the effect of single genes have been identified.

**Figure 55.3** The genetics of learning.

Rats that made the fewest errors in the parental population were interbred to select for rats that had improved maze-learning ability (green), and rats that made the most errors were interbred to select for rats that were error prone (red).

### Inquiry question

What would happen if, after the seventh generation, rats were randomly assigned mates regardless of their ability to learn the maze?

Single genes have also been shown to influence behavior in animals ranging from mice to humans.

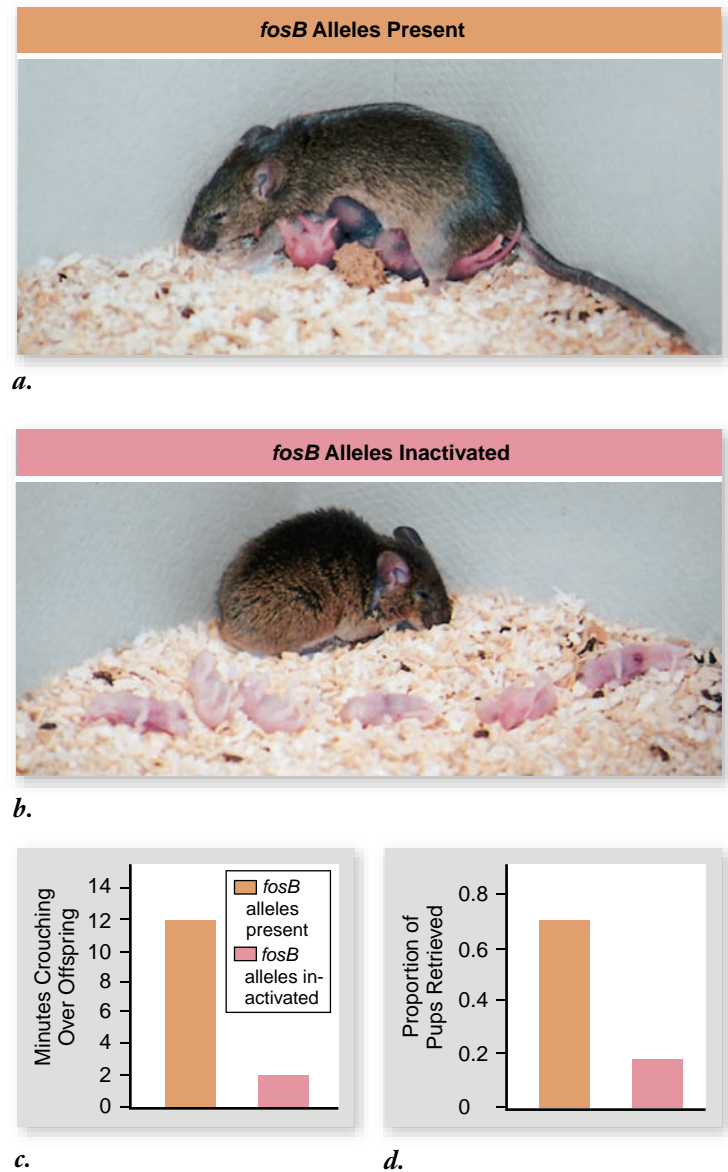

In fruit flies, individuals that possess alternative alleles for a particular gene differ greatly in their feeding behavior as larvae: Larvae with one allele move around a great deal as they eat, whereas individuals with the alternative allele move hardly at all. A wide variety of experimentally induced mutations at other genes affect courtship behavior in males and females. For example, *fru* is a regulatory gene whose transcription products govern the design of the courtship center of the fruit fly brain. This gene turns on other genes involved in the neural circuitry of courtship.

Single genes in mice are associated with spatial memory and parenting. For example, some mice with a particular mutation have trouble remembering recently learned information about where objects are located. This is apparently because they lack the ability to produce the enzyme  $\alpha$ -calcium-calmodulin-dependent kinase II, which plays an important role in the functioning of the hippocampus, a part of the brain important for spatial learning.

It is particularly interesting that genes are involved in behavior as complex as maternal care: The presence or absence of *fosB* determines whether female mice nurture their young in particular ways. Females with both *fosB* alleles disabled initially investigate their newborn babies, but then ignore them, in stark contrast to the caring and protective maternal behavior displayed by normal females (figure 55.4). The cause of this inattentiveness appears to result from a chain reaction. When mothers of new babies initially inspect them, information from their auditory, olfactory, and tactile senses is transmitted to the hypothalamus, where *fosB* alleles are activated. The *fosB* alleles produce a protein, which in turn activates other enzymes and genes that affect the neural circuitry of the hypothalamus. These modifications in the brain cause the female to behave maternally. If mothers lack the *fosB* alleles, this process is stopped midway. No protein is activated, the brain's neural circuitry is not rewired, and maternal behavior does not result. The “maternal instincts” of mice can thus be defined genetically!

Another fascinating example of the genetic basis of behavior concerns prairie and montane voles, two closely related species of North American rodents that differ profoundly in their social behavior. Male and female prairie voles form monogamous pair bonds and share parental care, whereas montane voles are promiscuous (meaning they mate with multiple partners and go their separate ways). The act of mating leads to the release of the neuropeptides vasopressin and oxytocin, and the response to these peptides differs dramatically in each species. Injection of either peptide into prairie voles leads to pair bonding even without mating. Conversely, injecting a chemical that blocks the action of these neuropeptides causes prairie voles not to form pair bonds after mating. By contrast, montane voles are unaffected by either of these manipulations.

These different responses have been traced to interspecific differences in brain structure (figure 55.5). The prairie vole has many receptors for these peptides in a particular part of the brain, the nucleus accumbens, which seems to be involved in the expression of pair-bonding behavior. By contrast, few such receptors occur in the same brain region in the montane vole. In laboratory experiments with prairie voles, blocking these receptors tends to prevent pair-bonding, whereas stimulating them

**Figure 55.4 Genetically caused defect in maternal care.**

- a.** In mice, normal mothers take very good care of their offspring, retrieving them if they move away and crouching over them.
- b.** Mothers with the mutant *fosB* allele perform neither of these behaviors, leaving their pups exposed.
- c.** Amount of time female mice were observed crouching in a nursing posture over offspring.
- d.** Proportion of pups retrieved when they were experimentally moved.

### Inquiry question

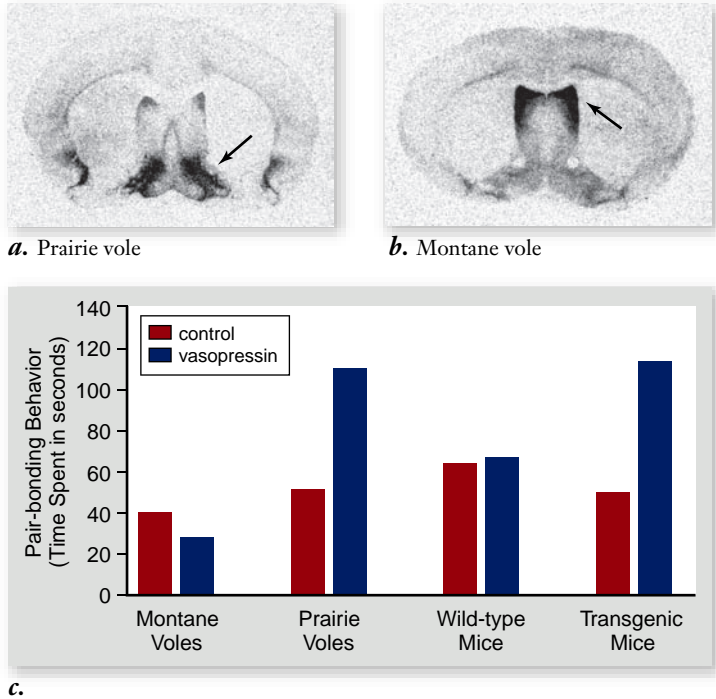

**?** Why does the lack of *fosB* alleles lead to maternal inattentiveness?

leads to pair-bonding behavior. The gene that codes for the peptide receptors has also been identified, and a difference in the DNA structure between the species has been discovered. To test the hypothesis that this genetic difference was responsible for the differences in behavior, scientists created transgenic mice with the prairie vole version of the gene, and sure enough, when injected with vasopressin, the transgenic mice exhibited pair-bonding behavior very similar to that of prairie voles, whereas normal mice showed no response (see figure 55.5). The

## 55.4 Learning

### Learning Outcomes

1. Describe the mechanisms of learning.
2. Define learning preparedness.
3. Explain how instinct influences learning preparedness.

**Figure 55.5 Genetic basis of differences in pair-bonding behavior in two rodent species.** *a.* and *b.* The prairie (*Microtus ochrogaster*) and montane (*M. montanus*) voles differ in the distribution of one type of vasopressin receptor in the brain. *c.* Transgenic mice created with the prairie-voles version of the receptor genes respond to injections of vasopressin by exhibiting heightened levels of pair-bonding behavior in 5-min trials compared with their response to a control injection. By contrast, normal wild-type mice (control) show no increase in such behaviors.

vasopressin receptor gene varies in structure among primate species that vary in degree of pair bonding. In human males, the gene has recently been found to be associated with the strength of marital bonds and satisfaction in marriage.

The production of monoamine oxidases (MAOs), enzymes that degrade neurotransmitters such as serotonin and dopamine, are controlled by single genes. Transgenic mice that lack MAOA (monoamine oxidase-A) are highly aggressive. In humans, a single point mutation results in the lack of the ability to produce MAOA, resulting in antisocial behavior and violence. MAO abnormalities are also associated with mood disorders in humans.

### Learning Outcomes Review 55.3

A relationship between genes and behavior has been demonstrated in many ways, including artificial selection experiments and studies on the effects of single genes. Genes can regulate behavior by producing molecular factors that influence the function of the nervous system; mutations altering these factors have been found to affect behavior.

- **What would you infer about the role of genes in pair-bonding in prairie voles if you learned that males sometimes seek to copulate with females other than their own mate?**

Instincts can guide an animal's actions, but behavior can also develop from previous experiences, a process termed learning. Traditionally, psychologists studied the mechanisms of learning using laboratory rodents, but today both proximate and ultimate causes of learning are understood by integrating learning into an ecological and evolutionary framework.

### Learning mechanisms include habituation and association

Habituation is a simple form of learning defined as a decrease in response to a repeated stimulus that has no positive or negative consequences. Initially, the stimulus may evoke a strong response, but the response declines with repeated exposure. For example, young birds see many types of objects moving overhead. At first, they may respond by crouching and remaining still. But frequently seen objects, such as falling leaves or members of their own species flying overhead, have no positive or negative consequence to the nestlings. Over time, the young birds may habituate to such stimuli and stop responding. Thus, habituation can be thought of as learning not to respond to a stimulus.

One ecological context in which habituation has adaptive value is prey defense. Birds that feed on insects search for suitable prey in a visually complex environment. Insects that have camouflaged bodies appear to be twigs or leaves, which are commonly encountered as birds search for prey. Because birds see these objects very frequently, they habituate to their appearance. Insects that look like twigs or leaves are therefore protected because they do not trigger an attack, and they survive to reproduce.

More complex forms of learning concern changes in behavior through an association between two stimuli or between a stimulus and a response. In associative learning, for example, (figure 55.6) a behavior is modified, or conditioned, through the association. The two major types of associative learning—classical conditioning and operant conditioning—differ in the way the associations are established. In **classical conditioning**, the paired presentation of two different kinds of stimuli causes the animal to form an association between the stimuli. Classical conditioning is also called **Pavlovian conditioning**, after the Russian psychologist Ivan Pavlov, who first described it.

Pavlov presented meat powder, an unconditioned stimulus, to a dog and noted that the dog responded by salivating, an unconditioned response. If an unrelated stimulus, such as the ringing of a bell, was repeatedly presented at the same time as the meat powder, the dog would soon salivate in response to the sound of the bell alone. The dog had learned to associate the unrelated sound stimulus with the meat powder stimulus. Its

**Figure 55.6 Learning what is edible.** Associative learning is involved in predator–prey interactions. *a.* A naive toad is offered a bumblebee as food. *b.* The toad is stung, and *(c)* subsequently avoids feeding on bumblebees or any other insects having black-and-yellow coloration. The toad has associated the appearance of the insect with pain and modifies its behavior.

response to the sound stimulus was, therefore, conditioned, and the sound of the bell is referred to as a conditioned stimulus.

In **operant conditioning**, an animal learns to associate its behavioral response with a reward or punishment. American psychologist B. F. Skinner studied operant conditioning in rats by placing them in an apparatus that came to be called a “Skinner box.” As the rat explored the box, it would occasionally press a lever by accident, causing a pellet of food to appear. Soon it learned to associate pressing the lever (the behavioral response) with obtaining food (the reward). This sort of trial-and-error learning is of major importance to most vertebrates. Learning provides flexibility that allows behavior to be fine-tuned to an environment.

### Instinct governs learning preparedness

Psychologists once believed that any two stimuli could be linked through learning and that animals could be conditioned to perform any learnable behavior. This view has changed. Today, researchers believe that instinct guides learning by determining what type of information can be learned. Animals may have innate predispositions toward forming certain associations. For example, if a rat is offered a food pellet at the same time it is exposed to X-rays (which later produce nausea), the rat remembers the taste of the food pellet but not its size, and in the future will avoid food with that taste, but will readily eat pellets of the same size if they have a different taste. Similarly, pigeons can learn to associate food with colors, but not with sounds. In contrast, they can associate danger with sounds, but not with colors.

These examples of learning preparedness demonstrate that what an animal can learn is biologically influenced—that is, learning is possible only within the boundaries set by evolution. Innate programs for learning have evolved because they lead to adaptive responses. In nature, food that is toxic to a rat is likely to have a particular taste; thus, it is adaptive to be able to associate a taste with a feeling of sickness that may develop hours later. The seed a pigeon eats may have a distinctive color that the pigeon can see, but it makes no sound the pigeon can hear.

An animal’s ecology is key to understanding its learning capabilities. Some species of birds, such as Clark’s nutcracker, feed on seeds. When seeds are abundant, these birds store them in buried caches so they will have food during the winter. Seed caches (up to 2000!) may be buried and then recovered as long as nine months later. One would expect these birds to have an

extraordinary spatial memory, and this is indeed what has been found (figure 55.7). Clark’s nutcracker, and other seed-hoarding birds, have an unusually large hippocampus, the center for memory storage in the brain. This illustrates how feeding ecology (caching seeds to survive the winter) affects the evolution of brain anatomy (an enlarged hippocampus).

#### Learning Outcomes Review 55.4

Habituation is a diminishing response to a repeated stimulus that is neither positive nor negative. Association may occur as either classical conditioning or operant conditioning. Animals can change their behavior through learning in a variety of ways. Although learning mechanisms may be similar across species, animals also differ in their learning abilities according to their ecology.

- *In some rodents, males travel far while females remain close to the nest. Do males or females have greater spatial memory? What experiment could you conduct to test your hypothesis?*

**Figure 55.7 The Clark’s nutcracker has an extraordinary memory.** A Clark’s nutcracker (*Nucifraga columbiana*) can remember the locations of up to 2000 seed caches months after hiding them. After conducting experiments, scientists have concluded that the birds use features of the landscape and other surrounding objects as spatial references to memorize the locations of the caches.

## 55.5 The Development of Behavior

### Learning Outcomes

1. Discuss the role of the critical period in imprinting.
2. Explain how social contact can influence growth and development.
3. Explain how the study of song learning in white-crowned sparrows illustrates the interaction of instinct and learning.

Behavioral biologists recognize that behavior has both genetic and learned components. Thus far in this chapter, we have discussed the influence of genes and learning separately. But as you will see, these factors interact during development to shape behavior.

### Parent–offspring interactions influence how behavior develops

As an animal matures, it may form social attachments to other individuals or develop preferences that will influence behavior later in life. This process of behavioral development is called **imprinting**. The success of imprinting is highest during a critical period (roughly 13 to 16 hours after hatching in geese). During this time, information required for normal development must be acquired. In **filial imprinting**, social attachments form between parents and offspring. For example, young birds like ducks and geese begin to follow their mother within a few hours after hatching, and their following response results in a social bond between mother and young. The young birds' initial experience, through imprinting, can determine how social behavior develops later in life. The ethologist Konrad Lorenz showed that geese will follow the first object they see after hatching and direct their social behavior toward that object, even if it is not their mother! Lorenz raised geese from eggs, and when he offered himself as a model for imprinting, the goslings treated him as if he were their parent, following him dutifully (figure 55.8).

Interactions between parents and offspring are key to the normal development of social behavior. The psychologist Harry Harlow gave orphaned rhesus monkey infants the opportunity to form social attachments with two surrogate “mothers,” one made of soft cloth covering a wire frame and the other made only of wire (figure 55.9). The infants chose to spend time with the cloth mother, even if only the wire mother provided food, indicating that texture and tactile contact, rather than provision of food, may be among the key qualities in a mother that promote infant social attachment. If infant monkeys are deprived of normal social contact, their development is abnormal. Greater degrees of deprivation lead to greater abnormalities in social behavior during childhood and adulthood. Studies of orphaned human infants similarly suggest that a constant “mother figure” is required for normal growth and psychological development.

**Figure 55.8** An unlikely parent.

The eager goslings follow Konrad Lorenz as if he were their mother. He is the first object they saw when they hatched, and they have used him as a model for imprinting. Lorenz won the 1973 Nobel Prize in medicine or physiology for this work.

Recent research has revealed a biological need for the stimulation that occurs during parent–offspring interactions early in life. Female rats lick their pups after birth, and this stimulation inhibits the release of a brain peptide that can block normal growth. Pups that receive normal tactile stimulation also have more brain receptors for glucocorticoid hormones, thus a greater tolerance for stress, and longer-lived brain cells. Premature human infants who are massaged gain weight rapidly. These studies indicate that the need for normal social interaction is based in the brain, and that touch and

**Figure 55.9** Choice trial on infant monkeys. Given a choice between a wire frame that provided food and a similar frame covered with cloth and given a monkey-like head, orphaned rhesus monkeys (*Macaca mulatta*) chose the monkeylike figure over the food.

other aspects of contact between parents and offspring are important for physical as well as behavioral development.

## Instinct and learning may interact as behavior develops

We began this chapter by considering the proximate and ultimate causation of bird song. Let's continue with the classic studies by Peter Marler on song learning in white-crowned sparrows to examine how innate programs and experience each contribute to the development of behavior.

Mature male white-crowned sparrows sing a species-specific courtship song during the mating season. Through a series of elegant experiments, Peter Marler asked if the song was the result of an instinctive program, learning, or both. Marler reared male birds in soundproof incubators equipped with speakers and microphones to control what a bird heard as it matured, and then recorded the song it produced as an adult. Males that heard no song at all during development sang a poorly developed song as adults (figure 55.10), indicating that instinct alone did not guide song production. In a second study, males were played only the song of a different species, the song sparrow. These males sang a poorly structured song as well. This experiment showed that males would not imitate any song they heard to learn to sing. But birds that heard the song of their own species, or that heard the songs of both the white-crowned sparrow and the song sparrow, sang a fully developed, white-crowned sparrow song as adults.

These results suggest males have a selective **genetic template**, or innate program, that guides them to learn the appropriate song. During a critical period in development, the template will accept the white-crowned sparrow song as a model. Thus, song acquisition depends on learning, but only the song of the correct species can be learned; the genetic template limits what can be learned.

a.

b.

**Figure 55.10 Song development in birds.** a. The sonograms of songs produced by male white-crowned sparrows (*Zonotrichia leucophrys*) that had been exposed to their own species' song during development are different from (b) those of male sparrows that heard no song during rearing. This difference indicates that the genetic program itself is insufficient to produce a normal song.

**Figure 55.11 Brood parasite.** Cuckoos lay their eggs in the nests of other species of birds. Because the young cuckoos (large bird to the right) are raised by a different species (such as this meadow pipit, smaller bird to the left), they have no opportunity to learn the cuckoo song; the cuckoo song they later sing is innate.

But learning plays a prominent role as well. If a young male becomes deaf after it hears its species' song during the critical period, it will sing a poorly developed song as an adult. Therefore, the bird must hear the correct song at the right time, and then “practice” listening to himself sing, matching what he hears to the model his genetic template has accepted.

Although this explanation of song development stood unchallenged for many years, white-crowned sparrow males can learn another species' song under certain conditions. If a live male strawberry finch is placed in a cage next to a young male sparrow, the young sparrow will learn to sing the strawberry finch's song. This finding indicates that social stimuli—in this case, being able to see, hear, and interact with another bird—is more effective than a tape-recorded song in altering the innate template that guides song development.

The males of some bird species may have no opportunity to hear the song of their own species. In such cases, it appears that the males instinctively “know” their own species' song. For example, cuckoos are **brood parasites**; females lay their eggs in the nest of another species of bird, and the young that hatch are reared by the foster parents (figure 55.11). When the cuckoos become adults, they sing the song of their own species rather than that of their foster parents. Because male brood parasites would most likely hear the song of their host species during development, it is adaptive for them to ignore such “incorrect” stimuli. They hear no adult males of their own species singing, so no correct song models are available. In these species, natural selection has produced a completely genetically guided song. Other birds can also sing a correct species-typical song, even if reared in isolation.

### Inquiry question

Imagine there is only one bird species on an island. Do you think instinct, learning, or both will guide song development?

## Studies on twins reveal a role for both genes and environment in human behavior

The interaction of genes and the environment can be seen in humans by comparing the behavior of identical twins (which are genetically the same), raised in the same environment or separated at birth and raised apart in different environments. Data on human twins raised together or raised apart allows researchers to determine whether similarities in behavior result from their genetic similarity or from shared environmental experiences. Twins studies indicate many similarities in a wide range of personality traits even though twins were raised in very different environments. Other studies show that antisocial behavior in humans, for which genetic factors such as MAOA deficiencies are known in individuals in the study sample, results from a combination of genes and experience during childhood. These similarities indicate that genetics plays a role in behavior even in humans, although the relative importance of genetics versus environment is still debated.

### Learning Outcomes Review 55.5

During the critical period, offspring must engage in certain social interactions for normal behavioral development. Parent–offspring contact stimulates the release of physiological factors, such as hormones and brain receptors, crucial to growth and brain development. In white-crowned sparrows, young males must hear their species' song to sing it correctly, indicating that both instinct and learning affect song development.

- *Some researchers have tried to link IQ and genes in humans. Why would this research be seen as controversial?*

## 55.6 Animal Cognition

### Learning Outcome

1. *Explain why behavioral biologists today are more open to considering that animals can think.*

For many decades, students of animal behavior flatly rejected the notion that nonhuman animals can think. Now serious attention is given to animal awareness. The central question of whether animals show **cognitive behavior**—that is, they process information and respond in a manner that suggests thinking—is widely supported (figure 55.12).

In a series of classic experiments conducted in the 1920s, a chimpanzee was left in a room with bananas hanging from the ceiling out of reach. Also in the room were several boxes lying on the floor. After some unsuccessful attempts to jump up and grab the bananas, the chimp stacked the boxes beneath the suspended bananas, and climbed up to claim its prize (figure 55.13). Field researchers have observed that Japanese macaques learned

**Figure 55.12 Animal thinking?** *a.* This chimpanzee is stripping the leaves from a twig, which it will then use to probe a termite nest. This behavior strongly suggests that the chimpanzee is consciously planning ahead, with full knowledge of what it intends to do. *b.* This sea otter is using a rock as an “anvil,” against which it bashes a clam to break it open. A sea otter will often keep a favorite rock for a long time, as though it has a clear idea of its future use of the rock. Behaviors such as these suggest that animals have cognitive abilities.

to wash sand off potatoes and to float grain to separate it from sand. Chimpanzees pull leaves off a tree branch and then stick the branch into the entrance of a termite nest to “fish” for food. Chimps also crack open nuts using pieces of wood in a “hammer and anvil” technique. Even more remarkable is that parents appear to teach nut cracking to their offspring!

Recent studies have found that chimpanzees and other primates show amazing behaviors that provide strong evidence of cognition. Chimpanzees will eat the leaves of medicinal plants when infected with certain parasites. Chimps also cooperate with other chimps in ways that suggest an understanding of past success. Cognitive ability is not limited to primates: Ravens and other corvid birds also show extraordinary insight and problem-solving ability (figure 55.14).

**Figure 55.13 Problem solving by a chimpanzee.** Unable to get the bananas by jumping, the chimpanzee devises a solution.

**Figure 55.14 Problem solving by a raven.**

Confronted with a problem it has never previously faced, the raven figures out how to get the meat at the end of the string by repeatedly pulling up a bit of string and stepping on it.

**Learning Outcome Review 55.6**

Research has provided compelling evidence that some nonhuman animals are able to solve problems and use reasoning, cognitive abilities once thought uniquely human.

- How could you determine whether a chimpanzee had the ability to count objects?

**55.7 Orientation and Migratory Behavior**

**Learning Outcomes**

1. Define migration.
2. Distinguish between orientation and navigation.
3. Describe different systems for navigation.

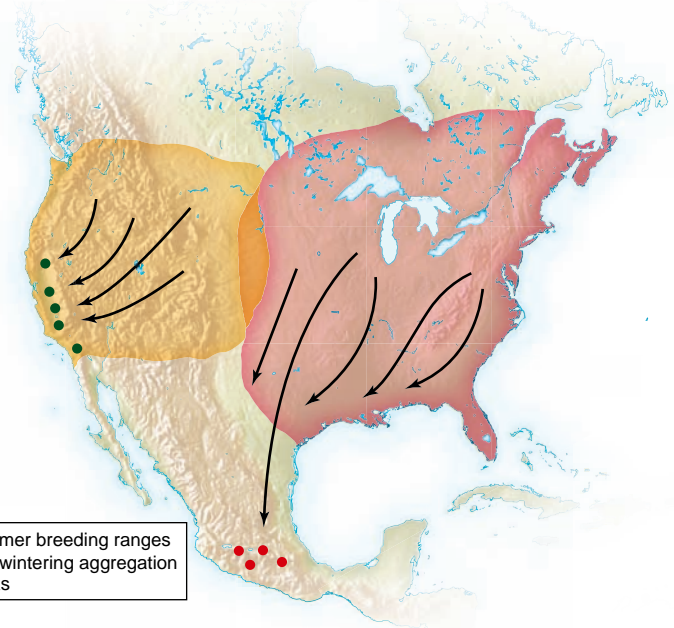

Monarch butterflies and many birds travel thousands of miles over continents to overwintering sites in the tropics. Many animals travel away from a nest and then return. To do so, they track cues in the environment, often showing exceptional skill at orientation. Animals with a homing instinct, such as pigeons, recognize complex features of the environment to return to their home. Despite decades of study, our understanding of animal orientation is far from complete.

**Migration often involves populations moving large distances**

Long-range, two-way movements are known as migrations. Each fall, ducks, geese, and many other birds migrate south along flyways from Canada across the United States, heading as far as South America, and then returning each spring.

Monarch butterflies also migrate each fall from central and eastern North America to their overwintering sites in several small, geographically isolated areas of coniferous forest in the mountains of central Mexico (figure 55.15). Each August, the butterflies begin a flight southward and at the end of winter, the monarchs begin the return flight to their summer breeding ranges. Two to five generations may be produced as the butterflies fly north: butterflies that migrate in the autumn to the precise locations in Mexico have never been there before!

Recent geographic range expansions by some migrating birds have revealed how migratory patterns change. When colonies of bobolinks became established in the western United States, far from their normal range in the Midwest and East, they did not migrate directly to their winter range in South America. Instead, they migrated east to their ancestral range, and then south along the original flyway (figure 55.16). Rather than changing the original migration pattern, they simply added a new segment. Scientists continue to study the western bobolinks to learn whether, in time, a more efficient migration path will evolve or

a.

b.

c.

**Figure 55.15 Migration of monarch butterflies (*Danaus plexippus*).** a. Monarchs from western North America overwinter in areas of mild climate along the Pacific coast. Those from eastern North America migrate over 3000 kilometers to Mexico.

b. Monarch butterflies arrive at the remote forests of the overwintering grounds in Mexico, where they (c) form aggregations on the tree trunks.

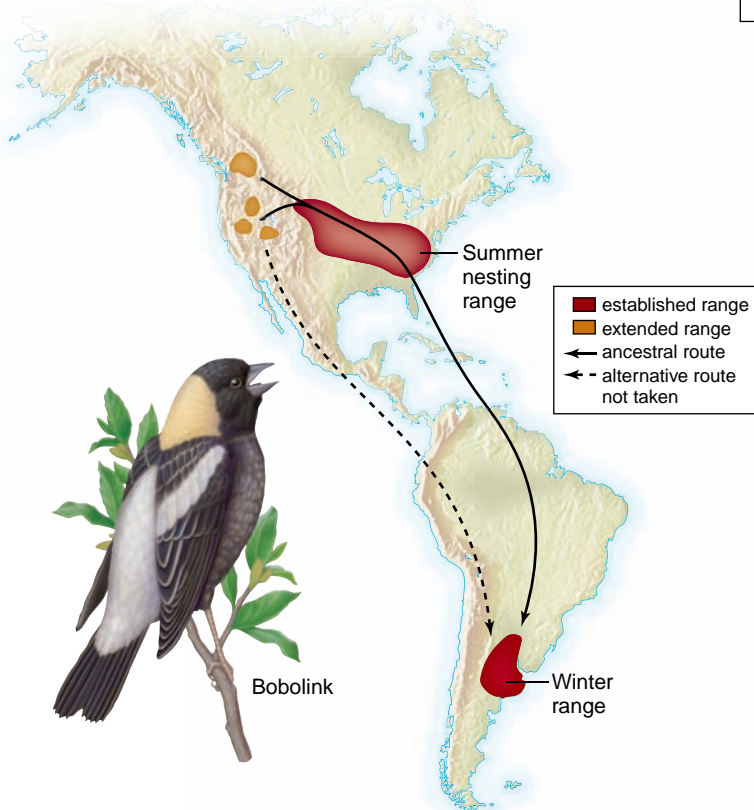

whether the birds will always follow their ancestral course. The behavior of butterflies and birds accentuate the mysteries of the mechanism employed during migration.

## Migrating animals must be capable of orientation and navigation

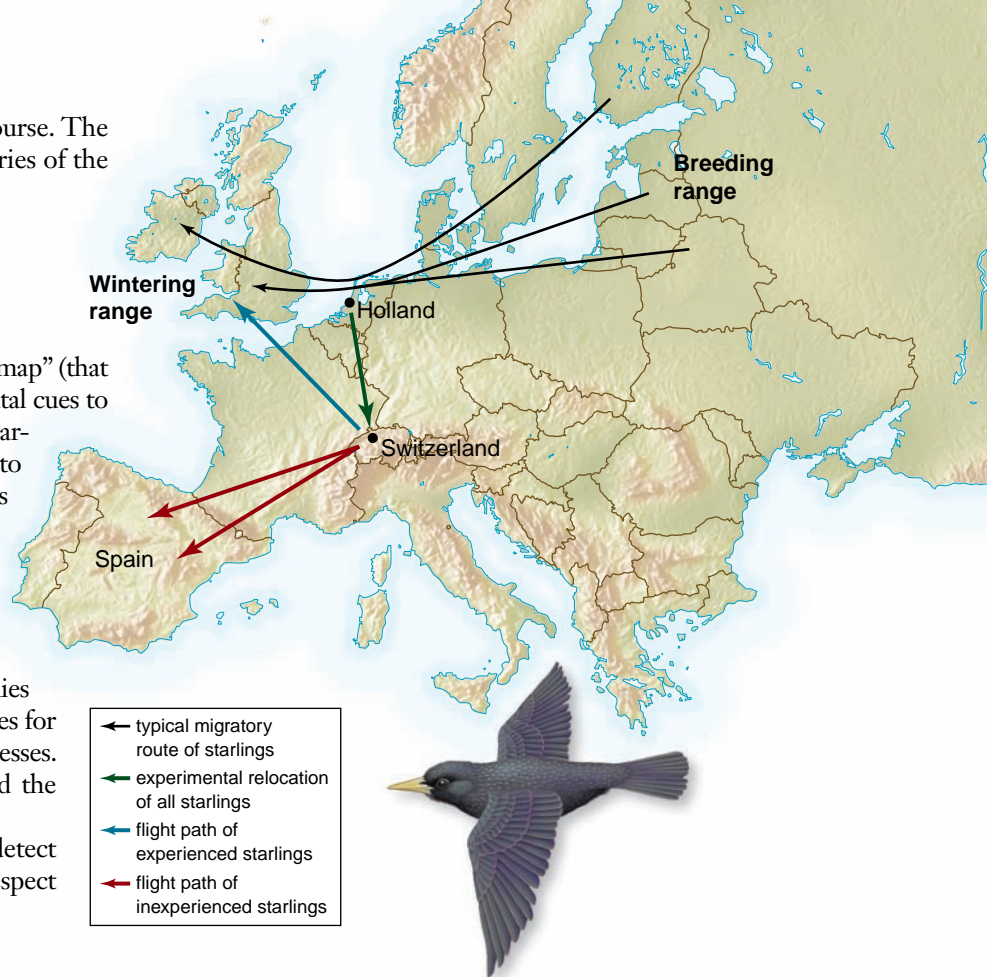

To get from one place to another, animals must have a “map” (that is, know where to go) and a “compass” (use environmental cues to guide their journey). Orientation requires following a bearing such as a source of light, but navigation is the ability to set or adjust a bearing, and then follow it. The former is analogous to using a compass, while the latter is like using a compass in conjunction with a map. The nature of the “map” animals use is unclear.

Birds and other animals navigate by looking at the sun during the day and the stars at night. The indigo bunting is a short-distance nocturnal migrant bird. It flies during the day using the Sun as a guide, and compensates for the movement of the Sun in the sky as the day progresses. These birds use the positions of constellations around the North Star in the night sky as a compass.

Many migrating birds also have the ability to detect Earth’s magnetic field and to orient themselves with respect

**Figure 55.16 Birds on the move.** The summer range of bobolinks (*Dolichonyx oryzivorus*) recently extended to the far western United States from their established range in the Midwest. When birds in these newly established populations migrate to South America in the winter, they do not fly directly to the winter range; instead, they first fly to the Midwest and then use the ancestral flyway, going much farther than if they flew directly to their winter range.

**Figure 55.17 Migratory behavior of starlings (*Sturnus vulgaris*).** The navigational abilities of inexperienced birds differ from those of adults that have made the migratory journey before. Starlings were captured in Holland, halfway along their full migratory route from Baltic breeding grounds to wintering grounds in the British Isles; these birds were transported to Switzerland and released. Experienced older birds compensated for the displacement and flew toward the normal wintering grounds (blue arrow). Inexperienced young birds kept flying in the same direction, on a course that took them toward Spain (red arrows). These observations imply that inexperienced birds fly by orientation, but experienced birds learn true navigation.

to it when cues from the Sun or stars are not available. In an indoor cage, they will attempt to move in the correct geographic direction, even though there are no visible external cues. However, the placement of a magnet near the cage can alter the direction in which the birds attempt to move. Researchers have found magnetite, a magnetized iron ore, in the eyes and upper beaks of some birds, but how these sensory organs function is not known.

The first migration of a bird appears to be innately guided by both celestial cues (the birds fly mainly at night) and Earth’s magnetic field. When the two cues are experimentally manipulated to give conflicting directions, the information provided by the stars seems to override the magnetic information. Recent studies, however, indicate that celestial cues indicate the general direction for migration, whereas magnetic cues indicate the specific migratory path (perhaps a turn the bird must make mid-route). Experiments on starlings indicate that inexperienced birds migrate by orientation, but older birds that have migrated previously use true navigation (figure 55.17).

## 55.8 Animal Communication

We know relatively little about how other migrating animals navigate. For instance, green sea turtles migrate from Brazil halfway across the Atlantic Ocean to Ascension Island, where the females lay their eggs. How do they find this tiny island in the middle of the ocean, which they haven't seen for perhaps 30 years? How do the young that hatch on the island know how to find their way to Brazil? Newly hatched turtles use wave action as a cue to head to sea. Some sea turtles use the Earth's magnetic field to maintain position in the North Atlantic, but turtle migration is still largely a mystery.

### Learning Outcomes Review 55.7

Migration is the long-distance movement of a population, often in a cyclic way. Orientation refers to following a bearing or a direction; navigation involves setting a bearing or direction based on some sort of map or memory. Many species use celestial navigation; they may also be able to detect magnetic fields when those cues are absent. The precision of animal migration remains a mystery in many species.

- **Animals as diverse as butterflies and birds migrate over long distances. Would you expect them to use different navigation systems? Why or why not?**

### Learning Outcomes

1. **Explain the nature of signals used in mate attraction.**
2. **Explain the role of courtship signals in reproductive isolation.**
3. **Describe how honeybees communicate information about the location of new food sources.**

Communication is central to species recognition and reproductive isolation, and to the interactions that are essential to social behavior. Much research in behavior analyzes the nature of communication signals, determining how they are produced and received, and identifies their ecological roles and evolutionary origins. Communication involves several signal modalities, including visual, acoustic, chemical, electric, and vibrational signals.

**Figure 55.18 A stimulus–response chain.** Stickleback courtship involves a sequence of behaviors leading to the fertilization of eggs.

## Successful reproduction depends on appropriate signals and responses

During courtship, animals produce signals to communicate with potential mates and with other members of their own sex. A stimulus–response chain sometimes occurs, in which the behavior of the male in turn releases a behavior in the female, resulting in mating (figure 55.18). These signals are usually highly species-specific. Many studies on communication involve designing experiments to determine which key stimuli associated with an animal’s visual appearance, sounds, or odors convey information about the nature of the signals produced by the sender. One classical study analyzed territorial defense and courtship communication in stickleback fish (figure 55.19).

### Finding a mate: Communicating information about species identity

Courtship signals often restrict communication to members of the same species and in doing so serve a key function in reproductive isolation (see chapter 22). The flashes of fireflies (which are actually beetles) are species-specific signals: females recognize conspecific males by their flash pattern (figure 55.20), and

#### SCIENTIFIC THINKING

**Hypothesis:** *The red underside of male stickleback is the key stimulus that releases an aggressive response by a territory-holding male.*

**Prediction:** *Models with red coloration will trigger an attack by a resident male.*

**Test:** *Construct plastic models, some of which accurately resemble a stickleback male, but lack the red underside. Construct other models that vary in their fishlike appearance, but have red-colored undersides. Expose a territorial male to the models one at a time, and record the number of attacks.*

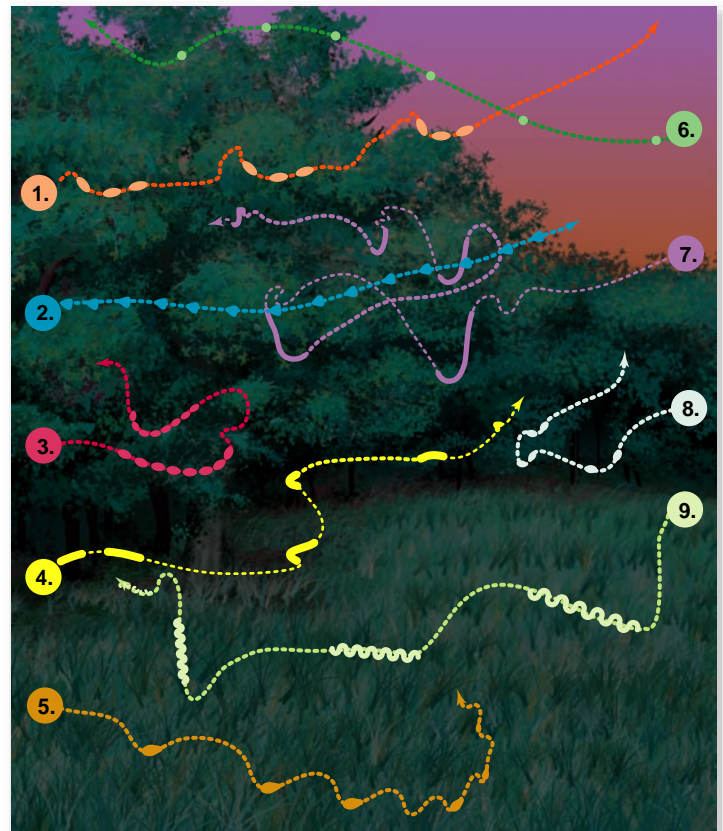

**Result:** *Realistic models lacking red elicit no response. Odd-shape models trigger an attack if they have red undersides, even if they poorly resemble fish.*

**Conclusion:** *The red underside of a male stickleback is the key stimulus that triggers aggressive behavior.*

**Further Experiments:** *How would you determine if the color of a male stickleback was a releaser of aggressive behavior? How would you know if sound was important? Could you determine if stimuli have additive effects? How? Why do you think the color red is important in territorial defense? Might it also be a courtship signal? What information might the color red encode for a female looking for a mate? (see also figure 55.18)*

**Figure 55.19** Key stimulus in stickleback fish.

**Figure 55.20** Firefly fireworks. The bioluminescent displays of these lampyrid beetles are species-specific and serve as behavioral mechanisms of reproductive isolation. Each number represents the flash pattern of a male of a different species.

males recognize conspecific females by their flash response. This series of reciprocal responses provides a continuous “check” on the species identity of potential mates.

Pheromones, chemical messengers used for communication between individuals of the same species, serve as sex attractants in many animals. Female silk moths (*Bombyx mori*) produce a sex pheromone called bombykol in a gland associated with the reproductive system. The male’s antennae contain numerous highly sensitive sensory receptors, and neurophysiological studies show they specifically detect bombykol. In some moth species, males can detect extremely low concentrations of sex pheromone and locate females from as far as 7 km away!

Many insects, amphibians, and birds produce species-specific acoustic signals to attract mates. Bullfrog males call by inflating and discharging air from their vocal sacs, located beneath the lower jaw. Females can distinguish a conspecific male’s call from those of other frogs that may be in the same habitat and calling at the same time. As mentioned earlier, male birds sing to advertise their presence and to attract females. In many species, variations in the males’ songs identify individual males in a population. In these species, the song is individually specific as well as species-specific. Vibrations, like sound signals, are a form of mechanical communication used by insects, amphibians, and other animals.

Courtship behaviors play a major role in sexual selection, which we discuss later in this chapter.

**Figure 55.21 Alarm calling by a prairie dog (*Cynomys ludovicianus*).** When a prairie dog sees a predator, it stands on its hind legs and gives an alarm call, which causes other prairie dogs to rapidly return to their burrows.

### Communication enables information exchange among group members

Many insects, fish, birds, and mammals live in social groups in which information is communicated between group members. For example, some individuals in mammalian societies serve as sentinels, vigilantly on the lookout for danger. When a predator appears, they give an alarm call, and group members respond by seeking shelter (figure 55.21). Social insects such as ants and honeybees produce alarm pheromones that trigger attack behavior. Ants also deposit trail pheromones between the nest and a food source to lead other colony members to food. Honeybees have an extremely complex dance language that directs hivemates to nectar sources.

#### The dance language of the honeybee

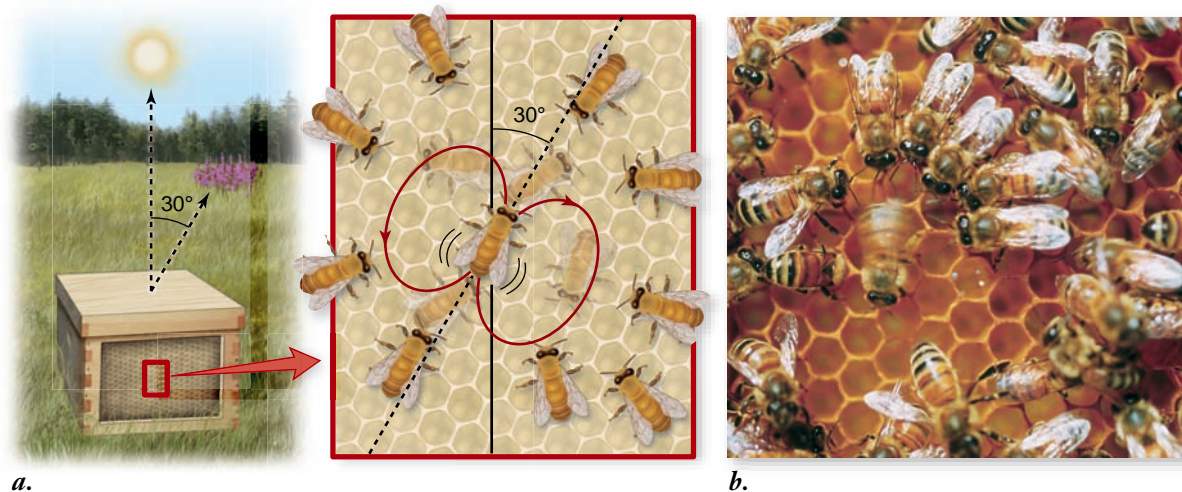

The European honeybee lives in colonies of tens of thousands of individuals whose behaviors are integrated into a complex,

cooperative society. Worker bees may forage miles from the hive, collecting nectar and pollen from a variety of plants and switching between plant species depending on their energetic rewards. Food sources used by bees tend to occur in patches, and each patch offers much more food than a single bee can transport to the hive. A colony is able to exploit the resources of a patch because of the behavior of scout bees, which locate patches and communicate their location to hivemates through a dance language. Over many years, Nobel laureate Karl von Frisch (who shared the 1973 prize with Tinbergen and Lorenz), together with generations of students and colleagues, was able to unravel the details of dance language communication.

When a scout bee returns after finding a distant food source, she performs a remarkable behavior pattern called a waggle dance on a vertical comb in the darkness of the hive. The path of the bee during the dance resembles a figure-eight. On the straight part of the path (indicated with dashes in figure 55.22), the bee vibrates (“waggles”) her abdomen while producing bursts of sound. The bee may stop periodically to give her hivemates a sample of the nectar carried in her crop. As she dances, she is followed closely by other bees, which soon appear at the new food source to assist in collecting food.

Von Frisch and his colleagues performed experiments to show that hivemates use information in the waggle dance to locate new food sources. The scout bee indicates the direction of the food source by representing the angle between the food source, the hive, and the Sun as the deviation from vertical of the straight run of the dance performed on the hive comb. Thus if the bee danced with the straight run pointing directly up, then the food source would be in the direction of the Sun. If the food is at a  $30^\circ$  angle to the right of the Sun’s position, then the straight run would be oriented upward at a  $30^\circ$  angle to the right of vertical (figure 55.22a). The distance to the food source is indicated by the duration of the straight run. One ingenious experiment designed to show that the bees actually use the information in the dance tricked bees that were unaware of the location of food into misinterpreting the directions given by the scout bee’s dance. Computer-controlled robot bees have also been used to give hivemates incorrect information, again demonstrating that bees use the directions coded in the dance!

**Figure 55.22 The waggle dance of honeybees (*Apis mellifera*).** *a.* The angle between the food source, the nest, and the Sun is represented by a dancing bee as the angle between the straight part of the dance and vertical. The food is  $30^\circ$  to the right of the Sun, and the straight part of the bee’s dance on the hive is  $30^\circ$  to the right of vertical. *b.* A scout bee dances on a comb in the hive.

**Figure 55.23 Primate semantics.** Vervet monkeys (*Cercopithecus aethiops*) give different alarm calls (*a*) when troop members sight an eagle, leopard, or snake. *b.* Each distinctive call elicits a different and adaptive escape behavior.

### Language in nonhuman primates and humans

Evolutionary biologists have sought the origins of human language in the communication systems of monkeys and apes. Some nonhuman primates have a “vocabulary” that allows individuals to signal the identity of specific predators. Different vocalizations of African vervet monkeys, for example, indicate eagles, leopards, or snakes, among other threats (figure 55.23).

The complexity of human language would at first appear to defy biological explanation, but closer examination suggests that the differences are in fact superficial—all languages share many basic similarities. All of the roughly 3000 languages draw from the same set of 40 consonant and vowel sounds (English uses two dozen of them), and humans of all cultures can acquire and learn them. Researchers believe these similarities reflect the way our brains handle abstract information. The discovery of *FoxP2*, the so-called “language gene,” supports the idea that human language has a hereditary basis.

#### Learning Outcomes Review 55.8

Animal communication involves production and reception of signals, in the form of sounds, chemicals, or movements, that primarily have an ecological function. Courtship signals are highly species-specific and serve as a mechanism of reproductive isolation. Animals living in social groups, such as honeybees, may use complex systems of communication to exchange information about food and predators.

- *Two species of moth use the same sex pheromone to locate mates. Explain how these species could nevertheless be reproductively isolated.*

## 55.9 Behavioral Ecology

### Learning Outcomes

1. Describe behavioral ecology.
2. Discuss the economic analysis of behaviors.

Niko Tinbergen pioneered the study of the adaptive function of behavior. Stated simply, this is how behavior allows an animal to stay alive and keep its offspring alive. For example, Tinbergen observed that after gull nestlings hatch, the parents remove the eggshells from the nest. To understand why (ultimate causation), he painted chicken eggs to resemble gull eggs (figure 55.24), which had camouflage coloration to allow them

**Figure 55.24 The adaptive value of egg coloration.**

Niko Tinbergen, a winner of the 1973 Nobel Prize in physiology or medicine, painted chicken eggs to resemble the mottled brown camouflage of gull eggs. The eggs were used to test the hypothesis that camouflaged eggs are more difficult for predators to find and thus increase the young’s chances of survival.

to be inconspicuous against the natural background. He distributed them throughout the area in which the gulls were nesting, placing broken eggshells with their prominent white interiors next to some of the eggs. As a control, he left other camouflaged eggs alone without eggshells. He then noted which eggs were found more easily by crows. Because the crows could use the white interior of a broken eggshell as a cue, they ate more of the camouflaged eggs that were near eggshells. Tinbergen concluded that eggshell removal behavior is adaptive: it reduces predation and thus increases the offspring's chances of survival.

Tinbergen is credited with being one of the founders of **behavioral ecology**, the study of how natural selection shapes behavior. This branch of ecology examines the adaptive significance of behavior, or how behavior may increase survival and reproduction. Current research in behavioral ecology focuses on how behavior contributes to an animal's reproductive success, or fitness. As we saw in section 55.3, differences in behavior among individuals often result from genetic differences. Therefore, natural selection operating on behavior has the potential to produce evolutionary change.

Consequently, the field of behavioral ecology is concerned with two questions. First, is behavior adaptive? Although it is tempting to assume that behavior must in some way represent an adaptive response to the environment, this need not be the case. As you saw in chapter 20, traits can appear for many reasons other than natural selection, such as genetic drift, gene flow, or the correlated consequences of selection on other traits. Moreover, traits may be present in a population because they evolved as adaptations in the past, but are no longer useful. These possibilities hold true for behavioral traits as much as for any other kind of trait.

If behavior is adaptive, the next question is: How is it adaptive? Although the ultimate criterion is reproductive success, behavioral ecologists are interested in how behavior can lead to greater reproductive success. Does a behavior enhance energy intake, thus increasing the number of offspring produced? Does it increase mating success? Does it decrease the chance of predation? The job of a behavioral ecologist is to determine the effect of a behavioral trait—for example, foraging efficiency—on each of these activities and then to discover whether increases translate into increased fitness. Benefits and costs of behaviors, estimated in terms of energy or offspring, are often used to analyze the adaptive nature of behavior.

## Foraging behavior can directly influence energy intake and individual fitness

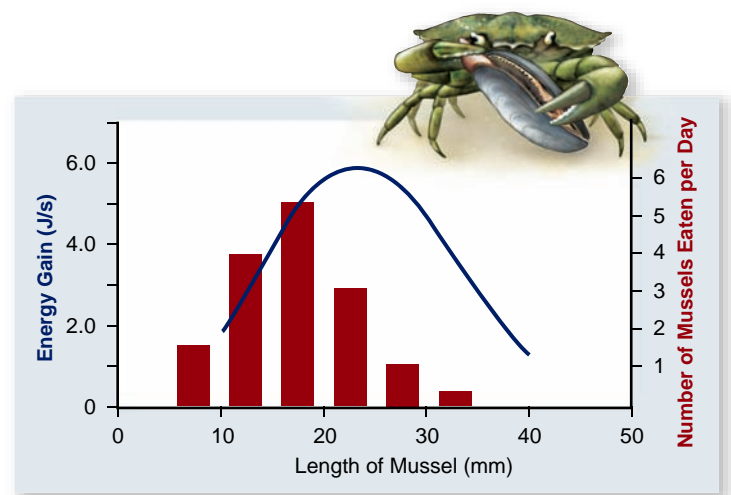

A useful way to understand the approach of behavioral ecology is by focusing on foraging behavior. For many animals, food comes in a variety of sizes. Larger foods may contain more energy but may be harder to capture and less abundant. In addition, animals may forage for some types of food that are farther away than other types. For these animals foraging involves a trade-off between a food's energy content and the cost of obtaining it. The net energy (estimated in calories or joules) gained by feeding on prey of each size is simply the energy content of the prey minus the energy costs of pursuing and handling it. According to

**optimal foraging theory**, natural selection favors individuals whose foraging behavior is as energetically efficient as possible. In other words, animals tend to feed on prey that maximize their net energy intake per unit of foraging time.

A number of studies have demonstrated that foragers do prefer prey that maximize energy return. Shore crabs, for example, tend to feed primarily on intermediate-sized mussels, which provide the greatest energy return; larger mussels yield more energy, but also take considerably more energy to crack open (figure 55.25).

This optimal foraging approach assumes natural selection will favor behavior that maximizes energy acquisition if the increased energy reserves lead to increases in reproductive success. In both Colombian ground squirrels and captive zebra finches, a direct relationship exists between net energy intake and the number of offspring raised; similarly, the reproductive success of orb-weaving spiders is related to how much food they can capture.

Animals have other needs besides energy, however, and sometimes these needs conflict. One obvious need is the avoidance of predators: Often, the behavior that maximizes energy intake is not the one that minimizes predation risk. In this case, the behavior that maximizes fitness often may reflect a trade-off between obtaining the most energy at the least risk of being eaten. Not surprisingly, many studies have shown that a wide variety of animal species alter their foraging behavior—becoming less active, spending more time watching for predators, or staying nearer to cover—when predators are present. Compromises, in this case a trade-off between vigilance and feeding, may thus be made during foraging.

**Figure 55.25 Optimal diet.** The shore crab selects a diet of energetically profitable prey. The curve describes the net energy gain (equal to energy gained minus energy expended) derived from feeding on different sizes of mussels. The bar graph shows the numbers of mussels of each size in the diet. Shore crabs tend to feed on those mussels that provide the most energy.

### Inquiry question

? What factors might be responsible for the slight difference in peak prey length relative to the length optimal for maximum energy gain?

Optimal foraging theory assumes that energy-maximizing behavior has evolved by natural selection. Therefore, it must have a genetic basis. For example, female zebra finches particularly successful in maximizing net energy intake tend to have similarly successful offspring. In this study, young birds were removed from their mothers before they were able to leave the nest, so this similarity indicates that foraging behavior probably has a genetic component. Studies on other animals show that age, experience, and learning are also important to the development of efficient foraging.

### Territorial behavior evolves if the benefits of holding a territory exceed the costs

Animals often move over a large area, or home range, during their course of activity. In many species, the home range of several individuals overlaps in time or in space, but each individual defends a portion of its home range and uses it and its resources exclusively. This behavior is called **territoriality** (figure 55.26).

The defining characteristic of territorial behavior is defense against intrusion and resource use by other individuals. Territories are defended by displays advertising that territories are occupied, and by overt aggression. A bird sings from its perch within a territory to prevent take-over by a neighboring bird. If a potential usurper is not deterred by the song, the territory owner may attack and try to drive it away. But territorial defense has its costs. Singing is energetically expensive, and attacks can lead to injury. Using a signal (a song or visual display) to advertise occupancy can reveal a bird's position to a predator.

Why does an animal bear the costs of territorial defense? Energetic benefits of territoriality may take the form of increased food intake due to exclusive use of resources, access to mates, or access to refuges from predators. Studies of nectar-feeding birds such as hummingbirds and sunbirds provide an example (figure 55.27). A bird benefits from having the exclusive use of a patch of flowers because it can efficiently harvest the nectar the flowers produce. To maintain exclusive use, the bird

**Figure 55.26 Competition for space.** Territory size in birds is adjusted according to the number of competitors. When six pairs of great tits (*Parus major*) were removed from their territories (indicated by R in the left figure), their territories were taken over by other birds in the area and by four new pairs (indicated by N in the right figure). Numbers correspond to the birds present before and after.

**Figure 55.27 The benefit of territoriality.** Sunbirds (on the left), found in Africa and ecologically similar to New World hummingbirds (on the right), protect their food source by attacking other sunbirds that approach flowers in their territory.

must actively defend the patch. The benefits of exclusive use outweigh the costs of defense only under certain conditions.

Sunbirds, for example, expend 3000 calories per hour chasing intruders from a territory. Whether the benefit of defending a territory will exceed this cost depends on the amount of nectar in the flowers and how efficiently the bird can collect it. When flowers are very scarce or nectar levels are very low, a nectar-feeding bird may not gain enough energy to balance the energy used in defense. Under these conditions, it is not energetically advantageous to be territorial. Similarly, when flowers are very abundant, a bird can efficiently meet its daily energy requirements without behaving territorially and adding the costs of defense. Again, from an energetic standpoint, defending abundant resources isn't worth the cost, either. Territoriality therefore only occurs at intermediate levels of flower availability and nectar production, when the benefits of defense outweigh the costs.

In many species, access to females is a more important determinant of territory size for males than is food availability. In some lizards, for example, males maintain enormous territories during the breeding season. These territories, which encompass the territories of several females, are much larger than would be required to supply enough food, and they are defended vigorously. In the nonbreeding season, by contrast, male territory size decreases dramatically, as does aggressive territorial behavior.

### Learning Outcomes Review 55.9

Behavioral ecology is the study of the adaptive significance of behavior—that is, how it affects survival and reproductive success. An economic approach estimates the energy benefits and costs of a behavior and assumes that animals gain more from a behavior than they expend, obtaining a fitness advantage. Foraging behavior and defense of a territory can be analyzed in this way. Apart from energy gains, considerations such as avoiding predators are also important to fitness.

- **The Hawaiian honeycreeper, a nectar-feeding bird, fails to defend flowers that are either infrequently encountered or very abundant. Why?**

## 55.10 Reproductive Strategies and Sexual Selection

### Learning Outcomes

1. Explain parental investment and the prediction it makes about mate choice.
2. Describe how sexual selection leads to the evolution of secondary sexual characteristics.
3. Explain why some species are generally monogamous and other are polygynous.

During the breeding season, animals make several important life-history “decisions” concerning their choice of mates, how many mates to have, and how much time and energy to devote to rearing offspring. These decisions are all aspects of an animal’s **reproductive strategy**, a set of behaviors that presumably have evolved to maximize reproductive success. Energetic costs of reproduction appear to have been critically important to behavioral differences between females and males. Ecological factors such as the way food resources, nest sites, and members of the opposite sex are spatially distributed in the environment, as well as disease, are important in the evolution of reproductive decisions.

### The sexes often have different reproductive strategies

Males and females have the common goal of improving the quantity and quality of offspring they produce, but usually

differ in the way they attempt to maximize fitness. Such a difference in reproductive behavior is clearly seen in mate choice. Darwin was the first to observe that females often do not mate with the first male they encounter, but instead seem to evaluate a male’s quality and then decide whether to mate. Peahens prefer to mate with peacocks that have more eyespots on their elaborate tail feathers (figure 55.28*b, c*). Similarly, female frogs prefer to mate with males having more acoustically complex, and thus attractive, calls. This behavior, called mate choice, is well known in many invertebrate and vertebrate species.

Males are selective in choosing a mate much less frequently than females. Why should this be? Many of the differences in reproductive strategies between the sexes can be understood by comparing the parental investment made by males and females. **Parental investment** refers to the energy and time each sex makes (“invests”) in producing and rearing offspring; it is, in effect, an estimate of the energy expended by males and females in each reproductive event.

Numerous studies have shown that females generally have a higher parental investment. One reason is that eggs are much larger than sperm—195,000 times larger in humans! Eggs contain proteins and lipids in the yolk and other nutrients for the developing embryo, but sperm are little more than mobile DNA packages. In some groups of animals (mammals, for example), females are responsible for gestation and lactation, costly reproductive functions only they can carry out.

The consequence of such inequalities in reproductive investment is that the sexes face very different selective pressures. Because any single reproductive event is relatively inexpensive for males, they can best increase their fitness by mating with as many females as possible. This is because

a.

b.

c.

### Figure 55.28 Products of sexual selection.

Attracting mates with long feathers is common in bird species such as (a) the African paradise whydah (*Vidua paradisaea*), and (b) the peacock (*Pavo cristatus*) which show pronounced sexual dimorphism. c. Female peahens prefer to mate with males having greater numbers of eyespots in their tail feathers.

### Inquiry question

Why do females prefer males with more spots?

male fitness is likely limited by the amount of sperm they can produce. By contrast, each reproductive event for females is much more costly, and the number of eggs that can be produced often limits reproductive success. For this reason, a female should be choosy, trying to pick the male that can provide the greatest benefit to her offspring and thus improve her fitness.

These conclusions hold only when female reproductive investment is much greater than that of males. In species with biparental care, males may contribute equally to the cost of raising young; in this case, the degree of mate choice should be more equal between the sexes.

In some cases, male investment exceeds that of females. For example, male Mormon crickets transfer a protein-containing packet (a spermatophore) to females during mating. Almost 30% of a male's body weight is made up by the spermatophore, which provides nutrition for the female and helps her develop her eggs. As we might expect from our model of mate choice, in this case it is the females that compete with one another for access to males, which are the choosy sex. Indeed, males are quite selective, favoring heavier females. Heavier females have more eggs; thus, males that choose larger females leave more offspring (figure 55.29).

Males care for eggs and developing young in many species, including seahorses and a number of birds and insects. As with Mormon crickets, these males are often choosy, and females compete for mates.

**Figure 55.29** The advantage of male mate choice. Male Mormon crickets (*Anabrus simplex*) choose heavier females as mates, and larger females have more eggs. Thus, male mate selection increases fitness.

### Inquiry question

? Is there a benefit to females for mating with large males?

## Sexual selection occurs through mate competition and mate choice

As discussed in chapter 20, the reproductive success of an individual is determined by how long the individual lives, how frequently it mates, and how many offspring it produces per mating. The second of these factors, competition for mates, is termed **sexual selection**. Some people consider sexual selection to be distinctive from natural selection, but others see it as a subset of natural selection, just one of the many factors affecting an organism's fitness.

Sexual selection involves both **intrasexual selection**, or competitive interactions between members of one sex (“the power to conquer other males in battle,” as Darwin put it), and **intersexual selection**, which is another name for mate choice (“the power to charm”). Sexual selection leads to the evolution of structures used in combat with other males, such as a deer's antlers and a ram's horns, as well as ornaments used to “persuade” members of the opposite sex to mate, such as long tail feathers and bright plumage (see figure 55.28*a, b*). These traits are called **secondary sexual characteristics**.

Selection strongly favors any trait that confers greater ability in mate competition. Larger body size is a great advantage if dominance is important, as it is in territorial species. Males may thus be considerably larger than females. Such differences between the sexes are referred to as sexual dimorphism. In other species, structures used for fighting, such as horns, antlers, and large canine teeth, have evolved to be larger in males because of the advantage they give in intrasexual competition.

Sometimes **sperm competition** occurs between the sperm of different males if females mate with multiple males. This type of competition, which occurs after mating, has selected for sperm-transfer organs designed to remove the sperm of a prior mating, large testes to produce more sperm per mating, and sperm that hook themselves together to swim more rapidly. These traits enhance the likelihood of fertilizing an egg.

### Intrasexual selection

In many species, individuals of one sex—usually males—compete with one another for the opportunity to mate. Competition can occur for a territory in which females feed or bear young. Males may also directly compete for the females themselves. A few successful males may engage in an inordinate number of matings, while most males do not mate at all. For example, elephant seal males control territories on breeding beaches and a few dominant males do most of the breeding (figure 55.30). On one beach, for example, eight males impregnated 348 females, while the remaining males mated rarely, if at all.

### Intersexual selection

Intersexual selection concerns the active choice of a mate. Mate choice has both direct and indirect benefits.

**Direct benefits of mate choice.** In some cases, the benefits of mate choice are obvious. If males help raise offspring, females benefit by choosing the male that can provide the best

**Figure 55.30** Female defense polygyny in northern elephant seals (*Mirounga angustirostris*). Male elephant seals fight with one another for possession of territories. Only the largest males can hold territories, which contain many females.

care—the better the parent, the more offspring she is likely to rear. In other species, males provide no care, but maintain territories that provide food, nesting sites, and predator refuges. In red deer, males that hold territories with the highest quality grasses mate with the most females. In this case, there is a direct benefit of a female mating with such a territory owner: She feeds with little disturbance on quality food.

**Indirect benefits of mate choice.** In many species, however, males provide no direct benefits of any kind to females. In such cases, it is not intuitively obvious what females have to gain by being “choosy.” Moreover, what could be the possible benefit of choosing a male with an extremely long tail or a complex song?

A number of theories have been proposed to explain the evolution of such preferences. One idea is that females choose the male that is the healthiest or oldest. Large males, for example, have probably been successful at living long, acquiring a lot of food, and resisting parasites and disease. In other species, features other than size may indicate a male’s condition. In guppies and some birds, the brightness of a male’s color reflects the quality of his diet and overall health. Females may gain two benefits from mating with the healthiest males. First, healthy males are less likely to be carrying diseases, which might be transmitted to the female during mating. Second, to the extent that the males’ success in living long and prospering is the re-

sult of his genetic makeup, the female will be ensuring that her offspring receive good genes from their father.

Several experimental studies in fish and moths have examined whether female mate choice leads to greater reproductive success. In these experiments, females in one group were allowed to choose males, whereas males were randomly mated to a different group of females. Offspring of females that chose their mates were more vigorous and survived better than offspring from females given no choice, which suggests that females preferred males with a better genetic makeup.

A variant of this theory goes one step further. In some cases, females prefer mates with traits that appear to be detrimental to survival (see figure 55.28c). The long tail of the peacock is a hindrance in flying and makes males more vulnerable to predators. Why should females prefer males with such traits? The **handicap hypothesis** states that only genetically superior mates can survive with such a handicap. By choosing a male with the largest handicap, the female is ensuring that her offspring will receive these quality genes. Of course, the male offspring will also inherit the genes for the handicap. For this reason, evolutionary biologists are still debating the merit of this hypothesis.

#### Alternative theories about the evolution of mate choice.

Some courtship displays appear to have evolved from a predisposition in the female’s sensory system to respond to certain stimuli. For example, females may be better able to detect particular colors or sounds at a certain frequency, and thus be attracted to such signals. **Sensory exploitation** involves the evolution in males of a signal that “exploits” these preexisting biases. For example, if females are particularly adept at detecting red objects, then red coloration may evolve in males as part of a courtship display.

To understand the evolution of courtship calls, consider the vocalizations of the Túngara frog (figure 55.31). Unlike related species, males include a short burst of sound, termed a “chuck,” at the end of their calls. Recent research suggests that not only are females of this species particularly attracted to calls of this sort, but so are females of related species, even though males of these species do not produce “chucks.”

A great variety of other hypotheses have been proposed to explain the evolution of mating preferences. Many of these hypotheses may be correct in some circumstances, but none seems capable of explaining all of the variation in mating behavior in the animal world. This is an area of vibrant research, with new discoveries appearing regularly.

**Figure 55.31** Male Túngara frog (*Physalaemus pustulosus*) calling. Female frogs of several species in the genus *Physalaemus* prefer males that include a “chuck” in their call. However, only males of the Túngara frog (a) produce such calls (b); males of other species do not (c).

a.

b.

c.

## Mating systems reflect the ability of parents to care for offspring and are influenced by ecology

The number of individuals with which an animal mates during the breeding season varies among species. Mating systems include monogamy (one male mates with one female), polygyny (one male mates with more than one female; see figure 55.30), and polyandry (one female mates with more than one male). Only monogamous mating includes a pair bond (like prairie voles). Like mate choice, mating systems have evolved to allow females and males to maximize fitness.

The option of having more than one mate may be constrained by the need for offspring care. If females and males are able to care for young, then the presence of both parents may be necessary for young to be reared successfully. Monogamy may thus be favored. Generally this is the case for birds, in which over 90% of all species appear to be monogamous. A male may either remain with his mate and provide care for the offspring or desert that mate to search for others; both strategies may increase his fitness. The strategy that natural selection will favor depends on the requirement for male assistance in feeding or defending the offspring. In some species (like humans!), offspring are **altricial**—they require prolonged and extensive care. In these species, the need for care by two parents reduces the tendency for the male to desert his mate and seek other matings. In species in which the young are **precocial** (requiring little parental care), males may be more likely to be polygynous because the need for their parenting is lower. In mammals, only females lactate, freeing males from feeding offspring. It follows that most mammals are polygynous.

Mating systems are strongly influenced by ecology. A male may defend a territory that holds nest sites or food sources sufficient for more than one female. If territories vary in quality or quantity of resources, a female's fitness is maximized if she mates with a male holding a high-quality territory, even if he has mated. Although a male may already have a mate, it is still more advantageous for the female to breed with a mated male holding a high-quality territory than with an unmated male holding a low-quality territory. This favors the evolution of polygyny.

Polyandry is relatively rare, but the evolution of multiple mating by females is becoming better understood. It is best known in birds like spotted sandpipers and jacanas living in highly productive environments such as marshes and wetlands. Here, females take advantage of the increased resources available to rear offspring by laying clutches of eggs with more than one male. Males provide all incubation and parenting, and females mate and leave eggs with two or more males.

Females may also mate with several males to genetically diversify their offspring, which in turn increases disease resistance. This appears to be the case in honey bees, for example, in which a queen may mate with many males.

### Extra-pair copulations

The “monogamy” of many bird species has been re-evaluated as DNA fingerprinting (see chapter 15) has become commonly used to determine paternity and precisely quantify the reproductive success of individual males (figure 55.32a). In red-winged blackbirds (figure 55.32b), researchers established that

a.

b.

**Figure 55.32 The study of paternity.** a. A DNA fingerprinting gel from the dunnock (*Prunella modularis*). The bands represent fragments of DNA of different lengths. The four nestlings (D–G) were in the nest of the female. By comparing the bands present in the two males and the female, we can determine which male fathered which offspring. The triangles point to the bands that are diagnostic for one male and not the other. In this case, the  $\beta$ -male fathered three (D, E, F, but not G) of the four offspring. b. Results of a DNA fingerprinting study in red-winged blackbirds (*Agelaius phoeniceus*). Fractions indicate the proportion of offspring fathered by the male in whose territory the nest occurred. Arrows indicate how many offspring were fathered by particular males outside of each territory. Nests on some territories were not sampled.

## 55.11 Altruism

### Learning Outcomes

1. Explain altruism and its benefits.
2. Explain kin selection and inclusive fitness.
3. Discuss how haplodiploidy influences kin selection in eusocial insects.

half of all nests contained at least one hatchling fertilized by a male other than the territory owner; overall, 20% of the offspring were the result of such **extra-pair copulations (EPCs)**.

What is the evolutionary advantage of EPCs? For males, the answer is obvious: increased reproductive success. Females, on the other hand, may mate with genetically superior individuals even if already paired with a male, thus enhancing the genes passed on to their offspring. The female doesn't produce more offspring, but offspring of better genetic quality. In some birds and other animals, EPCs may help females increase the amount of care they get from males to raise their offspring. This is exactly what happens in a common English bird, the dunnock. Females mate not only with the territory owner, but also with subordinate males that hang around the edge of the territory. If these subordinates mate a sufficient number of times with a female, they will help raise her young, presumably because they may have fathered some of these young.

### Alternative mating strategies

Natural selection has led to the evolution of many ways of increasing reproductive success. For example, in many species of fish, there are two genetic classes of males. One group is large and defends territories to obtain matings. The other group is small and adopts a completely different strategy. These males do not maintain territories, but loiter at the edge of the territories of large males. Just at the end of a male's courtship, when the female is laying her eggs and the territorial male is depositing sperm, the smaller male darts in and releases its own sperm into the water, thus fertilizing some of the eggs. If this strategy is successful, natural selection will favor the evolution of these two different male reproductive strategies.

Similar patterns are seen in other organisms. In some dung beetles, territorial males have large horns that they use to guard the chambers in which females reside, whereas genetically small males don't have horns. Instead, the smaller males dig side tunnels and attempt to intercept the female inside her chamber. In Isopods, there are three genetic size classes. The medium-sized males pass for females and enter a large male's territory in this way; the smallest class are so tiny, they are able to sneak in completely undetected.

This is just a glimpse of the rich diversity in mating systems and mating tactics that have evolved. The bottom line is: If there is a way of increasing reproductive success, natural selection will favor its evolution.

### Learning Outcomes Review 55.10

The sex that invests more in reproduction (parental investment) tends to exhibit mate choice. Females or males can be selective, depending on the energy and time they devote to parental care. Sexual selection governs evolution of secondary sex characteristics in that mates are chosen on the basis of phenotype and competitive success. Reproductive success influences whether males and females mate monogamously or with multiple partners.

- Pipefish males incubate young in a brood pouch. Which sex would you expect to show mate choice? Why?

Understanding the evolution of altruism has been a particular challenge to evolutionary biologists, including Darwin himself. Why should an individual decrease his or her own fitness to help another? How could genes for altruism be favored by natural selection, given that the frequency of such genes should decrease in populations through time?

In fact, there can be great benefits to being an altruist, even if the altruism leads an individual to forego reproduction or even sacrifice its own life. Let's examine how this can work.

**Altruism** is behavior that benefits another individual at a cost to the actor. Humans sacrificing themselves in times of war or placing themselves in jeopardy to help their children are examples, but altruism also has been described in an extraordinary variety of organisms. In many bird species, for example, there are "helpers at the nest"—birds other than parents who assist in raising their young. In both mammals and birds, individuals that spy a predator may give an alarm call, alerting other members of their group to allow them to escape, even though such an act might call the predator's attention to the caller. And in social insects like ants, workers are sterile offspring that help their mother, the colony's queen, to reproduce.

A number of explanations have been put forward to explain the evolution of altruism. Once it was thought that altruism evolved for the "good of the species." Individuals that fail to mate, for example, have been called "altruists" because their lack of success in competition has been misinterpreted as a willingness to forego reproduction so that the population or species does not increase in size, exhaust its resources, and go extinct. This group selection explanation (selection acting on a population or species) is simply incorrect because individuals that fail to secure mates and not breed will not leave any offspring. Therefore, their "altruism" would not be favored by selection.

Current studies of altruism note that seemingly altruistic acts are in fact selfish. For example, helpers at the nest are often young birds that gain valuable parenting experience by assisting established breeders; this may give them an advantage when they breed. Moreover, they may have limited opportunities to reproduce on their own, and by hanging around breeding pairs, may inherit the territory when established breeders die.

### Reciprocity theory explains altruism between unrelated individuals

One explanation of altruism proposes that genetically unrelated individuals may form "partnerships" in which mutual exchanges of altruistic acts occur because they benefit both participants.

Partners are willing to give aid at one time and delay “repayment” for the good deed to a time in the future when they themselves are in need. In **reciprocal altruism**, the partnerships are stable because “cheaters” (nonreciprocators) are discriminated against and do not receive future aid. According to this hypothesis, if the altruistic act is relatively inexpensive, the small benefit a cheater receives by not reciprocating is far outweighed by the potential cost of not receiving future aid. Under these conditions, cheating behavior should be eliminated by selection.

Vampire bats roost in hollow trees, caves, and mines in groups of 8 to 12 individuals (figure 55.33). Because bats have a high metabolic rate, individuals that have not fed recently may die. Bats that have found a host imbibe a great deal of blood, so giving up a small amount to keep a roostmate from starvation presents no great energy cost to the donor. Vampire bats tend to share blood with past reciprocators that are not necessarily relatives. If an individual fails to give blood to a bat from which it received blood in the past, it will be excluded from future bloodsharing. Reciprocity routinely occurs in many primates, including humans (obviously!).

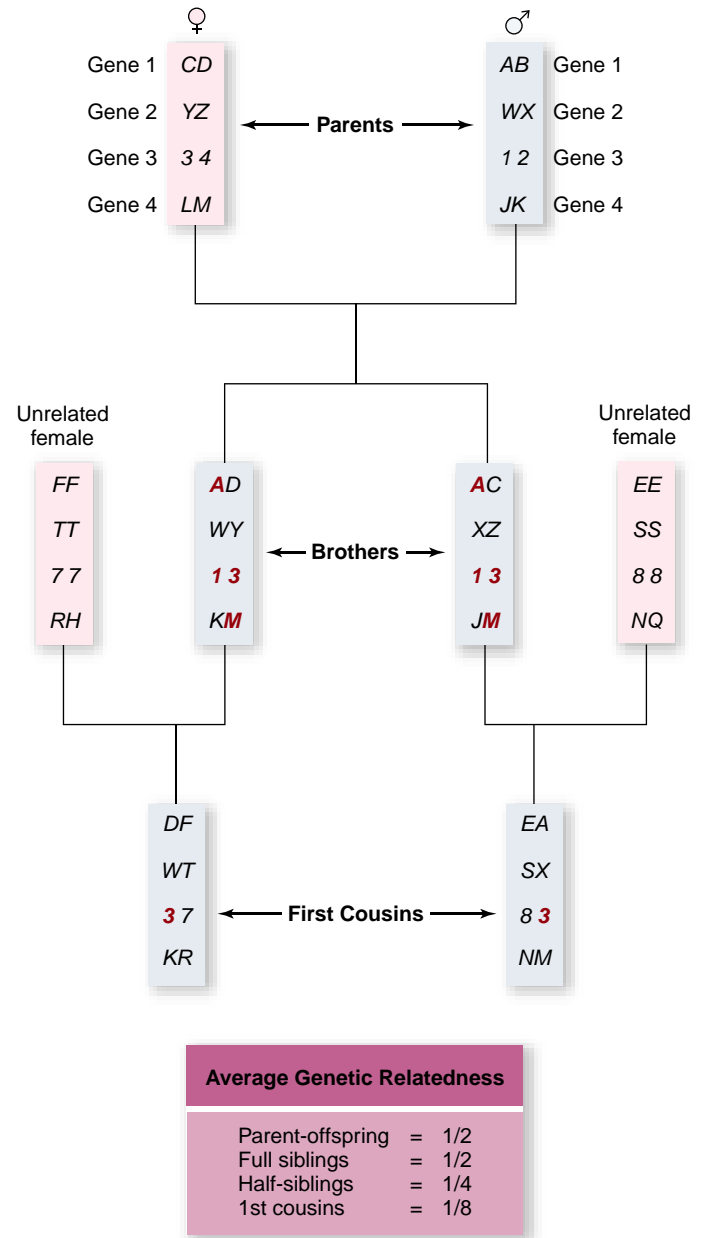

### Kin selection theory proposes a direct genetic advantage to altruism

The great population geneticist J. B. S. Haldane once passionately said in a pub that he would willingly lay down his life for two brothers or eight first cousins.

Evolutionarily speaking, this sacrifice makes sense, because for each allele Haldane received from his parents, his brothers each had a 50% chance of receiving the same allele (figure 55.34). Statistically, it is expected that two of his brothers would pass on as many of Haldane’s particular combination

**Figure 55.33 Truth is stranger than fiction: Reciprocal altruism in vampire bats (*Desmodus rotundus*).** Vampire bats do feed on the blood of large mammals, but they don’t transform into people and sleep in coffins. Vampires live in groups and share blood meals. They remember which bats have provided them with blood in the past and are more likely to share with those bats that have shared with them previously. The bats here are feeding on cattle in Brazil.

**Figure 55.34 Hypothetical example of genetic relationships.** On average, full siblings share half of their alleles. By contrast, cousins only share one-eighth of their alleles on average. Each letter and number represents a different allele.

of alleles to the next generation as Haldane himself would. Similarly, Haldane and a first cousin would share an eighth of their alleles (see figure 55.34). Their parents, who are siblings, would each share half their alleles, and each of their children would receive half of these, of which half on the average would be in common:  $1/2 \times 1/2 \times 1/2 = 1/8$ . Eight first cousins would therefore pass on as many of those alleles to the next generation as Haldane himself would.

The most compelling explanation for the kin-related origin of altruism was presented by one of the most influential evolutionary biologists of our time, William D. Hamilton, in 1964. Hamilton understood Haldane’s point: Natural selection will favor any behavior, including the sacrifice of life, that increases the propagation of an individual’s alleles.

Hamilton mathematically showed that by directing aid toward close genetic relatives, an altruist may increase the reproductive success of its relatives enough to not only compensate for the reduction in its own fitness, but even increase its fitness beyond what would be possible without assisting relatives. Because the altruist's behavior increases the propagation of alleles in relatives, it will be favored by natural selection. Selection that favors altruism directed toward relatives is called kin selection. Although the behaviors are altruistic, the genes are actually "behaving selfishly," because they encourage the organism to favor the success of copies of themselves in relatives. In other words, if an individual has a dominant allele that causes altruism, any action that increases the frequency of this allele in future generations will be favored, even if that action is detrimental to the actor.

Hamilton then defined reproductive success with a new concept—inclusive fitness. Inclusive fitness considers gene propagation through both direct (personal fitness) and indirect (the fitness of relatives) reproduction. Hamilton's kin selection model predicts that altruism is likely to be directed toward close relatives. The more closely related two individuals are, the greater the potential genetic payoff, and the greater inclusive fitness. This is described by Hamilton's rule, which states that altruistic acts are favored when  $rb > c$ . In this expression,  $b$  and  $c$  are the benefits and costs of the altruistic act, respectively, and  $r$  is the coefficient of relatedness, the proportion of alleles shared by two individuals through common descent. For example, an individual should be willing to have one less child ( $c = 1$ ) if such actions allow a half-sibling, which shares one-quarter of its genes ( $r = 0.25$ ), to have five or more additional offspring ( $b = 5$ ).

### **Haplodiploidy and altruism in ants, bees, and wasps**

The relationship between genetic relatedness, kin selection, and altruism can be best understood using social insects as an example. A hive of honeybees consists of a single queen, who is the sole egg-layer, and tens of thousands of her offspring, female workers with nonfunctional ovaries (figure 55.35). Honeybees are eusocial ("truly" social): their societies are defined by reproductive division of labor (only the queen reproduces), cooperative care of the brood (workers nurse, clean, and forage), and overlap of generations (the queen lives with several generations of her offspring).

Darwin was perplexed by eusociality. How could natural selection favor the evolution of sterile workers that left no offspring? It remained for Hamilton to explain the origin of eusociality in hymenopterans (bees, wasps, and ants) using his kin selection model. In these insects, males are haploid (produced from unfertilized eggs) and females are diploid. This system of sex determination and parthenogenesis, called haplodiploidy, leads to unusual genetic relatedness among colony members. If the queen is fertilized by a single male, then all female offspring will inherit exactly the same alleles from their father (because he is haploid and has only one copy of each allele). Female offspring (workers and future queens) will also share, on average, half of the alleles they get from their mother, the queen. Consequently, they will share, on average, 75% of their alleles with each sister (to verify this, rework figure 55.34, but allow the father to only have one allele for each gene).

Now recall Haldane's statement of commitment to family while you read this section. If a worker should have offspring of

**Figure 55.35 Reproductive division of labor in honeybees.** The queen (center) is the sole egg-layer. Her daughters are sterile workers.

her own, she would share only half of her alleles with her young (the other half would come from their father). Thus, because of this close genetic relatedness due to haplodiploidy, workers would propagate more of their own alleles by giving up their own reproduction to assist their mother in rearing their sisters, some of whom will be new queens, start new colonies, and reproduce.

In this way, the unusual haplodiploid system may have set the "genetic stage" for the evolution of eusociality. Indeed, eusociality has evolved at least 12 separate times in the Hymenoptera. One wrinkle in this theory, however, is that eusocial systems have evolved in other insects (thrips, weevils, and termites), and mammals (naked mole rats). Although thrips are also haplodiploid, termites and naked mole rats are not. Thus, although haplodiploidy may have facilitated the evolution of eusociality, other factors can influence social evolution.

### **Other examples of kin selection**

Kin selection may explain altruism in other animals. Belding's ground squirrels give alarm calls when they spot a predator such as a coyote or a badger. Such predators may attack a calling squirrel, so giving the signal places the caller at risk. A ground squirrel colony consists of a female and her daughters, sisters, aunts, and nieces. When males mature, they disperse long distances from where they are born, so adult males in the colony are not genetically related to the females. By marking all squirrels in a colony with an individual dye pattern on their fur and by recording which individuals gave calls and the social circumstances of their calling, researchers found that females who have relatives living nearby are more likely to give alarm calls than females with no kin nearby. Males tend to call much less frequently, as would be expected because they are not related to most colony members.

Another example of kin selection is provided by the white-fronted bee-eater, a bird which lives along river banks in Africa in colonies of 100 to 200 individuals (figure 55.36). In contrast to ground squirrels, the male bee-eaters usually remain in the colony in which they were born, and the females disperse to join new colonies. Many bee-eaters do not raise their own offspring, but instead help others. Most helpers are young birds,

**Figure 55.36** Kin selection in the white-fronted bee-eater (*Merops bullockoides*). Bee-eaters are small insectivorous birds that live in Africa in large colonies. Bee-eaters often help others raise their young; helpers usually choose to help close relatives.

but older birds whose nesting attempts have failed may also be helpers. The presence of a single helper, on average, doubles the number of offspring that survive. Two lines of evidence support the idea that kin selection is important in determining helping behavior in this species. First, helpers are normally males, which are usually related to other birds in the colony, and not females, which are not related. Second, when birds have the choice of helping different parents, they almost invariably choose the parents to which they are most closely related.

### Learning Outcomes Review 55.11

Genetic and ecological factors have contributed to evolution of altruism, a behavior that benefits another individual at a cost to the actor. Individuals may benefit directly if cooperative acts are reciprocated among unrelated interactants. Kin selection explains how altruistic acts directed toward relatives, which share alleles, increase an individual's inclusive fitness. Haplodiploidy has resulted in eusociality among some insects by increasing genetic relatedness; it is not found in vertebrates.

- *Imagine that you witness older group members rescuing infants in a troupe of monkeys when a predator appears. How would you test whether the altruistic act you see is reciprocity or kin selection?*

## 55.12 The Evolution of Group Living and Animal Societies

### Learning Outcomes

1. *Explain the possible advantages of group living.*
2. *Contrast the nature of insect and vertebrate societies.*
3. *Discuss social organization in African weaver birds and how it is influenced by ecology.*

Organisms from cnidarians and insects to fish, whales, chimpanzees, and humans live in social groups. To encompass the

wide variety of social phenomena, we can broadly define a society as a group of organisms of the same species that are organized in a cooperative manner.

Why have individuals in some species given up a solitary existence to become members of a group? One hypothesis is that individuals in groups benefit directly from social living. For example, a bird in a flock may be better protected from predators. As flock size increases, the risk of predation decreases because there are more individuals to scan the environment for predators (figure 55.37).

A member of a flock may also increase its feeding success if it can acquire information from other flock members about the location of new, rich food sources. In some predators, hunting in groups can increase success and allow the group to tackle prey too large for any one individual.

### Insect societies form efficient colonies containing specialized castes

We've already discussed the origin of eusociality in the insect order Hymenoptera (ants, bees, and wasps). Additionally, all termites (order Isoptera) are also eusocial, and a few other insect and arthropod species are eusocial. Social insect colonies are composed of different *castes*, groups of individuals that differ in reproductive ability (queens vs. workers), size, and morphology and perform different tasks. Workers nurse, maintain the nest, and forage; soldiers are large and have powerful jaws specialized for defense.

The structure of an insect society is illustrated by leaf-cutters, which form colonies of as many as several million individuals. These ants cut leaves and use it to grow crops of fungi beneath the ground. Workers divide the tasks of leaf cutting, defense, mulching the fungus garden, and implanting fungal hyphae according to their body size (figure 55.38).

### The structure of a vertebrate society is related to ecology

In contrast to the highly structured and integrated insect societies and their remarkable forms of altruism, vertebrate social

**Figure 55.37** Flocking behavior decreases predation.

When more pigeons are present in the flock, they can detect hawks at greater distances, thus allowing more time for the pigeons to escape. As a result, as the size of a pigeon flock increases, hawks are less successful at capturing pigeons.

**Inquiry question**  
? How would living in a flock affect the time available for foraging by individual pigeons?

groups are usually less rigidly organized and less cohesive. It seems paradoxical that vertebrates, which have larger brains and are capable of more complex behaviors, are generally less altruistic than insects (the exception, of course, is humans). Reciprocity and kin-selected altruism are common in vertebrate societies, although there is often more conflict and aggression among group members. Conflicts generally center on access to food and mates and occur because a vertebrate society is a made up of individuals striving to improve their own fitness.

Social groups of vertebrates have a size, stability of members, number of breeding males and females, and type of mating system characteristic of a given species. Diet and predation

are important factors in shaping social groups. For example, meerkats take turns watching for predators while other group members forage for food (figure 55.39).

African weaver birds, which construct nests from vegetation, provide an excellent example of the relationship between ecology and social organization. Their roughly 90 species can be divided according to the type of social group they form. One group of species lives in the forest and builds camouflaged, solitary nests. Males and females are monogamous; they forage for insects to feed their young. The second group of species nests in colonies in trees on the savanna. They are polygynous and feed in flocks on seeds.

The feeding and nesting habits of these two groups of species are correlated with their mating systems. In the forest, insects are hard to find, and both parents must cooperate in feeding the young. The camouflaged nests do not call the attention of predators to their brood. On the open savanna, building a hidden nest is not an option. Rather, savanna-dwelling weaver birds protect their young from predators by nesting in trees, which are not very abundant. This shortage of safe nest sites means that birds must nest together in colonies. Because seeds occur abundantly, a female can acquire all the food needed to rear young without a male's help. The male, free from the duties of parenting, spends his time courting many females—a polygynous mating system.

One exception to the general rule that vertebrate societies are not organized like those of insects is the naked mole rat, a small, hairless rodent that lives in and near East Africa. Unlike other kinds of mole rats, which live alone or in small family groups, naked mole rats form large underground colonies with a far-ranging system of tunnels and a central nesting area. It is not unusual for a colony to contain 80 individuals.

Naked mole rats feed on bulbs, roots, and tubers, which they locate by constant tunneling. As in insect societies, there is a division of labor among the colony members, with some individuals working as tunnelers while others perform different

**Figure 55.38** Castes of ants. These leaf-cutter ants are members of different castes. The large ant is a worker carrying leaves to the nest, whereas the smaller ants are protecting the worker from attack.

**Figure 55.39 Foraging and predator avoidance.** A meerkat sentinel on duty. Meerkats (*Suricata suricata*) are a species of highly social mongoose living in the semiarid sands of the Kalahari Desert in southern Africa. This meerkat is taking its turn to act as a lookout for predators. Under the security of its vigilance, the other group members can focus their attention on foraging.

tasks, depending on the size of their bodies. Large mole rats defend the colony and dig tunnels.

Naked mole rat colonies have a reproductive division of labor similar to the one normally associated with the eusocial insects. All of the breeding is done by a single female, or “queen,” who has one or two male consorts. The workers, consisting of both sexes, keep the tunnels clear and forage for food.

### Learning Outcomes Review 55.12

Advantages of group living include protection from predators and increased feeding success. Eusocial insects form complex, highly altruistic societies that increase the fitness of the colony. The members of vertebrate societies exhibit more conflict and competition, but also cooperate and behave altruistically, especially toward kin. African weaver birds have developed different types of societies depending on the ecology of their habitat, particularly the safety of nesting sites.

- What are the benefits and costs associated with living in social groups?
- Why is altruism directed toward kin considered to be selfish behavior?
- Is a human army more like an insect society or a vertebrate society? Explain your answer.

## Chapter Review

### 55.1 The Natural History of Behavior

*Behavior can be analyzed in terms of mechanisms (cause) and evolutionary origin (adaptive nature).*

Proximate causation refers to the mechanisms of behavior. Ultimate causation examines a behavior’s evolutionary significance.

*Ethology emphasizes the study of instinct and its origins.*

Innate, or instinctive, behavior is a response to an environmental stimulus or trigger that does not require learning (see figure 55.1).

### 55.2 Nerve Cells, Neurotransmitters, Hormones, and Behavior

Instinctive behaviors are accomplished by neural circuits, which develop under genetic control. Hormones and neurotransmitters can act to regulate behavior.

### 55.3 Behavioral Genetics

*Artificial selection and hybrid studies link genes and behavior.*

Breeding fast-learning and slow-learning rats among each other for several generations produced two distinct behavioral populations (see figure 55.3).

*Some behaviors appear to be controlled by a single gene.*

### 55.4 Learning

*Learning mechanisms include habituation and association.*

Habituation, a form of nonassociative learning, is a decrease in response to repeated nonessential stimuli. Associative learning is a change in behavior by association of two stimuli or of a behavior and a response (conditioning).

Classical (Pavlovian) conditioning occurs when two stimuli are associated with each other. Operant conditioning occurs when an animal associates a behavior with reward or punishment.

***Instinct governs learning preparedness.***

What an animal can learn is biologically influenced—that is, learning is possible only within the boundaries set by evolution.

## 55.5 The Development of Behavior

***Parent–offspring interactions influence how behavior develops.***

In imprinting, a young animal forms an attachment to other individuals or develops preferences that influence later behavior.

***Instinct and learning may interact as behavior develops.***

Animals may have an innate genetic template that guides their learning as behavior develops, such as song development in birds.

***Studies on twins reveal a role for both genes and environment in human behavior.***

## 55.6 Animal Cognition

Some animals exhibit cognitive behavior and can respond to novel situations using logic (see figures 55.12, 55.13).

## 55.7 Orientation and Migratory Behavior

***Migration often involves populations moving large distances.***

***Migrating animals must be capable of orientation and navigation (see figure 55.16).***

Orientation is the mechanism by which animals move by tracking environmental stimuli such as celestial clues or Earth's magnetic field. Navigation is following a route based on orientation and some sort of “map.” The nature of the map in animals is not known.

## 55.8 Animal Communication

***Successful reproduction depends on appropriate signals and responses.***

Courtship signals are usually species-specific and help to ensure reproductive isolation (see figure 55.19).

***Communication enables information exchange among group members (see figures 55.20, 55.21).***

## 55.9 Behavioral Ecology

***Foraging behavior can directly influence energy intake and individual fitness.***

Natural selection favors optimal foraging strategies in which energy acquisition (cost) is minimized and reproductive success (benefit) is maximized.

***Territorial behavior evolves if the benefits of holding a territory exceed the costs.***

## 55.10 Reproductive Strategies and Sexual Selection

***The sexes often have different reproductive strategies.***

One sex may be choosier than the other, and which one often depends on the degree of parental investment.

***Sexual selection occurs through mate competition and mate choice.***

Intrasexual selection involves competition among members of the same sex for the chance to mate. Intersexual selection is one sex choosing a mate.

Mate choice may provide direct benefits (increased resource availability or parental care) or indirect benefits (genetic quality of the mate).

***Mating systems reflect the ability of parents to care for offspring and are influenced by ecology.***

Mating systems include monogamy, polygyny, and polyandry; they are influenced by ecology and constrained by needs of offspring.

## 55.11 Altruism

***Reciprocity theory explains altruism between unrelated individuals.***

Mutual exchanges benefit both participants; a participant that does not reciprocate would not receive future aid.

***Kin selection theory proposes a direct genetic advantage to altruism.***

Kin selection increases the reproductive success of relatives and increased frequency of alleles shared by kin, and thus increases an individual's inclusive fitness.

Ants, bees, and wasps have haplodiploid reproduction, and therefore high degree of gene sharing.

## 55.12 The Evolution of Group Living and Animal Societies

A social system is a group organized in a cooperative manner.

***Insect societies form efficient colonies containing specialized castes (see figure 55.38).***

Social insect societies are composed of different castes that are specialized to reproduce or to perform certain colony maintenance tasks.

***The structure of a vertebrate society is related to ecology.***

Vertebrate social systems are less rigidly organized and cohesive and are influenced by food availability and predation.

## Review Questions

### UNDERSTAND

1. A key stimulus, innate releasing mechanism, and fixed action pattern
  - a. are mechanisms associated with behaviors that are learned.
  - b. are components of behaviors that are innate.
  - c. involve behaviors that cannot be explained in terms of ultimate causation.
  - d. involve behaviors that are not subject to natural selection.
2. In operant conditioning
  - a. an animal learns that a particular behavior leads to a reward or punishment.
  - b. an animal associates an unconditioned stimulus with a conditioned response.
  - c. learning is unnecessary.
  - d. habituation is required for an appropriate response.

3. The study of song development in sparrows showed that
  - a. the acquisition of a species-specific song is innate.
  - b. there are two components to this behavior: a genetic template and learning.
  - c. song acquisition is an example of associative learning.
  - d. All of these are correct.
4. The difference between following a set of driving directions given to you by somebody on the street (for example “. . . take a right at the next light, go four blocks and turn left . . .”) and using a map to find your destination is
  - a. the difference between navigation and orientation, respectively.
  - b. the difference between learning and migration, respectively.
  - c. the difference between orientation and navigation, respectively.
  - d. why birds are not capable of orientation.
5. In courtship communication
  - a. the signal itself is always species-specific.
  - b. the sign communicates species identity.
  - c. it involves a stimulus–response chain.
  - d. courtship signals are produced only by males.
6. Behavioral ecology assumes
  - a. that all behavioral traits are innate.
  - b. learning is the dominant determinant of behavior.
  - c. behavioral traits are subject to natural selection.
  - d. behavioral traits do not affect fitness.
7. According to optimal foraging theory
  - a. individuals minimize energy intake per unit of time.
  - b. energy content of a food item is the only determinant of a forager’s food choice.
  - c. time taken to capture a food item is the only determinant of a forager’s food choice.
  - d. a higher energy item might be less valuable than a lower energy item if it takes too much time to capture the larger item.
8. The elaborate tail feathers of a male peacock evolved because they
  - a. improve reproductive success of males and females.
  - b. improve male survival.
  - c. reduce survival.
  - d. None of the above.
9. From the perspective of females, extra-pair copulations (EPCs)
  - a. are always disadvantageous to females.
  - b. can be associated with receiving male aid.
  - c. are too rare to affect female fitness.
  - d. can only be of benefit if the EPC male has elaborate secondary sexual traits.
10. In the haplodiploidy system of sex determination, males are
  - a. haploid.
  - b. diploid.
  - c. sterile.
  - d. not present because bees exist as single-sex populations.
11. According to kin selection, saving the life of your \_\_\_\_ would do the least for increasing your inclusive fitness.
 

a. mother	c. sister-in-law
b. brother	d. niece
12. Altruism
  - a. is only possible through reciprocity.
  - b. is only possible through kin selection.
  - c. can only be explained by group selection.
  - d. will only occur when the fitness benefit of a given act is greater than the fitness cost.

## APPLY

1. Refer to figure 55.25. Data on size of mussels eaten by shore crabs suggest they eat sizes smaller than expected by an optimal foraging model. Suggest a hypothesis for why and describe an experiment to test your hypothesis.
2. Refer to figure 55.26. Six pairs of birds were removed but only four pairs moved in. Where did the new pairs come from? Additionally, it appears that many of the birds that were not removed expanded their territories and that the new residents ended up with smaller territories than the pairs they replaced. Explain.
3. Refer to figure 55.28. Peahens prefer to mate with peacocks that have more eyespots in their tail feathers (that is, longer tail feathers). It has also been suggested that the longer the tail feathers, the more impaired the flight of the males. One possible hypothesis to explain such a preference by females is that the males with the longest tail feathers experience the most severe handicap, and if they can nevertheless survive, it reflects their “vigor.” Suggest some studies that would allow you to test this idea. Your description should include the kinds of traits that you would measure and why.
4. An altruistic act is defined as one that benefits another individual at a cost to the actor. There are two theories to explain how such behavior evolves: reciprocity and kin selection. How would you distinguish between the two in a field study? In the context of natural selection, is an altruistic act “costly” to an individual who performs it?

## SYNTHESIZE

1. Insects that sting or contain toxic chemicals often have black and yellow coloration and consequentially are not eaten by predators. How could you determine if a predator has an innate avoidance of insects that are colored this way, or if the avoidance is learned? If avoidance is learned, how would you determine the learning mechanism involved? How would you measure the adaptive significance of the black and yellow coloration to the prey insect?
2. Behavioral genetics has made great advances from detailed studies of a single animal such as the fruit fly as a model system to develop general principles of how genes regulate behavior. What are advantages and disadvantages of this “model system” approach? How would you determine how broadly applicable the results of such studies are to other animals?
3. If a female bird chooses to live in the territory of a particular male, why might she mate with a male other than the territory owner?

# Ecology of Individuals and Populations

## Chapter Outline

- 56.1 The Environmental Challenges
- 56.2 Populations: Groups of a Single Species in One Place
- 56.3 Population Demography and Dynamics
- 56.4 Life History and the Cost of Reproduction
- 56.5 Environmental Limits to Population Growth
- 56.6 Factors That Regulate Populations
- 56.7 Human Population Growth

## Introduction

*Ecology, the study of how organisms relate to one another and to their environments, is a complex and fascinating area of biology that has important implications for each of us. In our exploration of ecological principles, we first consider how organisms respond to the abiotic environment in which they exist and how these responses affect the properties of populations, emphasizing population dynamics. In chapter 57, we discuss communities of coexisting species and the interactions that occur among them. In subsequent chapters, we discuss the functioning of entire ecosystems and of the biosphere, concluding with a consideration of the problems facing our planet and our fellow species.*

## 56.1 The Environmental Challenges

### Learning Outcomes

1. List some challenges that organisms face in their environments.
2. Describe ways in which individuals respond to environmental changes.
3. Explain how species adapt to environmental conditions.

The nature of the physical environment in large measure determines which organisms live in a particular climate or region. Key elements of the environment include:

**Temperature.** Most organisms are adapted to live within a relatively narrow range of temperatures and will not thrive if temperatures are colder or warmer. The growing season of plants, for example, is importantly influenced by temperature.

**Water.** All organisms require water. On land, water is often scarce, so patterns of rainfall have a major influence on life.

**Figure 56.1 Meeting the challenge of obtaining moisture.** On the dry sand dunes of the Namib Desert in southwestern Africa, the fog-basking beetle (*Onymacris unguicularis*) collects moisture from the fog by holding its abdomen up at the crest of a dune to gather condensed water; water condenses as droplets and trickles down to the beetle's mouth.

**Sunlight.** Almost all ecosystems rely on energy captured by photosynthesis; the availability of sunlight influences the amount of life an ecosystem can support, particularly below the surface in marine communities.

**Soil.** The physical consistency, pH, and mineral composition of the soil often severely limit terrestrial plant growth, particularly the availability of nitrogen and phosphorus.

An individual encountering environmental variation may maintain a “steady-state” internal environment, a condition known as *homeostasis*. Many animals and plants actively employ physiological, morphological, or behavioral mechanisms to maintain homeostasis. The beetle in figure 56.1 is using a behavioral mechanism to cope with drastic changes in water availability. Other animals and plants are known as conformers because they conform to the environment in which they find themselves, their bodies adopting the temperature, salinity, and other physical aspects of their surroundings.

Responses to environmental variation can be seen over both the short and the long term. In the short term, spanning periods of a few minutes to an individual's lifetime, organisms have a variety of ways of coping with environmental change. Over longer periods, natural selection can operate to make a population better adapted to the environment.

### Organisms are capable of responding to environmental changes that occur during their lifetime

During the course of a day, a season, or a lifetime, an individual organism must cope with a range of living conditions. They do so through the physiological, morphological, and behavioral abilities they possess. These abilities are a product of natural selection acting in a particular environmental setting over time, which explains why an individual organism that is moved to a different environment may not survive.

TABLE 56.1		Physiological Changes at High Elevation
Increased rate of breathing		
Increased erythrocyte production, raising the amount of hemoglobin in the blood		
Decreased binding capacity of hemoglobin, increasing the rate at which oxygen is unloaded in body tissues		
Increased density of mitochondria, capillaries, and muscle myoglobin		

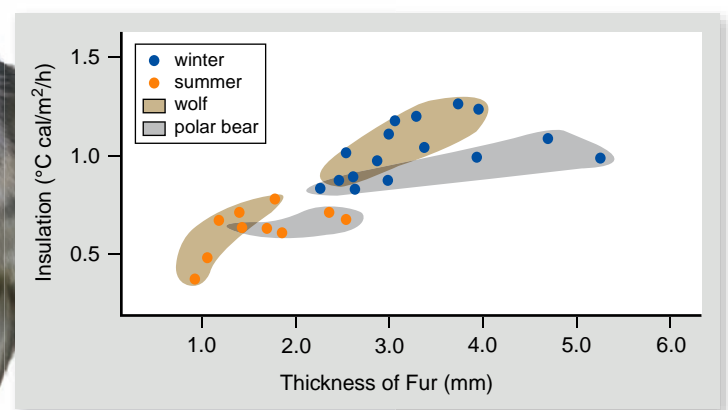

### Physiological responses

Many organisms are able to adapt to environmental change by making physiological adjustments. For example, you sweat when it is hot, increasing evaporative heat loss and thus preventing overheating. Similarly, people who visit high altitudes may initially experience altitude sickness—the symptoms of which include heart palpitations, nausea, fatigue, headache, mental impairment, and in serious cases, pulmonary edema—because of the lower atmospheric pressure and consequent lower oxygen availability in the air. After several days, however, the same people usually feel fine, because a number of physiological changes have increased the delivery of oxygen to their body tissues (table 56.1).

Some insects avoid freezing in the winter by adding glycerol “antifreeze” to their blood; others tolerate freezing by converting much of their glycogen reserves into alcohols that protect their cell membranes from freeze damage.

### Morphological capabilities

Animals that maintain a constant internal temperature (endotherms) in a cold environment have adaptations that tend to minimize energy expenditure. For example, many mammals grow thicker coats during the winter, their fur acting as insulation to retain body heat. In general, the thicker the fur, the greater the insulation (figure 56.2). Thus, a wolf's fur is about three times thicker in winter than in summer and insulates more than twice as well.

**Figure 56.2 Morphological adaptation.** Fur thickness in North American mammals has a major effect on the degree of insulation the fur provides.

## Behavioral responses

Many animals deal with variation in the environment by moving from one patch of habitat to another, avoiding areas that are unsuitable. The tropical lizard in figure 56.3 manages to maintain a fairly uniform body temperature in an open habitat by basking in patches of sunlight and then retreating to the shade when it becomes too hot. By contrast, in shaded forests, the same lizard does not have the opportunity to regulate its body temperature through behavioral means. Thus, it becomes a conformer and adopts the temperature of its surroundings.

Behavioral adaptations can be extreme. Spadefoot toads (genus *Scaphiopus*), which live in the deserts of North America, can burrow nearly a meter below the surface and remain there for as long as nine months of each year, their metabolic rates greatly reduced as they live on fat reserves. When moist, cool conditions return, the toads emerge and breed. The young toads mature rapidly and burrow underground.

## Natural selection leads to evolutionary adaptation to environmental conditions

The ability of an individual to alter its physiology, morphology, or behavior is itself an evolutionary adaptation, the result of natural selection. The results of natural selection can also be detected by comparing closely related species that live in different environments. In such cases, species often have evolved striking adaptations to the particular environment in which they live.

**Figure 56.3 Behavioral adaptation.** In open habitats, the Puerto Rican crested lizard (*Anolis cristatellus*) maintains a relatively constant temperature by seeking out and basking in patches of sunlight; as a result, it can maintain a relatively high temperature even when the air is cool. In contrast, in shaded forests, this behavior is not possible, and the lizard's body temperature conforms to that of its surroundings.

### Inquiry question

? When given the opportunity, lizards regulate their body temperature to maintain a temperature optimal for physiological functioning. Would lizards in open habitats exhibit different escape behaviors from lizards in shaded forest?

For example, animals that live in different climates show many differences. Mammals from colder climates tend to have shorter ears and limbs—a phenomenon termed *Allen's rule*—which reduces the surface area across which animals lose heat. Lizards that live in different climates exhibit physiological adaptations for coping with life at different temperatures. Desert lizards are unaffected by high temperatures that would kill a lizard from northern Europe, but the northern lizards are capable of running, capturing prey, and digesting food at cooler temperatures at which desert lizards would be completely immobilized.

Many species also exhibit adaptations to living in areas where water is scarce. Everyone knows of the camel and other desert animals that can go extended periods without drinking water. Another example of desert adaptation is seen in frogs. Most frogs have moist skins through which water permeates readily. Such animals could not survive in arid climates because they would rapidly dehydrate and die. However, some frogs have solved this problem by evolving a greatly reduced rate of water loss through the skin. One species, for example, secretes a waxy substance from specialized glands that waterproofs its skin and reduces rates of water loss by 95%.

Adaptation to different environments can also be studied experimentally. For example, when strains of *E. coli* were grown at high temperatures (42°C), the speed at which the bacteria utilized resources improved through time. After 2000 generations, this ability increased 30% over what it had been when the experiment started. The means by which efficiency of resource use increased is unknown and is the focus of current research.

### Learning Outcomes Review 56.1

Environmental conditions include temperature, water and light availability, and soil characteristics. When the environment changes, individual organisms use a variety of physiological, morphological, and behavioral mechanisms to adjust. Over time, adaptations to different environments may evolve in populations.

- How might a species respond if its environment grew steadily warmer over time?

## 56.2 Populations: Groups of a Single Species in One Place

### Learning Outcomes

1. Distinguish between a population and a metapopulation.
2. Understand what causes a species' geographic ranges to change through time.

Organisms live as members of populations, groups of individuals that occur together at one place and time. In the rest of this chapter, we consider the properties of populations, focusing on factors that influence whether a population grows or shrinks, and at what rate. The explosive growth of the world's human population in the last few centuries provides a focus for our inquiry.

The term *population* can be defined narrowly or broadly. This flexibility allows us to speak in similar terms of the world's human population, the population of protists in the gut of a termite, or the population of deer that inhabit a forest. Sometimes the boundaries defining a population are sharp, such as the edge of an isolated mountain lake for trout, and sometimes they are fuzzier, as when deer readily move back and forth between two forests separated by a cornfield.

Three characteristics of population ecology are particularly important: (1) population range, the area throughout which a population occurs; (2) the pattern of spacing of individuals within that range; and (3) how the population changes in size through time.

### A population's geographic distribution is termed its range

No population, not even one composed of humans, occurs in all habitats throughout the world. Most species, in fact, have relatively limited geographic ranges, and the range of some species is miniscule. For example, the Devil's Hole pupfish lives in a single spring in southern Nevada (figure 56.4), and the Socorro isopod (*Thermosphaeroma thermophilus*) is known from a single spring system in New Mexico. At the other extreme, some species are widely distributed. The common dolphin (*Delphinus delphis*), for example, is found throughout all the world's oceans.

As discussed earlier, organisms must be adapted for the environment in which they occur. Polar bears are exquisitely adapted to survive the cold of the Arctic, but you won't find them in the tropical rain forest. Certain prokaryotes can live in the near-boiling waters of Yellowstone's geysers, but they do not occur in cooler streams nearby. Each population has its own requirements—temperature, humidity, certain types of food, and a host of other factors—that determine where it can live and reproduce and where it can't. In addition, in places that are otherwise suitable, the presence of predators, competitors, or parasites may prevent a population from occupying an area, a topic we will take up in chapter 57.

**Figure 56.4** The Devil's Hole pupfish (*Cyprinodon diabolis*). This fish has the smallest range of any vertebrate species in the world.

### Ranges undergo expansion and contraction

Population ranges are not static but change through time. These changes occur for two reasons. In some cases, the environment changes. As the glaciers retreated at the end of the last ice age, approximately 10,000 years ago, many North American plant and animal populations expanded northward. At the same time, as climates warmed, species experienced shifts in the elevation at which they could live (figure 56.5).

**Figure 56.5** Altitude shifts in altitudinal distributions of trees in the mountains of southwestern North America.

During the glacial period 15,000 years ago, conditions were cooler than they are now. As the climate warmed, tree species that require colder temperatures shifted their range upward in altitude so that they live in the climatic conditions to which they are adapted.

**Figure 56.6** Range expansion of the cattle egret

**(*Bubulcus ibis*).** The cattle egret—so named because it follows cattle and other hoofed animals, catching any insects or small vertebrates it disturbs—first arrived in South America from Africa in the late 1800s. Since the 1930s, the range expansion of this species has been well documented, as it has moved northward into much of North America, as well as southward along the western side of the Andes to near the southern tip of South America.

In addition, populations can expand their ranges when they are able to circumvent inhospitable habitat to colonize suitable, previously unoccupied areas. For example, the cattle egret is native to Africa. Some time in the late 1800s, these birds appeared in northern South America, having made the nearly 3500-km transatlantic crossing, perhaps aided by strong winds. Since then, they have steadily expanded their range and now can be found throughout most of the United States (figure 56.6).

### The human effect

By altering the environment, humans have allowed some species, such as coyotes, to expand their ranges and move into areas they previously did not occupy. Moreover, humans have served as an agent of dispersal for many species. Some of these transplants have been widely successful, as is discussed in greater detail in chapter 60. For example, 100 starlings were introduced into New York City in 1896 in a misguided attempt to establish every species of bird mentioned by Shakespeare. Their population steadily spread so

that by 1980, they occurred throughout the United States. Similar stories could be told for countless plants and animals, and the list increases every year. Unfortunately, the success of these invaders often comes at the expense of native species.

### Dispersal mechanisms

Dispersal to new areas can occur in many ways. Lizards have colonized many distant islands, as one example, probably due to individuals or their eggs floating or drifting on vegetation. Bats are the only mammals on many distant islands because they can fly to them.

Seeds of plants are designed to disperse in many ways (figure 56.7). Some seeds are aerodynamically designed to be blown long distances by the wind. Others have structures that stick to the fur or feathers of animals, so that they are carried long distances before falling to the ground. Still others are enclosed in fleshy fruits. These seeds can pass through the digestive systems of mammals or birds and then germinate where they are defecated. Finally, seeds of mistletoes (*Arceuthobium*) are violently propelled from the base of the fruit in an explosive discharge. Although the probability of long-distance dispersal events leading to successful establishment of new populations is low, over millions of years, many such dispersals have occurred.

**Figure 56.7** Some of the many adaptations of seeds.

Seeds have evolved a number of different means of facilitating dispersal from their maternal plant. Some seeds can be transported great distances by the wind, whereas seeds enclosed in adherent or fleshy fruits can be transported by animals.

## Individuals in populations exhibit different spacing patterns

Another key characteristic of population structure is the way in which individuals of a population are distributed. They may be randomly spaced, uniformly spaced, or clumped.

### Random spacing

Random spacing of individuals within populations occurs when they do not interact strongly with one another and when they are not affected by nonuniform aspects of their environment. Random distributions are not common in nature. Some species of trees, however, appear to exhibit random distributions in Panamanian rain forests.

### Uniform spacing

Uniform spacing within a population may often, but not always, result from competition for resources. This spacing is accomplished, however, in many different ways

In animals, uniform spacing often results from behavioral interactions, as described in chapter 55. In many species, individuals of one or both sexes defend a territory from which other individuals are excluded. These territories provide the owner with exclusive access to resources, such as food, water, hiding refuges, or mates, and tend to space individuals evenly across the habitat. Even in nonterritorial species, individuals often maintain a defended space into which other animals are not allowed to intrude.

Among plants, uniform spacing is also a common result of competition for resources. Closely spaced individual plants compete for available sunlight, nutrients, or water. These contests can be direct, as when one plant casts a shadow over another, or indirect, as when two plants compete by extracting nutrients or water from a shared area. In addition, some plants, such as the creosote bush, produce chemicals in the surrounding soil that are toxic to other members of their species. In all of these cases, only plants that are spaced an adequate distance from each other will be able to coexist, leading to uniform spacing.

### Clumped spacing

Individuals clump into groups or clusters in response to uneven distribution of resources in their immediate environments. Clumped distributions are common in nature because individual animals, plants, and microorganisms tend to occur in habitats defined by soil type, moisture, or other aspects of the environment to which they are best adapted.

Social interactions also can lead to clumped distributions. Many species live and move around in large groups, which go by a variety of names (for example, flock, herd, pride). These groupings can provide many advantages, including increased awareness of and defense against predators, decreased energy cost of moving through air and water, and access to the knowledge of all group members.

On a broader scale, populations are often most densely populated in the interior of their range and less densely distributed toward the edges. Such patterns usually result from the manner in which the environment changes in different areas.

Populations are often best adapted to the conditions in the interior of their distribution. As environmental conditions

change, individuals are less well adapted, and thus densities decrease. Ultimately, the point is reached at which individuals cannot persist at all; this marks the edge of a population's range.

## A metapopulation comprises distinct populations that may exchange members

Species often exist as a network of distinct populations that interact with one another by exchanging individuals. Such networks, termed **metapopulations**, usually occur in areas in which suitable habitat is patchily distributed and is separated by intervening stretches of unsuitable habitat.

### Dispersal and habitat occupancy

The degree to which populations within a metapopulation interact depends on the amount of dispersal; this interaction is often not symmetrical: Populations increasing in size tend to send out many dispersers, whereas populations at low levels tend to receive more immigrants than they send off. In addition, relatively isolated populations tend to receive relatively few arrivals.

Not all suitable habitats within a metapopulation's area may be occupied at any one time. For a number of reasons, some individual populations may become extinct, perhaps as a result of an epidemic disease, a catastrophic fire, or the loss of genetic variation following a population bottleneck (see chapter 60). Dispersal from other populations, however, may eventually recolonize such areas. In some cases, the number of habitats occupied in a metapopulation may represent an equilibrium in which the rate of extinction of existing populations is balanced by the rate of colonization of empty habitats.

### Source-sink metapopulations

A species may also exhibit a metapopulation structure in areas in which some habitats are suitable for long-term population maintenance, but others are not. In these situations, termed **source-sink metapopulations**, the populations in the better areas (the sources) continually send out dispersers that bolster the populations in the poorer habitats (the sinks). In the absence of such continual replenishment, sink populations would have a negative growth rate and would eventually become extinct.

Metapopulations of butterflies have been studied particularly intensively. In one study, researchers sampled populations of the Glanville fritillary butterfly at 1600 meadows in southwestern Finland (figure 56.8). On average, every year, 200 populations became extinct, but 114 empty meadows were colonized. A variety of factors seemed to increase the likelihood of a population's extinction, including small population size, isolation from sources of immigrants, low resource availability (as indicated by the number of flowers on a meadow), and lack of genetic variation within the population.

The researchers attribute the greater number of extinctions than colonizations to a string of very dry summers. Because none of the populations is large enough to survive on its own, continued survival of the species in southwestern Finland would appear to require the continued existence of a metapopulation network in which new populations are continually

## 56.3 Population Demography and Dynamics

### Learning Outcomes

1. Define demography.
2. Describe the factors that influence a species' demography.
3. Explain the significance of survivorship curves.

The dynamics of a population—how it changes through time—are affected by many factors. One important factor is the age distribution of individuals—that is, what proportion of individuals are adults, juveniles, and young.

**Demography** is the quantitative study of populations. How the size of a population changes through time can be studied at two levels: as a whole or broken down into parts. At the most inclusive level, we can study the whole population to determine whether it is increasing, decreasing, or remaining constant. Put simply, populations grow if births outnumber deaths and shrink if deaths outnumber births. Understanding these trends is often easier, however, if we break the population into smaller units composed of individuals of the same age (for example, 1-year-olds) and study the factors affecting birth and death rates for each unit separately.

### Sex ratio and generation time affect population growth rates

Population growth can be influenced by the population's sex ratio. The number of births in a population is usually directly related to the number of females; births may not be as closely related to the number of males in species in which a single male can mate with several females. In many species, males compete for the opportunity to mate with females, as you learned in the preceding chapter; consequently, a few males have many matings, and many males do not mate at all. In such species, the sex ratio is female-biased and does not affect population growth rates; reduction in the number of males simply changes the identities of the reproductive males without reducing the number of births. By contrast, among monogamous species, pairs may form long-lasting reproductive relationships, and a reduction in the number of males can then directly reduce the number of births.

**Generation time** is the average interval between the birth of an individual and the birth of its offspring. This factor can also affect population growth rates. Species differ greatly in generation time. Differences in body size can explain much of this variation—mice go through approximately 100 generations during the course of one elephant generation (figure 56.9). But small size does not always mean short generation time. Newts, for example, are smaller than mice, but have considerably longer generation times.

In general, populations with short generations can increase in size more quickly than populations with long generations. Conversely, because generation time and life span are

**Figure 56.8 Metapopulations of butterflies.**

The Glanville fritillary butterfly (*Melitaea cinxia*) occurs in metapopulations in southwestern Finland on the Åland Islands. None of the populations is large enough to survive for long on its own, but continual immigration of individuals from other populations allows some populations to survive. In addition, continual establishment of new populations tends to offset extinction of established populations, although in recent years, extinctions have outnumbered colonizations.

created and existing populations are supplemented by immigrants. Continued bad weather thus may doom the species, at least in this part of its range.

Metapopulations, where they occur, can have two important implications for the range of a species. First, through continuous colonization of empty patches, metapopulations prevent long-term extinction. If no such dispersal existed, then each population might eventually perish, leading to disappearance of the species from the entire area. Moreover, in source–sink metapopulations, the species occupies a larger area than it otherwise might, including marginal areas that could not support a population without a continual influx of immigrants. For these reasons, the study of metapopulations has become very important in conservation biology as natural habitats become increasingly fragmented.

### Learning Outcomes Review 56.2

A population is a group of individuals of a single species existing together in an area. A population's range, the area it occupies, changes over time. Populations, in turn, may form a network, or metapopulation, connected by individuals that move from one group to another. Within a population, the distribution of individuals can be random, uniform, or clumped, and the distribution is determined in part by the availability of resources.

- How might the geographic range of a species change if populations could not exchange individuals with each other?

**Figure 56.9** The relationship between body size and generation time. In general, larger organisms have longer generation times, although there are exceptions.

### Inquiry question

**?** If resources became more abundant, would you expect smaller or larger species to increase in population size more quickly?

usually closely correlated, populations with short generation times may also diminish in size more rapidly if birth rates suddenly decrease.

### Age structure is determined by the numbers of individuals in different age groups

A group of individuals of the same age is referred to as a cohort. In most species, the probability that an individual will reproduce or die varies through its life span. As a result, within

a population, every cohort has a characteristic birth rate, or **fecundity**, defined as the number of offspring produced in a standard time (for example, per year), and death rate, or **mortality**, the number of individuals that die in that period.

The relative number of individuals in each cohort defines a population's **age structure**. Because different cohorts have different fecundity and death rates, age structure has a critical influence on a population's growth rate. Populations with a large proportion of young individuals, for example, tend to grow rapidly because an increasing proportion of their individuals are reproductive. Human populations in many developing countries are an example, as will be discussed later in this chapter. Conversely, if a large proportion of a population is relatively old, populations may decline. This phenomenon now characterizes Japan and some countries in Europe.

### Life tables show probability of survival and reproduction through a cohort's life span

To assess how populations in nature are changing, ecologists use a **life table**, which tabulates the fate of a cohort from birth until death, showing the number of offspring produced and the number of individuals that die each year. Table 56.2 shows an example of a life table analysis from a study of the meadow grass *Poa annua*. This study follows the fate of 843 individuals through time, charting how many survive in each interval and how many offspring each survivor produces.

In table 56.2, the first column indicates the age of the cohort (that is, the number of 3-month intervals from the start of the study). The second and third columns indicate the number of survivors and the proportion of the original cohort still alive at the beginning of that interval. The fifth column presents the **mortality rate**, the proportion of individuals that started that interval alive but died by the end of it. The seventh column indicates the average number of seeds produced by each surviving individual in that interval, and the last column shows the number of seeds produced relative to the size of the original cohort.

Much can be learned by examining life tables. In the case of *P. annua*, we see that both the probability of dying and the number of offspring produced per surviving individual steadily increases with age. By adding up the numbers in the last column, we get the total number of offspring produced per individual in the initial cohort. This number is almost 2, which means that for every original member of the cohort, on average two new individuals have been produced. A figure of 1.0 would be the break-even number, the point at which the population was neither growing nor shrinking. In this case, the population appears to be growing rapidly.

In most cases, life table analysis is more complicated than this. First, except for organisms with short life spans, it is difficult to track the fate of a cohort until the death of the last individual. An alternative approach is to construct a cross-sectional study, examining the fate of cohorts of different ages in a single period. In addition, many factors—such as offspring

TABLE 56.2

Life Table of the Meadow Grass (*Poa annua*) for a Cohort Containing 843 Seedlings

Age (in 3-month intervals)	Number Alive at Beginning of Time Interval	Proportion of Cohort Alive at Beginning of Time Interval (survivorship)	Deaths During Time Interval	Mortality Rate During Time Interval	Seeds Produced During Time Interval	Seeds Produced per Surviving Individual (fecundity)	Seeds Produced per Member of Cohort (fecundity $\times$ survivorship)
0	843	1.000	121	0.143	0	0.00	0.00
1	722	0.857	195	0.271	303	0.42	0.36
2	527	0.625	211	0.400	622	1.18	0.74
3	316	0.375	172	0.544	430	1.36	0.51
4	144	0.171	90	0.626	210	1.46	0.25
5	54	0.064	39	0.722	60	1.11	0.07
6	15	0.018	12	0.800	30	2.00	0.04
7	3	0.004	3	1.000	10	3.33	0.01
8	0	0.000	—		Total = 1665		Total = 1.98

reproducing before all members of their parents' cohort have died—complicate the interpretation of whether populations are growing or shrinking.

### Survivorship curves demonstrate how survival probability changes with age

The percentage of an original population that survives to a given age is called its **survivorship**. One way to express some aspects of the age distribution of populations is through a *survivorship curve*. Examples of different survivorship curves are shown in figure 56.10. Oysters produce vast numbers of offspring, only a few of which live to reproduce. However, once they become established and grow into reproductive individuals, their mortality rate is extremely low (type III survivorship curve). Note that in this type of curve, survival and mortality rates are inversely related. Thus, the rapid decrease in the proportion of oysters surviving indicates that few individuals survive, thus producing a high mortality rate. In contrast, the relatively flat line at older ages indicates high survival and low mortality.

In hydra, animals related to jellyfish, individuals are equally likely to die at any age. The result is a straight survivorship curve (type II).

Finally, mortality rates in humans, as in many other animals and in protists, rise steeply later in life (type I survivorship curve).

Of course, these descriptions are just generalizations, and many organisms show more complicated patterns. Examination of the data for *P. annua*, for example, reveals that it is most similar to a type II survivorship curve (figure 56.11).

**Figure 56.10** Survivorship curves. By convention, survival (the vertical axis) is plotted on a log scale. Humans have a type I life cycle, hydra (an animal related to jellyfish) type II, and oysters type III.

**Figure 56.11** Survivorship curve for a cohort of the meadow grass. After several months of age, mortality increases at a constant rate through time.

### Inquiry question

? Suppose you wanted to keep meadow grass in your room as a houseplant. Suppose, too, that you wanted to buy an individual plant that was likely to live as long as possible. What age plant would you buy? How might the shape of the survivorship curve affect your answer?

### Learning Outcomes Review 56.3

Demography is the quantitative study of populations. Demographic characteristics include age structure, life span, sex ratio, generation time, and birth and mortality rates. The age structure of a population and the manner in which mortality and birth rates vary among different age cohorts, determine whether a population will increase or decrease in size.

- Will populations with higher survivorship rates always have higher population growth rates than populations with lower survivorship rates?

## 56.4 Life History and the Cost of Reproduction

### Learning Outcomes

1. Describe reproductive trade-offs in an organism's life history.
2. Compare the costs and benefits of allocating resources to reproduction.

Natural selection favors traits that maximize the number of surviving offspring left in the next generation by an individual organism. Two factors affect this quantity: how long an individual lives, and how many young it produces each year.

Why doesn't every organism reproduce immediately after its own birth, produce large families of offspring, care for them intensively, and perform these functions repeatedly throughout a long life, while outcompeting others, escaping predators, and capturing food with ease? The answer is that no one organism can do all of this, simply because not enough resources are available. Consequently, organisms allocate resources either to current reproduction or to increasing their prospects of surviving and reproducing at later life stages.

The complete life cycle of an organism constitutes its life history. All life histories involve significant trade-offs. Because resources are limited, a change that increases reproduction may decrease survival and reduce future reproduction. As one example, a Douglas fir tree that produces more cones increases its current reproductive success—but it also grows more slowly. Because the number of cones produced is a function of how large a tree is, this diminished growth will decrease the number of cones it can produce in the future. Similarly, birds that have more offspring each year have a higher probability of dying during that year or of producing smaller clutches the following year (figure 56.12). Conversely, individuals that delay reproduction may grow faster and larger, enhancing future reproduction.

In one elegant experiment, researchers changed the number of eggs in the nests of a bird, the collared flycatcher (figure 56.13). Birds whose clutch size (the number of eggs produced in one breeding event) was decreased expended less energy raising their young and thus were able to lay more eggs the next year, whereas those given more eggs worked harder and consequently produced fewer eggs the following year. Ecologists refer to the reduction in future reproductive potential resulting from current reproductive efforts as the **cost of reproduction**.

**Figure 56.12** Reproduction has a price. Data from many bird species indicate that increased fecundity in birds correlates with higher mortality, ranging from the albatross (lowest) to the sparrow (highest). Birds that raise more offspring per year have a higher probability of dying during that year.

**Figure 56.13 Reproductive events per lifetime.** Adding eggs to nests of collared flycatchers (*Ficedula albicollis*), which increases the reproductive efforts of the female rearing the young, decreases clutch size the following year; removing eggs from the nest increases the next year's clutch size. This experiment demonstrates the trade-off between current reproductive effort and future reproductive success.

Natural selection favors the life history that maximizes lifetime reproductive success. When the cost of reproduction is low, individuals should produce as many offspring as possible because there is little cost. Low costs of reproduction may occur when resources are abundant and may also be relatively low when overall mortality rates are high. In the latter case, individuals may be unlikely to survive to the next breeding season anyway, so the incremental effect of increased reproductive efforts may have little effect on future survival.

Alternatively, when costs of reproduction are high, lifetime reproductive success may be maximized by deferring or minimizing current reproduction to enhance growth and survival rates. This situation may occur when costs of reproduction significantly affect the ability of an individual to survive or decrease the number of offspring that can be produced in the future.

### A trade-off exists between number of offspring and investment per offspring

In terms of natural selection, the number of offspring produced is not as important as how many of those offspring themselves survive to reproduce. Assuming that the amount of energy to be invested in offspring is limited, a balance must be reached between the number of offspring produced and the size of each offspring (figure 56.14). This trade-off has been experimentally demonstrated in the side-blotched lizard, which normally lays between four and five eggs at a time. When some of the eggs are removed surgically early in the reproductive cycle, the female lizard produces only one to three eggs, but supplies each of these eggs with greater amounts of yolk, producing eggs and, subsequently, hatchlings that are much larger than normal (figure 56.15). Alternatively, by removing yolk from eggs, scientists have demonstrated that smaller young would be produced.

**Figure 56.14 The relationship between clutch size and offspring size.**

In great tits (*Parus major*), the size of the nestlings is inversely related to the number of eggs laid. The more mouths they have to feed, the less the parents can provide to any one nestling.

### Inquiry question

Would natural selection favor producing many small young or a few large ones?

**Figure 56.15 Variation in the size of baby side-blotched lizards (*Uta stansburiana*) produced by experimental manipulations.** In clutches in which some developing eggs were surgically removed, the remaining offspring were larger (center) than lizards produced in control clutches in which all the eggs were allowed to develop (right). In experiments in which some of the yolk was removed from the eggs, smaller lizards hatched (left).

## 56.5 Environmental Limits to Population Growth

### Learning Outcomes

1. Explain exponential growth.
2. Discuss why populations cannot grow exponentially forever.
3. Define carrying capacity.

In the side-blotched lizard and many other species, the size of offspring is critical—larger offspring have a greater chance of survival. Producing many offspring with little chance of survival might not be the best strategy, but producing only a single, extraordinarily robust offspring also would not maximize the number of surviving offspring. Rather, an intermediate situation, in which several fairly large offspring are produced, should maximize the number of surviving offspring.

### Reproductive events per lifetime represent an additional trade-off

The trade-off between age and fecundity plays a key role in many life histories. Annual plants and most insects focus all their reproductive resources on a single large event and then die. This life history adaptation is called **semelparity**. Organisms that produce offspring several times over many seasons exhibit a life history adaptation called **iteroparity**.

Species that reproduce yearly must avoid overtaxing themselves in any one reproductive episode so that they will be able to survive and reproduce in the future. Semelparity, or “big bang” reproduction, is usually found in short-lived species that have a low probability of staying alive between broods, such as plants growing in harsh climates. Semelparity is also favored when fecundity entails large reproductive cost, exemplified by Pacific salmon migrating upriver to their spawning grounds. In these species, rather than investing some resources in an unlikely bid to survive until the next breeding season, individuals put all their resources into one reproductive event.

### Age at first reproduction correlates with life span

Among mammals and many other animals, longer-lived species put off reproduction longer than short-lived species, relative to expected life span. The advantage of delayed reproduction is that juveniles gain experience before expending the high costs of reproduction. In long-lived animals, this advantage outweighs the energy that is invested in survival and growth rather than reproduction.

In shorter-lived animals, on the other hand, time is of the essence; thus, quick reproduction is more critical than juvenile training, and reproduction tends to occur earlier.

#### Learning Outcomes Review 56.4

Life history adaptations involve many trade-offs between reproductive cost and investment in survival. These trade-offs take a variety of forms, from laying fewer than the maximum possible number of eggs to putting all energy into a single bout of reproduction. Natural selection favors maximizing reproductive success, but number of offspring produced must be tempered by available resources.

- How might the life histories of two species differ if one was subject to high levels of predation and the other had few predators?

Populations often remain at a relatively constant size, regardless of how many offspring are born. As you saw in chapter 1, Darwin based his theory of natural selection partly on this seeming contradiction. Natural selection occurs because of checks on reproduction, with some individuals producing fewer surviving offspring than others. To understand populations, we must consider how they grow and what factors in nature limit population growth.

### The exponential growth model applies to populations with no growth limits

The rate of population increase,  $r$ , is defined as the difference between the birth rate,  $b$ , and the death rate,  $d$ , corrected for movement of individuals in or out of the population ( $e$ , rate of movement out of the area;  $i$ , rate of movement into the area). Thus,

$$r = (b - d) + (i - e)$$

Movements of individuals can have a major influence on population growth rates. For example, the increase in human population in the United States during the closing decades of the 20th century was mostly due to immigration.

The simplest model of population growth assumes that a population grows without limits at its maximal rate and also that rates of immigration and emigration are equal. This rate, called the **biotic potential**, is the rate at which a population of a given species increases when no limits are placed on its rate of growth. In mathematical terms, this is defined by the following formula:

$$\frac{dN}{dt} = r_i N$$

where  $N$  is the number of individuals in the population,  $dN/dt$  is the rate of change in its numbers over time, and  $r_i$  is the intrinsic rate of natural increase for that population—its innate capacity for growth.

The biotic potential of any population is exponential (red line in figure 56.16). Even when the *rate* of increase remains constant, the actual *number* of individuals accelerates rapidly as the size of the population grows. The result of unchecked exponential growth is a population explosion.

A single pair of houseflies, laying 120 eggs per generation, could produce more than 5 trillion descendants in a year. In 10 years, their descendants would form a swarm more than 2 m thick over the entire surface of the Earth! In practice, such patterns of unrestrained growth prevail only for short periods, usually when an organism reaches a new habitat with abundant

**Figure 56.16 Two models of population growth.** The red line illustrates the exponential growth model for a population with an  $r$  of 1.0. The blue line illustrates the logistic growth model in a population with  $r = 1.0$  and  $K = 1000$  individuals. At first, logistic growth accelerates exponentially; then, as resources become limited, the death rate increases and growth slows. Growth ceases when the death rate equals the birth rate. The carrying capacity ( $K$ ) ultimately depends on the resources available in the environment.

resources. Natural examples of such short period of unrestrained growth include dandelions arriving in the fields, lawns, and meadows of North America from Europe for the first time; algae colonizing a newly formed pond; or cats introduced to an island with many birds, but previously lacking predators.

### Carrying capacity

No matter how rapidly populations grow, they eventually reach a limit imposed by shortages of important environmental factors, such as space, light, water, or nutrients. A population ultimately may stabilize at a certain size, called the **carrying capacity** of the particular place where it lives. The carrying capacity, symbolized by  $K$ , is the maximum number of individuals that the environment can support.

### The logistic growth model applies to populations that approach their carrying capacity

As a population approaches its carrying capacity, its rate of growth slows greatly, because fewer resources remain for each new individual to use. The growth curve of such a population, which is always limited by one or more factors in the environment, can be approximated by the following logistic growth equation:

$$\frac{dN}{dt} = rN \left( \frac{K - N}{K} \right)$$

In this model of population growth, the growth rate of the population ( $dN/dt$ ) is equal to its intrinsic rate of natural increase ( $r$  multiplied by  $N$ , the number of individuals present at any one time), adjusted for the amount of resources available. The adjust-

**Figure 56.17 Relationship between population growth rate and population size.** Populations far from the carrying capacity ( $K$ ) have high growth rates—positive if the population is below  $K$ , and negative if it is above  $K$ . As the population approaches  $K$ , growth rates approach zero.

### Inquiry question

? Why does the growth rate converge on zero?

ment is made by multiplying  $rN$  by the fraction of  $K$ , the carrying capacity, still unused  $[(K - N)/K]$ . As  $N$  increases, the fraction of resources by which  $r$  is multiplied becomes smaller and smaller, and the rate of increase of the population declines.

Graphically, if you plot  $N$  versus  $t$  (time), you obtain a **sigmoidal growth curve** characteristic of many biological populations. The curve is called “sigmoidal” because its shape has a double curve like the letter **S**. As the size of a population stabilizes at the carrying capacity, its rate of growth slows, eventually coming to a halt (blue line in figure 56.16).

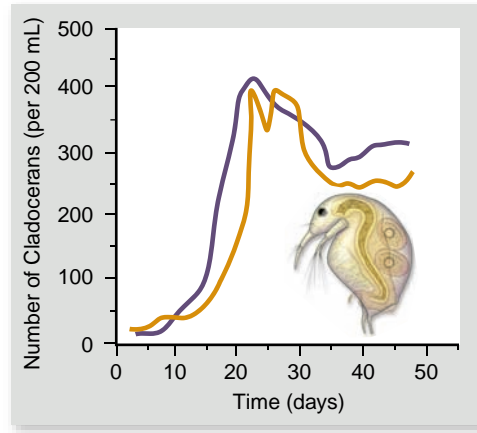

In mathematical terms, as  $N$  approaches  $K$ , the *rate* of population growth ( $dN/dt$ ) begins to slow, reaching 0 when  $N = K$  (figure 56.17). Conversely, if the population size exceeds the carrying capacity, then  $K - N$  will be negative, and the population will experience a negative growth rate. As the population size then declines toward the carrying capacity, the magnitude of this negative growth rate will decrease until it reaches 0 when  $N = K$ .

Notice that the population tends to move toward the carrying capacity regardless of whether it is initially above or below it. For this reason, logistic growth tends to return a population to the same size. In this sense, such populations are considered to be in equilibrium because they would be expected to be at or near the carrying capacity at most times.

In many cases, real populations display trends corresponding to a logistic growth curve. This is true not only in the laboratory, but also in natural populations (figure 56.18a). In some cases, however, the fit is not perfect (figure 56.18b), and as we shall see shortly, many populations exhibit other patterns.

a.

b.

**Figure 56.18** Many populations exhibit logistic growth. *a.* A fur seal (*Callorhinus ursinus*) population on St. Paul Island, Alaska. *b.* Two laboratory populations of the cladoceran *Bosmina longirostris*. Note that the populations first exceeded the carrying capacity, before decreasing to a size that was then maintained.

### Learning Outcomes Review 56.5

Exponential growth refers to population growth in which the number of individuals accelerates even when the rate of increase remains constant; it results in a population explosion. Exponential growth is eventually limited by resource availability. The size at which a population in a particular location stabilizes is defined as the carrying capacity of that location for that species. Populations often grow to the carrying capacity of their environment.

- What might cause a population's carrying capacity to change, and how would the population respond?

## 56.6 Factors That Regulate Populations

### Learning Outcomes

1. Compare density-dependent and density-independent factors.
2. Evaluate why the size of some populations cycle.
3. Consider how the life history adaptations of species may differ depending on how often populations are at their carrying capacity.

A number of factors may affect population size through time. Some of these factors depend on population size and are therefore termed *density-dependent*. Other factors, such as natural disasters, affect populations regardless of size; these factors are termed *density-independent*. Many populations exhibit cyclic fluctuations in size that may result from complex interactions of factors.

### Density-dependent effects occur when reproduction and survival are affected by population size

The reason population growth rates are affected by population size is that many important processes have **density-dependent effects**. That is, as population size increases, either reproductive rates decline or mortality rates increase, or both, a phenomenon termed *negative feedback* (figure 56.19).

Populations can be regulated in many different ways. When populations approach their carrying capacity, competition for resources can be severe, leading both to a decreased birth rate and an increased risk of death (figure 56.20). In addition, predators often focus their attention on a particularly common prey species, which also results in increasing rates of mortality as populations increase. High population densities can also lead to an accumulation of toxic wastes in the environment.

**Figure 56.19** Density-dependent population regulation. Density-dependent factors can affect birth rates, death rates, or both.

### Inquiry question

? Why might birth rates be density-dependent?

**Figure 56.20** Density dependence in the song sparrow (*Melospiza melodia*) on Mandarte Island. Reproductive success decreases and mortality rates increase as population size increases.

### Inquiry question

? What would happen if researchers supplemented the food available to the birds?

Behavioral changes may also affect population growth rates. Some species of rodents, for example, become antisocial, fighting more, breeding less, and generally acting stressed-out. These behavioral changes result from hormonal actions, but their ultimate cause is not yet clear; most likely, they have evolved as adaptive responses to situations in which resources are scarce. In addition, in crowded populations, the population growth rate may decrease because of an increased rate of emigration of individuals attempting to find better conditions elsewhere (figure 56.21).

However, not all density-dependent factors are negatively related to population size. In some cases, growth rates increase with population size. This phenomenon is referred to as the **Allee effect** (after Warder Allee, who first described it), and is an example of *positive feedback*. The Allee effect can take several forms. Most obviously, in populations that are too sparsely distributed, individuals may have difficulty finding mates. Moreover, some species may rely on large groups to deter predators or to provide the necessary stimulation for breeding activities. The Allee effect

**Figure 56.21** Density-dependent effects. Migratory locusts (*Locusta migratoria*) are a legendary plague of large areas of Africa and Eurasia. At high population densities, the locusts have different hormonal and physical characteristics and take off as a swarm.

is a major threat for many endangered species, which may never recover from decreased population sizes caused by habitat destruction, overexploitation, or other causes (see chapter 60).

## Density-independent effects include environmental disruptions and catastrophes

Growth rates in populations sometimes do not correspond to the logistic growth equation. In many cases, such patterns result because growth is under the control of **density-independent effects**. In other words, the rate of growth of a population at any instant is limited by something unrelated to the size of the population.

A variety of factors may affect populations in a density-independent manner. Most of these are aspects of the external environment, such as extremely cold winters, droughts, storms, or volcanic eruptions. Individuals often are affected by these occurrences regardless of the size of the population.

Populations in areas where such events occur relatively frequently display erratic growth patterns in which the populations increase rapidly when conditions are benign, but exhibit large reductions whenever the environment turns hostile (figure 56.22). Needless to say, such populations do not produce the sigmoidal growth curves characteristic of the logistic equation.

## Population cycles may reflect complex interactions

In some populations, density-dependent effects lead not to an equilibrium population size but to cyclic patterns of increase and decrease. For example, ecologists have studied cycles in hare

**Figure 56.22** Fluctuations in the number of pupae of four moth species in Germany. The population fluctuations suggest that density-independent factors are regulating population size. The concordance in trends through time suggests that the same factors are regulating population size in all four species.

populations since the 1820s. They have found that the North American snowshoe hare (*Lepus americanus*) follows a “10-year cycle” (in reality, the cycle varies from 8 to 11 years). Hare population numbers fall 10-fold to 30-fold in a typical cycle, and 100-fold changes can occur (figure 56.23). Two factors appear to be generating the cycle: food plants and predators.

**Food plants.** The preferred foods of snowshoe hares are willow and birch twigs. As hare density increases, the quantity of these twigs decreases, forcing the hares to feed on high-fiber (low-quality) food. Lower birthrates, low juvenile survivorship, and low growth rates follow. The hares also spend more time searching for food, an activity that increases their exposure to predation. The result is a precipitous decline in willow and birch twig abundance, and a corresponding fall in hare abundance. It takes 2 to 3 years for the quantity of mature twigs to recover.

**Predators.** A key predator of the snowshoe hare is the Canada lynx. The Canada lynx shows a “10-year” cycle of abundance that seems remarkably entrained to the hare abundance cycle (see figure 55.23). As hare numbers increase, lynx numbers do too, rising in response to the increased availability of the lynx’s food. When hare numbers fall, so do lynx numbers, their food supply depleted.

Which factor is responsible for the predator–prey oscillations? Do increasing numbers of hares lead to overharvesting of plants (a hare–plant cycle), or do increasing numbers of lynx lead to overharvesting of hares (a hare–lynx cycle)? Field experiments carried out by Charles Krebs and coworkers in 1992 provide an answer.

**Figure 56.23** Linked population cycles of the snowshoe hare (*Lepus americanus*) and the northern lynx (*Lynx canadensis*). These data are based on records of fur returns from trappers in the Hudson Bay region of Canada. The lynx population carefully tracks that of the snowshoe hare, but lags behind it slightly.

### Inquiry question

Suppose experimenters artificially kept the hare population at a high and constant level; what would happen to the lynx population? Conversely, if experimenters artificially kept the lynx population at a high and constant level, what would happen to the hare population?

In Canada’s Yukon, Krebs set up experimental plots that contained hare populations. If food is added (no food shortage effect) and predators are excluded (no predator effect) in an experimental area, hare numbers increase 10-fold and stay there—the cycle is lost. However, the cycle is retained if either of the factors is allowed to operate alone: exclude predators but don’t add food (food shortage effect alone), or add food in the presence of predators (predator effect alone). Thus, both factors can affect the cycle, which in practice seems to be generated by the interaction between the two.

Population cycles traditionally have been considered to occur rarely. However, a recent review of nearly 700 long-term (25 years or more) studies of trends within populations found that cycles were not uncommon; nearly 30% of the studies—including birds, mammals, fish, and crustaceans—provided evidence of some cyclic pattern in population size through time, although most of these cycles are nowhere near as dramatic in amplitude as the hare–lynx cycles. In some cases, such as that of the snowshoe hare and lynx, density-dependent factors may be involved, whereas in other cases, density-independent factors, such as cyclic climatic patterns, may be responsible.

## Resource availability affects life history adaptations

As you have seen, some species usually maintain stable population sizes near the carrying capacity, whereas in other species population sizes fluctuate markedly and are often far below carrying capacity. The selective factors affecting such species differ markedly. Individuals in populations near their carrying capacity may face stiff competition for limited resources; by contrast, individuals in populations far below carrying capacity have access to abundant resources.

We have already described the consequences of such differences. When resources are limited, the cost of reproduction often will be very high. Consequently, selection will favor individuals that can compete effectively and utilize resources efficiently. Such adaptations often come at the cost of lowered reproductive rates. Such populations are termed **K-selected** because they are adapted to thrive when the population is near its carrying capacity ( $K$ ). Table 56.3 lists some of the typical features of  $K$ -selected populations. Examples of  $K$ -selected species include coconut palms, whooping cranes, whales, and humans.

By contrast, in populations far below the carrying capacity, resources may be abundant. Costs of reproduction are low, and selection favors those individuals that can produce the maximum number of offspring. Selection here favors individuals with the highest reproductive rates; such populations are termed **r-selected**. Examples of organisms displaying  $r$ -selected life history adaptations include dandelions, aphids, mice, and cockroaches.

Most natural populations show life history adaptations that exist along a continuum ranging from completely  $r$ -selected traits to completely  $K$ -selected traits. Although these tendencies hold true as generalities, few populations are purely  $r$ - or  $K$ -selected and show all of the traits listed in table 56.3. These attributes should be treated as generalities, with the recognition that many exceptions exist.

**TABLE 56.3*****r*-Selected and *K*-Selected Life History Adaptations**

Adaptation	<i>r</i> -Selected Populations	<i>K</i> -Selected Populations
Age at first reproduction	Early	Late
Life span	Short	Long
Maturation time	Short	Long
Mortality rate	Often high	Usually low
Number of offspring produced per reproductive episode	Many	Few
Number of reproductions per lifetime	Few	Many
Parental care	None	Often extensive
Size of offspring or eggs	Small	Large

**Learning Outcomes Review 56.6**

Density-dependent factors such as resource availability come into play particularly when population size is larger; density-independent factors such as natural disasters operate regardless of population size. Population density may be cyclic due to complex interactions such as resource cycles and predator effects. Populations with density-dependent regulation often are near their carrying capacity; in species with populations well below carrying capacity, natural selection may favor high rates of reproduction when resources are abundant.

- Can a population experience both positive and negative density-dependent effects?

**56.7 Human Population Growth****Learning Outcomes**

1. Explain how the rate of human population growth has changed through time.
2. Describe the effects of age distribution on future growth.
3. Evaluate the relative importance of rapid population growth and resource consumption as threats to the biosphere and human welfare.

Humans exhibit many *K*-selected life history traits, including small brood size, late reproduction, and a high degree of parental care. These life history traits evolved during the early history of hominids, when the limited resources available from the environment controlled population size. Throughout most of

human history, our populations have been regulated by food availability, disease, and predators. Although unusual disturbances, including floods, plagues, and droughts, no doubt affected the pattern of human population growth, the overall size of the human population grew slowly during our early history.

Two thousand years ago, perhaps 130 million people populated the Earth. It took a thousand years for that number to double, and it was 1650 before it had doubled again, to about 500 million. In other words, for over 16 centuries, the human population was characterized by very slow growth. In this respect, human populations resembled many other species with predominantly *K*-selected life history adaptations.

**Human populations have grown exponentially**

Starting in the early 1700s, changes in technology gave humans more control over their food supply, enabled them to develop superior weapons to ward off predators, and led to the development of cures for many diseases. At the same time, improvements in shelter and storage capabilities made humans less vulnerable to climatic uncertainties. These changes allowed humans to expand the carrying capacity of the habitats in which they lived and thus to escape the confines of logistic growth and re-enter the exponential phase of the sigmoidal growth curve.

Responding to the lack of environmental constraints, the human population has grown explosively over the last 300 years. Although the birth rate has remained unchanged at about 30 per 1000 per year over this period, the death rate has fallen dramatically, from 20 per 1000 per year to its present level of 13 per 1000 per year. The difference between birth and death rates meant that the population grew as much as 2% per year, although the rate has now declined to 1.2% per year.

A 1.2% annual growth rate may not seem large, but it has produced a current human population of nearly 7 billion people (figure 56.24). At this growth rate, 78 million people would be added to the world population in the next year, and the human population would double in 58 years. Both the current human population level and the projected growth rate have potentially grave consequences for our future.

**Population pyramids show birth and death trends**

Although the human population as a whole continues to grow rapidly at the beginning of the 21st century, this growth is not occurring uniformly over the planet. Rather, most of the population growth is occurring in Africa, Asia, and Latin America (figure 56.25). By contrast, populations are actually decreasing in some countries in Europe.

The rate at which a population can be expected to grow in the future can be assessed graphically by means of a **population pyramid**, a bar graph displaying the numbers of people in each age category (figure 56.26). Males are conventionally shown to the left of the vertical age axis, females to the right. A human population pyramid thus displays the age composition of a population by sex. In most human population pyramids, the number of older females is disproportionately large compared with the

**Figure 56.24** History of human population size.

Temporary increases in death rate, even a severe one such as that occurring during the Black Death of the 1300s, have little lasting effect. Explosive growth began with the Industrial Revolution in the 1800s, which produced a significant, long-term lowering of the death rate. The current world population is 6.9 billion, and at the present rate, it will double in 58 years.

**Inquiry question**

? Based on what we have learned about population growth, what do you predict will happen to human population size?

**Figure 56.25** Projected population growth in 2050.

Developed countries are predicted to grow little; almost all of the population increase will occur in less-developed countries.

number of older males, because females in most regions have a longer life expectancy than males.

Viewing such a pyramid, we can predict demographic trends in births and deaths. In general, a rectangular pyramid is characteristic of countries whose populations are stable, neither growing nor shrinking. A triangular pyramid is characteristic of a country that will exhibit rapid future growth because most of

**Figure 56.26** Population pyramids from 2008.

Population pyramids are graphed according to a population's age distribution. Kenya's pyramid has a broad base because of the great number of individuals below childbearing age. When the young people begin to bear children, the population will experience rapid growth. The Swedish pyramid exhibits a slight bulge among middle-aged Swedes, the result of the "baby boom" that occurred in the middle of the 20th century, and many postreproductive individuals resulting from Sweden's long average life span.

**Inquiry question**

? What will the population distributions look like in 20 years?

its population has not yet entered the childbearing years. Inverted triangles are characteristic of populations that are shrinking, usually as a result of sharply declining birth rates.

Examples of population pyramids for Sweden and Kenya in 2008 are shown in figure 56.26. The two countries exhibit very different age distributions. The nearly rectangular population pyramid for Sweden indicates that its population is not expanding because birth rates have decreased and average life span has increased. The very triangular pyramid of Kenya, by contrast, results from relatively high birth rates and shorter average life spans, which can lead to explosive future growth. The difference is most apparent when we consider that only 16% of Sweden's population is less than 15 years old, compared with nearly half of all Kenyans. Moreover, the fertility rate (offspring per woman) in Sweden is 1.7; in Kenya, it is 4.7. As a result, Kenya's population could double in less than 35 years, whereas Sweden's will remain stable.

### Humanity's future growth is uncertain

Earth's rapidly growing human population constitutes perhaps the greatest challenge to the future of the biosphere, the world's interacting community of living things. Humanity is adding 78 million people a year to its population—over a million every 5 days, 150 every minute! In more rapidly growing countries, the resulting population increase is staggering (table 56.4). India, for example, had a population of 1.05 billion in 2002; by 2050, its population likely will exceed 1.6 billion.

A key element in the world's population growth is its uneven distribution among countries. Of the billion people added to the world's population in the 1990s, 90% live in developing countries (figure 56.27). The fraction of the world's population that lives in industrialized countries is therefore diminishing. In 1950, fully one-third of the world's population lived in industrialized countries; by 1996, that proportion had fallen to one-quarter; and in 2020, the proportion will have fallen to one-sixth.

**Figure 56.27 Distribution of population growth.** Most of the worldwide increase in population since 1950 has occurred in developing countries. The age structures of developing countries indicate that this trend will increase in the near future. World population in 2050 likely will be between 7.3 and 10.7 billion, according to a recent United Nations study. Depending on fertility rates, the population at that time will either be increasing rapidly or slightly, or in the best case, declining slightly.

In the future, the world's population growth will be centered in the parts of the world least equipped to deal with the pressures of rapid growth.

Rapid population growth in developing countries has had the harsh consequence of increasing the gap between rich and poor. Today, the 19% of the world's population that lives in the industrialized world have a per capita income of \$22,060, but 81% of the world's population lives in developing countries and has a per capita income of only \$3,580. Furthermore, of the

TABLE 56.4	A Comparison of 2005 Population Data in Developed and Developing Countries		
	United States (highly developed)	Brazil (moderately developed)	Ethiopia (poorly developed)
Fertility rate	2.1	1.9	5.3
Doubling time at current rate (years)	75	65	29
Infant mortality rate (per 1000 births)	6.5	30	95
Life expectancy at birth (years)	78	72	49
Per capita GDP (U.S. \$)*	\$40,100	\$8100	\$800
Population < 15 years old (%)	21	26	44

\*GDP, gross domestic product.

people in the developing world, about one-quarter of the population gets by on \$1 per day. Eighty percent of all the energy used today is consumed by the industrialized world, but only 20% is used by developing countries.

No one knows whether the world can sustain today's population of 6.9 billion people, much less the far greater numbers expected in the future. As chapter 58 outlines, the world ecosystem is already under considerable stress. We cannot reasonably expect to expand its carrying capacity indefinitely, and indeed we already seem to be stretching the limits.

Despite using an estimated 45% of the total biological productivity of Earth's landmasses and more than one-half of all renewable sources of fresh water, between one-fourth and one-eighth of all people in the world are malnourished. Moreover, as anticipated by Thomas Malthus in his famous 1798 work, *Essay on the Principle of Population*, death rates are beginning to rise in some areas. In sub-Saharan Africa, for example, population projections for the year 2025 have been scaled back from 1.33 billion to 1.05 billion (21%) because of the effect of AIDS. Similar decreases are projected for Russia as a result of higher death rates due to disease.

If we are to avoid catastrophic increases in the death rate, birth rates must fall dramatically. Faced with this grim dichotomy, significant efforts are underway worldwide to lower birth rates.

## The population growth rate has declined

The world population growth rate is declining, from a high of 2.0% in the period 1965–1970 to 1.2% in 2008. Nonetheless, because of the larger population, this amounts to an increase of 78 million people per year to the world population, compared with 53 million per year in the 1960s.

The United Nations attributes the growth rate decline to increased family planning efforts and the increased economic power and social status of women. The United States has led the world in funding family planning programs abroad, but some groups oppose spending money on international family planning. The opposition believes that money is better spent on improving education and the economy in other countries, leading to an increased awareness and lowered fertility rates. The U.N. certainly supports the improvement of education programs in developing countries, but interestingly, it has reported increased education levels *following* a decrease in family size as a result of family planning.

Most countries are devoting considerable attention to slowing the growth rate of their populations, and there are genuine signs of progress. For example, from 1984 to 2008, family planning programs in Kenya succeeded in reducing the fertility rate from 8.0 to 4.7 children per couple, thus lowering the population growth rate from 4.0% per year to 2.8% per year. Because of these efforts, the global population may stabilize at about 8.9 billion people by the middle of the current century. How many people the planet can support sustainably depends on the quality of life that we want to achieve; there are already more people than can be sustainably supported with current technologies.

## Consumption in the developed world further depletes resources

Population size is not the only factor that determines resource use; per capita consumption is also important. In this respect, we in the industrialized world need to pay more attention to lessening the impact each of us makes because, even though the vast majority of the world's population is in developing countries, the overwhelming percentage of consumption of resources occurs in the industrialized countries. Indeed, the wealthiest 20% of the world's population accounts for 86% of the world's consumption of resources and produces 53% of the world's carbon dioxide emissions, whereas the poorest 20% of the world is responsible for only 1.3% of consumption and 3% of carbon dioxide emissions. Looked at another way, in terms of resource use, a child born today in the industrialized world will consume many more resources over the course of his or her life than a child born in the developing world.

One way of quantifying this disparity is by calculating what has been termed the **ecological footprint**, which is the amount of productive land required to support an individual at the standard of living of a particular population through the course of his or her life. This figure estimates the acreage used for the production of food (both plant and animal), forest products, and housing, as well as the area of forest required to absorb carbon dioxide produced by the combustion of fossil fuels. As figure 56.28 illustrates, the

**Figure 56.28 Ecological footprints of individuals in different countries.** An ecological footprint calculates how much land is required to support a person through his or her life, including the acreage used for production of food, forest products, and housing, in addition to the forest required to absorb the carbon dioxide produced by the combustion of fossil fuels.

### Inquiry question

Which is a more important cause of resource depletion, overpopulation or overconsumption?

ecological footprint of an individual in the United States is more than 10 times greater than that of someone in India.

Based on these measurements, researchers have calculated that resource use by humans is now one-third greater than the amount that nature can sustainably replace. Moreover, consumption is increasing rapidly in parts of the developing world; if all humans lived at the standard of living in the industrialized world, two additional planet Earths would be needed.

Building a sustainable world is the most important task facing humanity's future. The quality of life available to our children will depend to a large extent on our success in limiting both population growth and the amount of per capita resource consumption.

### Learning Outcomes Review 56.7

For most of its history, the *K*-selected human population increased gradually. In the last 400 years, with resource control, the human population has grown exponentially; at the current rate, it would double in 58 years. A population pyramid shows the number of individuals in different age categories. Pyramids with a wide base are undergoing faster growth than those that are uniform from top to bottom. Growth rates overall are declining, but consumption per capita in the developed world is still a significant drain on resources.

- Which is more important, reducing global population growth or reducing resource consumption levels in developed countries?

## Chapter Review

### 56.1 The Environmental Challenges

Key environmental factors include temperature, water, sunlight, and soil type. Individuals seek to maintain internal homeostasis.

**Organisms are capable of responding to environmental changes that occur during their lifetime.**

Most individuals can cope with variations in their natural habitat, such as short-term changes in temperature and water availability.

**Natural selection leads to evolutionary adaptation to environmental conditions.**

Over evolutionary time, physiological, morphological, or behavioral adaptations evolve that make organisms better suited to the environment in which they live.

### 56.2 Populations: Groups of a Single Species in One Place

**A population's geographic distribution is termed its range.**

**Ranges undergo expansion and contraction.**

Most populations have limited geographic ranges that can expand or contract through time as the environment changes.

Dispersal mechanisms may allow some species to cross a barrier and expand their range. Human actions have led to range expansion of some species, often with detrimental effects.

**Individuals in populations exhibit different spacing patterns.**

Within a population, individuals are distributed randomly, uniformly, or are clumped. Nonrandom distributions may reflect resource distributions or competition for resources.

**A metapopulation comprises distinct populations that may exchange members.**

The degree of exchange between populations in a metapopulation is highest when populations are large and more connected.

Metapopulations may act as a buffer against extinction by permitting recolonization of vacant areas or marginal areas.

### 56.3 Population Demography and Dynamics

**Sex ratio and generation time affect population growth rates.**

Abundant females, a short generation time, or both can be responsible for more rapid population growth.

**Age structure is determined by the numbers of individuals in different age groups.**

Every age cohort has a characteristic fecundity and death rate, and so the age structure of a population affects growth.

**Life tables show probability of survival and reproduction through a cohort's life span.**

**Survivorship curves demonstrate how survival probability changes with age (see figures 56.11, 56.12).**

In some populations, survivorship is high until old age, whereas in others, survivorship is lowest among the youngest individuals.

### 56.4 Life History and the Cost of Reproduction

Because resources are limited, reproduction has a cost. Resources allocated toward current reproduction cannot be used to enhance survival and future reproduction (see figure 56.13).

**A trade-off exists between number of offspring and investment per offspring.**

When reproductive cost is high, fitness can be maximized by deferring reproduction, or by producing a few large-sized young that have a greater chance of survival.

**Reproductive events per lifetime represent an additional trade-off.**

Semelparity is reproduction once in a single large event. Iteroparity is production of offspring several times over many seasons.

**Age at first reproduction correlates with life span.**

Longer-lived species delay first reproduction longer compared with short-lived species, in which time is of the essence.

## 56.5 Environmental Limits to Population Growth

**The exponential growth model applies to populations with no growth limits.**

The rate of population increase,  $r$ , is defined as the difference between birth rate,  $b$ , and death rate,  $d$ .

Exponential growth occurs when a population is not limited by resources or by other species (see figure 56.16).

**The logistic model applies to populations that approach their carrying capacity.**

Logistic growth is observed as a population reaches its carrying capacity. Usually, a population's growth rate slows to a plateau. In some cases the population overshoots and then drops back to the carrying capacity.

## 56.6 Factors That Regulate Populations

**Density-dependent effects occur when reproduction and survival are affected by population size.**

Density-dependent factors include increased competition and disease. To stabilize a population size, birth rates must decline, death rates must increase, or both.

**Density-independent effects include environmental disruptions and catastrophes.**

Density-independent factors are not related to population size and include environmental events that result in mortality.

**Population cycles may reflect complex interactions.**

In some cases, population size is cyclic because of the interaction of factors such as food supply and predation (see figure 56.23).

**Resource availability affects life history adaptations.**

Populations at carrying capacity have adaptations to compete for limited resources; populations well below carrying capacity exhibit a high reproductive rate to use abundant resources.

## 56.7 Human Population Growth

**Human populations have grown exponentially.**

Technology and other innovations have simultaneously increased the carrying capacity and decreased mortality in the past 300 years.

**Population pyramids show birth and death trends.**

Populations with many young individuals are likely to experience high growth rates as these individuals reach reproductive age.

**Humanity's future growth is uncertain.**

The human population is unevenly distributed. Rapid growth in developing countries has resulted in poverty, whereas most resources are utilized by the industrialized world.

**The population growth rate has declined.**

Even at lower growth rates, the number of individuals on the planet is likely to plateau at 7 to 10 billion.

**Consumption in the developed world further depletes resources.**

Resource consumption rates in the developed world are very high; a sustainable future requires limits both to population growth and to per capita resource consumption.

## Review Questions

### UNDERSTAND

- Source-sink metapopulations are distinct from other types of metapopulations because
  - exchange of individuals only occurs in the former.
  - populations with negative growth rates are a part of the former.
  - populations never go extinct in the former.
  - all populations eventually go extinct in the former.
- The potential for social interactions among individuals should be maximized when individuals
  - are randomly distributed in their environment.
  - are uniformly distributed in their environment.
  - have a clumped distribution in their environment.
  - None of the above
- When ecologists talk about the cost of reproduction they mean
  - the reduction in future reproductive output as a consequence of current reproduction.
  - the amount of calories it takes for all the activity used in successful reproduction.
  - the amount of calories contained in eggs or offspring.
  - None of the above
- A life history trade-off between clutch size and offspring size
  - means that as clutch size increases, offspring size increases.
  - means that as clutch size increases, offspring size decreases.
  - means that as clutch size increases, adult size increases.
  - means that as clutch size increases, adult size decreases.
- The difference between exponential and logistic growth rates is
  - exponential growth depends on birth and death rates and logistic does not.
  - in logistic growth, emigration and immigration are unimportant.
  - that both are affected by density, but logistic growth is slower.
  - that only logistic growth reflects density-dependent effects on births or deaths.
- The logistic population growth model,  $dN/dt = rN[(K - N)/K]$ , describes a population's growth when an upper limit to growth is assumed. As  $N$  approaches (numerically) the value of  $K$ 
  - $dN/dt$  increases rapidly.
  - $dN/dt$  approaches 0.
  - $dN/dt$  increases slowly.
  - the population becomes threatened by extinction.

7. Which of the following is an example of a density-dependent effect on population growth?
  - a. An extremely cold winter
  - b. A tornado
  - c. An extremely hot summer in which cool burrow retreats are fewer than number of individuals in the population
  - d. A drought

- c. may increase the population size of a prey species if that prey's population was being regulated by predation from the predator.
- d. will lead to an Allee effect.

## APPLY

1. If the size of a population is reduced due to a natural disaster such as a flood
  - a. population growth rates may increase because the population is no longer near its carrying capacity.
  - b. population growth rates may decrease because individuals have trouble finding mates.
  - c. both effects a. and b. may occur and whether population rates increase or decrease cannot be predicted.
  - d. All of the above
2. In populations subjected to high levels of predation
  - a. individuals should invest little in reproduction so as to maximize their survival.
  - b. individuals should produce few offspring and invest little in any of them.
  - c. individuals should invest greatly in reproduction because their chance of surviving to another breeding season is low.
  - d. individuals should stop reproducing altogether.
3. In a population in which individuals are uniformly distributed
  - a. the population is probably well below its carrying capacity.
  - b. natural selection should favor traits that maximize the ability to compete for resources.
  - c. immigration from other populations is probably keeping the population from going extinct.
  - d. None of the above
4. The elimination of predators by humans
  - a. will cause its prey to experience exponential growth until new predators arrive or evolve.
  - b. will lead to an increase in the carrying capacity of the environment.

## SYNTHESIZE

1. Refer to figure 56.8. What are the implications for evolutionary divergence among populations that are part of a metapopulation versus populations that are independent of other populations?
2. Refer to figure 56.13. Given a trade-off between current reproductive effort and future reproductive success (the so-called cost of reproduction), would you expect old individuals to have the same “optimal” reproductive effort as young individuals?
3. Refer to figure 56.14. Because the number of offspring that a parent can produce is often a trade-off with the size of individual offspring, many circumstances lead to an intermediate number and size of offspring being favored. If the size of an offspring was completely unrelated to the quality of that offspring (its chances of surviving until it reaches reproductive age), would you expect parents to fall on the left or right side of the  $x$ -axis (clutch size)? Explain.
4. Refer to figure 56.26. Would increasing the mean generation time have the same kind of effect on population growth rate as reducing the number of children that an individual female has over her lifetime? Which effect would have a bigger influence on population growth rate? Explain.

# Chapter 57

## Community Ecology

### Chapter Outline

- 57.1** Biological Communities: Species Living Together
- 57.2** The Ecological Niche Concept
- 57.3** Predator–Prey Relationships
- 57.4** The Many Types of Species Interactions
- 57.5** Ecological Succession, Disturbance, and Species Richness

### Introduction

All the organisms that live together in a place are members of a community. The myriad of species that inhabit a tropical rain forest are a community. Indeed, every inhabited place on Earth supports its own particular array of organisms. Over time, the different species that live together have made many complex adjustments to community living, evolving together and forging relationships that give the community its character and stability. Both competition and cooperation have played key roles; in this chapter, we look at these and other factors in community ecology.

## Biological Communities: Species Living Together

### Learning Outcomes

1. Define community.
2. Describe how community composition may change across a geographic landscape.

Almost any place on Earth is occupied by species, sometimes by many of them, as in the rain forests of the Amazon, and sometimes by only a few, as in the near-boiling waters of Yellowstone's geysers (where a number of microbial species live). The term **community** refers to the species that occur at any particular locality (figure 57.1). Communities can be characterized either by their constituent species or by their properties, such as **species richness** (the number of species present) or **primary productivity** (the amount of energy produced).

Interactions among community members govern many ecological and evolutionary processes. These interactions, such as predation and mutualism, affect the population biology of particular species—whether a population increases or decreases in abundance, for example—as well as the ways in which energy and nutrients cycle through the ecosystem. Moreover, the community context affects the patterns of natural selection faced by a species, and thus the evolutionary course it takes.

Scientists study biological communities in many ways, ranging from detailed observations to elaborate, large-scale experiments. In some cases, studies focus on the entire community, whereas in other cases only a subset of species that are likely to

interact with one another are studied. Although scientists sometimes refer to such subsets as communities (for example, the “spider community”), the term **assemblage** is more appropriate to connote that the species included are only a portion of those present within the entire community.

### Communities have been viewed in different ways

Two views exist on the structure and functioning of communities. The *individualistic concept* of communities holds that a community is simply an aggregation of species that happen to occur together at one place.

By contrast, the **holistic concept** of communities views communities as an integrated unit. In this sense, the community could be viewed as a superorganism whose constituent species have coevolved to the extent that they function as part of a greater whole, just as the kidneys, heart, and lungs all function together within an animal's body. In this view, then, a community would amount to more than the sum of its parts.

These two views make differing predictions about the integrity of communities across space and time. If, as the individualistic view implies, communities are nothing more than a combination of species that occur together, then moving geographically across the landscape or back through time, we would not expect to see the same community. That is, species should appear and disappear independently, as a function of each species' own unique ecological requirements. By contrast, if a community is an integrated whole, then we would make the opposite prediction: Communities should stay the same through space or time, until being replaced by completely different communities when environmental differences are sufficiently great.

**Figure 57.1 An African savanna community.** A community consists of all the species—plants, animals, fungi, protists, and prokaryotes—that occur at a locality, in this case Etosha National Park in Namibia.

## Communities change over space and time

Most ecologists today favor the individualistic concept. For the most part, species seem to respond independently to changing environmental conditions. As a result, community composition changes gradually across landscapes as some species appear and become more abundant, while others decrease in abundance and eventually disappear.

A famous example of this pattern is the abundance of tree species in the Santa Catalina Mountains of Arizona along a geographic gradient running from very dry to very moist. Figure 57.2 shows that species can change abundance in patterns that are for the most part independent of one another. As a result, tree communities at different localities in these mountains fall on a continuum, one merging into the next, rather than representing discretely different sets of species.

Similar patterns through time are seen in paleontological studies. For example, a very good fossil record exists for the trees and small mammals that occurred in North America over the past 20,000 years. Examination of prehistoric communities shows little similarity to those that occur today. Many species that occur together today were never found together in the past. Conversely, species that used to occur in the same communities often do not overlap in their geographic ranges today. These findings suggest that as climate has changed during the waxing and waning of the Ice Ages, species have responded independently, rather than shifting their distributions together, as would be expected if the community were an integrated unit.

**Figure 57.2** Abundance of tree species along a moisture gradient in the Santa Catalina Mountains of southeastern Arizona. Each line represents the abundance of a different tree species. The species' patterns of abundance are independent of one another. Thus, community composition changes continually along the gradient.

### Inquiry question

? Why do species exhibit different patterns of response to change in moisture?

**Figure 57.3** Change in community composition across an ecotone. The plant assemblages on normal and serpentine soils are greatly different, and the transition from one community to another occurs over a short distance.

### Inquiry question

? Why is there a sharp transition between the two community types?

Nonetheless, in some cases the abundance of species in a community does change geographically in a synchronous pattern. Often, this occurs at **ecotones**, places where the environment changes abruptly. For example, in the western United States, certain patches of habitat have serpentine soils. This soil differs from normal soil in many ways—for example, high concentrations of nickel, chromium, and iron; low concentrations of copper and calcium. Comparison of the plant species that occur on different soils shows that distinct communities exist on each type, with an abrupt transition from one to the other over a short distance (figure 57.3). Similar transitions are seen wherever greatly different habitats come into contact, such as at the interface between terrestrial and aquatic habitats or where grassland and forest meet.

### Learning Outcomes Review 57.1

A community comprises all species that occur at one site. In most cases, the abundance of community members appears to vary independently across space and through time. Community composition also changes gradually depending on environmental factors when moving from one location to another, such as from a very dry area to a very moist area.

- In a community, would you expect greater variation over time in abundance of animal life or plant life? Why?

## 57.2 The Ecological Niche Concept

### Learning Outcomes

1. Define niche and resource partitioning.
2. Differentiate between fundamental and realized niches.
3. Explain how the presence of other species can affect a species' realized niche.

Each organism in a community confronts the challenge of survival in a different way. The **niche** an organism occupies is the total of all the ways it uses the resources of its environment. A niche may be described in terms of space utilization, food consumption, temperature range, appropriate conditions for mating, requirements for moisture, and other factors.

Sometimes species are not able to occupy their entire niche because of the presence or absence of other species. Species can interact with one another in a number of ways, and these interactions can either have positive or negative effects. One type of interaction, **interspecific competition**, occurs when two species attempt to use the same resource and there is not enough of the resource to satisfy both. Physical interactions over access to resources—such as fighting to defend a territory or displacing an individual from a particular location—are referred to as **interference competition**; consuming the same resources is called **exploitative competition**.

### Fundamental niches are potential; realized niches are actual

The entire niche that a species is capable of using, based on its physiological tolerance limits and resource needs, is called the

**fundamental niche**. The actual set of environmental conditions, including the presence or absence of other species, in which the species can establish a stable population is its **realized niche**. Because of interspecific interactions, the realized niche of a species may be considerably smaller than its fundamental niche.

### Competition between species for niche occupancy

In a classic study, Joseph Connell of the University of California, Santa Barbara, investigated competitive interactions between two species of barnacles that grow together on rocks along the coast of Scotland. Of the two species Connell studied, *Chthamalus stellatus* lives in shallower water, where tidal action often exposes it to air, and *Semibalanus balanoides* (called *Balanus balanoides* prior to 1995) lives lower down, where it is rarely exposed to the atmosphere (figure 57.4). In these areas, space is at a premium. In the deeper zone, *S. balanoides* could always outcompete *C. stellatus* by crowding it off the rocks, undercutting it, and replacing it even where it had begun to grow, an example of interference competition.

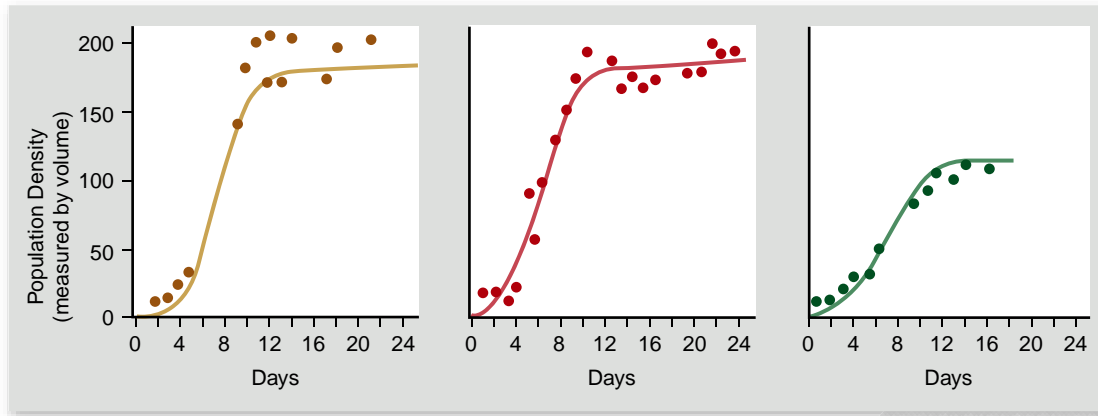

When Connell removed *S. balanoides* from the area, however, *C. stellatus* was easily able to occupy the deeper zone, indicating that no physiological or other general obstacles prevented it from becoming established there. In contrast, *S. balanoides* could not survive in the shallow-water habitats where *C. stellatus* normally occurs; it does not have the physiological adaptations to warmer temperatures that allow *C. stellatus* to occupy this zone. Thus, the fundamental niche of *C. stellatus* includes both shallow and deeper zones, but its realized niche is much narrower because *C. stellatus* can be outcompeted by *S. balanoides* in parts of its fundamental niche. By contrast, the realized and fundamental niches of *S. balanoides* appear to be identical.

### Other causes of niche restriction

Processes other than competition can also restrict the realized niche of a species. For example, the plant St. John's wort (*Hypericum perforatum*) was introduced and became widespread in

**Figure 57.4**  
**Competition among two species of barnacles.** The fundamental niche of *Chthamalus stellatus* includes both deep and shallow zones, but *Semibalanus balanoides* forces *C. stellatus* out of the part of its fundamental niche that overlaps the realized niche of *Semibalanus*.

a.

b.

c.

● *Paramecium caudatum*  
 ● *Paramecium aurelia*  
 ● *Paramecium bursaria*

**Figure 57.5 Competitive exclusion among three species of *Paramecium*.**

In the microscopic world, *Paramecium* is a ferocious predator that preys on smaller protists. **a.** In his experiments, Gause found that three species of *Paramecium* grew well alone in culture tubes. **b.** However, *P. caudatum* declined to extinction when grown with *P. aurelia* because they shared the same realized niche, and *P. aurelia* outcompeted *P. caudatum* for food resources. **c.** *P. caudatum* and *P. bursaria* were able to coexist because the two have different realized niches and thus avoided competition.

open rangeland habitats in California until a specialized beetle was introduced to control it. Population size of the plant quickly decreased, and it is now only found in shady sites where the beetle cannot thrive. In this case, the presence of a predator limits the realized niche of a plant.

In some cases, the absence of another species leads to a smaller realized niche. Many North American plants depend on insects for pollination; indeed, the value of insect pollination for American agriculture has been estimated as more than \$2 billion per year. However, pollinator populations are currently declining for several reasons. Conservationists are concerned that if these insects disappear from some habitats, the realized niche of many plant species will decrease or even disappear entirely. In this case, the absence—rather than the presence—of another species will be the cause of a relatively small realized niche.

### Competitive exclusion can occur when species compete for limited resources

In classic experiments carried out in 1934 and 1935, Russian ecologist Georgii Gause studied competition among three species of *Paramecium*, a tiny protist. Each of the three species grew well in culture tubes by themselves, preying on bacteria and yeasts that fed on oatmeal suspended in the culture fluid (figure 57.5a). However, when Gause grew *P. aurelia* together

with *P. caudatum* in the same culture tube, the numbers of *P. caudatum* always declined to extinction, leaving *P. aurelia* the only survivor (figure 57.5b). Why did this happen? Gause found that *P. aurelia* could grow six times faster than its competitor *P. caudatum* because it was able to better utilize the limited available resources, an example of exploitative competition.

From experiments such as this, Gause formulated what is now called the principle of **competitive exclusion**. This principle states that if two species are competing for a limited resource such as food or water, the species that uses the resource more efficiently will eventually eliminate the other locally. In other words, no two species with the same niche can coexist when resources are limiting.

### Niche overlap and coexistence

In a revealing experiment, Gause challenged *Paramecium caudatum*—the defeated species in his earlier experiments—with a third species, *P. bursaria*. Because he expected these two species to also compete for the limited bacterial food supply, Gause thought one would win out, as had happened in his previous experiments. But that's not what happened. Instead, both species survived in the culture tubes, dividing the food resources.

The explanation for the species' coexistence is simple. In the upper part of the culture tubes, where the oxygen concentration and bacterial density were high, *P. caudatum* dominated because it was better able to feed on bacteria. In the lower part

of the tubes, however, the lower oxygen concentration favored the growth of a different potential food, yeast, and *P. bursaria* was better able to eat this food. The fundamental niche of each species was the whole culture tube, but the realized niche of each species was only a portion of the tube. Because the realized niches of the two species did not overlap too much, both species were able to survive. However, competition did have a negative effect on the participants (figure 57.5c). When grown without a competitor, both species reached densities three times greater than when they were grown with a competitor.

### Competitive exclusion refined

Gause's principle of competitive exclusion can be restated as: No two species can occupy the same niche *indefinitely* when resources are limiting. Certainly species can and do coexist while competing for some of the same resources. Nevertheless, Gause's hypothesis predicts that when two species coexist on a long-term basis, either resources must not be limited or their niches will always differ in one or more features; otherwise, one species will outcompete the other, and the extinction of the second species will inevitably result.

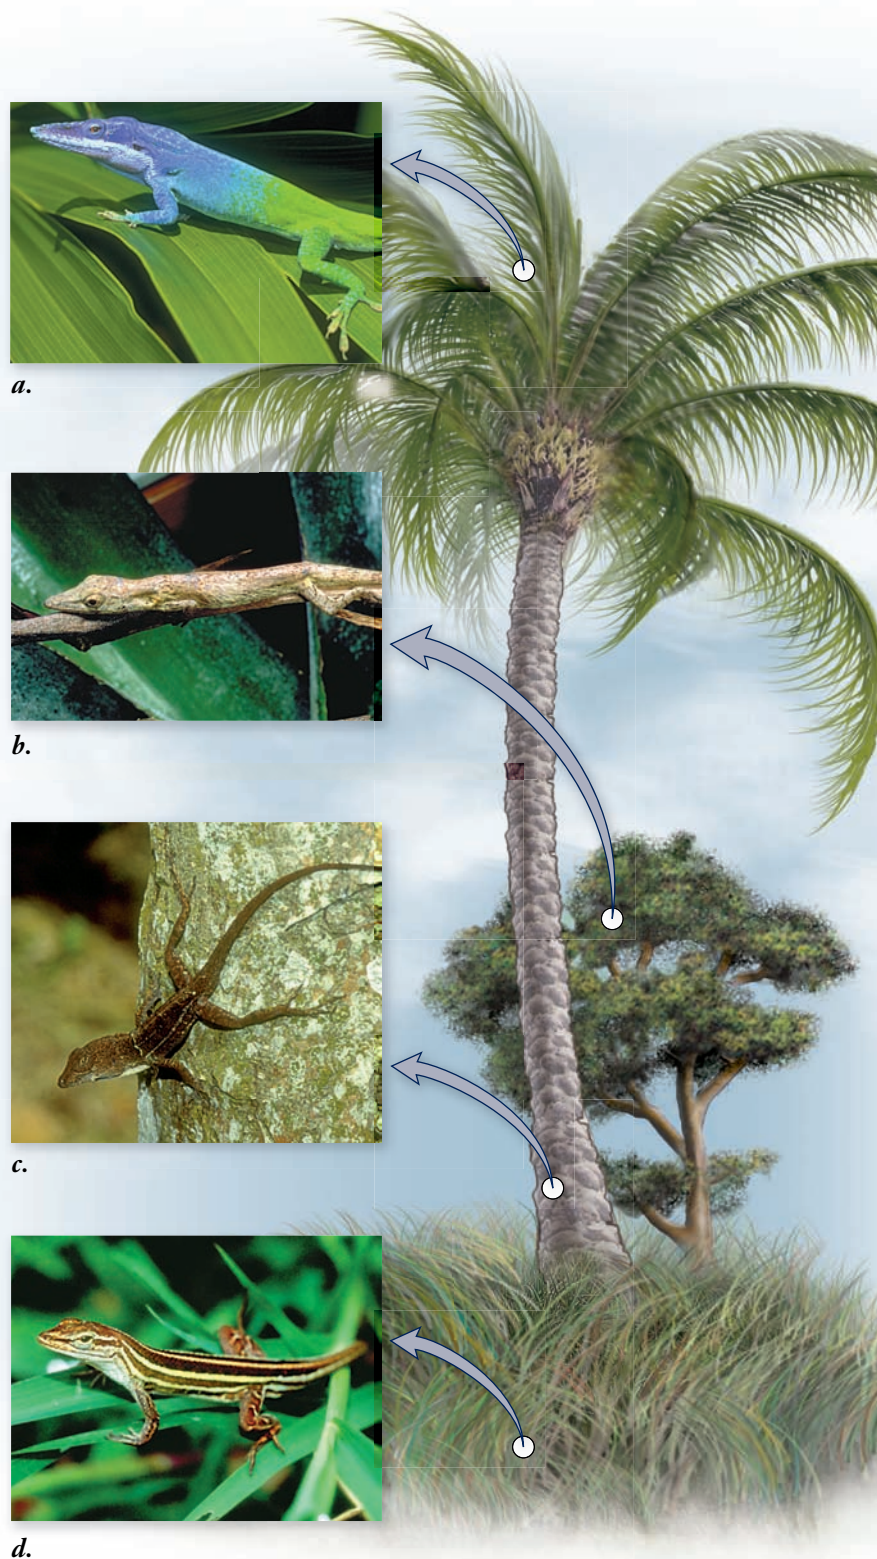

### Competition may lead to resource partitioning

Gause's competitive exclusion principle has a very important consequence: If competition for a limited resource is intense, then either one species will drive the other to extinction, or natural selection will reduce the competition between them.

When the ecologist Robert MacArthur studied five species of warblers, small insect-eating forest songbirds, he discovered that they appeared to be competing for the same resources. But when he studied them more carefully, he found that each species actually fed in a different part of spruce trees and so ate different subsets of insects. One species fed on insects near the tips of branches, a second within the dense foliage, a third on the lower branches, a fourth high on the trees, and a fifth at the very apex of the trees. Thus, each species of warbler had evolved so as to utilize a different portion of the spruce tree resource. They had *subdivided the niche* to avoid direct competition with one another. This niche subdivision is termed **resource partitioning**.

Resource partitioning is often seen in similar species that occupy the same geographic area. Such sympatric species often avoid competition by living in different portions of the habitat or by using different food or other resources (figure 57.6). This pattern of resource partitioning is thought to result from the process of natural selection causing initially similar species to diverge in resource use to reduce competitive pressures.

Whether such evolutionary divergence occurs can be investigated by comparing species whose ranges only partially overlap. Where the two species occur together, they often tend to exhibit greater differences in morphology (the form and structure of an organism) and resource use than do allopatric populations of the same species that do not occur with the other species. Called *character displacement*, the differences evident between sympatric species are thought to have been favored by

**Figure 57.6 Resource partitioning among sympatric lizard species.** Species of *Anolis* lizards on Caribbean islands partition their habitats in a variety of ways. **a.** Some species occupy leaves and branches in the canopy of trees, **(b)** others use twigs on the periphery, and **(c)** still others are found at the base of the trunk. In addition, **(d)** some use grassy areas in the open. When two species occupy the same part of the tree, they either utilize different-sized insects as food or partition the thermal microhabitat; for example, one might only be found in the shade, whereas the other would only bask in the sun.

**Figure 57.7** Character displacement in Darwin's finches. These two species of finches (genus *Geospiza*) have beaks of similar size when allopatric, but different size when sympatric.

natural selection as a means of partitioning resources and thus reducing competition.

As an example, the two Darwin's finches in figure 57.7 have bills of similar size where the finches are allopatric (that is, each living on an island where the other does not occur). On islands where they are sympatric (that is, occur together), the two species have evolved beaks of different sizes, one adapted to larger seeds and the other to smaller ones. Character displacement such as this may play an important role in adaptive radiation, leading new species to adapt to different parts of the environment, as discussed in chapter 22.

## Detecting interspecific competition can be difficult

It is not simple to determine when two species are competing. The fact that two species use the same resources need not imply competition if that resource is not in limited supply. Even if the population sizes of two species are negatively correlated, such that where one species has a large population, the other species has a small population and vice versa, the two species may not be competing for the same limiting resource. Instead, the two species might be independently responding to the same feature of the environment—perhaps one species thrives best in warm conditions and the other where it's cool.

### Experimental studies of competition

Some of the best evidence for the existence of competition comes from experimental field studies. By setting up experiments in which two species occur either alone or together, scientists can determine whether the presence of one species has a negative effect on a population of the second species.

For example, a variety of seed-eating rodents occur in North American deserts. In 1988, researchers set up a series of 50-m × 50-m enclosures to investigate the effect of kangaroo rats on smaller, seed-eating rodents. Kangaroo rats were removed from half of the enclosures, but not from the others. The walls of all of the enclosures had holes that allowed rodents to come and go, but in the plots in which the kangaroo

rats had been removed, the holes were too small to allow the kangaroo rats to reenter.

Over the course of the next 3 years, the researchers monitored the number of the smaller rodents present in the plots. As figure 57.8 illustrates, the number of other rodents was substantially higher in the absence of kangaroo rats, indicating that kangaroo rats compete with the other rodents and limit their population sizes.

A great number of similar experiments have indicated that interspecific competition occurs between many species of plants and animals. The effects of competition can be seen in aspects of population biology other than population size, such

## SCIENTIFIC THINKING

**Question:** Does interspecific interaction occur between rodent species?

**Hypothesis:** The larger kangaroo rat will have a negative effect on other species.

**Experiment:** Build large cages in desert areas. Remove kangaroo rats from some cages, leaving them present in others.

**Result:** In the absence of kangaroo rats, the number of other rodents increases quickly and remains higher than in the control cages throughout the course of the experiment.

**Interpretation:** Why do you think population sizes rise and fall in synchrony in the two cages?

## Figure 57.8 Detecting interspecific competition.

This experiment tested how removal of kangaroo rats affected the population size of other rodents. Immediately after kangaroo rats were removed, the number of other rodents increased relative to the enclosures that still contained kangaroo rats. Notice that population sizes (as estimated by number of captures) changed in synchrony in the two treatments, probably reflecting changes in the weather.

### Inquiry question

Why are there more individuals of other rodent species when kangaroo rats are excluded?

## 57.3 Predator–Prey Relationships

### Learning Outcomes

1. Define predation.
2. Describe the effects predation can have on a population.

as behavior and individual growth rates. For example, two species of *Anolis* lizards occur on the Caribbean island of St. Maarten. When one of the species, *A. gingivinus*, is placed in 12-m × 12-m enclosures without the other species, individual lizards grow faster and perch lower than do lizards of the same species when placed in enclosures in which *A. pogus*, a species normally found near the ground, is also present.

### Limitations of experimental studies

Experimental studies are a powerful means of understanding interactions between coexisting species and are now commonly conducted by ecologists. Nonetheless, they have their limitations.

First, care is necessary in interpreting the results of field experiments. Negative effects of one species on another do not automatically indicate the existence of competition. For example, many similarly sized fish have a negative effect on one another, but it results not from competition, but from the fact that adults of each species prey on juveniles of the other species.

In addition, the presence of one species may attract predators or parasites, which then also prey on the second species. In this case, even if the two species are not competing, the second species may have a lower population size in the presence of the first species due to predators or parasites. Indeed, we can't rule out this possibility with the results of the kangaroo rat exclusion study just mentioned, although the close proximity of the enclosures (they were adjacent) would suggest that the same predators and parasites were present in all of them. Thus, experimental studies are most effective when combined with detailed examination of the ecological mechanisms causing the observed effect of one species on another.

Second, experimental studies are not always feasible. For example, the coyote population has increased in the United States in recent years concurrently with the decline of the grey wolf. Is this trend an indication that the species compete? Because of the size of the animals and the large geographic areas occupied by each individual, manipulative experiments involving fenced areas with only one or both species—with each experimental treatment replicated several times for statistical analysis—are not practical. Similarly, studies of slow-growing trees might require many centuries to detect competition between adult trees. In such cases, detailed studies of the ecological requirements of each species are our best bet for understanding interspecific interactions.

### Learning Outcomes Review 57.2

A niche comprises the total number of ways in which an organism utilizes resources in its environment. A fundamental niche is the entire niche possible to a species; a realized niche is the niche a species actually utilizes. If resources are limiting, two species cannot occupy the same niche indefinitely without competition driving one to local extinction. Resource partitioning allows two sympatric species to occupy a niche, reducing competition between them and also lessening the size of the realized niche.

- Under what circumstances can two species with identical niches coexist indefinitely?

**Predation** is the consuming of one organism by another. In this sense, predation includes everything from a leopard capturing and eating an antelope, to a deer grazing on spring grass.

When experimental populations are set up under simple laboratory conditions, as illustrated in figure 57.9 with the predatory protist *Didinium* and its prey *Paramecium*, the predator often exterminates its prey and then becomes extinct itself, having nothing left to eat. If refuges are provided for the *Paramecium*, however, its population drops to low levels but not to extinction. Low prey population levels then provide inadequate food for the *Didinium*, causing the predator population to decrease. When this occurs, the prey population can recover.

### Predation strongly influences prey populations

In nature, predators often have large effects on prey populations. As the previous example indicates, however, the interaction is a two-way street: prey can also affect the dynamics of predator populations. The outcomes of such interactions are complex and depend on a variety of factors.

**Figure 57.9** Predator–prey in the microscopic world.

When the predatory *Didinium* is added to a *Paramecium* population, the numbers of *Didinium* initially rise, and the numbers of *Paramecium* steadily fall. When the *Paramecium* population is depleted, however, the *Didinium* individuals also die.

### Inquiry question

Can you think of any ways this experiment could be changed so that *Paramecium* might not go extinct?

### Prey population explosions and crashes

Some of the most dramatic examples of the interconnection between predators and their prey involve situations in which humans have either added or eliminated predators from an area. For example, the elimination of large carnivores from much of the eastern United States has led to population explosions of white-tailed deer, which strip the habitat of all edible plant life within their reach. Similarly, when sea otters were hunted to near extinction on the western coast of the United States, populations of sea urchins, a principal prey item of the otters, exploded.

Conversely, the introduction of rats, dogs, and cats to many islands around the world has led to the decimation of native fauna. Populations of Galápagos tortoises on several islands are endangered by introduced rats, pigs, dogs, and cats, which eat the eggs and the young tortoises. Similarly, in New Zealand, several species of birds and reptiles have been eradicated by rat predation and now only occur on a few offshore islands that the rats have not reached. On Stephens Island, near New Zealand, every individual of the now-extinct Stephens Island wren was killed by a single lighthouse keeper's cat.

A classic example of the role predation can play in a community involves the introduction of prickly pear cactus to Australia in the 19th century. In the absence of predators, the cactus spread rapidly, so that by 1925 it occupied 12 million hectares of rangeland in an impenetrable morass of spines that made cattle ranching difficult. To control the cactus, a predator from its natural habitat in Argentina, the moth *Cactoblastis cactorum*, was introduced, beginning in 1926. By 1940, cactus populations had been greatly reduced and it now usually occurs in small populations.

### Predation and coevolution

Predation provides strong selective pressures on prey populations. Any feature that would decrease the probability of capture should be strongly favored. In turn, the evolution of such features causes natural selection to favor counteradaptations in predator populations. The process by which these adaptations are selected in lockstep fashion in two or more interacting species is termed **coevolution**. A coevolutionary “arms race” may ensue in which predators and prey are constantly evolving better defenses and better means of circumventing these defenses. In the sections that follow, you'll learn more about these defenses and responses.

### Plant adaptations defend against herbivores

Plants have evolved many mechanisms to defend themselves from herbivores. The most obvious are morphological defenses: Thorns, spines, and prickles play an important role in discouraging large plant eaters, and plant hairs, especially those that have a glandular, sticky tip, deter insect herbivores. Some plants, such as grasses, deposit silica in their leaves, both strengthening and protecting themselves. If enough silica is present, these plants are simply too tough to eat.

### Chemical defenses

As significant as morphological adaptations are, the chemical defenses that occur so widely in plants are even more widespread. Plants exhibit some amazing chemical adaptations to combat herbivores. For example, recent work demonstrates

that when attacked by caterpillars, wild tobacco plants emit a chemical into the air that attracts a species of bug that feeds on that caterpillar (discussed in greater detail in chapter 40).

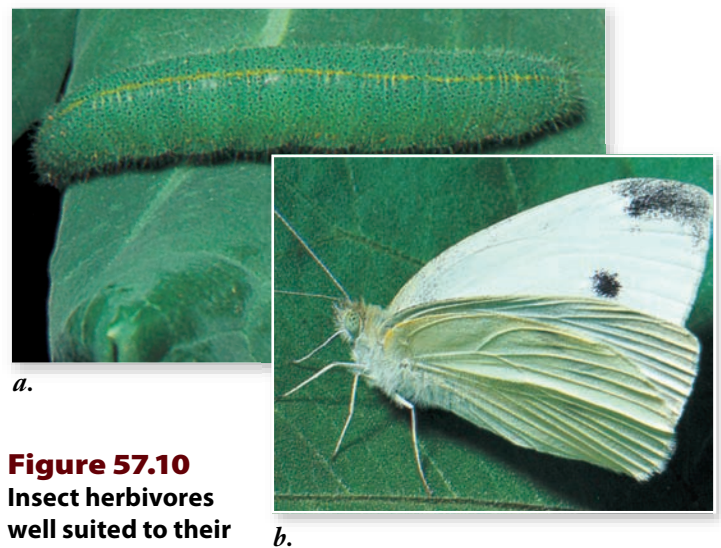

The best known and perhaps most important of the chemical defenses of plants against herbivores are *secondary chemical compounds*. These chemicals are distinguished from primary compounds, which are the components of a major metabolic pathway, such as respiration. Many plants, and apparently many algae as well, contain structurally diverse secondary compounds that are either toxic to most herbivores or disturb their metabolism greatly, preventing, for example, the normal development of larval insects. Consequently, most herbivores tend to avoid the plants that possess these compounds.

The mustard family (Brassicaceae) produces a group of chemicals known as mustard oils. These substances give the pungent aromas and tastes to plants such as mustard, cabbage, watercress, radish, and horseradish. The flavors we enjoy indicate the presence of chemicals that are toxic to many groups of insects. Similarly, plants of the milkweed family (Asclepiadaceae) and the related dogbane family (Apocynaceae) produce a milky sap that deters herbivores from eating them. In addition, these plants usually contain cardiac glycosides, molecules that can produce drastic deleterious effects on the heart function of vertebrates.

### The coevolutionary response of herbivores

Certain groups of herbivores are associated with each family or group of plants protected by a particular kind of secondary compound. These herbivores are able to feed on these plants without harm, often as their exclusive food source.

For example, cabbage butterfly caterpillars (subfamily Pierinae) feed almost exclusively on plants of the mustard and caper families, as well as on a few other small families of plants that also contain mustard oils (figure 57.10). Similarly, caterpillars of

**Figure 57.10**  
**Insect herbivores well suited to their plant hosts.** *a.* The

green caterpillars of the cabbage white butterfly (*Pieris rapae*) are camouflaged on the leaves of cabbage and other plants on which they feed. Although mustard oils protect these plants against most herbivores, the cabbage white butterfly caterpillars are able to break down the mustard oil compounds. *b.* An adult cabbage white butterfly.

monarch butterflies and their relatives (subfamily Danainae) feed on plants of the milkweed and dogbane families. How do these animals manage to avoid the chemical defenses of the plants, and what are the evolutionary precursors and ecological consequences of such patterns of specialization?

We can offer a potential explanation for the evolution of these particular patterns. Once the ability to manufacture mustard oils evolved in the ancestors of the caper and mustard families, the plants were protected for a time against most or all herbivores that were feeding on other plants in their area. At some point, certain groups of insects—for example, the cabbage butterflies—evolved the ability to break down mustard oils and thus feed on these plants without harming themselves. Having developed this new capability, the butterflies were able to use a new resource without competing with other herbivores for it. As we saw in chapter 22, exposure to an underutilized resource often leads to evolutionary diversification and adaptive radiation.

### Animal adaptations defend against predators

Some animals that feed on plants rich in secondary compounds receive an extra benefit. For example, when the caterpillars of monarch butterflies feed on plants of the milkweed family, they do not break down the cardiac glycosides that protect these plants from herbivores. Instead, the caterpillars concentrate and store the cardiac glycosides in fat bodies; they then pass them through the chrysalis stage to the adult and even to the eggs of the next generation.

The incorporation of cardiac glycosides protects all stages of the monarch life cycle from predators. A bird that eats a monarch butterfly quickly regurgitates it (figure 57.11) and in the future avoids the conspicuous orange-and-black pattern that characterizes the adult monarch. Some bird species have

**Figure 57.11 A blue jay learns not to eat monarch butterflies.** *a.* This cage-reared jay had never seen a monarch butterfly before it tried eating one. *b.* The same jay regurgitated the butterfly a few minutes later. This bird will probably avoid trying to capture all orange-and-black insects in the future.

**Figure 57.12 Vertebrate chemical defenses.** Frogs of the family Dendrobatidae, abundant in the forests of Central and South America, are extremely poisonous to vertebrates; 80 different toxic alkaloids have been identified from different species in this genus. Dendrobatids advertise their toxicity with bright coloration. As a result of either instinct or learning, predators avoid such brightly colored species that might otherwise be suitable prey.

evolved the ability to tolerate the protective chemicals; these birds eat the monarchs.

### Chemical defenses

Animals also manufacture and use a startling array of defensive substances. Bees, wasps, predatory bugs, scorpions, spiders, and many other arthropods use chemicals to defend themselves and to kill their own prey. In addition, various chemical defenses have evolved among many marine invertebrates, as well as a variety of vertebrates, including frogs, snakes, lizards, fishes, and some birds.

The poison-dart frogs of the family Dendrobatidae produce toxic alkaloids in the mucus that covers their brightly colored skin; these alkaloids are distasteful and sometimes deadly to animals that try to eat the frogs (figure 57.12). Some of these toxins are so powerful that a few micrograms will kill a person if injected into the bloodstream. More than 200 different alkaloids have been isolated from these frogs, and some are playing important roles in neuromuscular research. Similarly intensive investigations of marine animals, venomous reptiles, algae, and flowering plants are underway in search of new drugs to fight cancer and other diseases, or to use as sources of antibiotics.

### Defensive coloration

Many insects that feed on milkweed plants are brightly colored; they advertise their poisonous nature using an ecological strategy known as warning coloration.

Showy coloration is characteristic of animals that use poisons and stings to repel predators; organisms that lack specific chemical defenses are seldom brightly colored. In fact, many have cryptic coloration—color that blends with the surroundings and thus hides the individual from predators (figure 57.13). Camouflaged animals usually do not live together in groups because a predator that discovers one individual gains a valuable clue to the presence of others.

**Figure 57.13** **Cryptic coloration and form.** An inchworm caterpillar (*Nacophora quernaria*) closely resembles the twig on which it is hanging.

### Mimicry allows one species to capitalize on defensive strategies of another

During the course of their evolution, many species have come to resemble distasteful ones that exhibit warning coloration. The mimic gains an advantage by looking like the distasteful model. Two types of mimicry have been identified: Batesian mimicry and Müllerian mimicry.

#### Batesian mimicry

**Batesian mimicry** is named for Henry Bates, the British naturalist who first brought this type of mimicry to general attention in 1857. In his journeys to the Amazon region of South America, Bates discovered many instances of palatable insects that resembled brightly colored, distasteful species. He reasoned that the mimics would be avoided by predators, who would be fooled by the disguise into thinking the mimic was the distasteful species.

Many of the best-known examples of Batesian mimicry occur among butterflies and moths. Predators of these insects must use visual cues to hunt for their prey; otherwise, similar color patterns would not matter to potential predators. Increasing evidence indicates that Batesian mimicry can involve non-visual cues, such as olfaction, although such examples are less obvious to humans.

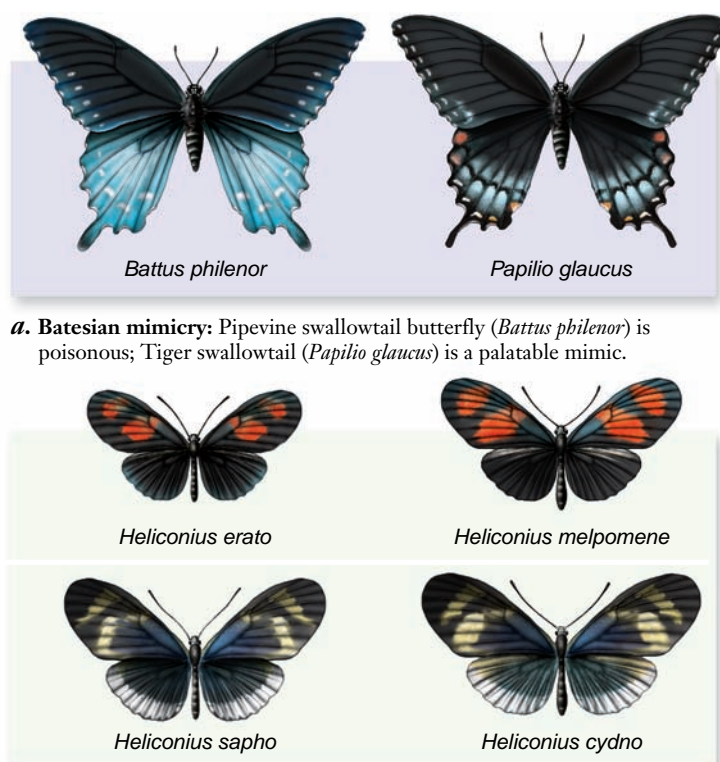

The kinds of butterflies that provide the models in Batesian mimicry are, not surprisingly, members of groups whose caterpillars feed on only one or a few closely related plant families. The plant families on which they feed are strongly protected by toxic chemicals. The model butterflies incorporate the poisonous molecules from these plants into their bodies. The mimic butterflies, in contrast, belong to groups in which the feeding habits of the caterpillars are not so restricted. As caterpillars, these butterflies feed on a number of different plant families that are unprotected by toxic chemicals.

One often-studied mimic among North American butterflies is the tiger swallowtail, whose range occurs throughout the eastern United States and into Canada (figure 57.14a). In areas in which the poisonous pipevine swallowtail occurs, female tiger swallowtails are polymorphic and one color form is extremely similar in appearance to the pipevine swallowtail.

The caterpillars of the tiger swallowtail feed on a variety of trees, including tulip, aspen, and cherry, and neither caterpillars nor adults are distasteful to birds. Interestingly, the Batesian mimicry seen in the adult tiger swallowtail butterfly does not extend to the caterpillars: Tiger swallowtail caterpillars are camouflaged on leaves, resembling bird droppings, but the pipevine swallowtail's distasteful caterpillars are very conspicuous.

#### Müllerian mimicry

Another kind of mimicry, **Müllerian mimicry**, was named for the German biologist Fritz Müller, who first described it in 1878. In Müllerian mimicry, several unrelated but protected animal species come to resemble one another (figure 57.14b). If animals that resemble one another are all poisonous or dangerous, they gain an advantage because a predator will learn more quickly to avoid them. In some cases, predator populations even evolve an innate avoidance of species; such evolution may occur more quickly when multiple dangerous prey look alike.

**a. Batesian mimicry:** Pipevine swallowtail butterfly (*Battus philenor*) is poisonous; Tiger swallowtail (*Papilio glaucus*) is a palatable mimic.

**b. Müllerian mimicry:** Two pairs of mimics; all are distasteful.

**Figure 57.14** **Mimicry.** **a.** Batesian mimicry. Pipevine swallowtail butterflies (*Battus philenor*) are protected from birds and other predators by the poisonous compounds they derive from the food they eat as caterpillars and store in their bodies. Adult pipevine swallowtails advertise their poisonous nature with warning coloration. Tiger swallowtails (*Papilio glaucus*) are Batesian mimics of the poisonous pipevine swallowtail and are not chemically protected. **b.** Pairs of Müllerian mimics. *Heliconius erato* and *H. melpomene* are sympatric, and *H. sapho* and *H. cydno* are sympatric. All of these butterflies are distasteful. They have evolved similar coloration patterns in sympatry to minimize predation; predators need only learn one pattern to avoid.

In both Batesian and Müllerian mimicry, mimic and model must not only look alike but also act alike. For example, the members of several families of insects that closely resemble wasps behave surprisingly like the wasps they mimic, flying often and actively from place to place.

### Learnings Outcomes Review 57.3

Predation is the consuming of one organism by another. High predation can drive prey populations to extinction; conversely, in the absence of predators, prey populations often explode and exhaust their resources. Defensive adaptations may evolve in prey species, such as becoming distasteful or poisonous, or having defensive structures, appearance, or capabilities.

- A nonpoisonous scarlet king snake has red, black, and yellow bands of color similar to that of the poisonous eastern coral snake. What type of mimicry is being exhibited?

## 57.4 The Many Types of Species Interactions

### Learning Outcomes

1. Explain the different forms of symbiosis.
2. Describe how coevolution occurs between mutualistic partners.
3. Explain how the occurrence of one ecological process may affect the outcome of another occurring at the same time.

The plants, animals, protists, fungi, and prokaryotes that live together in communities have changed and adjusted to one another continually over millions of years. We have already discussed competition and predation, but other types of ecological interactions commonly occur. For example, many features of flowering plants have evolved in relation to the dispersal of the plant's gametes by animals (figure 57.15). These animals, in turn, have evolved a number of special traits that enable them to obtain food or other resources efficiently from the plants they visit, often from their flowers. While doing so, the animals pick up pollen, which they may deposit on the next plant they visit, or seeds, which may be left elsewhere in the environment, sometimes a great distance from the parent plant.

### Symbiosis involves long-term interactions

In symbiosis, two or more kinds of organisms interact in often elaborate and more-or-less permanent relationships. All symbiotic relationships carry the potential for coevolution between the organisms involved, and in many instances the results of this coevolution are fascinatingly complex.

Examples of symbiosis include lichens, which are associations of certain fungi with green algae or cyanobacteria. Another important example are mycorrhizae, associations between fungi and the roots of most kinds of plants. The fungi expedite the plant's absorption of certain nutrients, and the plants in

**Figure 57.15** Pollination by a bat. Many flowers have coevolved with other species to facilitate pollen transfer. Insects are widely known as pollinators, but they're not the only ones: birds, bats, and even small marsupials and lizards serve as pollinators for some species. Notice the cargo of pollen on the bat's snout.

turn provide the fungi with carbohydrates (both mycorrhizae and lichens are discussed in greater detail in chapter 31). Similarly, root nodules that occur in legumes and certain other kinds of plants contain bacteria that fix atmospheric nitrogen and make it available to their host plants.

In the tropics, leaf-cutter ants are often so abundant that they can remove a quarter or more of the total leaf surface of the plants in a given area in a single year (see figure 31.18). They do not eat these leaves directly; rather, they take them to underground nests, where they chew them up and inoculate them with the spores of particular fungi. These fungi are cultivated by the ants and brought from one specially prepared bed to another, where they grow and reproduce. In turn, the fungi constitute the primary food of the ants and their larvae. The relationship between leaf-cutter ants and these fungi is an excellent example of symbiosis. Recent phylogenetic studies using DNA and assuming a molecular clock (see chapter 23) suggest that these symbioses are ancient, perhaps originating more than 50 MYA.

The major kinds of symbiotic relationships include (1) commensalism, in which one species benefits and the other neither benefits nor is harmed; (2) mutualism, in which both participating species benefit; and (3) **parasitism**, in which one species benefits but the other is harmed. Parasitism can also be viewed as a form of predation, although the organism that is preyed on does not necessarily die.

## Commensalism benefits one species and is neutral to the other

In commensalism, one species benefits and the other is neither hurt nor helped by the interaction. In nature, individuals of one species are often physically attached to members of another. For example, epiphytes are plants that grow on the branches of other plants. In general, the host plant is unharmed, and the epiphyte that grows on it benefits. An example is Spanish moss, which hangs on trees in the southern United States. This plant and other members of its genus, which is in the pineapple family, grow on trees to gain access to sunlight; they generally do not harm the trees (figure 57.16).

Similarly, various marine animals, such as barnacles, grow on other, often actively moving sea animals, such as whales, and thus are carried passively from place to place. These “passengers” presumably gain more protection from predation than they would if they were fixed in one place, and they also reach new sources of food. The increased water circulation that these animals receive as their host moves around may also be of great importance, particularly if the passengers are filter feeders. Unless the number of these passengers gets too large, the host species is usually unaffected.

### When commensalism may not be commensalism

One of the best known examples of symbiosis involves the relationships between certain small tropical fishes (clownfish) and sea anemones, shown in the first figure of this chapter. The fish have evolved the ability to live among the stinging tentacles of sea anemones, even though these tentacles would quickly paralyze other fishes that touched them. The clownfish feed on food particles left from the meals of the host anemone, remaining uninjured under remarkable circumstances.

On land, an analogous relationship exists between birds called oxpeckers and grazing animals such as cattle or ante-

### Figure 57.17 Commensalism, mutualism, or parasitism?

In this symbiotic relationship, oxpeckers definitely receive a benefit in the form of nutrition from the ticks and other parasites they pick off their host (in this case, an impala, *Aepyceros melampus*). But the effect on the host is not always clear. If the ticks are harmful, their removal benefits the host, and the relationship is mutually beneficial. If the oxpeckers also pick at scabs, causing blood loss and possible infection, the relationship may be parasitic. If the hosts are unharmed by either the ticks or the oxpeckers, the relationship may be an example of commensalism.

lopes (figure 57.17). The birds spend most of their time clinging to the animals, picking off parasites and other insects, carrying out their entire life cycles in close association with the host animals.

No clear-cut boundary exists between commensalism and mutualism; in each of these cases, it is difficult to be certain whether the second partner receives a benefit or not. A sea anemone may benefit by having particles of food removed from its tentacles because it may then be better able to catch other prey. Similarly, although often thought of as commensalism, the association of grazing mammals and gleaning birds is actually an example of mutualism. The mammal benefits by having parasites and other insects removed from its body, but the birds also benefit by gaining a dependable source of food.

On the other hand, commensalism can easily transform itself into parasitism. Oxpeckers are also known to pick not only parasites, but also scabs off their grazing hosts. Once the scab is picked, the birds drink the blood that flows from the wound. Occasionally, the cumulative effect of persistent attacks can greatly weaken the herbivore, particularly when conditions are not favorable, such as during droughts.

**Figure 57.16** An example of commensalism. Spanish moss (*Tillandsia usneoides*) benefits from using trees as a substrate, but the trees generally are not affected positively or negatively.

## Mutualism benefits both species

Mutualism is a symbiotic relationship between organisms in which both species benefit. Mutualistic relationships are of fundamental importance in determining the structure of biological communities.

### **Mutualism and coevolution**

Some of the most spectacular examples of mutualism occur among flowering plants and their animal visitors, including insects, birds, and bats. During the course of flowering-plant evolution, the characteristics of flowers evolved in relation to the characteristics of the animals that visit them for food and, in the process, spread their pollen from individual to individual. At the same time, characteristics of the animals have changed, increasing their specialization for obtaining food or other substances from particular kinds of flowers.

Another example of mutualism involves ants and aphids. Aphids are small insects that suck fluids from the phloem of living plants with their piercing mouthparts. They extract a certain amount of the sucrose and other nutrients from this fluid, but they excrete much of it in an altered form through their anus. Certain ants have taken advantage of this—in effect, domesticating the aphids. Like ranchers taking cattle to fresh fields to graze, the ants carry the aphids to new plants and then consume as food the “honeydew” that the aphids excrete.

### **Ants and acacias: A prime example of mutualism**

A particularly striking example of mutualism involves ants and certain Latin American tree species of the genus *Acacia*. In these species, certain leaf parts, called stipules, are modified as paired, hollow thorns. The thorns are inhabited by stinging ants of the genus *Pseudomyrmex*, which do not nest anywhere else (figure 57.18). Like all thorns that occur on plants, the acacia thorns serve to deter herbivores.

At the tip of the leaflets of these acacias are unique, protein-rich bodies called Beltian bodies, named after the 19th-century British naturalist Thomas Belt. Beltian bodies do not occur in species of *Acacia* that are not inhabited by ants, and their role is clear: they serve as a primary food for the ants. In addition, the plants secrete nectar from glands near the bases of their leaves. The ants consume this nectar as well, feeding it and the Beltian bodies to their larvae.

Obviously, this association is beneficial to the ants, and one can readily see why they inhabit acacias of this group. The ants and their larvae are protected within the swollen thorns, and the trees provide a balanced diet, including the sugar-rich nectar and the protein-rich Beltian bodies. What, if anything, do the ants do for the plants?

Whenever any herbivore lands on the branches or leaves of an acacia inhabited by ants, the ants, which continually patrol the acacia's branches, immediately attack and devour the herbivore. The ants that live in the acacias also help their hosts compete with other plants by cutting away any encroaching branches that touch the acacia in which they are living. They create, in effect, a tunnel of light through which the acacia can grow, even in the lush tropical rain forests of lowland Central America. In fact, when an ant colony is experimentally removed

**Figure 57.18 Mutualism: Ants and acacias.** Ants of the genus *Pseudomyrmex* live within the hollow thorns of certain species of acacia trees in Latin America. The nectaries at the bases of the leaves and the Beltian bodies at the ends of the leaflets provide food for the ants. The ants, in turn, supply the acacias with organic nutrients and protect the acacias from herbivores and shading from other plants.

from a tree, the acacia is unable to compete successfully in this habitat. Finally, the ants bring organic material into their nests. The parts they do not consume, together with their excretions, provide the acacias with an abundant source of nitrogen.

### **When mutualism may not be mutualism**

As with commensalism, however, things are not always as they seem. Ant-acacia associations also occur in Africa; in Kenya, several species of acacia ants occur, but only a single species is found on any one tree. One species, *Crematogaster nigriceps*, is competitively inferior to two of the other species. To prevent invasion by these other ant species, *C. nigriceps* prunes the branches of the acacia, preventing it from coming into contact with branches of other trees, which would serve as a bridge for invaders.

Although this behavior is beneficial to the ant, it is detrimental to the tree because it destroys the tissue from which flowers are produced, essentially sterilizing the tree. In this case, what initially evolved as a mutualistic interaction has instead become a parasitic one.

## Parasitism benefits one species at the expense of another

Parasitism is harmful to the prey organism and beneficial to the parasite. In many cases, the parasite kills its host, and thus the ecological effects of parasitism can be similar to those of predation. In the past parasitism was studied mostly in terms of its effects on individuals and the populations in which they live, but in recent years researchers have realized that parasitism can be an important factor affecting community structure.

### External parasites

Parasites that feed on the exterior surface of an organism are external parasites, or ectoparasites (figure 57.19). Many instances of external parasitism are known in both plants and animals. **Parasitoids** are insects that lay eggs in or on living hosts. This behavior is common among wasps, whose larvae feed on the body of the unfortunate host, often killing it.

### Internal parasites

Parasites that live within the body of their hosts, termed **endoparasites**, occur in many different phyla of animals and protists. Internal parasitism is generally marked by much more extreme specialization than external parasitism, as shown by the many protist and invertebrate parasites that infect humans.

The more closely the life of the parasite is linked with that of its host, the more its morphology and behavior are likely to have been modified during the course of its evolution (the same is true of symbiotic relationships of all sorts). Conditions within the body of an organism are different from those encountered outside and are apt to be much more constant. Consequently, the structure of an internal parasite is often simplified, and unnecessary armaments and structures are lost as it evolves (for example, see descriptions of tapeworms in chapter 33).

### Parasites and host behaviors

Many parasites have complex life cycles that require several different hosts for growth to adulthood and reproduction. Recent research has revealed the remarkable adaptations of certain parasites that alter the behavior of the host and thus facilitate transmission from one host to the next. For example, many parasites cause their hosts to behave in ways that make them more vulnerable to their predators; when the host is ingested, the parasite is able to infect the predator.

**Figure 57.19 An external parasite.** The yellow vines are the flowering plant dodder (*Cuscuta*), a parasite that has lost its chlorophyll and its leaves in the course of its evolution. Because it is heterotrophic (unable to manufacture its own food), dodder obtains its food from the host plants it grows on.

**Figure 57.20 Parasitic manipulation of host behavior.**

Due to a parasite in its brain, an ant climbs to the top of a grass blade, where it may be eaten by a grazing herbivore, thus passing the parasite from insect to mammal.

One of the most famous examples involves a parasitic flatworm, *Dicrocoelium dendriticum*, which lives in ants as an intermediate host, but reaches adulthood in large herbivorous mammals such as cattle and deer. Transmission from an ant to a cow might seem difficult because cows do not normally eat insects. The flatworm, however, has evolved a remarkable adaptation. When an ant is infected, one of the flatworms migrates to the brain and causes the ant to climb to the top of vegetation and lock its mandibles onto a grass blade at the end of the day, just when herbivores are grazing (figure 57.20). The result is that the ant is eaten along with the grass, leading to infection of the grazer.

### Ecological processes have interactive effects

We have seen the different ways in which species can interact with one another. In nature, however, more than one type of interaction often occurs at the same time. In many cases, the outcome of one type of interaction is modified or even reversed when another type of interaction is also occurring.

#### Predation reduces competition

When resources are limiting, a superior competitor can eliminate other species from a community through competitive exclusion. However, predators can prevent or greatly reduce exclusion by lowering the numbers of individuals of competing species.

A given predator may often feed on two, three, or more kinds of plants or animals in a given community. The predator's choice depends partly on the relative abundance of the prey options. In other words, a predator may feed on species A when it is abundant and then switch to species B when A is rare. Similarly, a given prey species may become a primary source of food for increasing numbers of species as it becomes more abundant. In this way, superior competitors may be prevented from competitively excluding other species.

Such patterns are often characteristic of communities in marine intertidal habitats. For example, in preying selectively on bivalves, sea stars prevent bivalves from monopolizing a habitat, opening up space for many other organisms (figure 57.21). When sea stars are removed from a habitat, species diversity falls precipitously, and the seafloor community comes to be dominated by a few species of bivalves.

Predation tends to reduce competition in natural communities, so it is usually a mistake to attempt to eliminate a major predator, such as wolves or mountain lions, from a community. The result may be a decrease in biological diversity.

### Parasitism may counter competition

Parasites may affect sympatric species differently and thus influence the outcome of interspecific interactions. One classic experiment investigated interactions between two sympatric flour beetles, *Tribolium castaneum* and *T. confusum*, with and without a parasite, *Adelina*. In the absence of the parasite, *T. castaneum* is dominant, and *T. confusum* normally becomes extinct. When the parasite is present, however, the outcome is reversed, and *T. castaneum* perishes.

Similar effects of parasites in natural systems have been observed in many species. For example, in the *Anolis* lizards of St. Maarten mentioned previously, the competitively inferior species is resistant to lizard malaria (a disease related to human

malaria), whereas the other species is highly susceptible. In places where the parasite occurs, the competitively inferior species can hold its own and the two species coexist; elsewhere, the competitively dominant species outcompetes and eliminates it.

### Indirect effects

In some cases, species may not directly interact, yet the presence of one species may affect a second by way of interactions with a third. Such effects are termed indirect effects.

The desert rodents described earlier in the experiment with kangaroo rats eat seeds, and so do the ants in their community; thus, we might expect them to compete with each other. But when all rodents were removed from experimental enclosures and not allowed back in (unlike the previous experiment, no holes were placed in the enclosure walls), ant populations first increased but then declined (figure 57.22).

The initial increase was the expected result of removing a competitor. Why did it then reverse? The answer reveals the intricacies of natural ecosystems. Rodents prefer large seeds, whereas ants prefer smaller ones. Furthermore, in this system, plants with large seeds are competitively superior to plants with small seeds. The removal of rodents therefore led to an increase in the number of plants with large seeds, which reduced the number of small seeds available to ants, which in turn led to a decline in ant populations. In summary, the effect

## SCIENTIFIC THINKING

**Question:** Does predation affect the outcome of interspecific competitive interactions?

**Hypothesis:** In the absence of predators, prey populations will increase until resources are limiting, and some species will be competitively excluded.

**Experiment:** Remove predatory sea stars (*Pisaster ochraceus*) from some areas of rocky intertidal shoreline and monitor populations of species the sea stars prey upon. In control areas, pick up sea stars, but replace them where they were found.

a.

b.

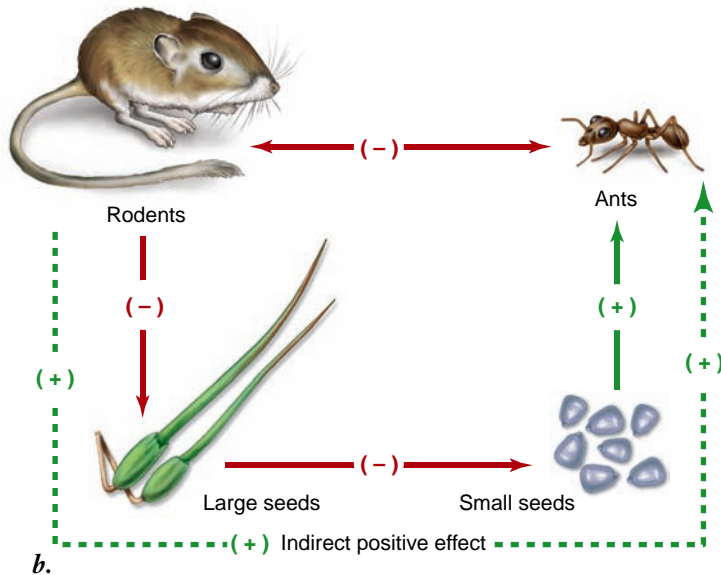

**Result:** In the absence of sea stars, the population of the mussel *Mytilus californianus* exploded, occupying all available space and eliminating many other species from the community.

**Interpretation:** What would happen if sea stars were returned to the experimental plots?

**Figure 57.21 Predation reduces competition.** a. In a controlled experiment in a coastal ecosystem, Robert Paine of the University of Washington removed a key predator, sea stars (*Pisaster*). b. In response, fiercely competitive mussels, a type of bivalve mollusk, exploded in population growth, effectively crowding out seven other indigenous species.

a.

b.

**Figure 57.22 Direct and indirect effects in an ecological community.** *a.* In the enclosures in which kangaroo rats had been removed, ants initially increased in population size relative to the ants in the control enclosures, but then these ant populations declined. *b.* Rodents and ants both eat seeds, so the presence of rodents has a direct negative effect on ants, and vice versa. However, the presence of rodents has a negative effect on large seeds. In turn, the presence of rodents has a negative effect on plants that produce large seeds, which the ants eat. Hence, the presence of rodents should increase the number of small seeds. In turn, the number of small seeds has a positive effect on ant populations. Thus, indirectly, the presence of rodents has a positive effect on ant population size.

### Inquiry question

How would you test the hypothesis that plant competition mediates the positive effect of kangaroo rats on ants?

of rodents on ants is complicated: a direct, negative effect of resource competition and an indirect, positive effect mediated by plant competition.

### Keystone species have major effects on communities

Species whose effects on the composition of communities are greater than one might expect based on their abundance are termed **keystone species**. Predators, such as the sea star described earlier, can often serve as keystone species by preventing one species from outcompeting others, thus maintaining high levels of species richness in a community.

A wide variety of other types of keystone species also exist. Some species manipulate the environment in ways that create new habitats for others. Beavers, for example, change running streams into small impoundments, altering the flow of water and flooding areas (figure 57.23). Similarly, alligators excavate deep holes at the bottoms of lakes. In times of drought, these holes are the only areas where water remains, thus allowing aquatic species that otherwise would perish to persist until the drought ends and the lake refills.

### Learning Outcomes Review 57.4

The types of symbiosis include mutualism, in which both participants benefit; commensalism, in which one benefits and the other is neutrally affected; and parasitism, in which one benefits at the expense of the other. Mutualistic species often undergo coevolution, such as the shape of flowers and the features of animals that feed on and pollinate them. Ecological interactions can affect many processes in a community; for example, predation and parasitism may lessen resource competition.

- How could the presence of a predator positively affect populations of a species on which it preys?

**Figure 57.23 Example of a keystone species.** Beavers, by constructing dams and transforming flowing streams into ponds, create new habitats for many plant and animal species.

## 57.5 Ecological Succession, Disturbance, and Species Richness

### Learning Outcomes

1. Define succession and distinguish primary versus secondary.
2. Describe how early colonizers may affect subsequent occurrence of other species.
3. Explain how disturbance can either positively or negatively affect species richness.

Even when the climate of an area remains stable year after year, communities have a tendency to change from simple to complex in a process known as **succession**. This process is familiar to anyone who has seen a vacant lot or cleared woods slowly become occupied by an increasing number of species.

### Succession produces a change in species composition

If a wooded area is cleared or burned and left alone, plants will slowly reclaim the area. Eventually, all traces of the clear-

ing will disappear, and the area will again be woods. This kind of succession, which occurs in areas where an existing community has been disturbed but organisms still remain, is called **secondary succession**.

In contrast, **primary succession** occurs on bare, lifeless substrate, such as rocks, or in open water, where organisms gradually move into an area and change its nature. Primary succession occurs in lakes and on land exposed after the retreat of glaciers, and on volcanic islands that rise from the sea (figure 57.24).

Primary succession on glacial moraines provides an example (see figure 57.24). On the bare, mineral-poor ground exposed when glaciers recede, soil pH is basic as a result of carbonates in the rocks, and nitrogen levels are low. Lichens are the first vegetation able to grow under such conditions. Acidic secretions from the lichens help break down the substrate and reduce the pH, as well as adding to the accumulation of soil. Mosses then colonize these pockets of soil, eventually building up enough nutrients in the soil for alder shrubs to take hold. Over a hundred years, the alders, which have symbiotic bacteria that fix atmospheric nitrogen (described in chapter 28), increase soil nitrogen levels, and their acidic leaves further lower soil pH. Eventually, spruce trees grow above the alders and shade them, crowding them out entirely and forming a dense spruce forest.

In a similar example, an *oligotrophic* lake—one poor in nutrients—may gradually, by the accumulation of organic matter, become *eutrophic*—rich in nutrients. As this occurs, the composition of communities will change, first increasing in species richness and then declining.

### Why succession happens

Succession happens because species alter the habitat and the resources available in it in ways that favor other species. Three dynamic concepts are of critical importance in the process: establishment, facilitation, and inhibition.

a.

**Figure 57.24** Primary succession at Alaska's Glacier Bay.

**a.** Initially, the glacial moraine at Glacier Bay, Alaska, had little soil nitrogen **b.** The first invaders of these exposed sites are pioneer moss species with nitrogen-fixing, mutualistic microbes. **c.** Within 20 years, young alder shrubs take hold. Rapidly fixing nitrogen, they soon form dense thickets. **d.** Eventually spruce overgrow the mature alders, forming a forest.

b.

c.

d.

- 1. Establishment.** Early successional stages are characterized by weedy, *r*-selected species that are tolerant of the harsh, abiotic conditions in barren areas (the preceding chapter discussed *r*-selected and *K*-selected species).
- 2. Facilitation.** The weedy early successional stages introduce local changes in the habitat that favor other, less weedy species. Thus, the mosses in the Glacier Bay succession convert nitrogen to a form that allows alders to invade (see figure 57.24). Similarly, the nitrogen build-up produced by the alders, though not necessary for spruce establishment, leads to more robust forests of spruce better able to resist attack by insects.
- 3. Inhibition.** Sometimes the changes in the habitat caused by one species, while favoring other species, also inhibit the growth of the original species that caused the changes. Alders, for example, do not grow as well in acidic soil as the spruce and hemlock that replace them.

Over the course of succession, the number of species typically increases as the environment becomes more hospitable. In some cases, however, as ecosystems mature, more *K*-selected species replace *r*-selected ones, and superior competitors force out other species, leading ultimately to a decline in species richness.

### Succession in animal communities

The species of animals present in a community also change through time in a successional pattern. As the vegetation changes during succession, habitat disappears for some species and appears for others.

A particularly striking example occurred on the Krakatau islands, which were devastated by an enormous volcanic eruption in 1883. Initially composed of nothing but barren ash-fields, the three islands of the group experienced rapid successional change as vegetation became reestablished. A few blades of grass appeared the next year, and within 15 years the coastal vegetation was well established and the interior was covered with dense grasslands. By 1930, the islands were almost entirely forested (figure 57.25).

The fauna of Krakatau changed in synchrony with the vegetation. Nine months after the eruption, the only animal found was a single spider, but by 1908, 200 animal species were found in a 3-day exploration. For the most part, the first animals were grassland inhabitants, but as trees became established, some of these early colonists, such as the zebra dove and the long-tailed shrike (a type of predatory bird), disappeared and were replaced by forest-inhabiting species, such as fruit bats and fruit-eating birds.

Although patterns of succession of animal species have typically been caused by vegetational succession, changes in the composition of the animal community in turn have affected plant occurrences. In particular, many plant species that are animal-dispersed or pollinated could not colonize Krakatau until their dispersers or pollinators had become established. For example, fruit bats were slow to colonize Krakatau, and until they appeared, few bat-dispersed plant species were present.

### Disturbances can play an important role in structuring communities

Traditionally, many ecologists considered biological communities to be in a state of equilibrium, a stable condition that resisted change and fairly quickly returned to its original state if disturbed by humans or natural events. Such stability was usually attributed to the process of interspecific competition.

In recent years, this viewpoint has been reevaluated. Increasingly, scientists are recognizing that communities are constantly changing as a result of climatic changes, species invasions, and disturbance events. As a result, many ecologists now invoke nonequilibrium models that emphasize change, rather than stability. A particular focus of ecological research concerns the role that disturbances play in determining the structure of communities.

Disturbances can be widespread or local. Severe disturbances, such as forest fires, drought, and floods, may affect large areas. Animals may also cause severe disruptions. Gypsy moths can devastate a forest by consuming all of the leaves on its trees. Unregulated deer populations may grow explosively, the deer

**Figure 57.25 Succession after a volcanic eruption.**

A major volcanic explosion in 1883 on the island of Krakatau destroyed all life on the island. **a.** This photo shows a later, much less destructive eruption of the volcano. **b.** Krakatau, forested and populated by animals.

overgrazing and so destroying the forest in which they live. On the other hand, local disturbances may affect only a small area, as when a tree falls in a forest or an animal digs a hole and up-roots vegetation.

### **Intermediate disturbance hypothesis**

In some cases, disturbance may act to increase the species richness of an area. According to the *intermediate disturbance hypothesis*, communities experiencing moderate amounts of disturbance will have higher levels of species richness than communities experiencing either little or great amounts of disturbance.

Two factors could account for this pattern. First, in communities where moderate amounts of disturbance occur, patches of habitat exist at different successional stages. Within the area as a whole, then, species diversity is greatest because the full range of species—those characteristic of all stages of succession—are present. For example, a pattern of intermittent episodic disturbance that produces gaps in the rain forest (as when a tree falls) allows invasion of the gap by other species (figure 57.26). Eventually, the species inhabiting the gap will go through a successional sequence, one tree replacing another, until a canopy tree species comes again to occupy the gap. But if there are many gaps of different ages in the forest, many different species will be coexisting, some in young gaps and others in older ones.

Second, moderate levels of disturbance may prevent communities from reaching the final stages of succession, in which a few dominant competitors eliminate most of the other species. In contrast, too much disturbance might leave the community continually in the earliest stages of succession, when species richness is relatively low.

Ecologists are increasingly realizing that disturbance is common, rather than exceptional, in many communities. As a result, the idea that communities inexorably move along a successional trajectory culminating in the development of a predictable end-state, or “climax,” community is no longer widely accepted. Rather, predicting the state of a community in the future may be difficult because the unpredictable occurrence of disturbances will often counter successional changes. Understanding the role that disturbances play in structuring communities is currently an important area of investigation in ecology.

**Figure 57.26 Intermediate disturbance.** A single fallen tree created a small light gap in the tropical rain forest of Panama. Such gaps play a key role in maintaining the high species diversity of the rain forest. In this case, a sunlight-loving plant is able to sprout up among the dense foliage of trees in the forest.

### **Learning Outcomes Review 57.5**

Communities change through time by a process termed succession. Primary succession occurs on bare, lifeless substrate; secondary succession occurs where an existing community has been disturbed. Early-arriving species alter the environment in ways that allow other species to colonize, and new colonizers may have negative effects on species already present. Sometimes, moderate levels of disturbance can lead to increased species richness because species characteristic of all levels of succession may be present.

- *From a community point of view, would clear-cutting a forest be better than selective harvest of individual trees? Why or why not?*

## **Chapter Review**

### **57.1 Biological Communities: Species Living Together**

A community is a group of different species that occupy a given location.

#### **Communities have been viewed in different ways.**

The individualistic concept of a community is a random assemblage of species that happen to occur in a given place. The holistic concept

of a community is an integrated unit composed of species that work together as part of a functional whole.

#### **Communities change over space and time.**

In accordance with the individualistic view, species generally respond independently to environmental conditions, and community composition gradually changes over space and time. However, in locations where conditions rapidly change, species composition may change greatly over short distances.

## 57.2 The Ecological Niche Concept

**Fundamental niches are potential; realized niches are actual.**

A niche is the total of all the ways a species uses environmental resources. The fundamental niche is the entire niche a species is capable of using if there are no intervening factors. The realized niche is the set of actual environmental conditions that allow establishment of a stable population.

Realized niches are usually smaller than fundamental niches because interspecific interactions limit a species' use of some resources.

**Competitive exclusion can occur when species compete for limited resources.**

The principle of competitive exclusion states that if resources are limiting, two species cannot simultaneously occupy the same niche; rather, one species will be eliminated.

**Competition may lead to resource partitioning.**

By using different resources (partitioning), sympatric species can avoid competing with each other and can coexist with reduced realized niches.

**Detecting interspecific competition can be difficult.**

Although experimentation is a powerful means of testing the hypothesis that species compete, practical limitations exist. Detailed knowledge of the ecology of species is important to evaluate the results of experiments and possible interactions.

## 57.3 Predator–Prey Relationships

**Predation strongly influences prey populations.**

Predation is the consuming of one organism by another, and includes not only one animal eating another, but also an animal eating a plant.

Natural selection strongly favors adaptations of prey species to prevent predation. In turn, sometimes predators evolve counter-adaptations, leading to an evolutionary “arms race.”

**Plant adaptations defend against herbivores.**

Plants produce secondary chemical compounds that deter herbivores. Sometimes the herbivores evolve an ability to ingest the compounds and use them for their own defense.

**Animal adaptations defend against predators.**

Animal adaptations include chemical defenses and defensive coloration such as warning coloration or camouflage.

**Mimicry allows one species to capitalize on defensive strategies of another.**

In Batesian mimicry, a species that is edible or nontoxic evolves warning coloration similar to that of an inedible or poisonous species.

In Müllerian mimicry, two species that are both toxic evolve similar warning coloration.

## 57.4 The Many Types of Species Interactions

**Symbiosis involves long-term interactions.**

Many symbiotic species have coevolved and have permanent relationships.

**Commensalism benefits one species and is neutral to the other.**

Examples of commensal relationships include epiphytes growing on large plants and barnacles growing on sea animals.

**Mutualism benefits both species.**

One example is the case of ants and acacias, in which *Acacia* plants provide a home and food for a species of stinging ants that protect them from herbivores.

**Parasitism benefits one species at the expense of another.**

Many organisms have parasitic lifestyles, living on or inside one or more host species and causing damage or disease as a result.

**Ecological processes have interactive effects.**

Because many processes may occur simultaneously, species may affect one another not only through direct interactions but also through their effects on other species in the community.

**Keystone species have major effects on communities.**

Keystone species are those that maintain a more diverse community by reducing competition between species or by altering the environment to create new habitats.

## 57.5 Ecological Succession, Disturbance, and Species Richness

**Succession produces a change in species composition.**

Primary succession begins with a barren, lifeless substrate, whereas secondary succession occurs after an existing community is disrupted by fire, clearing, or other events.

**Disturbances can play an important role in structuring communities.**

Community composition changes as a result of local and global disturbances that “reset” succession.

Intermediate levels of such disturbance may maximize species richness in two ways: by creating a patchwork of different habitats harboring different species, and by preventing communities from reaching the final stage of succession, which may be dominated by only a few, competitively superior species.

## Review Questions

### UNDERSTAND

1. Studies that demonstrate that species living in an ecological community change independently of one another in space and time
  - a. support the individualistic concept of ecological communities.
  - b. support the holistic concept of ecological communities.
  - c. suggest species interactions are the sole determinant of which species coexist in a community.
  - d. None of the above
2. If two species have very similar realized niches and are forced to coexist and share a limiting resource indefinitely,
  - a. both species would be expected to coexist.
  - b. both species would be expected to go extinct.
  - c. the species that uses the limiting resource most efficiently should drive the other species extinct.
  - d. both species would be expected to become more similar to one another.

3. According to the idea of coevolution between predator and prey, when a prey species evolves a novel defense against a predator
  - a. the predator is expected to always go extinct.
  - b. the prey population should increase irreversibly out of control of the predator.
  - c. the predator population should increase.
  - d. evolution of a predator response should be favored by natural selection.
4. In order for mimicry to be effective in protecting a species from predation, it must
  - a. occur in a palatable species that looks like a distasteful species.
  - b. have cryptic coloration.
  - c. occur such that mimics look and act like models.
  - d. occur in only poisonous or dangerous species.
5. Which of the following is an example of commensalism?
  - a. A tapeworm living in the gut of its host
  - b. A clownfish living among the tentacles of a sea anemone
  - c. An acacia tree and acacia ants
  - d. Bees feeding on nectar from a flower
6. A species whose effect on the composition of a community is greater than expected based on its abundance can be called a
  - a. predator.
  - b. primary succession species.
  - c. secondary succession species.
  - d. keystone species.
7. When a predator preferentially eats the superior competitor in a pair of competing species
  - a. the inferior competitor is more likely to go extinct.
  - b. the superior competitor is more likely to persist.
  - c. coexistence of the competing species is more likely.
  - d. None of the above
8. Species that are the first colonists in a habitat undergoing primary succession
  - a. are usually the fiercest competitors.
  - b. help maintain their habitat constant so their persistence is ensured.
  - c. may change their habitat in a way that favors the invasion of other species.
  - d. must first be successful secondary succession specialists.
- c. results in the fundamental and realized niches being the same.
- d. is more common in herbivores than carnivores.
4. Parasitism differs from predation because
  - a. the presence of parasitism doesn't lead to selection for defensive adaptations in parasitized species.
  - b. parasites and the species they parasitize never engage in an evolutionary "arms race."
  - c. parasites don't have strong effects on the populations of the species they parasitize.
  - d. None of the above
5. The presence of one species (A) in a community may benefit another species (B) if
  - a. a commensalistic relationship exists between the two.
  - b. The first species (A) preys on a predator of the second species (B).
  - c. The first species (A) preys on a species that competes with a species that is eaten by the second species (B).
  - d. All of the above

## SYNTHESIZE

1. Competition is traditionally indicated by documenting the effect of one species on the population of another. Are there alternative ways to study the potential effects of competition on organisms that are impractical to study with experimental manipulations because they are too big or live too long?
2. Refer to figure 57.9. If the single prey species of *Paramecium* was replaced by several different potential prey species that varied in their palatability or ease of subduing by the predator (leading to different levels of preference by the predator) what would you expect the dynamics of the system to look like; that is, would the system be more or less likely to go to extinction?
3. Refer to figure 57.22. Are there alternative hypotheses that might explain the increase followed by the decrease in ant colony numbers subsequent to rodent removal in the experiment described in figure 57.22? If so, how would you test the mechanism hypothesized in the figure?
4. Refer to figure 57.7. Examine the pattern of beak size distributions of two species of finches on the Galápagos Islands. One hypothesis that can be drawn from this pattern is that character displacement has taken place. Are there other hypotheses? If so, how would you test them?
5. Is it possible that some species function together as an integrated, holistic community, whereas other species at the same locality behave more individually? If so, what factors might determine which species function in which way?

## APPLY

1. Which of the following can cause the realized niche of a species to be smaller than its fundamental niche?
  - a. Predation
  - b. Competition
  - c. Parasitism
  - d. All of the above
2. The presence of a predatory species
  - a. always drives a prey species to extinction.
  - b. can positively affect a prey species by having a detrimental effect on competing species.
  - c. indicates that the climax stage of succession has been reached.
  - d. None of the above
3. Resource partitioning by sympatric species
  - a. always occurs when species have identical niches.
  - b. may not occur in the presence of a predator, which reduces prey population sizes.

Chapter **58**

# Dynamics of Ecosystems

## Chapter Outline

- 58.1** Biogeochemical Cycles
- 58.2** The Flow of Energy in Ecosystems
- 58.3** Trophic-Level Interactions
- 58.4** Biodiversity and Ecosystem Stability
- 58.5** Island Biogeography

## Introduction

*The Earth is a relatively closed system with respect to chemicals. It is an open system in terms of energy, however, because it receives energy at visible and near-visible wavelengths from the Sun and steadily emits thermal energy to outer space in the form of infrared radiation. The organisms in ecosystems interact in complex ways as they participate in the cycling of chemicals and as they capture and expend energy. All organisms, including humans, depend on the specialized abilities of other organisms—plants, algae, animals, fungi, and prokaryotes—to acquire the essentials of life, as explained in this chapter. In chapters 58 and 59, we consider the many different types of ecosystems that constitute the biosphere and discuss the threats to the biosphere and the species it contains.*

## 58.1 Biogeochemical Cycles

### Learning Outcomes

1. Define ecosystem.
2. List four chemicals whose cyclic interactions are critical to organisms.
3. Describe how human activities disrupt these cycles.

An ecosystem includes all the organisms that live in a particular place, plus the abiotic (nonliving) environment in which they live—and with which they interact—at that location. Ecosystems are intrinsically dynamic in a number of ways, including their processing of matter and energy. We start with matter.

### The atomic constituents of matter cycle within ecosystems

During the biological processing of matter, the atoms of which it is composed, such as the atoms of carbon or oxygen, maintain their integrity even as they are assembled into new compounds and the compounds are later broken down. The Earth has an essentially fixed number of each of the types of atoms of biological importance, and the atoms are recycled.

Each organism assembles its body from atoms that previously were in the soil, the atmosphere, other parts of the abiotic environment, or other organisms. When the organism dies, its atoms are released unaltered to be used by other organisms or returned to the abiotic environment. Because of the cycling of the atomic constituents of matter, your body is likely during

your life to contain a carbon or oxygen atom that once was part of Julius Caesar's body or Cleopatra's.

The atoms of the various chemical elements are said to move through ecosystems in biogeochemical cycles, a term emphasizing that the cycles of chemical elements involve not only biological organisms and processes, but also geological (abiotic) systems and processes. Biogeochemical cycles include processes that occur on many spatial scales, from cellular to planetary, and they also include processes that occur on multiple time-scales, from seconds (biochemical reactions) to millennia (weathering of rocks).

Biogeochemical cycles usually cross the boundaries of ecosystems to some extent, rather than being self-contained within individual ecosystems. For example, one ecosystem might import or export carbon to others.

In this section, we consider the cycles of some major elements along with the compound water. We also present an example of biogeochemical cycles in a forest ecosystem.

### Carbon, the basis of organic compounds, cycles through most ecosystems

Carbon is a major constituent of the bodies of organisms because carbon atoms help form the framework of all organic compounds (see chapter 3); almost 20% of the weight of the human body is carbon. From the viewpoint of the day-to-day dynamics of ecosystems, carbon dioxide ( $\text{CO}_2$ ) is the most significant carbon-containing compound in the abiotic environments of organisms. It makes up 0.03% of the volume of the atmosphere, meaning the atmosphere contains about 750 billion metric tons of carbon. In aquatic ecosystems,  $\text{CO}_2$  reacts spontaneously with the water to form bicarbonate ions ( $\text{HCO}_3^-$ ).

**Figure 58.1** The carbon cycle. Photosynthesis

by plants and algae captures carbon in the form of organic chemical compounds. Aerobic respiration by organisms and fuel combustion by humans return carbon to the form of carbon dioxide ( $\text{CO}_2$ ) or bicarbonate ( $\text{HCO}_3^-$ ). Microbial methanogens living in oxygen-free microhabitats, such as the mud at the bottom of the pond, might produce methane ( $\text{CH}_4$ ), a gas that would enter the atmosphere and then gradually be oxidized abiotically to carbon dioxide (shown in green circled inset).

**Figure 58.2 The water cycle.** Water circulates from the atmosphere to the surface of the Earth and back again. The Sun provides much of the energy required for evaporation.

### The basic carbon cycle

The carbon cycle is straightforward, as shown in figure 58.1. In terrestrial ecosystems, plants and other photosynthetic organisms take in  $\text{CO}_2$  from the atmosphere and use it in photosynthesis to synthesize the carbon-containing organic compounds of which they are composed (see chapter 8). The process is sometimes called *carbon fixation*; fixation refers to metabolic reactions that make nongaseous compounds from gaseous ones.

Animals eat the photosynthetic organisms and build their own tissues by making use of the carbon atoms in the organic compounds they ingest. Both the photosynthetic organisms and the animals obtain energy during their lives by breaking down some of the organic compounds available to them, through aerobic cellular respiration (see chapter 7). When they do this, they produce  $\text{CO}_2$ . Decaying organisms also produce  $\text{CO}_2$ . Carbon atoms returned to the form of  $\text{CO}_2$  are available once more to be used in photosynthesis to synthesize new organic compounds.

In aquatic ecosystems, the carbon cycle is fundamentally similar, except that inorganic carbon is present in the water not only as dissolved  $\text{CO}_2$ , but also as  $\text{HCO}_3^-$  ions, both of which act as sources of carbon for photosynthesis by algae and aquatic plants.

### Methane producers

Microbes that break down organic compounds by anaerobic cellular respiration (see chapter 7) provide an additional dimension to the global carbon cycle. Methanogens, for example, are microbes that produce methane ( $\text{CH}_4$ ) instead of  $\text{CO}_2$ . One major source of  $\text{CH}_4$  is wetland ecosystems, where methanogens live in the oxygen-free sediments. Methane that enters the atmosphere is oxidized abiotically to  $\text{CO}_2$ , but  $\text{CH}_4$  that remains isolated from oxygen can persist for great lengths of time.

### The rise of atmospheric carbon dioxide

Another dimension of the global carbon cycle is that over long stretches of time, some parts of the cycle may proceed more

rapidly than others. These differences in rate have ordinarily been relatively minor on a year-to-year basis; in any one year, the amount of  $\text{CO}_2$  made by breakdown of organic compounds almost matches the amount of  $\text{CO}_2$  used to synthesize new organic compounds.

Small mismatches, however, can have large consequences if continued for many years. The Earth's present reserves of coal were built up over geologic time. Organic compounds such as cellulose accumulated by being synthesized faster than they were broken down, and then they were transformed by geological processes into the fossil fuels. Most scientists believe that the world's petroleum reserves were created in the same way.

Human burning of fossil fuels today is creating large contemporary imbalances in the carbon cycle. Carbon that took millions of years to accumulate in the reserves of fossil fuels is being rapidly returned to the atmosphere, driving the concentration of  $\text{CO}_2$  in the atmosphere upward year by year and helping to spur fears of global warming (see chapter 59).

## The availability of water is fundamental to terrestrial ecosystems

The water cycle, seen in figure 58.2, is probably the most familiar of all biogeochemical cycles. All life depends on the presence of water; even organisms that can survive without water in resting states require water to regain activity. The bodies of most organisms consist mainly of water. The adult human body, for example, is about 60% water by weight. The amount of water available in an ecosystem often determines the nature and abundance of the organisms present, as illustrated by the difference between forests and deserts (see chapter 59).

Each type of biogeochemical cycle has distinctive features. A distinctive feature of the water cycle is that water is a compound, not an element, and thus it can be synthesized and broken down. It is synthesized during aerobic cellular respiration (see chapter 7) and chemically split during photosynthesis (see chapter 8). The rates of these processes are ordinarily about equal, and therefore a relatively constant amount of water cycles through the biosphere.

## The basic water cycle

One key part of the water cycle is that liquid water from the Earth's surface evaporates into the atmosphere. The change of water from a liquid to a gas requires a considerable addition of thermal energy, explaining why evaporation occurs more rapidly when solar radiation beats down on a surface.

Evaporation occurs directly from the surfaces of oceans, lakes, and rivers. In terrestrial ecosystems, however, approximately 90% of the water that reaches the atmosphere passes through plants. Trees, grasses, and other plants take up water from soil via their roots, and then the water evaporates from their leaves and other surfaces through a process called transpiration (see chapter 38).

Evaporated water exists in the atmosphere as a gas, just like any other atmospheric gas. The water can condense back into liquid form, however, mostly because of cooling of the air. Condensation of gaseous water (water vapor) into droplets or crystals causes the formation of clouds, and if the droplets or crystals are large enough, they fall to the surface of the Earth as precipitation (rain or snow).

## Groundwater

Less obvious than surface water, which we see in rivers and lakes, is water under ground—termed groundwater. Groundwater occurs in **aquifers**, which are permeable, underground layers of rock, sand, and gravel that are often saturated with water. Groundwater is the most important reservoir of water on land in many parts of the world, representing over 95% of all fresh water in the United States, for example.

Groundwater consists of two subparts. The upper layers of the groundwater constitute the water table, which is unconfined in the sense that it flows into streams and is partly accessible to the roots of plants. The lower, confined layers of the groundwater are generally out of reach to streams and plants, but can be tapped by wells. Groundwater is recharged by water that percolates downward from above, such as from precipitation. Water in an aquifer flows much more slowly than surface water, anywhere from a few millimeters to a meter or so per day.

In the United States, groundwater provides about 25% of the water used by humans for all purposes, and it supplies about 50% of the population with drinking water. In the Great Plains states, the deep Ogallala Aquifer is tapped extensively as a water source for agricultural and domestic needs. The aquifer is being depleted faster than it is recharged—a local imbalance in the water cycle—posing an ominous threat to the agricultural production of the area. Similar threats exist in many of the drier portions of the globe.

## Changes in ecosystems brought about by changes in the water cycle

Water is so crucial for life that changes in its supply in an ecosystem can radically alter the nature of the ecosystem. Such changes have occurred often during the Earth's geological history.

Consider, for example, the ecosystem of the Serengeti Plain in Tanzania, famous for its seemingly endless grasslands occupied by vast herds of antelopes and other grazing animals. The semiarid grasslands of today's Serengeti were rain forests

25 MYA. Starting at about that time, mountains such as Mount Kilimanjaro rose up between the rain forests and the Indian Ocean, their source of moisture. The presence of the mountains forced winds from the Indian Ocean upward, cooling the air and causing much of its moisture to precipitate before the air reached the rain forests. The land became much drier, and the forests turned to grasslands.

Today, human activities can alter the water cycle so profoundly that major changes occur in ecosystems. Changes in rain forests caused by deforestation provide an example. In healthy tropical rain forests, more than 90% of the moisture that falls as rain is taken up by plants and returned to the air by transpiration. Plants, in a very real sense, create their own rain: The moisture returned to the atmosphere falls back on the forests.

When human populations cut down or burn the rain forests in an area, the local water cycle is broken. Water that falls as rain thereafter drains away in rivers instead of rising to form clouds and fall again on the forests. Just such a transformation is occurring today in many tropical rain forests (figure 58.3). Large areas in Brazil, for example, were transformed in the 20th century from lush tropical forest to semiarid desert, depriving many unique plant and animal species of their native habitat.

## The nitrogen cycle depends on nitrogen fixation by microbes

Nitrogen is a component of all proteins and nucleic acids and is required in substantial amounts by all organisms; proteins are 16% nitrogen by weight. In many ecosystems, nitrogen is the chemical element in shortest supply relative to the needs of organisms. A paradox is that the atmosphere is 78% nitrogen by volume.

**Figure 58.3** Deforestation disrupts the local water cycle. Tropical deforestation can have severe consequences, such as the extensive erosion in this area in the Amazon region of Brazil.

## Nitrogen availability

How can nitrogen be in short supply if the atmosphere is so rich with it? The answer is that the nitrogen in the atmosphere is in its elemental form—molecules of nitrogen gas ( $N_2$ )—and the vast majority of organisms, including all plants and animals, have no way to use nitrogen in this chemical form.

For animals, the ultimate source of nitrogen is nitrogen-containing organic compounds synthesized by plants or by algae or other microbes. Herbivorous animals, for example, eat plant or algal proteins and use the nitrogen-containing amino acids in them to synthesize their own proteins.

Plants and algae use a number of simple nitrogen-containing compounds as their sources of nitrogen to synthesize proteins and other nitrogen-containing organic compounds in their tissues. Two commonly used nitrogen sources are ammonia ( $NH_3$ ) and nitrate ions ( $NO_3^-$ ). As described in chapter 39, certain prokaryotic microbes can synthesize ammonia and nitrate from  $N_2$  in the atmosphere, thereby constituting a part of the nitrogen cycle that makes atmospheric nitrogen accessible to plants and algae (figure 58.4). Other prokaryotes turn  $NH_3$  and  $NO_3^-$  into  $N_2$ , making the nitrogen inaccessible. The balance of the activities of these two sets of microbes determines the accessibility of nitrogen to plants and algae.

## Microbial nitrogen fixation, nitrification, and denitrification

The synthesis of nitrogen-containing compounds from  $N_2$  is known as **nitrogen fixation**. The first step in this process is the synthesis of  $NH_3$  from  $N_2$ , and biochemists sometimes use the

term *nitrogen fixation* to refer specifically to this step. After  $NH_3$  has been synthesized, other prokaryotic microbes oxidize part of it to form  $NO_3^-$ , a process called **nitrification**.

Certain genera of prokaryotes have the ability to accomplish nitrogen fixation using a system of enzymes known as the nitrogenase complex (the *nif* gene complex; see chapter 28). Most of the microbes are free-living, but on land some are found in symbiotic relationships with the roots of legumes (plants of the pea family, Fabaceae), alders, myrtles, and other plants.

Additional prokaryotic microbes (including both bacteria and archaea) are able to convert the nitrogen in  $NO_3^-$  into  $N_2$  (or other nitrogen gases such as  $N_2O$ ), a process termed **denitrification**. Ammonia can be subjected to denitrification indirectly by being converted first to  $NO_3^-$  and then to  $N_2$ .

## Nitrogenous wastes and fertilizer use

Most animals, when they break down proteins in their metabolism, excrete the nitrogen from the proteins as  $NH_3$ . Humans and other mammals excrete nitrogen as urea in their urine (see chapter 51); a number of types of microbes convert the urea to  $NH_3$ . The  $NH_3$  from animal excretion can be picked up by plants and algae as a source of nitrogen.

Human populations are radically altering the global nitrogen cycle by the use of fertilizers on lawns and agricultural fields. The fertilizers contain forms of fixed nitrogen that crops can use, such as ammonium ( $NH_4$ ) salts manufactured industrially from atmospheric  $N_2$ . Partly because of the production of fertilizers, humans have already doubled the rate of transfer of  $N_2$  in usable forms into soils and waters.

**Figure 58.4 The nitrogen cycle.** The nitrogen cycle is complicated because it involves multiple changes in the chemical form of nitrogen. Certain prokaryotes fix atmospheric nitrogen ( $N_2$ ), converting it to forms such as ammonia ( $NH_3$ ) and nitrate ( $NO_3^-$ ) that plants and algae can use. Other prokaryotes return nitrogen to the atmosphere as  $N_2$  by breaking down  $NH_3$  or other nitrogen-containing compounds. Ammonia, a gas, can enter the atmosphere directly from soils.

**Figure 58.5 The phosphorus cycle.** In contrast to carbon, water, and nitrogen, phosphorus occurs only in the liquid and solid states and thus does not enter the atmosphere.

### Phosphorus cycles through terrestrial and aquatic ecosystems, but not the atmosphere

Phosphorus is required in substantial quantities by all organisms; it occurs in nucleic acids, membrane phospholipids, and other essential compounds, such as adenosine triphosphate (ATP).

Unlike carbon, water, and nitrogen, phosphorus has no significant gaseous form and does not cycle through the atmosphere (figure 58.5). In this respect, the phosphorus cycle exemplifies the sorts of cycles also exhibited by calcium, silicon, and many other mineral elements. Another feature that greatly simplifies the phosphorus cycle compared with the nitrogen cycle is that phosphorus exists in ecosystems in just a single oxidation state, phosphate ( $\text{PO}_4^{3-}$ ).

#### Phosphate availability

Plants and algae use free inorganic  $\text{PO}_4^{3-}$  in the soil or water for synthesizing their phosphorus-containing organic compounds. Animals then tap the phosphorus in plant or algal tissue compounds to build their own phosphorus compounds. When organisms die, decay microbes—in a process called phosphate remineralization—break up the organic compounds in their bodies, releasing phosphorus as inorganic  $\text{PO}_4^{3-}$  that plants and algae again can use.

The phosphorus cycle includes critical abiotic chemical and physical processes. Free  $\text{PO}_4^{3-}$  exists in soil in only low concentrations both because it combines with other soil constituents to form insoluble compounds and because it tends to be washed away by streams and rivers. Weathering of many sorts of rocks releases new  $\text{PO}_4^{3-}$  into terrestrial systems, but then rivers carry the  $\text{PO}_4^{3-}$  into the ocean basins. There is a large one-way flux of  $\text{PO}_4^{3-}$  from terrestrial rocks to deep-sea sediments.

#### Phosphates as fertilizers

Human activities have greatly modified the global phosphorus cycle since the advent of crop fertilization. Fertilizers are typically designed to provide  $\text{PO}_4^{3-}$  because crops might otherwise be short of it; the  $\text{PO}_4^{3-}$  in fertilizers is typically derived from crushed phosphate-rich rocks and bones. Detergents are an-

other potential culprit in adding  $\text{PO}_4^{3-}$  to ecosystems, but laws now mandate low-phosphate detergents in much of the world.

### Limiting nutrients in ecosystems are those in short supply relative to need

A chain is only as strong as its weakest link. For the plants and algae in an ecosystem to grow—and to thereby provide food for animals—they need many different chemical elements. The simplest theory is that in any particular ecosystem, one element will be in shortest supply relative to the needs for it by the plants and algae. That element is the limiting nutrient—the weak link—in the ecosystem.

The cycle of a limiting nutrient is particularly important because it determines the rate at which the nutrient is made available for use. We gave the nitrogen and phosphorus cycles close attention precisely because those elements are the limiting nutrients in many ecosystems. Nitrogen is the limiting nutrient in about two-thirds of the oceans and in many terrestrial ecosystems.

Oceanographers have discovered in just the last 15 years that iron is the limiting nutrient for algal populations (phytoplankton) in about one-third of the world's oceans. In these waters, wind-borne soil dust seems often to be the chief source of iron. When wind brings in iron-rich dust, algal populations proliferate, provided the iron is in a usable chemical form. In this way, sand storms in the Sahara Desert, by increasing the dust in global winds, can increase algal productivity in Pacific waters (figure 58.6).

### Biogeochemical cycling in a forest ecosystem has been studied experimentally

An ongoing series of studies at the Hubbard Brook Experimental Forest in New Hampshire has yielded much of the available information about the cycling of nutrients in forest ecosystems.

**Figure 58.6 One world.** Every year, millions of metric tons of iron-rich dust is carried westward by the trade winds from the Sahara Desert and neighboring Sahel area. A working hypothesis of many oceanographers is that this dust fertilizes parts of the ocean, including parts of the Pacific Ocean, where iron is the limiting nutrient. Land use practices in Africa, which are increasing the size of the north African desert, can thus affect ecosystems on the other side of the globe.

*a.*

Hubbard Brook is the central stream of a large watershed that drains the hillsides of a mountain range covered with temperate deciduous forest. Multiple tributary streams carry water off the hillsides into Hubbard Brook.

Six tributary streams, each draining a particular valley, were equipped with measurement devices when the study was started. All of the water that flowed out of each valley had to pass through the measurement system, where the flow of water and concentrations of nutrients was quantified.

The undisturbed forests around Hubbard Brook are efficient at retaining nutrients. In a year, only small quantities of nutrients enter a valley from outside, doing so mostly as a result of precipitation. The quantities carried out in stream waters are small also. When we say “small,” we mean the influges and outfluxes represent just minor fractions of the total amounts of nutrients in the system—about 1% in the case of calcium, for example.

In 1965 and 1966, the investigators felled all the trees and cleared all shrubs in one of the six valleys and prevented regrowth (figure 58.7*a*). The effects were dramatic. The amount of water running out of that valley increased by 40%, indicating that water previously taken up by vegetation and evaporated into the atmosphere was now running off. The amounts of a number of nutrients running out of the system also greatly increased. For example, the rate of loss of calcium increased ninefold. Phosphorus, on the other hand, did not increase in the stream water; it apparently was locked up in insoluble compounds in the soil.

The change in the status of nitrogen in the disturbed valley was especially striking (figure 58.7*b*). The undisturbed forest in this valley had been accumulating  $\text{NO}_3^-$  at a rate of about 5 kg per hectare per year, but the deforested ecosystem lost  $\text{NO}_3^-$  at a rate of about 53 kg per hectare per year. The  $\text{NO}_3^-$  concentration in the stream water rapidly increased. The fertility of the valley decreased dramatically, while the run-off of nitrate generated massive algal blooms downstream, and the danger of downstream flooding greatly increased.

This experiment is particularly instructive at the start of the 21st century because forested land continues to be cleared worldwide (see chapter 59).

*b.*

**Figure 58.7 The Hubbard Brook experiment.** *a.* A 38-acre watershed was completely deforested, and the runoff monitored for several years. *b.* Deforestation greatly increased the loss of nutrients in runoff water from the ecosystem. The orange curve shows the nitrate concentration in the runoff water from the deforested watershed; the green curve shows the nitrate concentration in runoff water from an undisturbed neighboring watershed.

### Learning Outcomes Review 58.1

An ecosystem consists of the living and nonliving components of a particular place. Biogeochemical cycles describe how elements move between these components. Carbon, nitrogen, and phosphorus cycle in known ways, as does water, which is critical to ecosystems. Human populations disrupt these cycles with artificial fertilization, deforestation, diversion of water, and burning of fossil fuels.

- **Would fertilization with animal manure be less disruptive than fertilization with purified chemicals? Why or why not?**

## 58.2 The Flow of Energy in Ecosystems

### Learning Outcomes

1. Describe the different trophic levels.
2. Distinguish between energy and heat.
3. Explain how energy moves through trophic levels.

The dynamic nature of ecosystems includes the processing of energy as well as that of matter. Energy, however, follows very different principles than does matter. Energy is never recycled. Instead, radiant energy from the Sun that reaches the Earth makes a one-way pass through our planet's ecosystems before being converted to heat and radiated back into space, signifying that the Earth is an open system for energy.

### Energy can neither be created nor destroyed, but changes form

Why is energy so different from matter? A key part of the answer is that energy exists in several different forms, such as light, chemical-bond energy, motion, and heat. Although energy is neither created nor destroyed in the biosphere (the First Law of Thermodynamics), it frequently changes form.

A second key point is that organisms cannot convert heat to any of the other forms of energy. Thus, if organisms convert some chemical-bond or light energy to heat, the conversion is one-way; they cannot cycle that energy back into its original form.

### Living organisms can use many forms of energy, but not heat

To understand why the Earth must function as an open system with regard to energy, two additional principles need to be recognized. The first is that organisms can use only certain forms of energy. For animals to live, they must have energy specifically as chemical-bond energy, which they acquire from their foods. Plants must have energy as light. Neither animals nor plants (nor any other organisms) can use heat as a source of energy.

The second principle is that whenever organisms use chemical-bond or light energy, some of it is converted to heat; the Second Law of Thermodynamics states that a partial conversion to heat is inevitable. Put another way, animals and plants require chemical-bond energy and light to stay alive, but as they use these forms of energy, they convert them to heat, which they cannot use to stay alive and which they cannot cycle back into the original forms.

Fortunately for organisms, the Earth functions as an open system for energy. Light arrives every day from the Sun. Plants and other photosynthetic organisms use the newly arrived light to synthesize organic compounds and stay alive. Animals then eat the photosynthetic organisms, making use of the chemical-bond energy in their organic molecules to stay alive. Light and chemical-bond energy are partially converted to heat at every step. In fact, the light and chemical-bond energy are ultimately converted completely to heat. The heat leaves the Earth by being radiated into outer space at invisible, infrared wavelengths of the electromagnetic spectrum. For life to continue, new light energy is always required.

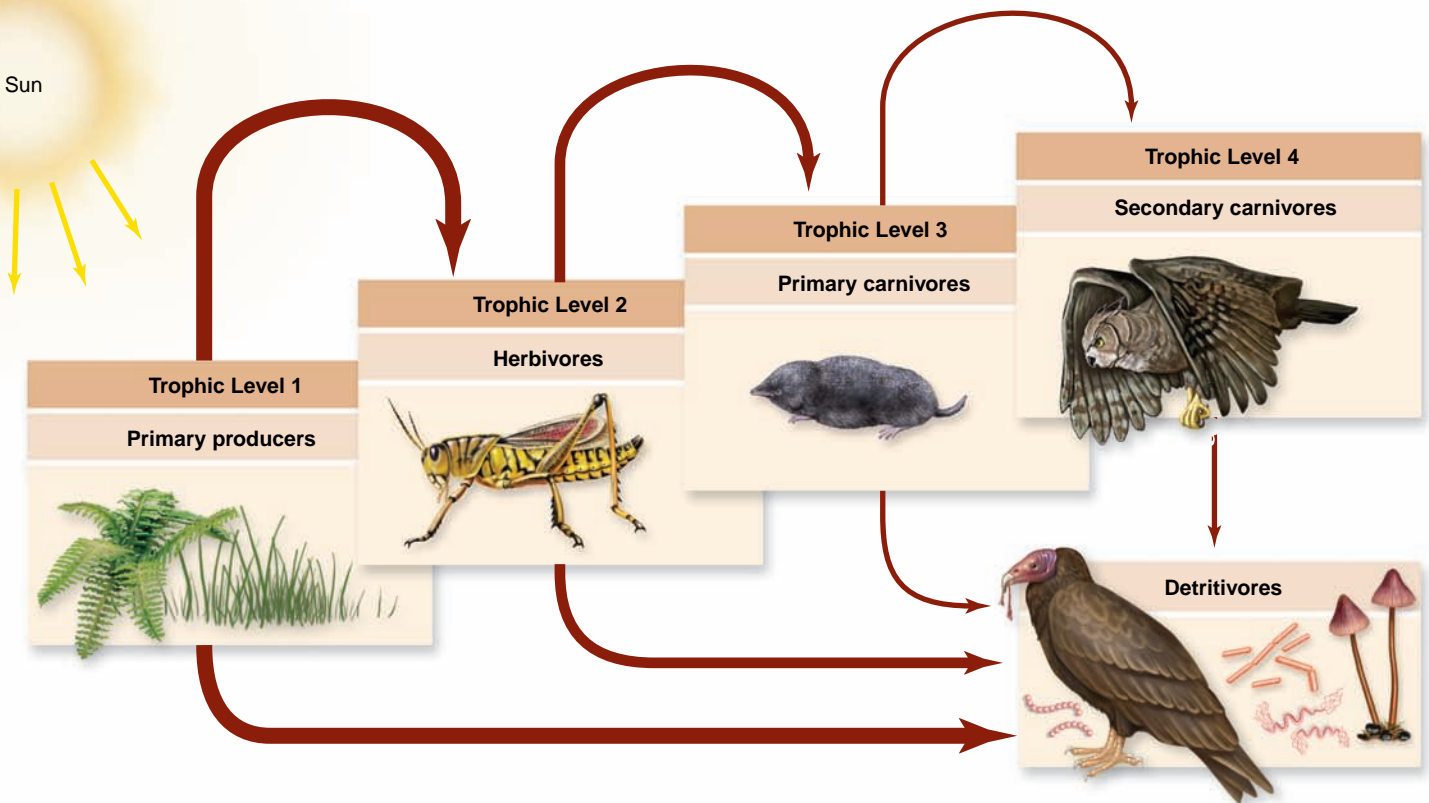

The Earth's incoming and outgoing flows of radiant energy must be equal for global temperature to stay constant. One concern is that human activities are changing the composition of the atmosphere in ways that impede the outgoing flow—the so-called *greenhouse effect*, which is described in the following chapter. Heat may be accumulating on Earth, causing global warming (see chapter 59).

### Energy flows through trophic levels of ecosystems

In chapter 7, we introduced the concepts of autotrophs (“self-feeders”) and heterotrophs (“fed by others”). **Autotrophs** synthesize the organic compounds of their bodies from inorganic precursors such as  $\text{CO}_2$ , water, and  $\text{NO}_3^-$  using energy from an abiotic source. Some autotrophs use light as their source of energy and therefore are **photoautotrophs**; they are the photosynthetic organisms, including plants, algae, and cyanobacteria. Other autotrophs are **chemoautotrophs** and obtain energy by means of inorganic oxidation reactions, such as the microbes that use hydrogen sulfide available at deep water vents (see chapter 59). All chemoautotrophs are prokaryotic. The photoautotrophs are of greatest importance in most ecosystems, and we focus on them in the remainder of this chapter.

Heterotrophs are organisms that cannot synthesize organic compounds from inorganic precursors, but instead live by taking in organic compounds that other organisms have made. They obtain the energy they need to live by breaking up some of the organic compounds available to them, thereby liberating chemical-bond energy for metabolic use (see chapter 7). Animals, fungi, and many microbes are heterotrophs.

When living in their native environments, species are often organized into chains that eat each other sequentially. For example, a species of insect might eat plants, and then a species of shrew might eat the insect, and a species of hawk might eat the shrew. Food passes through the four species in the sequence: plants  $\longrightarrow$  insect  $\longrightarrow$  shrew  $\longrightarrow$  hawk. A sequence of species like this is termed a food chain.

**Figure 58.8 Trophic levels within an ecosystem.** Primary producers such as plants obtain their energy directly from the Sun, placing them in trophic level 1. Animals that eat plants, such as plant-eating insects, are herbivores and are in trophic level 2. Animals that eat the herbivores, such as shrews, are primary carnivores and are in trophic level 3. Animals that eat the primary carnivores, such as owls, are secondary carnivores in trophic level 4. Each trophic level, although illustrated here by a particular species, consists of all the species in the ecosystem that function in a similar way in terms of what they eat. The organisms in the detritivore trophic level consume dead organic matter they obtain from all the other trophic levels.

In a whole ecosystem, many species play similar roles; there is typically not just a single species in each role. For example, the animals that eat plants might include not just a single insect species, but perhaps 30 species of insects, plus perhaps 10 species of mammals. To organize this complexity, ecologists recognize a limited number of feeding, or **trophic, levels** (figure 58.8).

### Definitions of trophic levels

The first trophic level in an ecosystem, called the **primary producers**, consists of all the autotrophs in the system. The other trophic levels consist of the heterotrophs—the **consumers**. All the heterotrophs that feed directly on the primary producers are placed together in a trophic level called the **herbivores**. In turn, the heterotrophs that feed on the herbivores (eating them or being parasitic on them) are collectively termed **primary carnivores**, and those that feed on the primary carnivores are called **secondary carnivores**.

Advanced studies of ecosystems need to take into account that organisms often do not line up in simple linear sequences in terms of what they eat; some animals, for example, eat both primary producers and other animals. A linear sequence of trophic levels is a useful organizing principle for many purposes, however.

An additional consumer level is the **detritivore** trophic level. Detritivores differ from the organisms in the other

trophic levels in that they feed on the remains of already-dead organisms; detritus is dead organic matter. A subcategory of detritivores is the **decomposers**, which are mostly microbes and other minute organisms that live on and break up dead organic matter.

### Concepts to describe trophic levels

Trophic levels consist of whole populations of organisms. For example, the primary-producer trophic level consists of the whole populations of all the autotrophic species in an ecosystem. Ecologists have developed a special set of terms to refer to the properties of populations and trophic levels.

The **productivity** of a trophic level is the rate at which the organisms in the trophic level collectively synthesize new organic matter (new tissue substance). **Primary productivity** is the productivity of the primary producers. An important complexity in analyzing the primary producers is that not only do they synthesize new organic matter by photosynthesis, but they also break down some of the organic matter to release energy by means of aerobic cellular respiration (see chapter 7). The **respiration** of the primary producers, in this context, is the rate at which they break down organic compounds. **Gross primary productivity (GPP)** is simply the raw rate at which the primary producers synthesize new organic matter; **net primary productivity (NPP)** is the GPP minus the respiration of the

primary producers. The NPP represents the organic matter available for herbivores to use as food.

The productivity of a heterotroph trophic level is termed **secondary productivity**. For instance, the rate that new organic matter is made by means of individual growth and reproduction in all the herbivores in an ecosystem is the secondary productivity of the herbivore trophic level. Each heterotroph trophic level has its own secondary productivity.

### How trophic levels process energy

The fraction of incoming solar radiant energy that the primary producers capture is small. Averaged over the course of a year, something around 1% of the solar energy impinging on forests or oceans is captured. Investigators sometimes observe far lower levels, but also see percentages as high as 5% under some conditions. The solar energy not captured as chemical-bond energy through photosynthesis is immediately converted to heat.

The primary producers, as noted before, carry out respiration in which they break down some of the organic compounds in their bodies to release chemical-bond energy. They use a portion of this chemical-bond energy to make ATP, which they in turn use to power various energy-requiring processes. Ultimately, the chemical-bond energy they release by respiration turns to heat.

Remember that organisms cannot use heat to stay alive. As a result, whenever energy changes form to become heat, it loses much or all of its usefulness for organisms as a fuel source. What we have seen so far is that about 99% of the solar energy impinging on an ecosystem turns to heat because it fails to be used by photosynthesis. Then some of the energy captured by photosynthesis also becomes heat because of respiration by the primary producers. All the heterotrophs in an ecosystem must live on the chemical-bond energy that is left.

### An example of energy loss between trophic levels

As chemical-bond energy is passed from one heterotroph trophic level to the next, a great deal of the energy is diverted all along the way. This principle has dramatic consequences. It means that, over any particular period of time, the amount of chemical-bond energy available to primary carnivores is far less than that available to herbivores, and the amount available to secondary carnivores is far less than that available to primary carnivores.

Why does the amount of chemical-bond energy decrease as energy is passed from one trophic level to the next? Consider the use of energy by the herbivore trophic level as an example (figure 58.9). After an herbivore such as a leaf-eating insect ingests some food, it produces feces. The chemical-bond energy in the compounds in the feces is not passed along to the primary carnivore trophic level. The chemical-bond energy of the food that is assimilated by the herbivore is used for a number of functions. Part of the assimilated energy is liberated by cellular respiration to be used for tissue repair, body movements, and other such functions. The energy used in these ways turns to heat and is not passed along to the carnivore trophic level. Some chemical-bond energy is built into the tissues of the herbivore and can serve as food for a carnivore. However, some herbivore individuals die of disease or accident rather than being eaten by predators.

### Figure 58.9 The fate of ingested chemical-bond energy: Why all the energy ingested by a heterotroph is not available to the next trophic level.

A heterotroph such as this herbivorous insect assimilates only a fraction of the chemical-bond energy it ingests. In this example, 50% is not assimilated and is eliminated in feces; this eliminated chemical-bond energy cannot be used by the primary carnivores. A third (33%) of the ingested energy is used to fuel cellular respiration and thus is converted to heat, which cannot be used by the primary carnivores. Only 17% of the ingested energy is converted into insect biomass through growth and can serve as food for the next trophic level, but not even that percentage is certain to be used in that way because some of the insects die before they are eaten.

In the end, of course, some of the initial chemical-bond energy acquired from the leaf is built into the tissues of herbivore individuals that are eaten by primary carnivores. Much of the initial chemical-bond energy, however, is diverted into heat, feces, and the bodies of herbivore individuals that carnivores do not get to eat. The same scenario is repeated at each step in a series of trophic levels (figure 58.10).

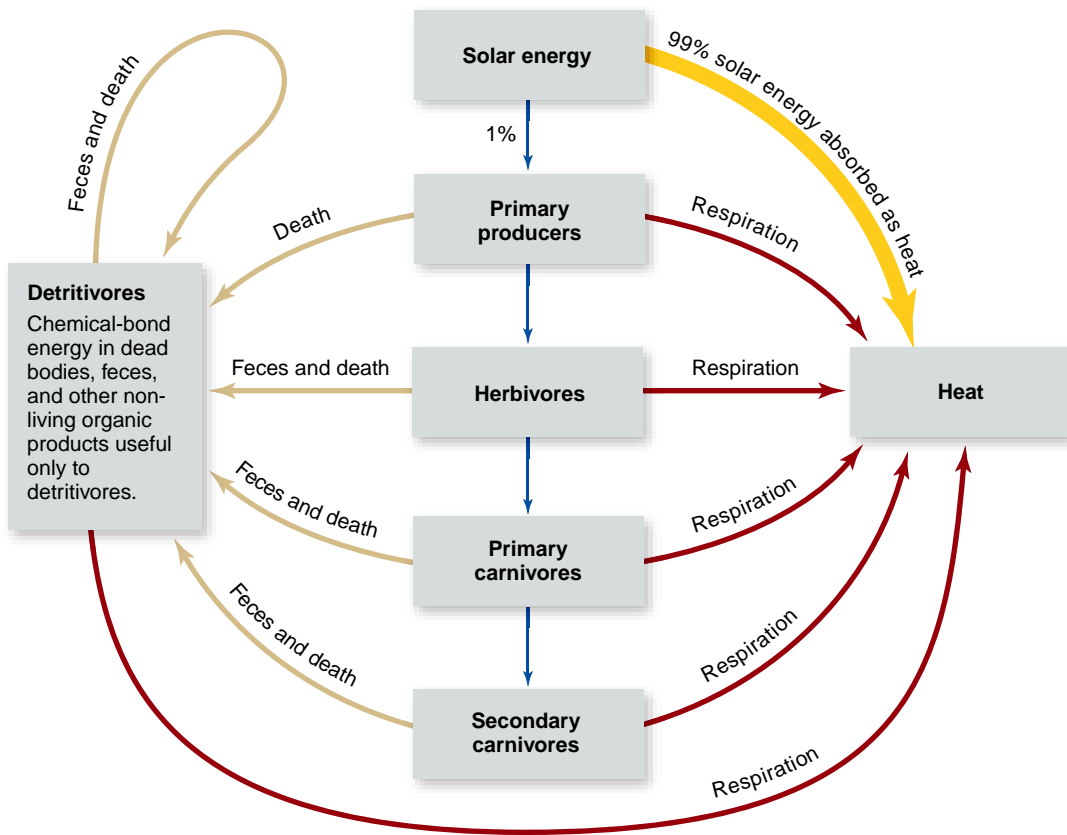

Ecologists figure as a rule of thumb that the amount of chemical-bond energy available to a trophic level over time is about 10% of that available to the preceding level over the same period of time. In some instances the percentage is higher, even as high as 30%.

### Heat as the final energy product

Essentially all of the chemical-bond energy captured by photosynthesis in an ecosystem eventually becomes heat as the chemical-bond energy is used by various trophic levels. To see this important point, recognize that when the detritivores in the ecosystem metabolize all the dead bodies, feces, and other materials made available to them, they produce heat just like the other trophic levels do.

### Productive ecosystems

Ecosystems vary considerably in their NPP. Wetlands and tropical rain forests are examples of particularly productive ecosystems (figure 58.11); in them, the NPP, measured as dry weight of new organic matter produced, is often around 2000 g/m<sup>2</sup>/year. By contrast, the corresponding figures for some other types of ecosystems are 1200 to 1300 for temperate forests, 900 for savanna, and 90 for deserts. (These general ecosystem types, termed *biomes*, are described in the following chapter.)

**Figure 58.10** The flow of energy through an ecosystem. Blue arrows represent the flow of energy that enters the ecosystem as light and is then passed along as chemical-bond energy to successive trophic levels. At each step energy is diverted, meaning that the chemical-bond energy available to each trophic level is less than that available to the preceding trophic level. Red arrows represent diversions of energy into heat. Tan arrows represent diversions of energy into feces and other organic materials useful only to the detritivores. Detritivores may be eaten by carnivores, so some of the chemical-bond energy returns to higher trophic levels.

### The number of trophic levels is limited by energy availability

The rate at which chemical-bond energy is made available to organisms in different trophic levels decreases exponentially as energy makes its way from primary producers to herbivores and

then to various levels of carnivores. To envision this critical point, assume for simplicity that the primary producers in an ecosystem gain 1000 units of chemical-bond energy over a period of time. If the energy input to each trophic level is 10% of the input to the preceding level, then the input of chemical-bond energy to the herbivore trophic level is 100 units, to the

**Figure 58.11** Ecosystem productivity per year. The first column of data shows the average net primary productivity (NPP) per square meter per year. The second column of data factors in the area covered by the ecosystem type; it is the product of the productivity per square meter per year times the number of square meters occupied by the ecosystem type worldwide. Note that an ecosystem type that is very productive on a square-meter basis may not contribute much to global productivity if it is an uncommon type, such as wetlands. On the other hand, a very widespread ecosystem type, such as the open ocean, can contribute greatly to global productivity even if its productivity per square meter is low.

primary carnivores, 10 units, and to the secondary carnivores, 1 unit over the same period of time.

### Limits on top carnivores

The exponential decline of chemical-bond energy in a trophic chain limits the lengths of trophic chains and the numbers of top carnivores an ecosystem can support. According to our model calculations, if an ecosystem includes secondary carnivores, only about one-thousandth of the energy captured by photosynthesis passes all the way through the series of trophic levels to reach these animals as usable chemical-bond energy. Tertiary carnivores would receive only one ten-thousandth. This helps explain why no predators subsist solely on eagles or lions.

The decline of available chemical-bond energy also helps explain why the numbers of individual top-level carnivores in an ecosystem tend to be low. The whole trophic level of top carnivores receives relatively little energy, and yet such carnivores tend to be big: They have relatively large individual body sizes and great individual energy needs. Because of these two factors, the population numbers of top predators tend to be small.

The longest trophic chains probably occur in the oceans. Some tunas and other top-level ocean predators probably function as third- and fourth-level carnivores at times. The challenge of explaining such long trophic chains is obvious, but the solutions are not well understood presently.

### Humans as consumers: A case study

The flow of energy in Cayuga Lake in upstate New York (figure 58.12) helps illustrate how the energetics of trophic levels can affect the human food supply. Researchers calculated from the actual properties of this ecosystem that about 150 of each 1000 calories of chemical-bond energy captured by primary producers in the lake were transferred into the bodies of herbivores. Of these calories, about 30 were transferred into the bodies of smelt, small fish that were the principal primary carnivores in the system.

If humans ate the smelt, they gained about 6 of the 1000 calories that originally entered the system. If trout ate the smelt and humans ate the trout, the humans gained only about 1.2 calories. For human populations in general, more energy is available if plants or other primary producers are eaten than if animals are eaten—and more energy is available if herbivores rather than carnivores are consumed.

### Ecological pyramids illustrate the relationship of trophic levels

Imagine that the trophic levels of an ecosystem are represented as boxes stacked on top of each other. Imagine also that the width of each box is proportional to the productivity of the trophic level it represents. The stack of boxes will always have the shape of a pyramid; each box is narrower than the one under it because of the inviolable rules of energy flow. A diagram of this sort is called a pyramid of energy flow or pyramid of productivity (figure 58.13*a*). It is an example of an ecological pyramid.

There are several types of ecological pyramids. Pyramid diagrams can be used to represent standing crop biomass or numbers of individuals, as well as productivity.

In a **pyramid of biomass**, the widths of the boxes are drawn to be proportional to standing crop biomass. Usually, trophic levels that have relatively low productivity also have relatively little biomass present at a given time. Thus, pyramids of biomass are usually upright, meaning each box is narrower than the one below it (figure 58.13*b*). An upright pyramid of biomass is not mandated by fundamental and inviolable rules like an upright pyramid of productivity is, however. In some ecosystems, the pyramid of biomass is **inverted**, meaning that at least one trophic level has greater biomass than the one below it (figure 58.13*c*).

How is it possible for the pyramid of biomass to be inverted? Consider a common sort of aquatic system in which the primary producers are single-celled algae (phytoplankton), and the herbivores are rice grain-sized animals (such as copepods) that feed directly on the algal cells. In such a system, the turnover of the algal cells is often very rapid: The cells multiply rapidly, but the animals consume them equally rapidly. In these circumstances, the algal cells never develop a large population size or large biomass. Nonetheless, because the algal cells are very productive, the ecosystem can support a substantial

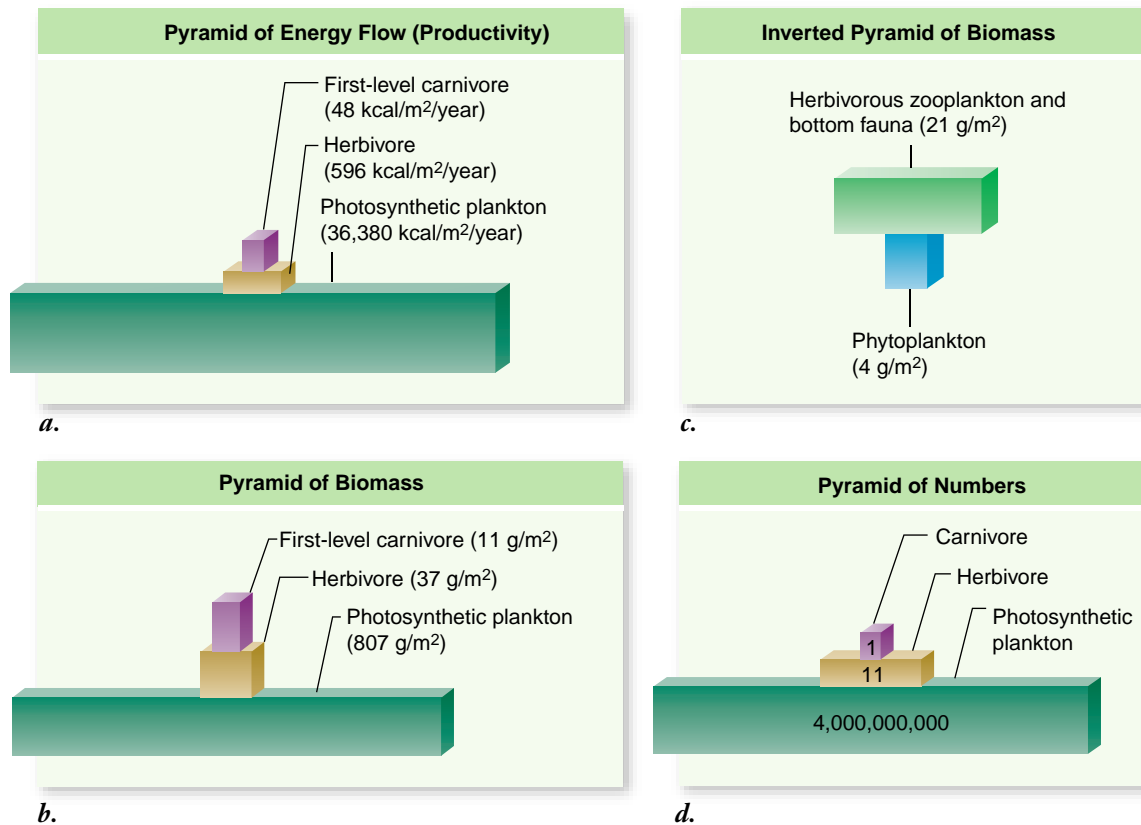

**Figure 58.12** Flow of energy through the trophic levels of Cayuga Lake. Autotrophic plankton (algae and cyanobacteria) fix the energy of the Sun, the herbivores (animal plankton) feed on them, and both are consumed by smelt. The smelt are eaten by trout. The amount of fish flesh produced per unit time for human consumption is at least five times greater if people eat smelt rather than trout, but people typically prefer to eat trout.

### Inquiry question

Why does it take so many calories of algae to support so few calories of humans?

**Figure 58.13 Ecological pyramids.** In an ecological pyramid, successive trophic levels in an ecosystem are represented as stacked boxes, and the widths of the boxes represent the magnitude of an ecological property in the various trophic levels. Ecological pyramids can represent several different properties. *a.* Pyramid of energy flow (productivity). *b.* Pyramid of biomass of the ordinary type. *c.* Inverted pyramid of biomass. *d.* Pyramid of numbers.

**Inquiry question**  
 ? How can the existence of inverted pyramids of biomass be explained?

biomass of the animals, a biomass larger than that ever observed in the algal population.

In a pyramid of numbers, the widths of the boxes are proportional to the numbers of individuals present in the various trophic levels (figure 58.13*d*). Such pyramids are usually, but not always, upright.

### Learning Outcomes Review 58.2

Trophic levels in an ecosystem include primary producers, herbivores, primary carnivores, and secondary carnivores. Detritivores consume dead or waste matter from all levels. As energy passes from one level to another, some is inevitably lost as heat, which cannot be reclaimed. Photosynthetic primary producers capture about 1% of solar energy as chemical-bond energy. As this energy is passed through the other trophic levels, some is diverted at each step into heat, feces, and dead matter; only about 10% is available to the next level.

- Describe the different ways that matter, such as carbon atoms, and energy move through ecosystems?

## 58.3 Trophic-Level Interactions

### Learning Outcomes

1. Explain the meaning of trophic cascade.
2. Distinguish between top-down and bottom-up effects.

The existence of food chains creates the possibility that species in any one trophic level may have effects on more than one trophic level. Primary carnivores, for example, may have effects not only on the animals they eat, but also, indirectly, on the plants or algae eaten by their prey. Conversely, increases in primary productivity may provide more food not just to herbivores, but also, indirectly, to carnivores.

The process by which effects exerted at an upper trophic level flow down to influence two or more lower levels is termed a **trophic cascade**. The effects themselves are called **top-down effects**. When an effect flows up through a trophic chain, such as from primary producers to higher trophic levels, it is termed a **bottom-up effect**.

### Top-down effects occur when changes in the top trophic level affect primary producers

The existence of top-down effects has been confirmed by controlled experiments in some types of ecosystems, particularly freshwater ones. For example, in one study, sections of a stream were enclosed with a mesh that prevented fish from entering. Brown trout—predators on invertebrates—were added to some enclosures but not others. After 10 days, the numbers of invertebrates in the enclosures with trout were only two-thirds as great as the numbers in the no-fish enclosures (figure 58.14). In turn, the biomass of algae, which the invertebrates ate, was five times greater in the trout enclosures than the no-fish ones.

The logic of the trophic cascade just described leads to the expectation that if secondary carnivores are added to

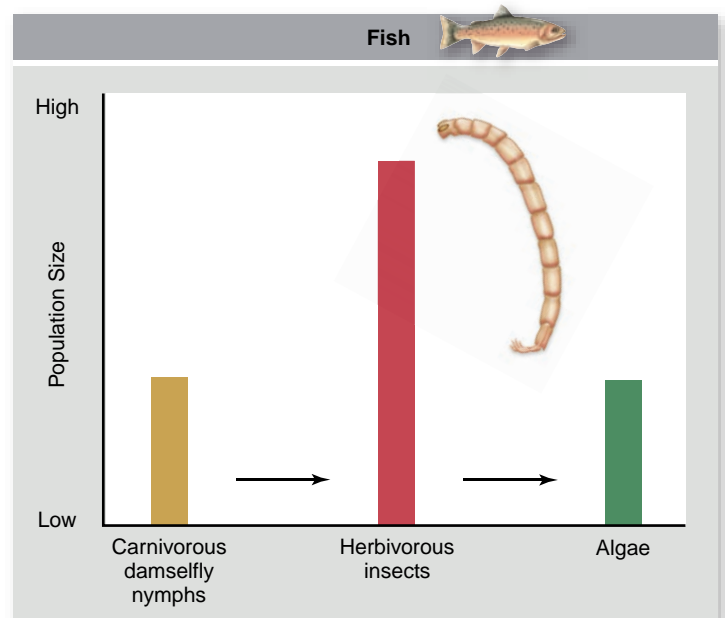

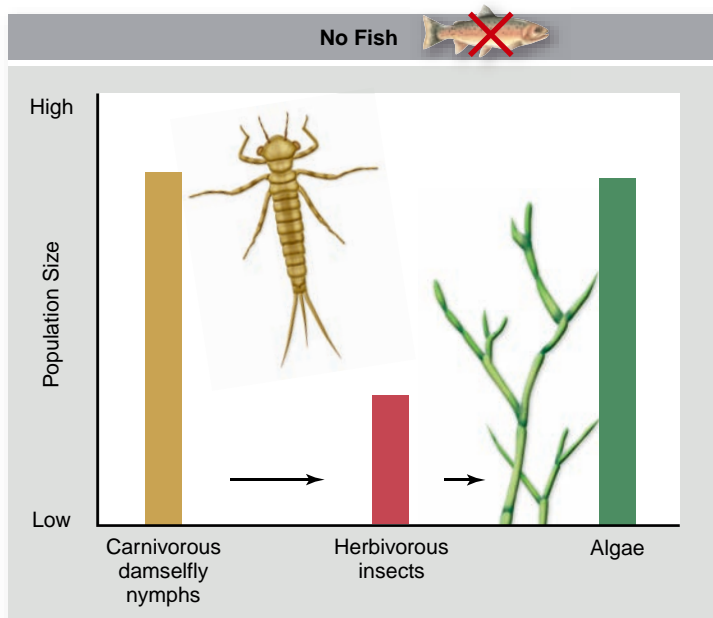

**Figure 58.14 Top-down effects demonstrated by experiment in a simple trophic cascade.** In a New Zealand stream, enclosures with trout had fewer herbivorous invertebrates (see the left-hand panel) and more algae (see the right-hand panel) than ones without trout.

### Inquiry question

? Why do streams with trout have more algae?

enclosures, they would also cause cascading effects. The secondary carnivores would be predicted to keep populations of primary carnivores in check, which would lead to a profusion of herbivores and a scarcity of primary producers.

**Figure 58.15 Top-down effects demonstrated by an experiment in a four-level trophic cascade.** Stream enclosures with large, carnivorous fish (on right) have fewer primary carnivores, such as damselfly nymphs, more herbivorous insects (exemplified here by the number of chironomids, a type of aquatic insect), and lower levels of algae.

### Inquiry question

? What might be the effect if snakes that prey on fish were added to the enclosures?

In an experiment similar to the one just described, enclosures were created in free-flowing streams in northern California. In these streams, the principal primary carnivores were damselfly larvae (termed *nymphs*). Fish that preyed on the nymphs and on other primary carnivores were added to some enclosures but not others. In the enclosures with fish, the numbers of damselfly nymphs were reduced, leading to higher numbers of their prey, including herbivorous insects, which led in turn to a decreased biomass of algae (figure 58.15).

Trophic cascades in large-scale ecosystems are not as easy to verify by experiment as ones in stream enclosures, and the workings of such cascades are not thoroughly known. Nonetheless, certain cascades in large-scale ecosystems are recognized by most ecologists. One of the most dramatic involves sea otters, sea urchins, and kelp forests along the West Coast of North America (figure 58.16).

The otters eat the urchins, and the urchins eat young kelps, inhibiting the development of kelp forests. When the otters are abundant, the kelp forests are well developed because there are relatively few urchins in the system. But when the otters are sparse, the urchins are numerous and impair development of the kelp forests. Orcas (killer whales) also enter the picture because in recent years they have started to prey intensively on the otters, driving otter populations down.

## Human removal of carnivores produces top-down effects

Human activities are believed to have had top-down effects in a number of ecosystems, usually by the removal of top-level

**Figure 58.16** A trophic cascade in a large-scale ecosystem. Along the West Coast of North America, the sea otter/sea urchin/kelp system exists in two states: In the state shown in panel *a*, low populations of sea otters permit high populations of urchins, which suppress kelp populations; in the state shown in panel *b*, high populations of otters keep urchins in check, permitting profuse kelp growth. According to a recent hypothesis, a switch of orcas to preying on otters rather than other mammals is leading the ecosystem today to be mostly in the state represented on the left.

carnivores. The great naturalist Aldo Leopold posited such effects long before the trophic cascade hypothesis had been scientifically articulated when he wrote in *Sand County Almanac*:

“I have lived to see state after state extirpate its wolves. I have watched the face of many a new wolfless mountain, and seen the south-facing slopes wrinkle with a maze of new deer trails. I have seen every edible bush and seedling browsed, first to anemic desuetude, and then to death. I have seen every edible tree defoliated to the height of a saddle horn.”

Many similar examples exist in which the removal of predators has led to cascading effects on lower trophic levels. Large predators such as jaguars and mountain lions are absent on Barro Colorado Island, a hilltop turned into an island by the construction of the Panama Canal at the beginning of the last century. As a result, smaller predators whose populations are normally held in check—including monkeys, peccaries (a relative of the pig), coatimundis, and armadillos—have become extraordinarily abundant. These animals eat almost anything they

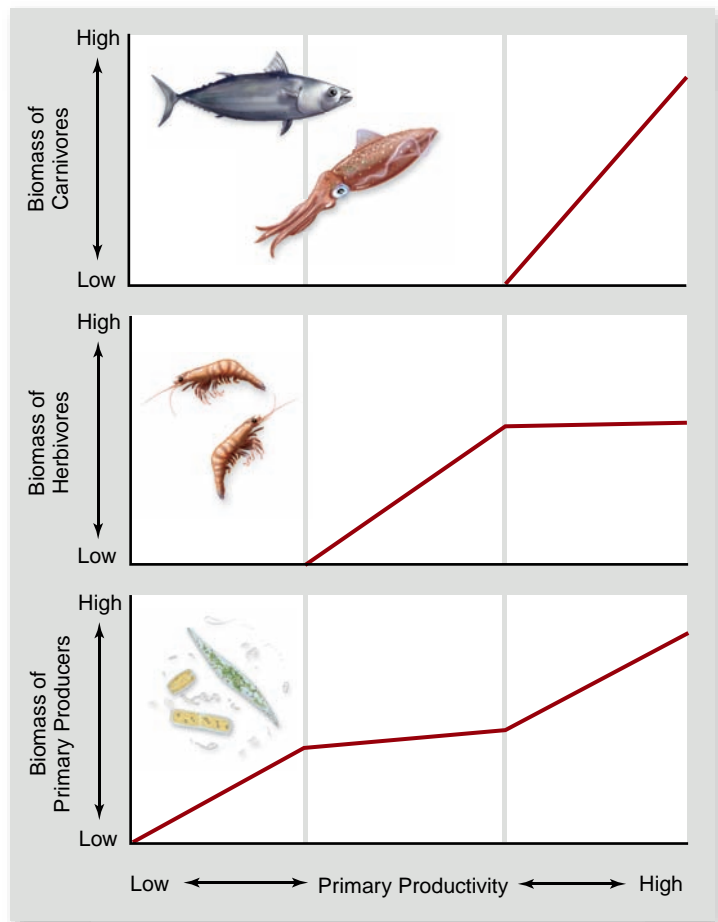

find. Ground-nesting birds are particularly vulnerable, and many species have declined; at least 15 bird species have vanished from the island entirely.

Similarly, in the world’s oceans, large predatory fish such as billfish and cod have been reduced by overfishing to an average of 10% of their previous numbers in virtually all parts of the world’s oceans. In some regions, the prey of cod—such as certain shrimp and crabs—have become many times more abundant than they were before, and further cascading effects are evident at still lower trophic levels.

### Bottom-up effects occur when changes to primary producers affect higher trophic levels

In predicting bottom-up effects, ecologists must take account of the life histories of the organisms present. A model of bottom-up effects thought to apply to a number of types of ecosystems is diagrammed in figure 58.17.

According to the model, when primary productivity is low, producer populations cannot support significant herbivore populations. As primary productivity increases, herbivore populations become a feature of the ecosystem. Increases in primary productivity are then entirely devoured by the herbivores, as the populations of which increase in size while keeping the populations of primary producers from increasing.

**Figure 58.17** A model of bottom-up effects. At low levels of primary productivity, herbivore populations cannot obtain enough food to be maintained; without herbivory, the standing crop biomass of the primary producers such as these diatoms increases as their productivity increases. Above some threshold, increases in primary productivity lead to increases in herbivore populations and herbivore biomass; the biomass of the primary producers then does not increase as primary productivity increases because the increasing productivity is cropped by the herbivores. Above another threshold, populations of primary carnivores can be sustained. As primary productivity increases above this threshold, the carnivores consume the increasing productivity of the herbivores, so the biomass of the herbivore populations remains relatively constant while the biomass of the carnivore populations increases. The biomass of the primary producers is no longer constrained by increases in the herbivore populations and thus also increases with increasing primary productivity. A key to understanding the model is to maintain a distinction between the concepts of productivity and standing crop biomass.

### Inquiry question

? How is it possible for the biomass of the primary producers to stay relatively constant as the primary productivity increases?

As primary productivity becomes still higher, herbivore populations become large enough that primary carnivores can be supported. Further increases in primary productivity then does not lead to increases in herbivore populations, but rather to increases in carnivore populations.

Experimental evidence for the bottom-up effects predicted by the model was provided by a study conducted in enclosures on a river (figure 58.18). The enclosures excluded large fish (secondary carnivores). A roof was placed above each enclosure. Some roofs were clear, whereas others were tinted to various degrees, so that the enclosures differed in the amount of sunlight entering them.

Experimental evidence for the bottom-up effects predicted by the model was provided by a study conducted in enclosures on a river (figure 58.18). The enclosures excluded large fish (secondary carnivores). A roof was placed above each enclosure. Some roofs were clear, whereas others were tinted to various degrees, so that the enclosures differed in the amount of sunlight entering them.

**Figure 58.18** An experimental study of bottom-up effects in a river ecosystem. This system, studied on the Eel River in northern California, exhibited the patterns modeled by the red graphs of figure 58.17. Increases in the intensity of illumination led to increases in primary productivity and in the biomass of the primary producers. The biomass of the carnivore populations also increased. However, herbivore biomass did not increase much with increasing primary productivity because increases in herbivore productivity were consumed by the carnivores.

### Inquiry question

? Why is the amount of light an important determinant of carnivore biomass?

The primary productivity was highest in the enclosures with clear roofs and lowest in the ones with darkly tinted roofs. As primary productivity increased in parallel with illumination, the biomass of the primary producers increased, as did the biomass of the carnivores. However, the biomass of the trophic level sandwiched in between, the herbivores, did not increase much, as predicted by the model in figure 58.17 (see red graph lines).

### Learning Outcomes Review 58.3

Populations of species at different trophic levels affect one another, and these effects can propagate through the levels. Top-down effects, termed trophic cascades, are observed when changes in carnivore populations affect lower trophic levels. Bottom-up effects are observed when changes in primary productivity affect the higher trophic levels.

- Could top-down and bottom-up effects occur simultaneously?

## 58.4 Biodiversity and Ecosystem Stability

### Learning Outcomes

1. Define ecosystem stability.
2. Describe the effects of species richness on ecosystem function.
3. Name possible factors that contribute to species richness in the tropics.

In the preceding chapter, we discussed *species richness*—the number of species present in a community. Ecologists have long debated the consequences of differences in species richness between communities. One theory is that species-rich communities are more stable—that is, more constant in composition and better able to resist disturbance. This hypothesis has been elegantly studied by David Tilman and colleagues at the University of Minnesota’s Cedar Creek Natural History Area.

### Species richness may increase stability:

#### The Cedar Creek studies

Workers monitored 207 small rectangular plots of land (8–16 m<sup>2</sup>) for 11 years (figure 58.19*a*). In each plot, they counted the number of prairie plant species and measured the total amount of plant biomass (that is, the mass of all plants on the plot). Over the course of the study, plant species richness was related to community stability—plots with more species showed less year-to-year variation in biomass. Moreover, in two drought years, the decline in biomass was negatively related to species richness—that is, plots with more species were less affected by drought.

These findings were subsequently confirmed by an experiment in which plots were seeded with different numbers of

### SCIENTIFIC THINKING

**Question:** Does species richness affect the invasibility of a community?

**Hypothesis:** The rate of successful invasion will be lower in communities with greater richness.

**Experiment:** Add seeds from the same number of non-native plants to experimental plots that differ in the number of plant species.

a.

b.

**Result:** Although the number of successful invasive species is highly variable, more species-rich plots on average are invaded by fewer species.

**Interpretation:** What might explain why so much variation exists in the number of successful invading species in communities with the same species richness?

### Figure 58.19 Effect of species richness on ecosystem stability. a.

b. Community stability can be assessed by looking at the effect of species richness on community invasibility. Each dot represents data from one experimental plot in the Cedar Creek experimental fields. Plots with more species are harder to invade by nonnative species.

### Inquiry question

How could you devise an experiment on invasibility that didn’t rely on species from surrounding areas?

species. Again, more species-rich plots had greater year-to-year stability in biomass over a 10-year period.

In a related experiment, when seeds of other plant species were added to different plots, the ability of these species to become established was negatively related to species richness (figure 58.19*b*). More diverse communities, in other words, are more resistant to invasion by new species, which is another measure of community stability.

Species richness may also affect other ecosystem processes. Tilman and colleagues monitored 147 experimental plots that varied in number of species to estimate how much growth was occurring and how much nitrogen the growing plants were taking up from the soil. They found that the more species a plot had, the greater the nitrogen uptake and total amount of biomass produced. In his study, increased biodiversity clearly appeared to lead to greater productivity.

Laboratory studies on artificial ecosystems have provided similar results. In one elaborate study, ecosystems covering 1 m<sup>2</sup> were constructed in growth chambers that controlled temperature, light levels, air currents, and atmospheric gas concentrations. A variety of plants, insects, and other animals were introduced to construct ecosystems composed of 9, 15, or 31 species, with the lower diversity treatments containing a subset of the species in the higher diversity enclosures. As with Tilman's experiments, the amount of biomass produced was related to species richness, as was the amount of carbon dioxide consumed, another measure of the productivity of the ecosystem.

Tilman's conclusion that healthy ecosystems depend on diversity is not accepted by all ecologists, however. Critics question the validity and relevance of these biodiversity studies, arguing that the more species are added to a plot, the greater the probability that one species will be highly productive. To show that high productivity results from high species richness per se, rather than from the presence of particular highly productive species, experimental plots have to exhibit "overyielding"; in other words, plot productivity has to be greater than that of the single most productive species grown in isolation.

Although this point is still debated, recent work at Cedar Creek and elsewhere has provided evidence of overyielding, supporting the claim that species richness of communities enhances community productivity and stability.

## Species richness is influenced by ecosystem characteristics

A number of factors are known or hypothesized to affect species richness in a community. We discussed some in chapter 57, such as loss of keystone species and moderate physical disturbance. Here we discuss three more: primary productivity, habitat heterogeneity, and climatic factors.

### Primary productivity

Ecosystems differ substantially in primary productivity (see figure 58.11). Some evidence indicates that species richness is related to primary productivity, but the relationship between them is not linear. In a number of cases, for example, ecosystems with intermediate levels of productivity tend to have the greatest number of species (figure 58.20a).

Why this is so is debated. One possibility is that levels of productivity are linked with numbers of consumers. Applying this concept to plant species richness, the argument is that at low productivity, there are few herbivores, and superior competitors among the plants are able to eliminate most other plant species. In contrast, at high productivity so many herbivores are present that only the plant species most resistant to grazing survive, reducing species diversity. As a result, the greatest numbers of plant species coexist at intermediate levels of productivity and herbivory.

### Habitat heterogeneity

Spatially heterogeneous abiotic environments are those that consist of many habitat types—such as soil types, for example. These heterogeneous environments can be expected to accommodate more species of plants than spatially homogeneous environments. What's more, the species richness of animals can be expected to reflect the species richness of plants present. An

**Figure 58.20** Factors that affect species richness. *a. Productivity:* In plant communities of mountainous areas of South Africa, species richness of plants peaks at intermediate levels of productivity (biomass). *b. Spatial heterogeneity:* The species richness of desert lizards is positively correlated with the structural complexity of the plant cover in desert sites in the American Southwest. *c. Climate:* The species richness of mammals is inversely correlated with monthly mean temperature range along the West Coast of North America.

### Inquiry question

(a.) Why is species richness greatest at intermediate levels of productivity? (b.) Why do more structurally complex areas have more species? (c.) Why do areas with less variation in temperature have more species?

example of this latter effect is seen in figure 58.20*b*: The number of lizard species at various sites in the American Southwest mirrors the local structural diversity of the plants.

### **Climatic factors**

The role of climatic factors is more difficult to predict. On the one hand, more species might be expected to coexist in a seasonal environment than in a constant one because a changing climate may favor different species at different times of the year. On the other hand, stable environments are able to support specialized species that would be unable to survive where conditions fluctuate. The number of mammal species at locations along the West Coast of North America is inversely correlated with the amount of local temperature variation—the wider the variation, the fewer mammalian species—supporting the latter line of argument (figure 58.20*c*).

### **Tropical regions have the highest diversity, although reasons are unclear**

Since before Darwin, biologists have recognized that more different kinds of animals and plants inhabit the tropics than the temperate regions. For many types of organisms, there is a steady increase in species richness from the arctic to the tropics. Called a **species diversity cline**, this biogeographic gradient in numbers of species correlated with latitude has been reported for plants and animals, including birds (figure 58.21), mammals, and reptiles.

For the better part of a century, ecologists have puzzled over the species diversity cline from the arctic to the tropics. The difficulty has not been in forming a reasonable hypothesis of why more species exist in the tropics, but rather in sorting through these many reasonable hypotheses. Here, we consider five of the most commonly discussed suggestions.

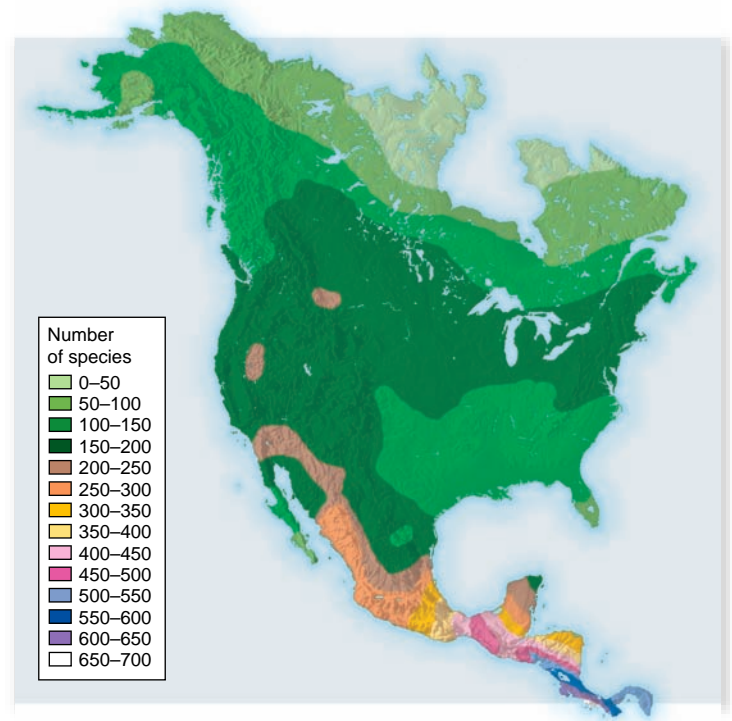

#### **Evolutionary age of tropical regions**

Scientists have frequently proposed that the tropics have more species than temperate regions because the tropics have existed over long, uninterrupted periods of evolutionary time, whereas temperate regions have been subject to repeated glaciations. The greater age of tropical communities would have allowed complex population interactions to coevolve within them, fostering a greater variety of plants and animals.

Recent work suggests that the long-term stability of tropical communities has been greatly exaggerated, however. An examination of pollen within undisturbed soil cores reveals that during glaciations, the tropical forests contracted to a few small refuges surrounded by grassland. This suggests that the tropics have not had a continuous record of species richness over long periods of evolutionary time.

#### **Increased productivity**

A second often-advanced hypothesis is that the tropics contain more species because this part of the Earth receives more solar radiation than do temperate regions. The argument is that more solar energy, coupled to a year-round growing season, greatly increases the overall photosynthetic activity of tropical plants.

**Figure 58.21 A latitudinal cline in species richness.** Among North and Central American birds, a marked increase in the number of species occurs moving toward the tropics. Fewer than 100 species are found at arctic latitudes, but more than 600 species live in southern Central America.

If we visualize the tropical forest's total resources as a pie, and its species niches as slices of the pie, we can see that a larger pie accommodates more slices. But as noted earlier, many field studies have indicated that species richness is highest at intermediate levels of productivity. Accordingly, increasing productivity would be expected to lead to lower, not higher, species richness.

#### **Stability/constancy of conditions**

Seasonal variation, though it does exist in the tropics, is generally substantially less than in temperate areas. This reduced seasonality might encourage specialization, with niches subdivided to partition resources and so avoid competition. The expected result would be a larger number of more specialized species in the tropics, which is what we see. Many field tests of this hypothesis have been carried out, and almost all support it, reporting larger numbers of narrower niches in tropical communities than in temperate areas.

#### **Predation**

Many reports indicate that predation may be more intense in the tropics. In theory, more intense predation could reduce the importance of competition, permitting greater niche overlap and thus promoting greater species richness.

#### **Spatial heterogeneity**

As noted earlier, spatial heterogeneity promotes species richness. Tropical forests, by virtue of their complexity, create a variety of microhabitats and so may foster larger numbers of species. Perhaps the long vertical column of vegetation through

which light passes in a tropical forest produces a wide range of light frequencies and intensities, creating a greater variety of light environments and so promoting species diversity.

### Learning Outcomes Review 58.4

An ecosystem is stable if it remains relatively constant in composition and is able to resist disturbance. Experimental field studies support the conclusion that species-rich communities are better able to resist invasion by new species, as well as have increased biomass production at the primary level, although not all ecologists agree with these conclusions. Species richness is greatest in the tropics, and the reasons may include habitat variation, increased sunlight, and long-term climate and seasonal stability.

- What might be the effects on primary productivity if air pollution decreased the amount of sunlight reaching Earth's surface?

## 58.5 Island Biogeography

### Learning Outcomes

1. Describe the species–area relationship.
2. Explain how area and isolation affect rates of colonization and extinction.

One of the most reliable patterns in ecology is the observation that larger islands contain more species than do smaller islands. In 1967, Robert MacArthur of Princeton University and Edward O. Wilson of Harvard University proposed that this species–area relationship was a result of the effect of geographic area and isolation on the likelihood of species extinction and colonization.

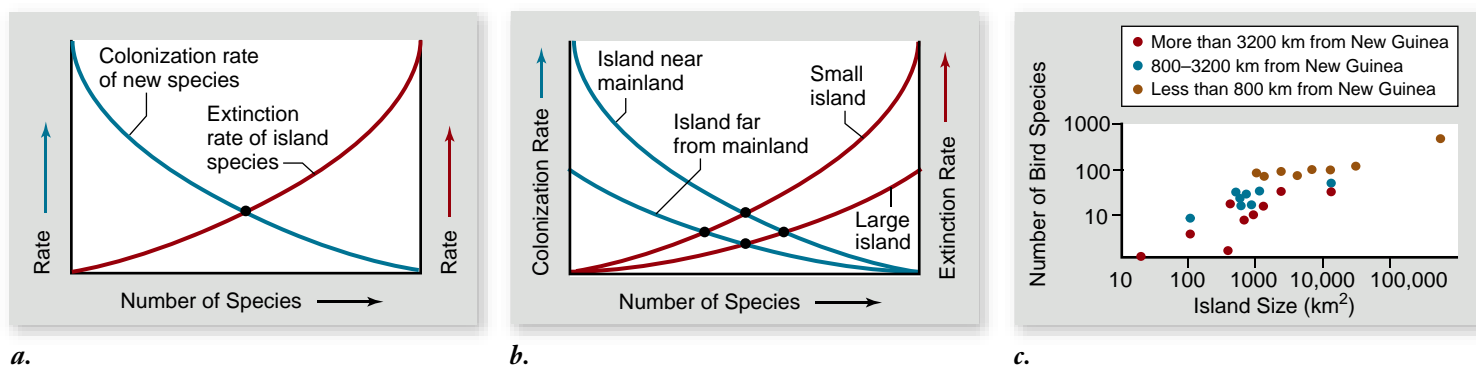

### The equilibrium model proposes that extinction and colonization reach a balance point

MacArthur and Wilson reasoned that species are constantly being dispersed to islands, so islands have a tendency to accumulate more and more species. At the same time that new species are added, however, other species are lost by extinction. As the number of species on an initially empty island increases, the rate of colonization must decrease as the pool of potential colonizing species not already present on the island becomes depleted. At the same time, the rate of extinction should increase—the more species on an island, the greater the likelihood that any given species will perish.

As a result, at some point, the number of extinctions and colonizations should be equal, and the number of species should then remain constant. Every island of a given size, then, has a characteristic equilibrium number of species that tends to persist through time (the intersection point in figure 58.22*a*)—though the species composition will change as some species become extinct and new species colonize.

MacArthur and Wilson's equilibrium model proposes that island species richness is a dynamic equilibrium between colonization and extinction. Both island size and distance from the mainland would affect colonization and extinction. We would expect smaller islands to have higher rates of extinction because their population sizes would, on average, be smaller. Also, we would expect fewer colonizers to reach islands that lie farther from the mainland. Thus, small islands far from the mainland would have the fewest species; large islands near the mainland would have the most (figure 58.22*b*).

The predictions of this simple model bear out well in field data. Asian Pacific bird species (figure 58.22*c*) exhibit a positive correlation of species richness with island size, but a negative correlation of species richness with distance from the source of colonists.

**Figure 58.22** The equilibrium model of island biogeography. *a.* Island species richness reaches an equilibrium (black dot) when the colonization rate of new species equals the extinction rate of species on the island. *b.* The equilibrium shifts depending on the rate of colonization, the size of an island, and its distance to sources of colonists. Species richness is positively correlated with island size and inversely correlated with distance from the mainland. Smaller islands have higher extinction rates, shifting the equilibrium point to the left. Similarly, more distant islands have lower colonization rates, again shifting the equilibrium point leftward. *c.* The effect of distance from a larger island, which can be the source of colonizing species, is readily apparent. More distant islands have fewer Asian Pacific bird species than do nearer islands of the same size.

## The equilibrium model is still being tested

Wilson and Dan Simberloff, then a graduate student, performed initial studies in the mid-1960s on small mangrove islands in the Florida keys. These islands were censused, cleared of animal life by fumigation, and then allowed to recolonize, with censuses being performed at regular intervals. These and other such field studies have tended to support the equilibrium model.

Long-term experimental field studies, however, are suggesting that the situation is more complicated than MacArthur and Wilson envisioned. Their model predicts a high level of species turnover as some species perish and others arrive. But studies of island birds and spiders indicate that very little turnover occurs from year to year. Those species that do come and go, moreover, comprise a subset of species that never attain high populations. A substantial proportion of the species appear to maintain high populations and rarely go extinct.

These studies have been going on for a relatively short period of time. It is possible that over periods of centuries, the equilibrium model is a good description of what determines island species richness.

### Learning Outcomes Review 58.5

The species–area relationship is an observation that an island of larger area contains more species. Species richness on islands appears to be a dynamic equilibrium between colonization and extinction. Distance from a mainland also affects the rates of colonization and extinction, and therefore fewer species would be found on small, isolated islands far from a mainland.

- Under what circumstances would a smaller island be expected to have more species than a larger island?

## Chapter Review

### 58.1 Biogeochemical Cycles

**The atomic constituents of matter cycle within ecosystems.**

The atoms of chemical elements move through ecosystems in biogeochemical cycles.

**Carbon, the basis of organic compounds, cycles through most ecosystems.**

The carbon cycle usually involves carbon dioxide, which is fixed through photosynthesis and released by respiration. Carbon is also present as bicarbonate ions and as methane. Burning of fossil fuels has created an imbalance in the carbon cycle (see figure 58.1).

**The availability of water is fundamental to terrestrial ecosystems.**

Water enters the atmosphere via evaporation and transpiration and returns to the Earth's surface as precipitation. It is broken down during photosynthesis and also produced during cellular respiration. Much of the Earth's water, including the groundwater in aquifers, is polluted, and human activities alter the water supply of ecosystems (see figure 58.2).

**The nitrogen cycle depends on nitrogen fixation by microbes.**

Nitrogen is usually the element in shortest supply even though  $N_2$  makes up 78% of the atmosphere. Nitrogen must be converted into usable forms by nitrogen-fixing microorganisms. Human use of nitrates in fertilizers has doubled the available nitrogen (see figure 58.4).

**Phosphorus cycles through terrestrial and aquatic ecosystems, but not the atmosphere.**

Phosphorus, another limiting nutrient, is released by weathering of rocks; it flows into the oceans where it is deposited in deep-sea sediments. Humans also use phosphates as fertilizers (see figure 58.5).

**Limiting nutrients in ecosystems are those in short supply relative to need.**

The cycle of a limiting nutrient, such as nitrogen, determines the rate at which the nutrient is made available for use.

**Biogeochemical cycling in a forest ecosystem has been studied experimentally.**

Ongoing experiments indicate that severe disturbance of an ecosystem results in mineral depletion and runoff of water.

### 58.2 The Flow of Energy in Ecosystems

**Energy can neither be created nor destroyed, but changes form.**

Energy exists in forms such as light, stored chemical-bond energy, motion, and heat. In any conversion, some energy is lost.

**Living organisms can use many forms of energy, but not heat.**

The Second Law of Thermodynamics states that whenever organisms use chemical-bond or light energy, some of it is inevitably converted to heat and cannot be retrieved.

**Energy flows through trophic levels of ecosystems.**

Organic compounds are synthesized by autotrophs and are utilized by both autotrophs and heterotrophs. As energy passes from organism to organism, each level is termed a trophic level, and the sequence through progressive trophic levels is called a food chain (see figure 58.8).

The base trophic level includes the primary producers; herbivores that consume primary producers are the next level. They in turn are eaten by primarily carnivores, which may be consumed by secondary carnivores. Detritivores feed on waste and the remains of dead organisms.

Only about 1% of the solar energy that impinges on the Earth is captured by photosynthesis. As energy moves through each trophic level, very little (approximately 10%) remains from the preceding trophic level (see figure 58.10).

**The number of trophic levels is limited by energy availability.**

The exponential decline of energy between trophic levels limits the length of food chains and the numbers of top carnivores that can be supported.

### Ecological pyramids illustrate the relationship of trophic levels.

Ecological pyramids based on energy flow, biomass, or numbers of organisms are usually upright. Inverted pyramids of biomass or numbers are possible if at least one trophic level has a greater biomass or more organisms than the level below it (see figure 58.13).

## 58.3 Trophic-Level Interactions

### Top-down effects occur when changes in the top trophic level affect primary producers.

A trophic cascade, or top-down effect, occurs when a change exerted at an upper trophic level affects a lower level (see figure 58.15).

### Human removal of carnivores produces top-down effects.

Removal of carnivores causes an increase in the abundance of species in lower trophic levels, such as an increase in deer populations when wolves or other predators are destroyed.

### Bottom-up effects occur when changes to primary producers affect higher trophic levels.

An increase of producers may lead to the appearance or increase of herbivores; however, further increase in producers may then lead to increase in carnivores, without a comparable increase in herbivores (see figure 58.17).

## 58.4 Biodiversity and Ecosystem Stability

### Species richness may increase stability: The Cedar Creek studies.

The Cedar Creek studies indicate that higher species richness results in less year-to-year variation in biomass and in greater resistance to drought and invasion by non-native species.

### Species richness is influenced by ecosystem characteristics.

Primary production, habitat heterogeneity, and climatic factors all affect the number of species in an ecosystem (see figure 58.20).

### Tropical regions have the highest diversity, although the reasons are unclear.

The higher diversity of tropical regions may reflect long evolutionary time, higher productivity from increased sunlight, less seasonal variation, greater predation that reduces competition, or spatial heterogeneity (see figure 58.21).

## 58.5 Island Biogeography

The species–area relationship reflects that larger islands contain more species than do smaller ones.

### The equilibrium model proposes that extinction and colonization reach a balance point (see figure 58.22).

Smaller islands have fewer species because of higher rates of extinction. Islands near a mainland have more species than distant islands because of higher rates of colonization. An equilibrium is reached when the extinction rate balances the colonization rate.

### The equilibrium model is still being tested.

Long-term studies are needed to clarify all the factors involved.

## Review Questions

### UNDERSTAND

- Which of the statements about groundwater is *not* accurate?
  - In the United States, groundwater provides 50% of the population with drinking water.
  - Groundwaters are being depleted faster than they can be recharged.
  - Groundwaters are becoming increasingly polluted.
  - Removal of pollutants from groundwaters is easily achieved.
- Photosynthetic organisms
  - fix carbon dioxide.
  - release carbon dioxide.
  - fix oxygen.
  - (a) and (b)
  - (a) and (c)
- Some bacteria have the ability to “fix” nitrogen. This means
  - they convert ammonia into nitrites and nitrates.
  - they convert atmospheric nitrogen gas into biologically useful forms of nitrogen.
  - they break down nitrogen-rich compounds and release ammonium ions.
  - they convert nitrate into nitrogen gas.
- Which of the following statements about the phosphorus cycle is correct?
  - Phosphorus is fixed by plants and algae.
  - Most phosphorus released from rocks is carried to the oceans by rivers.
  - Animals cannot get their phosphorus from eating plants and algae.
  - Fertilizer use has not affected the global phosphorus budget.
- As a general rule, how much energy is lost in the transmission of energy from one trophic level to the one immediately above it?
  - 1%
  - 10%
  - 90%
  - 50%
- Inverted ecological pyramids of real systems usually involve
  - energy flow.
  - biomass.
  - energy flow and biomass.
  - None of the above
- Bottom-up effects on trophic structure result from
  - a limitation of energy flowing to the next higher trophic level.
  - actions of top predators on lower trophic levels.

- c. climatic disruptions on top consumers.
  - d. stability of detritivores in ecosystems.
8. Species diversity
- a. increases with latitude as you move away from the equator to the arctic.
  - b. decreases with latitude as you move away from the equator to the arctic.
  - c. stays the same as you move away from the equator to the arctic.
  - d. increases with latitude as you move north of the equator and decreases with latitude as you move south of the equator.
9. The equilibrium model of island biogeography suggests all of the following *except*
- a. larger islands have more species than smaller islands.
  - b. the species richness of an island is determined by colonization and extinction.
  - c. smaller islands have lower rates of extinction.
  - d. islands closer to the mainland will have higher colonization rates.

### APPLY

1. Nitrogen is often a limiting nutrient in many ecosystems because
    - a. there is much less nitrogen in the atmosphere than carbon.
    - b. elemental nitrogen is very rapidly used by most organisms.
    - c. nitrogen availability is being reduced by pollution due to fertilizer use.
    - d. most organisms cannot use nitrogen in its elemental form.
  2. Based on results from studies at Hubbard Brook Experimental Forest, what would be the predicted effect of clearing trees from a watershed?
    - a. Increased loss of water and nutrients from a watershed
    - b. Decreased loss of water and nutrients from a watershed
    - c. Increased availability of phosphorus
    - d. Increased availability of nitrate
  3. According to the trophic cascade hypothesis, the removal of carnivores from an ecosystem may result in
    - a. a decline in the number of herbivores and a decline in the amount of vegetation.
    - b. a decline in the number of herbivores and an increase in the amount of vegetation.
    - c. an increase in the number of herbivores and an increase in the amount of vegetation.
    - d. an increase in the number of herbivores and a decrease in the amount of vegetation.
4. At Cedar Creek Natural History Area, experimental plots showed reduced numbers of invaders as species diversity of plots increased
    - a. suggesting that low species diversity increases stability of ecosystems.
    - b. suggesting that ecosystem stability is a function of primary productivity only.
    - c. consistent with the theory that intermediate disturbance results in the highest stability.
    - d. None of the above

### SYNTHESIZE

1. Given that ectotherms do not utilize a large fraction of ingested food energy to maintain a high and constant body temperature (generate heat), how would you expect the food chains of systems dominated by ectothermic herbivores and carnivores to compare with systems dominated by endothermic herbivores and carnivores?
2. Given that, in general, energy input is greatest at the bottom trophic level (primary producers) and decreases with increasing transfers across trophic levels, how is it possible for many lakes to show much greater standing biomass in herbivorous zooplankton than in the phytoplankton they consume?
3. Ecologists often worry about the potential effects of the loss of species (e.g., due to pollution, habitat degradation, or other human-induced factors) on an ecosystem for reasons other than just the direct loss of the species. Using figure 58.17 explain why.
4. Explain several detailed ways in which increasing plant structural complexity could lead to greater species richness of lizards (figure 58.20*b*). Could any of these ideas be tested? How?

# Chapter 59

## The Biosphere

### Chapter Outline

- 59.1** Ecosystem Effects of Sun, Wind, and Water
- 59.2** Earth's Biomes
- 59.3** Freshwater Habitats
- 59.4** Marine Habitats
- 59.5** Human Impacts on the Biosphere: Pollution and Resource Depletion
- 59.6** Human Impacts on the Biosphere: Climate Change

### Introduction

The biosphere includes all living communities on Earth, from the profusion of life in the tropical rain forests to the planktonic communities in the world's oceans. In a very general sense, the distribution of life on Earth reflects variations in the world's abiotic environments, such as the variations in temperature and availability of water from one terrestrial environment to another. The figure on this page is a satellite image of the Americas, based on data collected over 8 years. The colors are keyed to the relative abundance of chlorophyll, an indicator of the richness of biological communities. Green and dark green areas on land are areas with high primary productivity (such as thriving forests), whereas yellow areas include the deserts of the Americas and the tundra of the far north, which have lower productivity.

### 59.1 Ecosystem Effects of Sun, Wind, and Water

#### Learning Outcomes

1. Describe changes in wind and current direction with latitude.
2. Explain the Coriolis effect.
3. Describe how temperature changes with altitude and latitude.

The great global patterns of life on Earth are heavily influenced by (1) the amount of solar radiation that reaches different parts of the Earth and seasonal variations in that radiation; and (2) the patterns of global atmospheric circulation and the resulting patterns of oceanic circulation. Local characteristics, such as soil types and the altitude of the land, interact with the global patterns in sunlight, winds, and water currents to determine the conditions under which life exists and thus the distributions of ecosystems.

**Figure 59.1 Relationships between the Earth and the Sun are critical in determining the nature and distribution of life on Earth.** *a.* A beam of solar energy striking the Earth in the middle latitudes of the northern hemisphere (or the southern) spreads over a wider area of the Earth's surface than an equivalent beam striking the Earth at the equator. *b.* The fact that the Earth orbits the Sun each year has a profound effect on climate. In the northern and southern hemispheres, temperature changes in an annual cycle because the Earth's axis is not perpendicular to its orbital plane and, consequently, each hemisphere tilts toward the Sun in some months but away from the Sun in others.

### Solar energy and the Earth's rotation affect atmospheric circulation

The Earth receives energy from the Sun at a high rate in the form of electromagnetic radiation at visible and near-visible wavelengths. Each square meter of the upper atmosphere receives about 1400 joules per second (J/sec), which is equivalent to the output of fourteen 100-watt (W) lightbulbs.

As the solar radiant energy passes through the atmosphere, its intensity and wavelength composition are modified. About half of the energy is absorbed within the atmosphere, and half reaches the Earth's surface. The gases in the atmosphere absorb some wavelengths strongly while allowing other wavelengths to pass freely through. As a result, the wavelength composition of the solar energy that reaches the Earth's surface is different from that emitted by the Sun. For example, the band of ultraviolet wavelengths known as UV-B is strongly absorbed by ozone (O<sub>3</sub>) in the atmosphere, and thus this wavelength is greatly reduced in the solar energy that reaches the Earth's surface.

#### How solar radiation affects climate

Some parts of the Earth's surface receive more energy from the Sun than others. These differences have a great effect on climate.

A major reason for differences in solar radiation from place to place is the fact that Earth is a sphere, or nearly so (figure 59.1*a*). The tropics are particularly warm because the Sun's rays arrive almost perpendicular to the surface of the Earth in regions near the equator. Closer to the poles, the angle at which the Sun's rays strike, called the *angle of incidence*, spreads the solar energy out over more of the Earth's surface, providing less energy per unit of surface area. As figure 59.2 shows, the highest annual mean temperatures occur near the equator (0° latitude).

The Earth's annual orbit around the Sun and its daily rotation on its own axis are also important in determining patterns of

solar radiation and their effects on climate (figure 59.1*b*). The axis of rotation of the Earth is not perpendicular to the plane in which the earth orbits the Sun. Because the axis is tilted by approximately 23.5°, a progression of seasons occurs on all parts of the Earth, especially at latitudes far from the equator. The northern hemisphere, for example, tilts toward the Sun during some months but away during others, giving rise to summer and winter.

#### Global circulation patterns in the atmosphere

Hot air tends to rise relative to cooler air because the motion of molecules in the air increases as temperature increases, making it less dense. Accordingly, the intense solar heating of the Earth's

**Figure 59.2 Annual mean temperature varies with latitude.** The red line represents the annual mean temperature at various latitudes, ranging from near the North Pole at the left to near Antarctica at the right; the equator is at 0° latitude. At each latitude, the upper edge of the blue zone is the highest mean monthly temperature observed in all the months of the year, and the lower edge is the lowest mean monthly temperature.

surface at equatorial latitudes causes air to rise from the surface to high in the atmosphere at these latitudes. This rising air is typically rich with water vapor; one reason is that the moisture-holding capacity of air increases when it is heated, and a second reason is that the intense solar radiation at the equator provides the heat needed for great quantities of water to evaporate. After the warm, moist air rises from the surface (figure 59.3), rising air underneath it is pushed away from the equator at high altitudes (above 10 km), to the north in the northern hemisphere and to the south in the southern hemisphere. To take the place of the rising air, cooler air flows toward the equator along the surface from both the north and the south. These air movements give rise to one of the major features of the global atmospheric circulation: air flows toward the equator in both hemispheres at the surface, rises at the equator, and flows away from the equator at high altitudes. The exact patterns of flow

**Figure 59.3 Global patterns of atmospheric circulation.**

The diagram shows the patterns of air circulation that prevail on average over weeks and months of time (on any one day the patterns might be dramatically different from these average patterns). Rising air that is cooled creates bands of relatively high precipitation near the equator and at latitudes near 60°N and 60°S. Air that has lost most of its moisture at high altitudes tends to descend to the surface of the Earth at latitudes near 30°N and 30°S, creating bands of relatively low precipitation. The red arrows show the winds blowing at the surface of the Earth; the blue arrows show the direction the winds blow at high altitude. The winds travel in curved paths relative to the Earth's surface because the Earth is rotating on its axis under them (the Coriolis effect). A terminological problem to recognize is that the formal names given to winds refer to the directions from which they come, rather than the directions toward which they go; thus, the winds between 30° and 60° are called Westerlies because they come out of the west. Unfortunately, oceanographers use the opposite approach, naming water currents for the directions in which they go.

are affected by the spinning of the Earth on its axis; we discuss this effect shortly.

For complex reasons, the air circulating up from the equator and away at high altitudes in both hemispheres tends to circulate back down to the surface of the Earth at about 30° of latitude, both north and south (see figure 59.3). During the course of this movement, the moisture content of the air changes radically because of the changes in temperature the air undergoes. Cooling dramatically decreases air's ability to hold water vapor. Consequently, much of the water vapor in the air rising from the equator condenses to form clouds and rain as the air moves upward. This rain falls in the latitudes near the equator, latitudes that experience the greatest precipitation on Earth.

By the time the air starts to descend back to the Earth's surface at latitudes near 30°, it is cold and thus has lost most of its water vapor. Although the air rewarms as it descends, it does not gain much water vapor on the way down. Many of the greatest deserts occur at latitudes near 30° because of the steady descent of dry air to the surface at those latitudes. The Sahara Desert is the most dramatic example.

The air that descends at latitudes near 30° flows only partly toward the equator after reaching the surface of the Earth. Some of it flows toward the poles, helping to give rise in each hemisphere to winds that blow over the Earth's surface from 30° toward 60° latitude. At latitudes near 60° air tends to rise from the surface toward high altitudes.

### Inquiry question

? Why is it hotter at latitudes near 0°?

### The Coriolis effect

If Earth did not rotate on its axis, global air movements would follow the simple patterns already described. Air currents—the winds—move across a rotating surface, however. Because the solid Earth rotates under the winds, the winds move in curved paths across the surface, rather than straight paths. The curvature of the paths of the winds due to Earth's rotation is termed the **Coriolis effect**, after the 19th-century French mathematician, Gaspard-Gustave Coriolis, who described it.

If you were standing on the North Pole, the Earth would appear to be rotating counterclockwise on its axis, but if you were at the South Pole, the Earth would appear to be rotating clockwise. This property of a rotating sphere, that its direction of rotation is opposite when viewed from its two poles, explains why the direction of the Coriolis effect is opposite in the two hemispheres. In the northern hemisphere, winds always curve to the right of their direction of motion; in the southern hemisphere, they always curve to the left.

The reason for these wind patterns is that the circumference of a sphere, the Earth, changes with latitude. It is zero at the poles and 38,000 km at the equator. Thus, land surface speed changes from about 0 to 1500 km per hour going from the poles to the equator. Air descending at 30° north latitude may be going roughly the same speed as the land surface below it. As it moves toward the equator, however, it is moving more slowly than the surface below it, so it is deflected to its right in the northern hemisphere and to its left in the southern hemisphere. In other words, in both the northern and southern

hemispheres, the winds blow westward as well as toward the equator. The result (see figure 59.3) is that winds on both sides of the equator—called the Trade Winds—blow out of the east and toward the west.

Conversely, air masses moving north from 30° are moving more rapidly than underlying land surfaces and thus are deflected again to their right, which in this case is eastward. Similarly, in the southern hemisphere, air masses between 30° and 60° are deflected eastward, to the left. In both hemispheres, therefore, winds between 30° and 60° blow out of the west and toward the east; these winds are called Westerlies.

### Global currents are largely driven by winds

The major ocean currents are driven by the winds at the surface of the Earth, which means that indirectly the currents are driven by solar energy. The radiant input of heat from the Sun sets the atmosphere in motion as already described, and then the winds set the ocean in motion.

In the north Atlantic Ocean (figure 59.4), the global winds follow this pattern: Surface winds tend to blow out of the east and toward the west near the equator, but out of the west and toward the east at midlatitudes (between 30° and 60°). Consequently, surface waters of the north Atlantic Ocean tend to move in a giant closed curve—called a **gyre**—flowing from North America toward Europe at midlatitudes, then re-

turning from Europe and Africa to North America at latitudes near the equator.

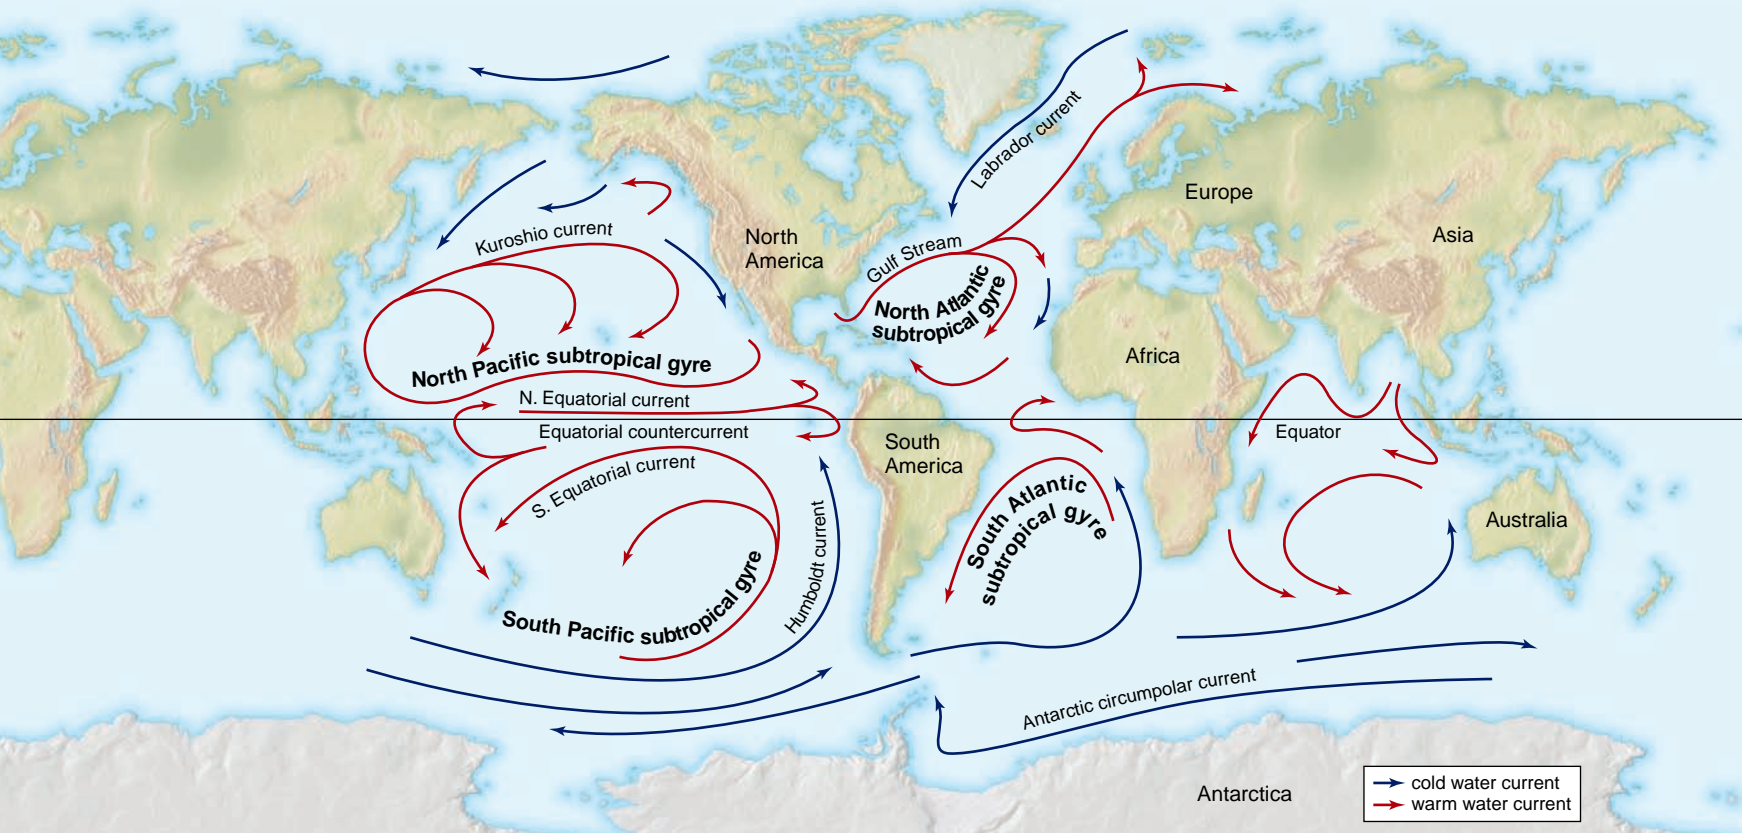

Water currents are affected by the Coriolis effect. Thus, the Coriolis effect contributes to this clockwise closed-curve motion. Water flowing across the Atlantic toward Europe at midlatitudes tends to curve to the right and enters the flow from east to west near the equator. This latter flow also tends to curve to its right and enters the flow from west to east at midlatitudes. In the south Atlantic Ocean, the same processes occur in a sort of mirror image, and similar clockwise and counterclockwise gyres occur in the north and south Pacific Ocean as well.

### Regional and local differences affect terrestrial ecosystems

The environmental conditions at a particular place are affected by regional and local effects of solar radiation, air circulation, and water circulation, not just the global patterns of these processes. In this section we look at just a few examples of regional and local effects, focusing on terrestrial systems. These include rain shadows, monsoon winds, elevation, and presence of microclimate factors.

#### Rain shadows

Deserts on land sometimes occur because mountain ranges intercept moisture-laden winds from the sea. When air flowing

**Figure 59.4 Ocean circulation.** In the centers of several of the great ocean basins, surface water moves in great closed-curve patterns called gyres. These water movements affect biological productivity in the oceans and sometimes profoundly affect the climate on adjacent landmasses, as when the Gulf Stream brings warm water to the region of the British Isles.

**Figure 59.5 The rain shadow effect exemplified in California.** Moisture-laden winds from the Pacific Ocean rise and are cooled when they encounter the Sierra Nevada Mountains. As the moisture-holding capacity of the air decreases at colder, higher altitudes, precipitation occurs, making the seaward-facing slopes of the mountains moist; tall forests occur on those slopes, including forests that contain the famous giant sequoias (*Sequoiadendron giganteum*). As the air descends on the eastern side of the mountain range, its moisture-holding capacity increases again, and the air picks up moisture from its surroundings. As a result, the eastern slopes of the mountains are arid, and rain shadow deserts sometimes occur.

landward from the oceans encounters a mountain range (figure 59.5), the air rises, and its moisture-holding capacity decreases because it becomes cooler at higher altitude, causing precipitation to fall on the mountain slopes facing the sea.

As the air—stripped of much of its moisture—then descends on the other side of the mountain range, it remains dry even as it is warmed, and as it is warmed its moisture-holding capacity increases, meaning it can readily take up moisture from soils and plants.

One consequence is that the two slopes of a mountain range often differ dramatically in how moist they are; in California, for example, the eastern slopes of the Sierra Nevada Mountains—facing away from the Pacific Ocean—are far drier than the western slopes. Another consequence is that a desert may develop on the dry side, the Mojave Desert being an example. The mountains are said to produce a rain shadow.

### Monsoons

The continent of Asia is so huge that heating and cooling of its surface during the passage of the seasons causes massive regional shifts in wind patterns. During summer, the surface of the Asian landmass heats up more than the surrounding oceans,

but during winter the landmass cools more than the oceans. The consequence is that winds tend to blow off the water into the interior of the Asian continent in summer, particularly in the region of the Indian Ocean and western tropical Pacific Ocean. These winds reverse to flow off the continent out over the oceans in winter. These seasonally shifting winds are called the monsoons. They affect rainfall patterns, and their duration and strength can spell the difference between food sufficiency and starvation for hundreds of millions of people in the region each year.

### Elevation

Another significant regional pattern is that in mountainous regions, temperature and other conditions change with elevation. At any given latitude, air temperature falls about 6°C for every 1000-m increase in elevation. The ecological consequences of the change of temperature with elevation are similar to those of the change of temperature with latitude (figure 59.6).

**Figure 59.6 Elevation affects the distribution of biomes in much the same manner as latitude does.** Biomes that normally occur far north of the equator at sea level also occur in the tropics at high mountain elevations. Thus, on a tall mountain in the tropics, one might see a sequence of biomes like the one illustrated above. In North America, a 1000-m increase in elevation results in a temperature drop equal to that of an 880-km increase in latitude.

## Microclimates

Conditions also vary in significant ways on very small spatial scales. For example, in a forest, a bird sitting in an open patch may experience intense solar radiation, a high air temperature, and a low humidity, even while a mouse hiding under a log 10 feet away may experience shade, a cool temperature, and air saturated with water vapor. Such highly localized sets of climatic conditions are called microclimates.

In some cases, species avoid competing by adapting to use different microclimates. Sympatric salamanders, for example, may be specialized for the different levels of moisture found in different parts of the habitat.

### Learning Outcomes Review 59.1

More intense solar heating of some global regions relative to others sets up global patterns of atmospheric circulation, which in turn cause global patterns of water circulation in the oceans. The Coriolis effect is caused by the Earth's spin beneath the moving air masses of the atmosphere. These patterns—plus seasonal changes—strongly affect the conditions that exist for living organisms in different parts of the world. In general, temperature declines as altitude or latitude increases.

- How would global air movement patterns be different if the Earth turned in the opposite direction?

## 59.2 Earth's Biomes

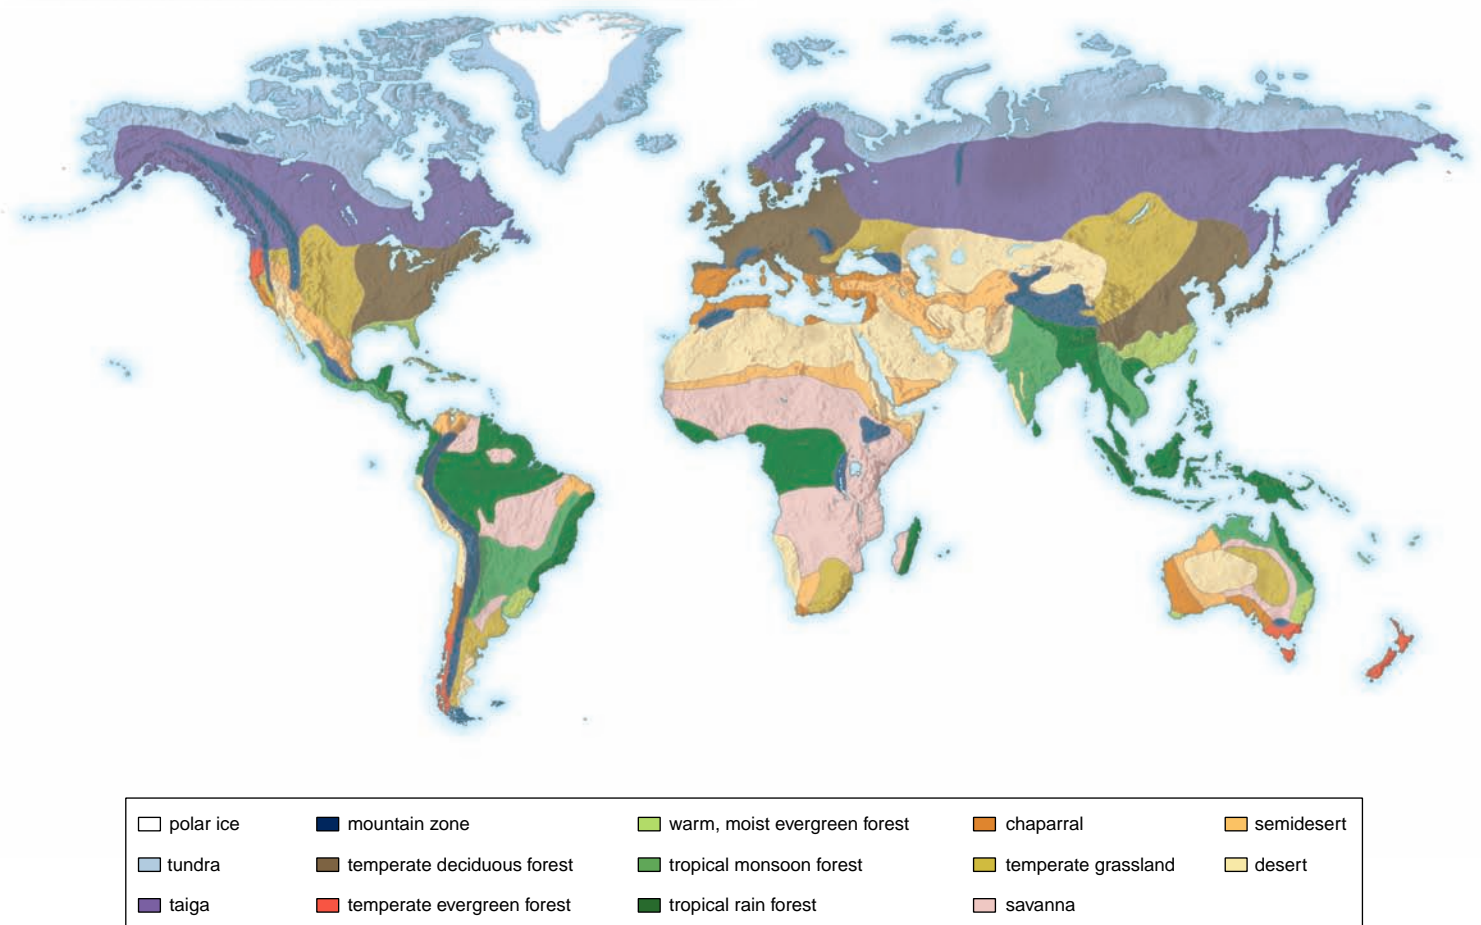

### Learning Outcomes

1. Define biome.
2. Explain the primary factors that determine which type of biome is found in a particular place.

**Biomes** are major types of ecosystems on land. Each biome has a characteristic appearance and is distributed over wide areas of land defined largely by sets of regional climatic conditions. Biomes are named according to their vegetational structures, but they also include the animals that are present.

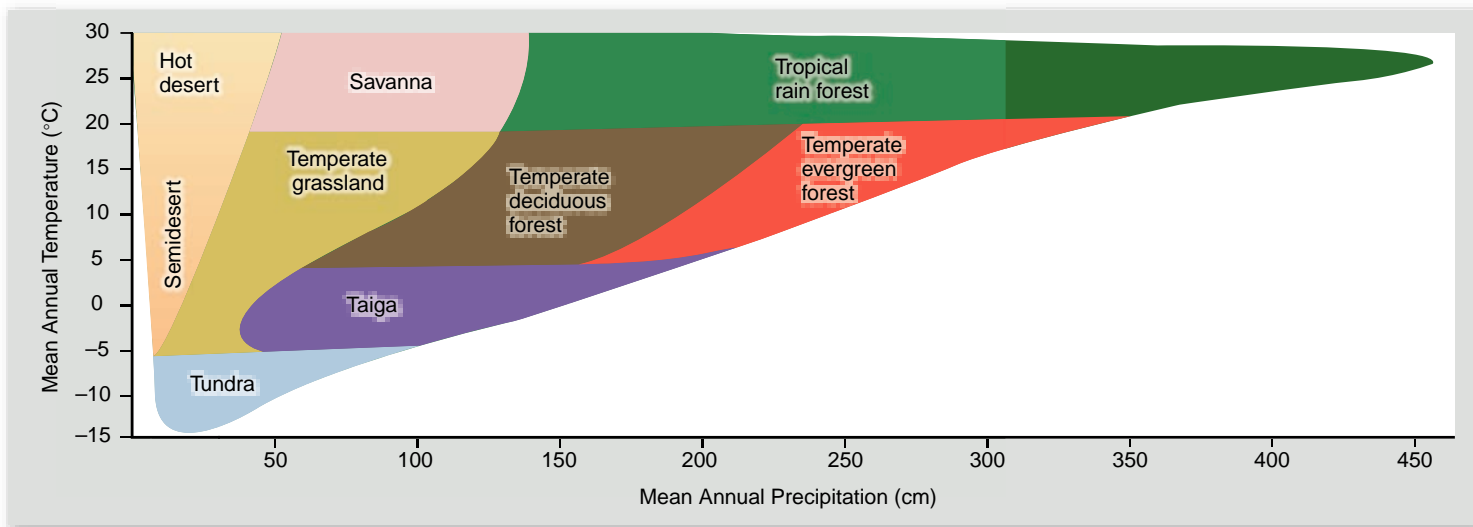

As you might imagine from the broad definition given for biomes, there are a number of ways to classify terrestrial ecosystems into biomes. Here we recognize eight principal biomes: (1) tropical rain forest, (2) savanna, (3) desert, (4) temperate grassland, (5) temperate deciduous forest, (6) temperate evergreen forest, (7) taiga, (8) tundra.

Six additional biomes recognized by some ecologists are: polar ice, mountain zone, chaparral, warm moist evergreen forest, tropical monsoon forest, and semidesert. Other ecologists lump these six with the eight major ones. Figure 59.7 shows the distributions of all 14 biomes.

**Figure 59.7** The distributions of biomes. Each biome is similar in vegetational structure and appearance wherever it occurs.

**Figure 59.8 Predictors of biome distribution.** Temperature and precipitation are quite useful predictors of biome distribution, although other factors sometimes also play critical roles.

Biomes are defined by their characteristic vegetational structures and associated climatic conditions, rather than by the presence of particular plant species. Two regions assigned to the same biome thus may differ in the species that dominate the landscape. Tropical rain forests around the world, for example, are all composed of tall, lushly vegetated trees, but the tree species that dominate a South American tropical rain forest are different from those in an Indonesian one. The similarity between such forests results from convergent evolution (see chapter 21).

### Temperature and moisture often determine biomes

In determining which biomes are found where, two key environmental factors are temperature and moisture. As seen in figure 59.8, if you know the mean annual temperature and mean annual precipitation in a terrestrial region, you often can predict the biome that dominates. Temperature and moisture affect ecosystems in a number of ways. One reason they are so influential is that primary productivity is strongly correlated with them, as described in the preceding chapter (figure 59.9).

Different places that are similar in mean annual temperature and precipitation sometimes support different biomes, indicating that temperature and moisture are not the only factors that can be important. Soil structure and mineral composition (see chapter 39) are among the other factors that can be influential. The biome that is present may also depend on whether the conditions of temperature and precipitation are strongly seasonal or relatively constant.

### Tropical rain forests are highly productive equatorial systems

**Tropical rain forests**, which typically require 140 to 450 cm of rain per year, are the richest ecosystems on land (figure 59.10).

*a.*

*b.*

**Figure 59.9 The correlations of primary productivity with precipitation and temperature.** The net primary productivity of ecosystems at 52 locations around the globe correlates significantly with (a) mean annual precipitation and (b) mean annual temperature.

### Inquiry question

Why might you expect primary productivity to increase with increasing precipitation and temperature?

**Figure 59.10**  
Tropical rainforest.

They are very productive because they enjoy the advantages of both high temperature and high precipitation (see figure 59.9). They also exhibit very high biodiversity, being home to at least half of all the species of terrestrial plants and animals—over 2 million species! In a single square mile of Brazilian rain forest, there can be 1200 species of butterflies—twice the number found in all of North America. Tropical rain forests recycle nutrients rapidly, so their soils often lack great reservoirs of nutrients.

### **Savannas are tropical grasslands with seasonal rainfall**

The **savannas** are tropical or subtropical grasslands, often dotted with widely spaced trees or shrubs. On a global scale, savannas often occur as transition ecosystems between tropical rain forests and deserts; they are characteristic of warm places where annual rainfall (50–125 cm) is too little to support rain forest, but not so little as to produce desert conditions.

Rainfall is often highly seasonal in savannas. The Serengeti ecosystem in East Africa is probably the world's most famous example of the savanna biome. In most of the Serengeti, no rain falls for many months of the year, but during other months rain is abundant. The huge herds of grazing animals in the ecosystem respond to the seasonality of the rain; a number of species migrate away from permanently flowing rivers only during the months when rain falls.

### **Deserts are regions with little rainfall**

**Deserts** are dry places where rain is both sparse (annual rainfall often less than 25–40 cm) and unpredictable. The unpredictability means that plants and animals cannot depend on experi-

encing rain even once each year. As mentioned earlier, many of the largest deserts occur at latitudes near 30°N and 30°S because of global air circulation patterns (see figure 59.3). Other deserts result from rain shadows (see figure 59.5).

Vegetation is sparse in deserts, and survival of both plants and animals depends on water conservation. Many desert organisms enter inactive stages during rainless periods. To avoid extreme temperatures, small desert vertebrates often live in deep, cool, and sometimes even somewhat moist burrows. Some emerge only at night. Among large desert animals, camels drink large quantities of water when it is available and then conserve it so well that they can survive for weeks without drinking. Oryxes (large, desert-dwelling antelopes) survive opportunistically on moisture in leaves or roots that they dig up, as well as drinking water when possible.

### **Temperate grasslands have rich soils**

Halfway between the equator and the poles are temperate regions where rich temperate grasslands grow. These grasslands, also called **prairies**, once covered much of the interior of North America, and they were widespread in Eurasia and South America as well.

The roots of perennial grasses characteristically penetrate far into the soil, and grassland soils tend to be deep and fertile. Temperate grasslands are often highly productive when converted to agricultural use, and vast areas have been transformed in this way. In North America prior to this change in land use, huge herds of bison and pronghorn antelope inhabited the temperate grasslands, migrating seasonally as resources changed over the course of the year. Natural temperate grasslands are one of the biomes adapted to periodic fire and therefore need fires to prosper.

## Temperate deciduous forests are adapted to seasonal change

Mild but seasonal climates (warm summers and cold winters), plus plentiful rains, promote the growth of temperate deciduous forests in the eastern United States, eastern Canada, and Eurasia (figure 59.11). A deciduous tree is one that drops its leaves in the winter. Deer, bears, beavers, and raccoons are familiar animals of these forests.

## Temperate evergreen forests are coastal

**Temperate evergreen forests** occur along coastlines with temperate climates, such as in the northwest of the United States. The dominant vegetation includes trees, such as spruces, pines, and redwoods, that do not drop their leaves (thus, they are *ever green*).

## Taiga is the northern forest where winters are harsh

Taiga and tundra (described next) differ from other biomes in that both stretch in great unbroken circles around the entire globe (see figure 58.7). The taiga consists of a great band of northern forest dominated by coniferous trees (spruce, hemlock, and fir) that retain their needle-like leaves all year long.

**Figure 59.11** Temperate deciduous forest.

The taiga is one of the largest biomes on Earth. The winters where taiga occurs are severely long and cold, and most of the limited precipitation falls in the summer. Many large herbivores, including elk, moose, and deer, plus carnivores such as wolves, bears, lynx, and wolverines, are characteristic of the taiga.

## Tundra is a largely frozen treeless area with a short growing season

In the far north, at latitudes above the taiga but south of the polar ice, few trees grow. The landscape that occurs in this band, called tundra, is open, windswept, and often boggy. This enormous biome covers one-fifth of the Earth's land surface. Little rain or snow falls. **Permafrost**—soil ice that persists throughout all seasons—usually exists within a meter of the ground surface.

What trees can be found are small and mostly confined to the margins of streams and lakes. Large grazing mammals, including musk-oxen and reindeer (caribou), and carnivores such as wolves, foxes, and lynx, live in the tundra. Populations of lemmings (a small rodent native to the Arctic) rise and fall dramatically, with important consequences for the animals that prey on them.

### Learning Outcomes Review 59.2

Major types of ecosystems called biomes can be distinguished in different climatic regions on land. These biomes are much the same wherever they are found on the Earth. Annual mean temperature and precipitation are effective predictors of biome type; however, the range of seasonal variation and the soil characteristics of a region also come into play.

- Why do different biomes occur at different latitudes?

## 59.3 Freshwater Habitats

### Learning Outcomes

1. Define photic zone.
2. Explain what causes spring and fall overturns in lakes.
3. Distinguish between eutrophic and oligotrophic lakes.

Of the major habitats, fresh water covers by far the smallest percentage of the Earth's surface: Only 2%, compared with 27% for land and 71% for ocean. The formation of fresh water starts with the evaporation of water into the atmosphere, which removes most dissolved constituents, much like distillation does. When water falls back to the Earth's surface as rain or snow, it arrives in an almost pure state, although it may have picked up biologically significant dissolved or particulate matter from the atmosphere.

Freshwater wetlands—marshes, swamps, and bogs—represent intermediate habitats between the freshwater and terrestrial realms. Wetlands are highly productive (see figure 58.11).

They also play key additional roles, such as acting as water storage basins that moderate flooding.

Primary production in freshwater bodies is carried out by single-celled algae (phytoplankton) floating in the water, by algae growing as films on the bottom, and by rooted plants such as water lilies. In addition, a considerable amount of organic matter—such as dead leaves—enters some bodies of fresh water from plant communities growing on the land nearby.

## Life in freshwater habitats depends on oxygen availability

The concentration of dissolved oxygen ( $O_2$ ) is a major determinant of the properties of freshwater communities. Oxygen dissolves in water just like sugar or salt does. Fish and other aquatic organisms obtain the oxygen they need by taking it up from solution. The solubility of oxygen is therefore critically important.

In reality, oxygen is not very soluble in water. Consequently, even when fresh water is fully aerated and at equilibrium with the atmosphere, the amount of oxygen it contains per liter is only 5%, or less, of that in air. This means that, in terms of acquiring the oxygen they need, freshwater organisms have a far smaller margin of safety than air-breathing ones.

Oxygen is constantly added to and removed from any body of fresh water. Oxygen is added by photosynthesis and by aeration from the atmosphere, and it is removed by animals and other heterotrophs. If a lot of decaying organic matter is present in a body of water, the oxygen demand of the decay microbes can be high and affect other life forms. Under conditions in which the rate of oxygen removal from water exceeds the rate of addition, the concentration of dissolved oxygen can fall so low that many aquatic animals cannot survive in it.

## Lake and pond habitats change with water depth

Bodies of relatively still fresh water are called lakes if large and ponds if small. Water absorbs light passing through it, and the intensity of sunlight available for photosynthesis decreases sharply with increasing depth. In deep lakes, only water relatively near the surface receives enough light for phytoplankton to exhibit a positive net primary productivity (figure 59.12). Those waters are described as the photic zone.

### The photic zone

The thickness of the photic zone depends on how much particulate matter is in the water. Water that is relatively free of particulate matter and clear allows light to penetrate to a depth of 10 m at sufficient intensity to support phytoplankton. Water that is thick with surface algal cells or soil from erosion may not allow light to penetrate very far before its intensity becomes too diminished for algal growth.

The supply of dissolved oxygen to the deep waters of a lake can be a problem because all oxygen enters any aquatic system near its surface. In the still waters of a lake, mixing between the surface and deeper layers may not occur except occasionally. When photosynthesis produces oxygen, it adds it to the photic zone of the lake near the surface. Thermal stratifica-

**Figure 59.12 Light in a lake.** The intensity of the sunlight available for photosynthesis decreases with depth in a lake. Consequently, only some of the upper waters—termed the photic zone—receive sufficient light for the net primary productivity of phytoplankton to be positive. The depth of the photic zone depends on how cloudy the water is. The shallows at the edge of a lake are called the littoral zone. They are well-illuminated to the bottom, so rooted plants and bottom algae can thrive there.

tion commonly affects how readily oxygen enters the deep waters from the surface waters.

### Thermal stratification

**Thermal stratification** is characteristic of many lakes and large ponds. In summer, as shown at the bottom of figure 59.13, water warmed by the Sun forms a layer known as the *epilimnion* at the surface—because warm water is less dense than cold water and tends to float on top. Colder, denser water, called the *hypolimnion*, lies below. Between the warm and cold layers is a transitional layer, the thermocline. Although here we are focusing on fresh water, a similar thermal structuring of the water column occurs also in many parts of the ocean.

In a lake, thermal stratification tends to cut off the oxygen supply to the bottom waters; a consequence of the stratification is that the upper waters that receive oxygen do not mix with the bottom waters. The concentration of oxygen at the bottom may then gradually decline over time as the organisms living there use oxygen faster than it is replaced. If the rate of oxygen use is high, the bottom waters may run out of oxygen and become oxygen-free before summer is over. Oxygen-free conditions, if they occur, kill most (although not all) animals.

In autumn, the temperature of the upper waters in a stratified lake drops until it is about the same as the temperature of the deep waters. The densities of the two water layers become similar, and the tendency for them to stay apart is weakened.

**Figure 59.13** The annual cycle of thermal stratification in a temperate-zone lake. During the summer (lower diagram), water warmed by the Sun (the epilimnion) floats on top of colder, denser water (the hypolimnion). The lake is also thermally stratified in winter (upper diagram) when water that is near freezing or frozen floats on top of water that is at 4°C (the temperature of greatest density for fresh water). Stratification is disrupted in the spring and fall overturns, when the lake is at an approximately uniform temperature and winds mix it from top to bottom.

Winds can then force the layers to mix, a phenomenon called the fall overturn (see figure 59.13). High oxygen concentrations are then restored in the bottom waters.

Chapter 2 discussed the unique properties of water. Fresh water is densest when its temperature is 4°C, and ice, at 0°, floats on top of this dense water. As a lake is cooled toward the freezing point with the onset of winter, the whole lake first reaches 4°C. Then, some water cools to an even lower temperature, and when it does, it becomes less dense and rises to the top. Further cooling of this surface water causes it to freeze into a layer of ice covering the lake. In spring, the ice melts, the surface water warms up, and again winds are able to mix the whole lake—the spring overturn.

Because temperature changes less over the course of the year in the tropics, many lakes there do not experience turnover. As a result, tropical lakes can have a permanent thermocline with depletion of oxygen near the bottom.

### Lakes differ in oxygen and nutrient content

Bodies of fresh water that are low in algal nutrients (such as nitrate or phosphate) and low in the amount of algal material per unit of volume are termed *oligotrophic*. Such waters are often crystal clear. Oligotrophic streams and rivers tend to be high in dissolved oxygen because the movement of the flowing water aerates them; the small amount of organic matter in the water means that oxygen is used at a relatively low rate. Similarly, oligotrophic lakes and ponds tend to be high in dissolved oxygen at all depths all year because they also have a low rate of oxygen use. Because the water is relatively clear, light can penetrate the waters readily, allowing photosynthesis to occur through much of the water column, from top to bottom (figure 59.14).

**Eutrophic** bodies of water are high in algal nutrients and often populated densely with algae. They are more likely to be low in dissolved oxygen, especially in summer. In a eutrophic body of water, decay microbes often place high demands on the

*a.*

*b.*

**Figure 59.14** Oligotrophic and eutrophic lakes. *a.* Oligotrophic lakes are low in algal nutrients, have high levels of dissolved oxygen, and are clear. *b.* Eutrophic lakes have high levels of algal nutrients and low levels of dissolved oxygen. Light does not penetrate deeply in such lakes.

oxygen available because when thick populations of algae die, large amounts of organic matter are made available for decomposition. Moreover, light does not penetrate eutrophic waters well because of all the organic matter in the water; photosynthetic oxygen addition is therefore limited to just a relatively thin layer of water at the top.

Human activities have often transformed oligotrophic lakes into eutrophic ones. For example, when people overfertilize their lawns or fields, nitrate and phosphate from the fertilizers wash off into local water systems. Lakes that receive these nutrients become more eutrophic. A consequence is that the bottom waters are more likely to become oxygen-free during the summer. Many species of fish that are characteristic of oligotrophic lakes, such as trout, are very sensitive to oxygen deprivation. When lakes become eutrophic, these species of fish disappear and are replaced with species like carp that can better tolerate low oxygen concentrations. Lakes can return toward an oligotrophic state over time if steps are taken to eliminate the addition of excess nitrates, phosphates, and foreign organic matter such as sewage.

### Learning Outcomes Review 59.3

The photic zone is the layer near the surface into which light penetrates. Photosynthesis can occur only in the photic zone. Thermal stratification is a major determinant of oxygen levels. In temperate lakes, mixing of different layers occurs when the layers reach the same temperature in spring and fall, and winds can cause the layers to mix. This overturn prevents oxygen depletion near the lake bottom. Eutrophic lakes are high in nutrients for algae but are low in dissolved oxygen; oligotrophic lakes are low in nutrients but high in dissolved oxygen at all depths.

- *Why do tropical lakes often not experience seasonal turnover, and what effect is this likely to have on the ecosystems of these lakes?*

## 59.4 Marine Habitats

### Learning Outcomes

1. *Know the different marine habitats.*
2. *Explain why El Niño events occur.*

About 71% of the Earth's surface is covered by ocean. Near the coastlines of the continents are the continental shelves, where the water is not especially deep (figure 59.15); the shelves, in essence, represent the submerged edges of the continents. Worldwide, the shelves average about 80 km wide, and the depth of the water over them increases from 1 m to about 130 m as one travels from the coast toward the open ocean.

Beyond the continental shelves, the depth suddenly becomes much greater. The average depth of the open ocean is 4000 to 5000 m, and some parts—called trenches—are far deeper, reaching 11,000 m in the Marianas Trench in the western Pacific Ocean.

**Figure 59.15 Basic concepts and terminology used in describing marine ecosystems.** The continental shelf is the submerged edge of the continent. The waters over it are termed neritic and, on a worldwide average basis, are only 130 m deep at their deepest. The region where the tides rise and fall along the shoreline is called the intertidal region. The bottom is called the benthic zone, whereas the water column in the open ocean is called the pelagic zone. The photic zone is the part of the pelagic zone in which enough light penetrates for the phytoplankton to have a positive net primary productivity. The vertical scale of this drawing is highly compressed; whereas the outer edge of the continental shelf is 130 m deep, the open ocean in fact averages 35 times deeper (4000–5000 m deep).

In most of the ocean, the principal primary producers are phytoplankton floating in the well-lit surface waters. A revolution is currently underway in scientific understanding of the limiting nutrients for ocean phytoplankton (see chapter 58). Primary production by the phytoplankton is presently understood to be nitrogen-limited in about two-thirds of the world's ocean, but iron-limited in about one-third. The principal known iron-limited areas are the great Southern Ocean surrounding Antarctica, parts of the equatorial Pacific Ocean, and parts of the subarctic, northeast Pacific Ocean. Where the water is shallow along coastlines, primary production is carried out not just by phytoplankton but also by rooted plants such as seagrasses and by bottom-dwelling algae, including seaweeds.

The world's ocean is so vast that it includes many different types of ecosystems. Some, such as coral reefs and estuaries, are high in their net primary productivity per unit of area (see figure 58.11), but others are low in productivity per unit area. Ocean ecosystems are of four major types: open oceans, continental shelf ecosystems, upwelling regions, and deep sea.

## Open oceans have low primary productivity

In speaking of the open oceans, we mean the waters far from land (beyond the continental shelves) that are near enough to the surface to receive sunlight or to interact on a daily or weekly basis with those waters. We will discuss the deep sea separately later on.

The intensity of solar illumination in the open oceans drops from being high at the surface to being essentially zero at 200 m of depth; photosynthesis is limited to this level of the ocean. However, nutrients for phytoplankton, such as nitrate, tend to be present at low concentrations in the photic zone because over eons of time in the past, ecological processes have exported nitrate and other nutrients from the upper waters to the deep waters, and no vigorous forces exist in the open ocean to return the nutrients to the sunlit waters.

Because of the low concentrations of nutrients in the photic zone, large parts of the open oceans are low in primary productivity per unit area (see figure 58.11) and aptly called a “biological desert.” These parts—which correspond to the centers of the great midocean gyres (see figure 59.4)—are often collectively termed the *oligotrophic ocean* (figure 59.16) in reference to their low nutrient levels and low productivity.

People fish the open oceans today for only a few species, such as tunas and some species of squids and whales. Fishing in the open oceans is limited to relatively few species for two reasons. First, because of the low primary productivity per unit of area, animals tend to be thinly distributed in the open oceans. The only ones that are commercially profitable to catch are

those that are individually large or tend to gather together in tight schools. Second, costs for travelling far from land are high. All authorities agree that as we turn to the sea to help feed the burgeoning human population, we cannot expect the open ocean regions to supply great quantities of food.

## Continental shelf ecosystems provide abundant resources

Many of the ecosystems on the continental shelves are relatively high in productivity per unit area. An important reason is that the waters over the shelves—termed the **neritic waters** (see figure 59.15)—tend to have relatively high concentrations of nitrate and other nutrients, averaged over the year.

Because the waters over the shelves are shallow, they have not been subject, over the eons of time, to the loss of nutrients into the deep sea, as the open oceans have. Over the shelves, nutrient-rich materials that sink hit the shallow bottom, and the nutrients they contain are stirred back into the water column by stormy weather. In addition, nutrients are continually replenished by run-off from nearby land.

Around 99% of the food people harvest from the ocean comes from continental shelf ecosystems or nearby upwelling regions. The shelf ecosystems are also particularly important to humankind in other ways. Mineral resources taken from the ocean, such as petroleum, come almost exclusively from the shelves. In addition, almost all recreational uses of the ocean, from sailing to scuba diving, take place on the shelves. The

**Figure 59.16 Major functional regions of the ocean.** The regions classed as oligotrophic ocean (colored dark blue) are “biological deserts” with low productivity per unit area. Continental shelf ecosystems (green at the edge of continents) are typically medium to high in productivity. Upwelling regions (yellow at the edge of continents) are the highest in productivity per unit area and rank with the most productive of all ecosystems on Earth.

shelves feature prominently in these ways because they are close to coastlines and relatively shallow.

### Estuaries

Estuaries are one of the types of shelf ecosystems. An estuary is a place along a coastline, such as a bay, that is partially surrounded by land and in which fresh water from streams or rivers mixes with ocean water, creating intermediate (brackish) salinities.

Estuaries, besides being bodies of water, include intertidal marshes or swamps. An **intertidal** habitat is an area that is exposed to air at low tide but under water at high tide. The marshes of the intertidal zone are called **salt marshes**. Intertidal swamps called **mangrove swamps** (dominated by trees and bushes) occur in tropical and subtropical parts of the world.

Estuaries are a vital and highly productive ecosystem—they provide shelter and food for many aquatic animals, especially the larvae and young, that people harvest for food. Estuaries are also important to a very large number of other animal species, such as migrating birds.

### Banks and coral reefs

Other types of shelf ecosystems include banks and coral reefs. **Banks** are local shallow areas on the shelves, often extremely important as fishing grounds; Georges Bank, 100 km off the shore of Massachusetts, was formerly one of the most productive and famous; much of this area has been closed to fishing since the mid-1990s because of overexploitation.

**Coral reef** ecosystems occur in subtropical and tropical latitudes. Their defining feature is that in them, stony corals—corals that secrete a solid, calcified type of skeleton—build three-dimensional frameworks that form a unique habitat in which many other distinctive organisms live, including reef fish and soft corals (figure 59.17).

**Figure 59.17 A coral reef ecosystem.** Reef-building corals, which consist of symbioses between cnidarians and algae, construct the three-dimensional structure of the reef and carry out considerable primary production. Fish and many other kinds of animals find food and shelter, making these ecosystems among the most diverse. About 20% of all fish species occur specifically in coral reef ecosystems.

All the 700 or so species of reef-building corals are animal–algal symbioses; the animals are cnidarians, and dinoflagellate symbionts live within the cells of their inner cell layer (the gastrodermis). These corals depend on photosynthesis by the algal symbionts, and thus require clear waters through which sunlight can readily penetrate. Reef-building corals are threatened worldwide, as described later in this chapter.

### Upwelling regions experience mixing of nutrients and oxygen

The upwelling regions of the ocean are localized places where deep water is drawn consistently to the surface because of the action of local forces such as local winds. The deep water is often rich in nitrate and other nutrients. Upwelling therefore steadily brings nutrients into the well-lit surface layers. Phytoplankton respond to the abundance of nutrients and light with prolific growth and reproduction. Upwelling regions have the highest primary productivity per unit area in the world's ocean.

The most famous upwelling region (see figure 59.16) is found along the coast of Peru and Ecuador, where upwelling occurs year-round. Another important upwelling region is the coastline of California, along which upwelling occurs during about half the year in the summer, explaining why swimmers find cold water at the beaches even in July and August.

Upwelling regions support prolific but vulnerable fisheries. Sardine fishing in the California upwelling region crashed a few decades ago, but previously was enormously important to the region, as Nobel Prize–winning author John Steinbeck chronicled in a number of his books, most notably *Cannery Row*.

### El Niño Southern Oscillation (ENSO)

The phenomenon named El Niño first came to the attention of science in studies of the Peru–Ecuador upwelling region. In that region, every 2 to 7 years on an irregular and relatively unpredictable basis, the water along the coastline becomes profoundly warm, and simultaneously the primary productivity becomes unusually low.

Because of the low primary productivity, the ordinarily prolific fish populations weaken, and populations of seabirds and sea mammals that depend on the fish are stressed or plummet. The local people had named a mild annual warming event, which occurred around Christmas each year, “El Niño” (literally, “the child,” after the Christ Child). Scientists adopted the term El Niño Southern Oscillation (ENSO) to refer to those dramatic warming events.

The immediate cause of El Niño took several decades to figure out, but research ultimately showed that the cause is a weakening of the east-to-west Trade Winds in the region. The Trade Winds ordinarily blow warm surface water to the west, away from the Peru–Ecuador coast. This thins the warm surface layer of water along the coast, so that deep water—cold but highly rich in nutrients—is drawn to the surface, leading to high primary production.

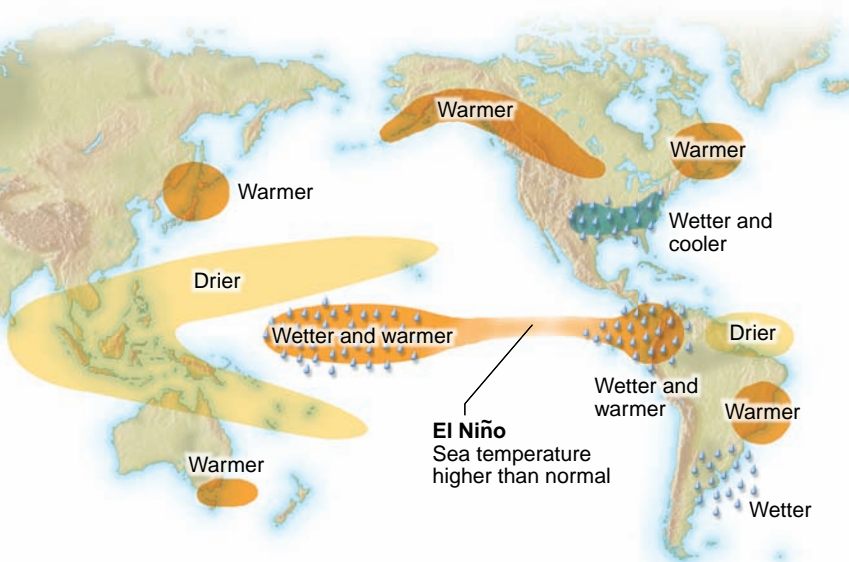

Weakening of the Trade Winds allows the warm surface layer to become thicker. Upwelling continues, but under such circumstances it merely recirculates the thick warm surface layer, which is nutrient-depleted.

After these fundamentals had been discovered, researchers in the 1980s realized that the weakening of the Trade Winds is actually part of a change in wind circulation patterns that recurs irregularly. One reason the Trade Winds blow east-to-west in ordinary times is that the surface waters in the western equatorial Pacific are warmer than those in the eastern equatorial Pacific; air rises from the warm western areas, creating low pressure at the surface there, and air blows out of the east into the low pressure. During an El Niño, the warmer the eastern ocean gets, the more similar it becomes to the western ocean, reducing the difference in pressure across the ocean. Thus, once the Trade Winds weaken a bit, the pressure difference that makes them blow is lessened, weakening the Trade Winds further. Warm water ordinarily kept in the west by the Trade Winds creeps progressively eastward at equatorial latitudes because of this self-reinforcing series of events. Ultimately, effects of El Niño occur across large parts of the world's weather systems, affecting sea temperatures in California, rainfall in the southwestern United States, and even systems as far distant as Africa.

One specific result is to shift the weather systems of the western Pacific Ocean 6000 km eastward. The tropical rainstorms that usually drench Indonesia and the Philippines occur when warm seawater abutting these islands causes the air above it to rise, cool, and condense its moisture into clouds. When the warm water moves east, so do the clouds, leaving the previously rainy areas in drought. Conversely, the western edge of Peru and Ecuador, which usually receives little precipitation, gets a soaking.

El Niño can wreak havoc on ecosystems. During an El Niño event, plankton can drop to 1/20 of their normal abundance in the waters of Peru and Ecuador, and because of the drop in plankton productivity, commercial fish stocks virtually disappear (figure 59.18). In the Galápagos Islands, for example, seabird and sea lion populations crash as animals starve due to the lack of fish. By contrast, on land, the heavy rains produce a

**Figure 59.18 An El Niño winter.** This diagram shows just some of the worldwide alterations of weather that are often associated with the El Niño phenomenon.

*a.*

*b.*

**Figure 59.19 Life in the deep sea.** *a.* The luminous spot below the eye of this deep-sea fish results from the presence of a symbiotic colony of bioluminescent bacteria. Bioluminescence is a fairly common feature of mobile animals in the parts of the ocean that are so deep as to be dark. It is more common among species living part way down to the bottom than in ones living at the bottom. *b.* These large worms live along vents where hot water containing hydrogen sulfide rises through cracks in the seafloor crust. Much of the body of each worm is devoted to a colony of symbiotic sulfur-oxidizing bacteria. The worms transport sulfide and oxygen to the bacteria, which oxidize the sulfur and use the energy thereby obtained for primary production of new organic compounds, which they share with their worm hosts.

bumper crop of seeds, and land birds flourish. In Chile, similar effects on seed abundance propagate up the food chain, leading first to increased rodent populations and then to increased predator populations, a nice example of a bottom-up trophic cascade, as was discussed in chapter 58.

## The deep sea is a cold, dark place with some fascinating communities

The deep sea is by far the single largest habitat on Earth, in the sense that it is a huge region characterized by relatively uniform conditions throughout the globe. The deep sea is seasonless, cold (2–5°C), totally dark, and under high pressure (400–500 atmospheres where the bottom is 4000–5000 m deep).

In most regions of the deep sea, food originates from photosynthesis in the sunlit waters far above. Such food—in the form of carcasses, fecal pellets, and mucus—can take as much as a month to drift down from the surface to the bottom, and along the way about 99% of it is eaten by animals living in the water column. Thus, the bottom communities receive only about 1% of the primary production and are food-poor. Nonetheless, a great many species of animals—most of them small-bodied and thinly distributed—are now known to live in the deep sea. Some of the animals are bioluminescent (figure 59.19*a*) and thereby able to communicate or attract prey by use of light.

### Hydrothermal vent communities

The most astounding communities in the deep sea are the hydrothermal vent communities. Unlike most parts of the deep

sea, these communities are thick with life (figure 59.19b), including large-bodied animals such as worms the size of baseball bats. The reason such a profusion of life can be supported is that these communities live on vigorous, local primary production rather than depending on the photic zone far above.

The hydrothermal vent communities occur at places where tectonic plates are moving apart, and seawater—circulating through porous rock—is able to come into contact with very hot rock under the seafloor. This water is heated to temperatures in excess of 350°C and, in the process, becomes rich in hydrogen sulfide.

As the water rises up out of the porous rock, free-living and symbiotic bacteria oxidize the sulfide, and from this reaction they obtain energy, which, in a manner analogous to photosynthesis, they use to synthesize their own cellular substance, grow, and reproduce. These sulfur-oxidizing bacteria are chemoautotrophs (see chapter 58). Animals in the communities either survive on the bacteria or eat other animals that do. The hydrothermal vent communities are among the few communities on Earth that do not depend on the Sun's energy for primary production.

### Learning Outcomes Review 59.4

The oligotrophic ocean includes the open ocean and the deep sea, where little primary productivity occurs. Continental shelf ecosystems tend to be moderate to high in productivity; they include estuaries, salt marshes, fishing banks, and coral reefs. The highest levels of productivity are found in upwelling regions, such as those along the west coasts of North and South America, where prolific but vulnerable fisheries can be found. Periodic weakening of the Trade Winds in this region can prevent the upwelling of cold water and subsequently cause weather changes in an event termed El Niño.

- What sort of population cycles would you expect to see in regions that are affected by the ENSO?

## 59.5 Human Impacts on the Biosphere: Pollution and Resource Depletion

### Learning Outcomes

1. Name the major human threats to ecosystems.
2. Differentiate between point-source pollution and diffuse pollution.
3. Explain the effect of deforestation.

We all know that human activities can cause adverse changes in ecosystems. In discussing these, it is important to recognize that creative people can often come up with rational solutions to such problems.

An outstanding example is provided by the history of DDT in the United States. DDT is a highly effective insecti-

cide that was sprayed widely in the decades following World War II, often on wetlands to control mosquitoes. During the years of heavy DDT use, populations of ospreys, bald eagles, and brown pelicans—all birds that catch large fish—plummeted. Ultimately, the use of DDT was connected with the demise of these birds.

Scientists established that DDT and its metabolic products became more and more concentrated in the tissues of animals as the compounds were passed along food chains (figure 59.20). Animals at the bottom of food chains accumulated relatively low concentrations in their fatty tissues. But the primary carnivores that preyed on them accumulated higher concentrations from eating great numbers, and the secondary carnivores accumulated higher concentrations yet. Top-level carnivores, such as the birds that eat large fish, were dramatically affected by the DDT. In these birds, scientists found that metabolic products of DDT disrupted the formation of eggshells. The birds laid eggs with such thin shells that they often cracked before the young could hatch.

Researchers concluded that the demise of the fish-eating birds could be reversed by a rational plan to clean ecosystems of DDT, and laws were passed banning its use. Now, three decades later, populations of ospreys, eagles, and pelicans are rebounding dramatically. For some people, a major reason to study science is the opportunity to be part of success stories of this sort.

**Figure 59.20 Biological magnification of DDT concentration.** Because all the DDT an animal eats in its food tends to accumulate in its fatty tissues, DDT becomes increasingly concentrated in animals at higher levels of the food chain. The concentrations at the right are in parts per million (ppm). Before DDT was banned in the United States, bird species that eat large fish underwent drastic population declines because metabolic products of DDT made their eggshells so thin that the shells broke during incubation.

## Freshwater habitats are threatened by pollution and resource depletion

Fresh water is not just the smallest of the major habitats, but also the most threatened. One of the simplest yet most ominous threats to fresh water is that burgeoning human populations often extract excessive amounts of water from rivers, lakes, or streams. The Colorado River, for example, is one of the greatest rivers in North America, originating with snow melt in the Rocky Mountains and flowing through Utah, Arizona, Nevada, California, and northern Mexico before emptying into the ocean. Today, water is pumped out of the river all along its way to meet the water needs of cities (even ones as distant as Los Angeles) and to irrigate crops. The river now frequently runs out of water and dries up in the desert, never reaching the sea. Worldwide, many crises in the supply of fresh water loom on the horizon.

### Pollution: Point source versus diffuse

Pollution of fresh water is a global problem. Point-source pollution comes from an identifiable location—such as easily identified factories or other facilities that add pollutants at defined locations, such as an outfall pipe. Examples include sewage-treatment plants, which discharge treated effluents at specific spots on rivers, and factories that sometimes discharge water contaminated with heavy metals or chemicals. Laws and technologies can readily be brought to bear to moderate point-source pollution because the exact locations and types of pollution are well defined. In many countries, great progress has been made, but in other countries, often in the developing world, water pollution is still a major problem.

Diffuse pollution is exemplified by eutrophication caused by excessive run-off of nitrates and phosphates from lawn and agricultural field fertilization. When excessive nitrates and phosphates enter rivers and lakes, the character of the bodies of water is changed for the worse; the concentration of dissolved oxygen declines, and fish species such as carp take the place of more desirable species. The problem is exacerbated when rivers empty into the ocean. The eutrophication caused by the accumulation of chemicals can lead to enormous areas of water with no oxygen, causing massive die-offs of fish and other animals. The most famous such area, covering approximately 20,000 km<sup>2</sup> in 2008, occurs where the Mississippi River empties into the Gulf of Mexico, but other “dead zones” occur in places around the world.

The nitrates and phosphates that cause these problems originate on thousands of farms and lawns spread over whole watersheds, and they often enter fresh waters at virtually countless locations. The diffuseness of this sort of pollution renders it difficult to modify by simple technical fixes. Instead, solutions often depend on public education and political action.

### Pollution from coal burning: Acid precipitation

A type of pollution that has properties intermediate between the point-source and diffuse types is the pollution that can arise from burning of coal for power generation. Although each smokestack is a point source, there are many stacks, and the smoke and gases from these stacks spread over wide areas.

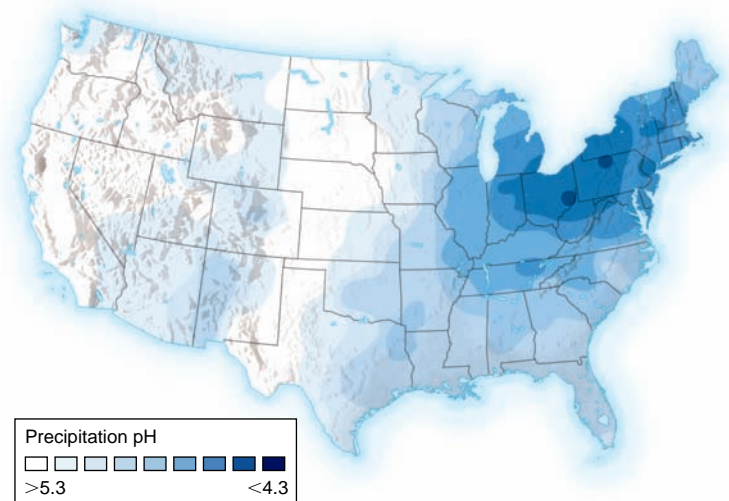

Acid precipitation is one aspect of this problem. When coal is burned, sulfur in the coal is oxidized. The sulfur oxides, unless controlled, are spewed into the atmosphere in the stack smoke, and there they combine with water vapor to produce sulfuric acid. Falling rain or snow picks up the acid and is excessively acidic when it reaches the surface of the Earth (figure 59.21).

Mercury emitted in stack smoke is a second potential problem. Burning of coal can be one of the major sources of environmental mercury, a serious public health issue because just small amounts of mercury can interfere with brain development in human fetuses and infants.

Acid precipitation and mercury pollution affect freshwater ecosystems. At pH levels below 5.0, many fish species and other aquatic animals die, unable to reproduce. Thousands of lakes and ponds around the world no longer support fish because of pH shifts induced by acid precipitation. Mercury that falls from atmospheric emissions into lakes and ponds accumulates in the tissues of food fish. In the Great Lakes region of the United States, people—especially pregnant women—are advised to eat little or no locally caught fish because of its mercury content.

## Forest ecosystems are threatened in tropical and temperate regions

Probably the single greatest problem for terrestrial habitats worldwide is deforestation by cutting or burning. There are many reasons for deforestation. In poverty-stricken countries, deforestation is often carried out diffusely by the general population; people burn wood to cook or stay warm, and they collect it from the local forests.

**Figure 59.21** pH values of rainwater in the United States. pH values of less than 7 represent acid conditions; the lower the values, the greater the acidity. Precipitation in parts of the United States, especially in the Northeast, is commonly more acidic than natural rainwater, which has a pH of 5.6 or higher.

At the other extreme, corporations still cut large tracts of virgin forests in an industrialized fashion, often shipping the wood halfway around the world to buyers. Tropical hardwoods, such as mahogany, from Southeast Asian rain forests are shipped to the United States for use in furniture, and softwood logs are shipped from Alaska to East Asia for pulping and paper production. Forests are sometimes simply burned to open up land for farming or ranching (figure 59.22*a*).

### Loss of habitat

The loss of forest habitat can have dire consequences. Particularly diverse sets of species depend on tropical rain forests for their habitat, for example. Thus, when rain forests are cleared, the loss of biodiversity can be extreme. Many tropical forest regions have been severely degraded, and recent estimates suggest that less than half of the world's tropical rain forests remain in pristine condition. All of the world's tropical rain forests will be degraded or gone in about 30 years at present rates of destruction.

Besides loss of habitat, deforestation can have numerous secondary consequences, depending on local contexts. In the Sahel region, South of the Sahara Desert in Africa, deforestation has been a major contributing factor in increased desertification. In the forests of the northeastern United States, as the Hubbard Brook experiment shows (see figure 58.7), deforestation can lead to both a loss of nutrients from forest soils and a simultaneous nutrient enrichment of bodies of water downstream.

### Disruption of the water cycle

As discussed in chapter 58, cutting of a tropical rain forest often interrupts the local water cycle in ways that permanently alter the landscape. After an area of tropical rain forest is cleared, rain water often runs off the land to distant places, rather than being returned to the atmosphere immediately above by transpiration. This change may render conditions unsuitable for the rain forest trees that originally lived there. Then the poorly vegetated land—exposed and no longer stabilized by thick root systems—may be ravaged by erosion (figure 59.22*b*).

### Acid rain

Deforestation can be a problem in temperate regions, as well as in the tropics. In addition, acid rain affects forests as well as lakes and streams; large tracts of trees in temperate regions have been adversely affected by acid rain. By changing the acidity of the soil, acid rain can lead to widespread tree mortality (figure 59.23).

## Marine habitats are being depleted of fish and other species

Overfishing of the ocean has risen to crisis proportions in recent decades and probably represents the single greatest current problem in the ocean realm. The ocean is so huge that it has tended to be more immune than fresh water or terrestrial ecosystems to global human alteration. Nonetheless, the total world fish catch has been pushed to its maximum for over two decades, even as demand for fish has continued to rise. Fishing pressure is so excessive that 25% to 30% of the world's ocean

*a.*

*b.*

### Figure 59.22 Destroying the tropical rain forests.

*a.* These fires are destroying a tropical rain forest in Brazil to clear it for cattle pasture. *b.* The consequences of deforestation can be seen on these middle-elevation slopes in Madagascar, which once supported tropical rain forest, but now support only low-grade pastures and permit topsoil to erode into the rivers (note the color of the water, stained brown by high levels of soil erosion). This sort of picture is seen in a number of places around the world, including Ecuador and Haiti as well as Madagascar.

fish stocks are presently officially rated as being overexploited, depleted, or in recovery; another 40% to 50% are rated as being maximally exploited.

Major cod fisheries in waters off of Nova Scotia, Massachusetts, and Great Britain have been closed to fishing in the past 15 years because of collapse (figure 59.24). Overfishing can

**Figure 59.23**  
**Damage to trees by acid precipitation at Clingman's Dome, Tennessee.** Acid precipitation weakens trees and makes them more susceptible to pests and predators.

**Figure 59.24 The collapse of a fishery.** The red line shows the biomass of cod (*Gadus morhua*) in the Georges Bank ecosystem as estimated by the U.S. National Marine Fisheries Service based on data collected by scientific sampling. The biomass declined steeply between the 1970s and 1990s because of fishing pressure. As the years passed, commercial landings of cod (blue line) remained fairly constant, in part because ships worked harder and harder to catch cod, until catches fell precipitously toward zero and the fishery collapsed in the mid-1990s. Regulatory agencies closed the fishery in the mid-1990s to permit the cod to recover, but even in 2009 recovery of cod was weak at best, and production from the fishery was far below historical norms.

have disturbing indirect effects. In impoverished parts of Africa, poaching on primates and other wild mammals in national parks increases when fish catches decline.

### **Aquaculture: At present only a quick fix**

Production of fish by aquaculture has grown steadily in the last two decades, and it is often viewed as a straightforward solution to the fisheries problem. But the dietary protein needs of many aquacultured fish, such as salmon, are met largely with wild-caught fish. In this case, exploitation has simply shifted to different species.

In addition, current aquaculture practices often damage natural ocean ecosystems. One example is the clearing of mangrove swamps along coasts to create shrimp and fish ponds, which are abandoned when their productivity declines. Research is needed to ameliorate these problems.

### **Pollution effects**

As large as the ocean is, enough pollutants are being added that at the start of the 21st century, polluting materials are easily detectable on a global basis. An expedition to some of the most remote, uninhabited islands in the vast Pacific Ocean recently reported, for example, that considerable amounts of plastic could be found washed up on the beaches. Similarly, even the waters of the Arctic are laced with toxic chemicals; biopsy samples of tissue from Arctic killer whales (*Orcinus orca*) revealed extremely high levels of many chemicals, including pesticides

and a flame-retardant chemical often used in carpets. Nonetheless, because of the ocean's vastness, concentrations of pollutants are not at crisis levels in the ocean at large.

### **Destruction of coastal ecosystems**

Second to overfishing, the greatest problem in the ocean realm is deterioration of coastal ecosystems. Estuaries along coastlines are often subject to severe eutrophication; since about 1970, for example, the bottom waters of the Chesapeake Bay near Washington, DC, have become oxygen-free each summer because of the decay of excessive amounts of organic matter.

Another coastal problem is destruction of salt marshes, which (like freshwater wetlands) are often perceived as disposable. Most authorities believe that the loss of salt marshes in the 20th century was a major contributing factor to the destruction of New Orleans by Hurricane Katrina in 2005; had the salt marshes and cypress swamps been present at their full extent, they would have absorbed a great deal of the flooding water and buffered the city from some of the storm's violence.

### **Stratospheric ozone depletion has led to an ozone "hole"**

The colors of the satellite photo in figure 59.25a represent different concentrations of ozone ( $O_3$ ) located 20 to 25 km above the Earth's surface in the stratosphere. Stratospheric ozone is depleted over Antarctica (purple region in the figure) to between one-half and one-third of its historically normal concentration, a phenomenon called the ozone hole.

Although depletion of stratospheric ozone is most dramatic over Antarctica, it is a worldwide phenomenon. Over the United States, the ozone concentration has been reduced by about 4%, according to the U.S. Environmental Protection Agency.

### **Stratospheric ozone and UV-B**

Stratospheric ozone is important because it absorbs ultraviolet (UV) radiation—specifically the wavelengths called **UV-B**—from incoming solar radiation. UV-B is damaging to living organisms in a number of ways; for instance, it increases risks of cataracts and skin cancer in people. Depletion of stratospheric ozone permits more UV-B to reach the Earth's surface and therefore increases the risks of UV-B damage. Every 1% drop in stratospheric ozone is estimated to lead to a 6% increase in the incidence of skin cancer, for example. UV exposure also may be detrimental to many types of animals, such as amphibians (figure 59.26)

### **Ozone depletion and CFCs**

The major cause of the depletion of stratospheric ozone is the addition of industrially produced chlorine- and bromine-containing compounds to the atmosphere. Of particular concern are chlorofluorocarbons (CFCs), used until recently as refrigerants in air conditioners and refrigerators, and in manufacturing. CFCs released into the atmosphere can ultimately liberate free chlorine atoms, which in the stratosphere catalyze the breakdown of ozone molecules ( $O_3$ ) to form ordinary oxygen ( $O_2$ ). Ozone is continually being made and broken down,

a.

b.

**Figure 59.25 The ozone hole over Antarctica.** NASA satellites currently track the extent of ozone depletion in the stratosphere over Antarctica each year. Every year since about 1980, an area of profound ozone depletion, called the ozone hole, has appeared in August (early spring in the southern hemisphere) when sunlight triggers chemical reactions in cold air trapped over the South Pole during the Antarctic winter. The hole intensifies during September before tailing off as temperature rises in November–December. **a.** In September, 2006, the 11.4 million-square-mile hole (purple in the satellite image shown) covered an area larger than the United States, Canada, and Mexico combined, the largest hole ever recorded. **b.** Concentrations of ozone-depleting chemical compounds in the atmosphere have probably peaked in the last few years and are expected to decline slowly over the decades ahead.

and free chlorine atoms tilt the balance toward a faster rate of breakdown.

The extreme depletion of ozone seen in the ozone hole is a consequence of the unique weather conditions that exist over Antarctica. During the continuous dark of the Antarctic winter, a strong stratospheric wind, the polar-night jet, develops and, blowing around the full circumference of the Earth, isolates the stratosphere over Antarctica from the rest of the atmosphere.

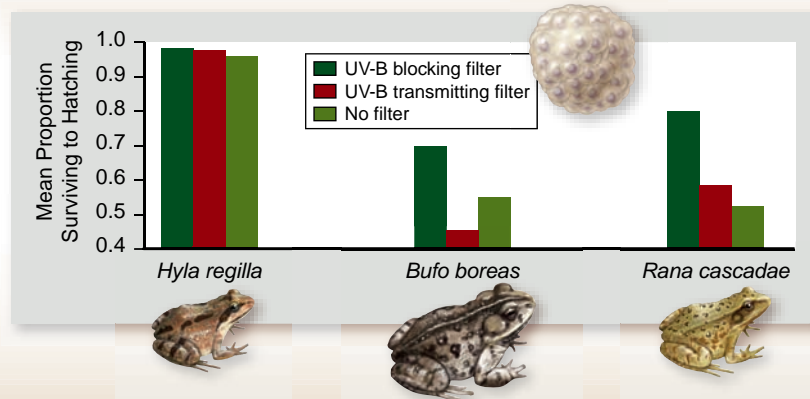

The Antarctic stratosphere stays extremely cold ( $-80^{\circ}\text{C}$  or lower) for many weeks as a consequence, permitting unique types of ice clouds to form. Reactions associated with the particles in these clouds lead to accumulation of diatomic chlorine,  $\text{Cl}_2$ . When sunlight returns in the early Antarctic spring, the diatomic chlorine is photochemically broken up to form free chlorine atoms in great abundance, and the ozone-depleting reactions ensue.

### SCIENTIFIC THINKING

**Question:** Does exposure to UV radiation affect the survival of amphibian eggs?

**Hypothesis:** Direct UV exposure is detrimental to eggs.

**Experiment:** Fertilized eggs from several frog species are placed into enclosures in full sunlight. All enclosures have screens, some of which filter out UV radiation, whereas others do not affect UV transmission. Eggs are monitored to see whether they survive to hatching or whether they die.

**Result:** Egg survival was greatly decreased in two of three species in the enclosures where UV radiation was not filtered out, as compared to survival in the filtered enclosures. Therefore, the hypothesis is confirmed: UV exposure is detrimental to amphibian eggs.

**Further Questions:** What factors might explain why some species are affected by UV exposure and others are not? How could your hypotheses be tested?

**Figure 59.26 The effect of UV radiation on amphibian eggs.**

## Phase-out of CFCs

After research revealed the causes of stratospheric ozone depletion, worldwide agreements were reached to phase out the production of CFCs and other compounds that lead to ozone depletion. Manufacture of such compounds ceased in the United States in 1996, and there is now a great deal of public awareness about the importance of using “ozone-safe” alternative chemicals. The atmosphere will cleanse itself of ozone-depleting compounds only slowly because the substances are chemically stable. Nonetheless, the problem of ozone depletion is diminishing and is expected to be substantially corrected by the second half of the 21st century.

The CFC story is an excellent example of how environmental problems arise and can be solved. Initially, CFCs were heralded as an efficient and cost-effective way to provide cooling, a clear improvement over previous technologies. At that time, their harmful consequences were unknown. Once the problems were identified, international agreements led to an effective solution, and creative technological advances led to replacements that solved the problem at little cost.

### Learning Outcomes Review 59.5

Pollution and resource depletion are the major human effects on the environment, with freshwater habitats being most threatened. Point-source pollution comes from identifiable locations, such as factories, whereas diffuse pollution comes from numerous sources, such as fertilized lawns. Deforestation is a major problem in that it destroys habitat, disrupts communities, depletes resources, and changes the local water cycle and weather patterns. Overfishing is the greatest problem in the oceans.

- Were CFCs an example of point-source or diffuse pollution? In general, how do efforts to combat pollution depend on their source?

## 59.6 Human Impacts on the Biosphere: Climate Change

### Learning Outcomes

1. Explain the link between atmospheric carbon dioxide and global warming.
2. Describe the consequences of global warming on ecosystems and human health.

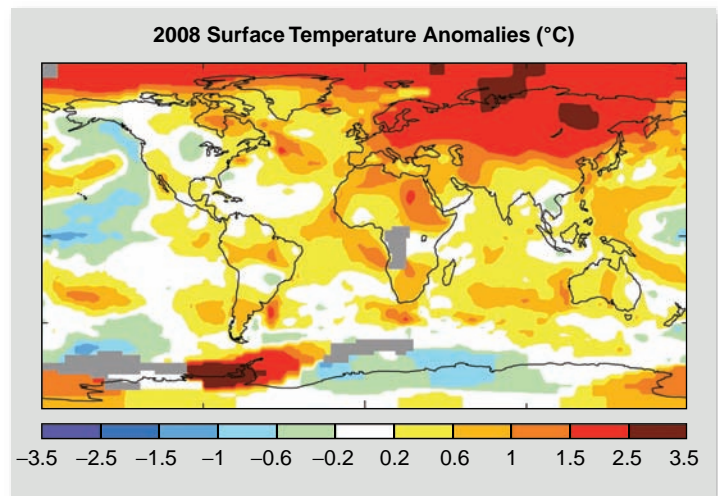

By studying the Earth’s history and making comparisons with other planets, scientists have determined that concentrations of gases in our atmosphere, particularly CO<sub>2</sub>, maintain the average temperature on Earth about 25°C higher than it would be if these gases were absent. This fact emphasizes that the composition of our atmosphere is a key consideration for life on Earth. Unfortunately, human activities are now changing the composition of the atmosphere in ways that most authorities conclude will be damaging or, in the long run, disastrous.

Because of changes in atmospheric composition, the average temperature of the Earth’s surface is increasing, a phenomenon called global warming. As you might imagine from what we said at the beginning of this chapter, changes in temperature alter global wind and water-current patterns in complicated ways. This means that as the average global temperature increases, some particular regions of the world warm to a lesser extent, whereas other regions heat up to a greater extent (figure 59.27). It also means that rainfall patterns are altered because global precipitation patterns depend on global wind patterns. Enormous computer models are used to calculate the effects predicted in all parts of the world.

### Independent computer models predict global changes

The Intergovernmental Panel on Climate Change, which shared the 2007 Nobel Peace Prize with Al Gore for their work on global climate change, recently released its fourth assessment report. Based on a variety of different scenarios, computer models predicted that global temperatures would increase 1.1°C to 6.4°C (2.0–11.5°F) by the end of this century.

More ominous perhaps than temperature are some of the predictions for precipitation. For example, although northern Europe is expected to receive more precipitation than today, another recent study predicted that parts of southern Europe will receive about 20% less, disrupting natural ecosystems, agriculture, and human water supplies. Some European countries may come out ahead economically, but others will come out behind, and political relationships among countries will likely change as some shift from being food exporters to the more tenuous role of requiring food imports.

**Figure 59.27** Geographic variation in global warming.

The 10 warmest years since record keeping began in 1880 all occur within the 12-year period 1997–2008, but some areas of the globe heated up more than others. Colors indicate how much warming occurred in 2008 relative to the mean temperature during a reference period (1951–1980) prior to full onset of the modern greenhouse effect.

**Figure 59.28 The greenhouse effect.** The concentration of carbon dioxide in the atmosphere has increased steadily since the 1950s, as shown by the blue line. The red line shows the change in average global temperature over the same period.

## Carbon dioxide is a major greenhouse gas

Carbon dioxide is the gas usually emphasized in discussing the cause of global warming (figure 59.28), although other atmospheric gases are also involved. A monitoring station on the top of the 13,700-foot (4200-m) Mauna Loa volcano on the island of Hawaii has monitored the concentration of atmospheric CO<sub>2</sub> since the 1950s. This station is particularly important because it is in the middle of the Pacific Ocean, far from the great continental landmasses where most people live, and it is therefore able to monitor the state of the global atmosphere without confounding influences of local events.

In 1958, the atmosphere was 0.031% CO<sub>2</sub>. By 2004, the concentration had risen to 0.038%. All authorities agree that the cause of this steady rise in atmospheric CO<sub>2</sub> is the burning of coal and petroleum products by the increasing (and increasingly energy-demanding) human population.

### How carbon dioxide affects temperature

The atmospheric concentration of CO<sub>2</sub> affects global temperature because carbon dioxide strongly absorbs electromagnetic radiant energy at some of the wavelengths that are critical for the global heat budget. As stressed in chapter 58, the Earth not only receives radiant energy from the Sun, but also emits radiant energy into outer space. The Earth's temperature will be constant only if the rates of these two processes are equal.

The incoming solar energy is at relatively short wavelengths of the electromagnetic spectrum: Wavelengths that are visible or near-visible. The outgoing energy from the Earth is at different, longer wavelengths. Carbon dioxide absorbs energy at certain of the important long-wave infrared wavelengths. This means that although carbon dioxide does not interfere with the arrival of radiant energy at short wavelengths, it retards the rate at which energy travels away from the Earth at long wavelengths into outer space.

Carbon dioxide is often called a greenhouse gas because its effects are analogous to those of a greenhouse. The reason

that a glass greenhouse gets warm inside is that window glass is transparent to light but only slightly transparent to long-wave infrared radiation. Energy that strikes a greenhouse as light enters the greenhouse freely. Once inside, the energy is absorbed as heat and then re-radiated as long-wave infrared radiation. The infrared radiation cannot easily get out through the glass, and therefore energy accumulates inside.

### Other greenhouse gases

Carbon dioxide is not the only greenhouse gas. Others include methane and nitrous oxide. The effect of any particular greenhouse gas depends on its molecular properties and concentration. For example, molecule-for-molecule, methane has about 20 times the heat-trapping effect of carbon dioxide; on the other hand, methane is less concentrated and less long-lived in the atmosphere than carbon dioxide.

Methane is produced in globally significant quantities in anaerobic soils and in the fermentation reactions of ruminant mammals, such as cows. Huge amounts of methane are presently locked up in Arctic permafrost. Melting of the permafrost could cause a sudden and large perturbation in global temperature by releasing methane rapidly.

Agricultural use of fertilizers is the largest source of nitrous oxide emissions, with energy consumption second and industrial use third.

## Global temperature change has affected ecosystems in the past and is doing so now

Evidence for warming can be seen in many ways. For example, on a worldwide statistical basis, ice on lakes and rivers forms later and melts sooner than it used to; on average, ice-free seasons are now 2.5 weeks longer than they were a century ago. Also, the extent of ice at the North Pole has decreased substantially, and glaciers are retreating around the world (figure 59.29).

**Figure 59.29 Disappearing glaciers.** Mount Kilimanjaro in Tanzania in 1970 (*top*) and 2000 (*bottom*). Note the decrease in glacier coverage over three decades.

Global warming—and cooling—have occurred in the past, most recently during the ice ages and intervening warm periods. Species often responded by shifting their geographic ranges, tracking their environments. For example, a number of cold-adapted North American tree species that are now found only in the far north, or at high elevations, lived much farther south or at substantially lower elevations 10,000–20,000 years ago, when conditions were colder. Present-day global warming is having similar effects. For example, many butterfly and bird species have shifted northward in recent decades (figure 59.30).

Many migratory birds arrive earlier at their summer breeding grounds than they did decades ago. Many insects and amphibians breed earlier in the year, and many plants flower earlier. In Australia, recent research shows that wild fruit fly populations have undergone changes in gene frequencies in the past 20 years, such that populations in cool parts of the country now genetically resemble ones in warm parts.

Reef-building corals seem to have narrow margins of safety between the sea temperatures to which they are accustomed and the maximum temperatures they can survive. Global warming seems already to be threatening some corals by inducing mass “bleaching,” a disruption of the normal and necessary symbiosis between the cnidarians and algal cells.

There are reasons to think that the effects of global warming on natural ecosystems today may, overall, be more severe than those of warming events in the distant past. One concern is that the rate of warming today is rapid, and therefore evolutionary adaptations would need to occur over relatively few generations to aid the survival of species. Another concern is that natural areas no longer cover the whole landscape but often take the form of parks that are completely surrounded by cities or farms. The parks are at fixed geographic locations and in general cannot be moved. If climatic conditions in a park become unsuitable for its inhabitants, the park will cease to perform its function. Moreover, the areas in which the park in-

habitants might then find suitable climatic conditions are likely to be developed, rather than being protected parks.

Similarly, as temperatures increase, many montane species have shifted to higher altitudes to find their preferred habitat. However, eventually they can shift no higher because they reach the mountain’s peak. As the temperature continues to increase, the species’ habitat disappears entirely. A number of Costa Rican frog species are thought to have become extinct for this reason. The same fate may befall many Arctic species as their habitat melts away.

## Global warming affects human populations as well

Global warming could affect human health and welfare in a variety of ways. Some of these changes may be beneficial, but even if they are detrimental, some countries—particularly the wealthier ones—will be able to adjust. But poorer countries may not be able to transform as quickly, and some changes will require extremely costly countermeasures that even wealthy countries will be hard-pressed to afford.

### Rising sea levels

During the second half of the 20th century, sea level rose at 2 to 3 cm per decade. The U.S. Environmental Protection Agency predicts that sea level is likely to rise two or three times faster in the 21st century because of two effects of global warming: (1) the melting of polar ice and glaciers, adding water to the ocean, and (2) the increase of average ocean temperature, causing an increase in volume because water expands as it warms. Such an increase would cause increased erosion and inundation of low-lying land and coastal marshes, and other habitats would also be imperiled. As many as 200 million people would be affected by increased flooding. Should sea levels continue to rise, coastal cities and some entire islands, such as the Maldives in the Indian Ocean, would be in danger of becoming submerged.

### Other climatic effects

Global warming is predicted to have a variety of effects besides increased temperatures. In particular, the frequency or severity of extreme meteorological events—such as heat waves, droughts, severe storms, and hurricanes—is expected to increase, and El Niño events, with their attendant climatic effects, may become more common.

In addition, rainfall patterns are likely to shift, and those geographic areas that are already water-stressed, which are currently home to nearly 2 billion people, will likely face even graver water shortage problems in the years to come. Some evidence suggests that these effects are already evident in the increase in powerful storms, hurricanes, and the frequency of El Niño events over the past few years.

### Effects on agriculture

Global warming may have both positive and negative effects on agriculture. On the positive side, warmer temperatures and increased atmospheric carbon dioxide tend to increase growth of some crops and thus may increase agricultural yields. Other crops, however, may be negatively affected. Furthermore, most

**Figure 59.30** **Butterfly range shift.** The distribution of the speckled wood butterfly, *Pararge aegeria*, in Great Britain in 1970–1997 (green) included areas far to the north of the distribution in 1915–1939 (black).

crops will be affected by increased frequencies of droughts. Moreover, although crops in north temperate regions may flourish with higher temperatures, many tropical crops are already growing at their maximal temperatures, so increased temperatures may lead to reduced crop yields.

Also on the negative side, changes in rainfall patterns, temperature, pest distributions, and various other factors will require many adjustments. Such changes may come relatively easily for farmers in the developed world, but the associated costs may be devastating for those in the developing countries.

### **Effects on human health**

Increasingly frequent storms, flooding, and drought will have adverse consequences on human health. Aside from their direct effect, such events often disrupt the fragile infrastructure of developing countries, leading to the loss of safe drinking water and other problems. As a result, epidemics of cholera and other diseases may be expected to occur more often.

In addition, as temperatures rise, areas suitable for tropical organisms will expand northward. Of particular concern are those organisms that cause human diseases. Many diseases currently limited to tropical areas may expand their range and become problematic in nontropical countries. Diseases transmitted by mosquitoes, such as malaria (see chapter 29), dengue fever, and several types of encephalitis, are examples. The distribution of mosquitoes is limited by cold; winter freezes kill many mosquitoes and their eggs. As a result, malaria only occurs in areas where temperatures are usually above 16°C, and yellow fever and dengue fever, transmitted by a different mosquito species from malaria, occur in areas where temperatures are normally above 10°C. Moreover, at higher temperatures, the malaria pathogen matures more rapidly.

Malaria already kills 1 million people every year; some projections suggest that the percentage of the human population at risk for malaria may increase by 33% by the end of the 21st century. Moreover, as predicted, malaria already appears to be on the move. By 1980, malaria had been eradicated from all of the United States except California, but in recent years it has appeared in a variety of southern, and even a few northern, states.

Dengue fever (sometimes called “breakbone fever” because of the pain it causes) is also spreading. Previously a disease restricted to the tropics and subtropics, where it infects 50 to 100 million people a year, it now occurs in the United States, southern South America, and northern Australia.

One of the most alarming aspects of these diseases is that no vaccines are available. Drug treatment is available (for malaria), but the parasites are rapidly evolving resistance and rendering the drugs ineffective. There is no drug treatment for dengue fever.

### **Solving the problem**

The release of the IPCC’s fourth assessment in 2007 may come to be seen as a turning point in humanity’s response to climate change. Global warming is now recognized, even by former skeptics, as an ongoing phenomenon caused in large part by human actions. Even formerly recalcitrant governments now seem poised to take action, and corporations are recognizing the opportunities provided by the need to reverse human impacts. The resulting “green” technologies and practices are becoming increasingly common. With concerted efforts from citizens, corporations, and governments, the more serious consequences of global climate change hopefully can be averted, just as ozone depletion was reversed in the last century.

### **Learning Outcomes Review 59.6**

Carbon dioxide is a significant greenhouse gas, meaning that it prevents heat from escaping the Earth so that temperatures rise. Global warming caused by changes in atmospheric composition—most notably CO<sub>2</sub> accumulation—may increase desertification and cause some habitats and species to disappear. Global warming may also melt ice caps and glaciers, altering coastlines as water levels rise. Violent weather events, disruption of water availability, and flooding of low-lying areas, as well as increased incidence of tropical diseases, may also occur.

- **In what ways does global climate change pose different questions from those posed by ozone depletion?**

## **Chapter Review**

### **59.1 Ecosystem Effects of Sun, Wind, and Water**

#### **Solar energy and the Earth’s rotation affect atmospheric circulation.**

The amount of solar radiation reaching the Earth’s surface has a great effect on climate. The seasons result from changes in the Earth’s position relative to the Sun (see figure 59.1). Hot air with its increased water content rises at the equator, then cools and loses its moisture, creating the equatorial rain forests (see figure 59.3).

As the drier cool air of the upper atmosphere moves away from the equator and then descends to Earth, it removes moisture from the Earth’s surface and creates deserts on its way back to the equator.

Winds travel in curved paths relative to the Earth’s surface because the Earth rotates on its axis (the Coriolis effect; see figure 59.3).

#### **Global currents are largely driven by winds (see figure 59.4).**

Four large circular gyres in ocean currents can be found, driven by wind direction. These also are influenced by the Coriolis effect.

#### **Regional and local differences affect terrestrial ecosystems.**

A rain shadow occurs when a range of mountains removes moisture from air moving over it from the windward side, creating a drier environment on the opposite side (see figure 59.5).

For every 1000-m increase in elevation, temperature drops approximately 6°C (see figure 59.6).

Microclimates are small-scale differences in conditions.

## 59.2 Earth's Biomes

**Temperature and moisture often determine biomes.**

Average annual temperature and rainfall, as well as the range of seasonal variation, determine different biomes. Eight major types of biomes are recognized.

**Tropical rain forests are highly productive equatorial systems.**

**Savannas are tropical grasslands with seasonal rainfall.**

**Deserts are regions with little rainfall.**

**Temperate grasslands have rich soils.**

**Temperate deciduous forests are adapted to seasonal change.**

**Temperate evergreen forests are coastal.**

**Taiga is the northern forest where winters are harsh.**

**Tundra is a largely frozen treeless area with a short growing season.**

## 59.3 Freshwater Habitats

**Life in freshwater habitats depends on oxygen availability.**

Oxygen is not very soluble in water. Oxygen is constantly added by photosynthesis of aquatic plants and removed by heterotrophs.

**Lake and pond habitats change with water depth.**

The photic zone, near the surface, is the zone of primary productivity; its depth varies with water clarity (see figure 59.12).

In the summer, the warmer water (epilimnion) floats on top of the colder water (hypolimnion). Freshwater lakes turn over twice a year as the temperature at the surface and at depth become the same, and the layers are set in motion by wind (see figure 59.13).

**Lakes differ in oxygen and nutrient content.**

Oligotrophic lakes have high oxygen and low nutrients, whereas eutrophic lakes are the opposite.

## 59.4 Marine Habitats

The ocean is divided into several zones: intertidal, neritic, photic, benthic, and pelagic zones (see figure 59.15).

**Open oceans have low primary productivity.**

Phytoplankton is the primary producer in open waters, and primary production is low due to low nutrient levels.

**Continental shelf ecosystems provide abundant resources.**

Neritic waters are found over continental shelves and have higher nutrient levels (see figure 59.15). Estuaries frequently contain rich

intertidal zones. Other ecosystems include productive banks on continental shelves and symbiotic coral reef ecosystems.

**Upwelling regions experience mixing of nutrients and oxygen.**

In upwelling regions, local winds bring up nutrient-rich deep waters, creating the highest rates of primary production. El Niño events occur when Trade Winds weaken, restricting upwelling to surface waters rather than to the deeper nutrient-rich waters.

**The deep sea is a cold, dark place with some fascinating communities.**

The deep sea is the single largest habitat. Hydrothermal vent communities occur where tectonic plates are moving apart; chemoautotrophs living there obtain energy from oxidation of sulfur.

## 59.5 Human Impacts on the Biosphere: Pollution and Resource Depletion

Dangerous chemicals like DDT are biomagnified as energy moves up the food chain (see figure 59.20).

**Freshwater habitats are threatened by pollution and resource depletion.**

Point-source and diffuse pollution, acid precipitation, and overuse threaten freshwater habitats (see figure 59.21).

**Forest ecosystems are threatened in tropical and temperate regions.**

Deforestation leads to loss of habitat, disruption of the water cycle, and loss of nutrients. Acid rain has a major detrimental effect on forests as well as on lakes and streams (see figure 59.23).

**Marine habitats are being depleted of fish and other species.**

Many fisheries, such as the Georges Bank ecosystem, have collapsed and have not recovered.

**Stratospheric ozone depletion has led to an ozone "hole."**

Increased transmission of UV-B radiation is harmful to life. Global regulation of CFCs seems to be reversing ozone depletion.

## 59.6 Human Impacts on the Biosphere: Climate Change

**Independent computer models predict global changes.**

**Carbon dioxide is a major greenhouse gas.**

Carbon dioxide allows solar radiation to pass through the atmosphere but prevents heat from leaving the Earth, creating warmer conditions.

**Global temperature change has affected ecosystems in the past and is doing so now.**

If temperatures change rapidly, natural selection cannot occur rapidly enough to prevent many species from becoming extinct.

**Global warming affects human populations as well.**

Changing sea levels, increased frequency of extreme climatic events, direct and indirect effects on agriculture, and the expansion of tropical diseases can all affect human life.

## Review Questions

### UNDERSTAND

- The Coriolis effect
  - drives the rotation of the Earth.
  - is responsible for the relative lack of seasonality at the equator.
  - drives global wind circulation patterns.
  - drives global wind and ocean circulation patterns.
- What two factors are most important in biome distribution?
  - Temperature and latitude
  - Rainfall and temperature
  - Latitude and rainfall
  - Temperature and soil type
- In a rain shadow, air is cooled as it rises and heated as it descends, often producing a wet and dry side because the water-holding capacity of the air
  - is directly related to air temperature.
  - is inversely related to air temperature.
  - is unaffected by air temperature.
  - produces changes in air temperature.
- Thermal stratification in a lake
  - is not modified by fall and spring overturn.
  - leads to higher oxygen in deep versus surface waters.
  - leads to higher oxygen in surface versus deep waters.
  - is reduced when ice forms on the surface of the lake.
- Oligotrophic lakes have
  - low oxygen, and high nutrient availability.
  - high oxygen, and high nutrient availability.
  - high oxygen, and low nutrient availability.
  - low oxygen, and low nutrient availability.
- Deep-sea hydrothermal vent communities
  - get their energy from photosynthesis in the photic zone near the surface.
  - use bioluminescence to generate food.
  - are built on the energy produced by the activity of chemoautotrophs that oxidize sulfur.
  - contain only bacteria and other microorganisms.
- Biological magnification occurs when
  - pollutants increase in concentration in tissues at higher trophic levels.
  - the effect of a pollutant is magnified by chemical interactions within organisms.
  - an organism is placed under a dissecting scope.
  - a pollutant has a greater than expected effect once ingested by an organism.
- Which of the following is a point source of pollution?
  - Lawns
  - Smokestacks of coal-fired power plants
  - Factory effluent pipe draining into a river
  - Acid rain

### APPLY

- If the Earth were not tilted on its axis of rotation, the annual cycle of seasons in the northern and southern hemispheres
  - would be reversed.
  - would stay the same.
  - would be reduced.
  - would not exist.

- Oligotrophic lakes can be turned into eutrophic lakes as a result of human activities such as
  - overfishing of sensitive species, which disrupts fish communities.
  - introducing nutrients into the water, which stimulates plant and algal growth.
  - disrupting terrestrial vegetation near the shore, which causes soil to run into the lake.
  - spraying pesticides into the water to control aquatic insect populations.
- If a pesticide is harmless at low concentrations (such as, DDT) and used properly, how can it become a threat to nontarget organisms?
  - Because after exposure to DDT, some species develop allergic reactions even at low levels of exposure
  - Because DDT molecules can combine so that their concentration increases through time
  - Because the concentration of chemicals such as DDT is increasingly concentrated at higher trophic levels
  - Because global warming and exposure to UV-B radiation renders molecules such as DDT increasingly potent
- If there are many greenhouse gases, why is only carbon dioxide considered a cause of global warming?
  - The other gases do not cause global warming.
  - Scientists are concerned about other causes; for example, release of methane from melting permafrost could have significant effects on global warming.
  - Other gases occur in such low quantities that they have little effect on the climate.
  - Carbon dioxide is the only gas that absorbs long-wavelength infrared radiation.

### SYNTHESIZE

- Discuss how figure 59.1 explains the pattern observed in figure 59.2.
- Why are most of the Earth's deserts found at approximately 30° latitude?
- If the world has experienced global warming many times in the past, why should we be concerned about it happening again now?

## Chapter 60

# Conservation Biology

## Chapter Outline

---

- 60.1 Overview of the Biodiversity Crisis
- 60.2 The Value of Biodiversity
- 60.3 Factors Responsible for Extinction
- 60.4 Approaches for Preserving Endangered Species and Ecosystems

## Introduction

---

Among the greatest challenges facing the biosphere is the accelerating pace of species extinctions. Not since the end of the Cretaceous period 65 MYA have so many species become extinct in so short a time span. This challenge has led to the emergence of the discipline of conservation biology. Conservation biology is an applied science that seeks to learn how to preserve species, communities, and ecosystems. It studies the causes of declines in species richness and attempts to develop methods for preventing such declines. In this chapter, we first examine the biodiversity crisis and its importance. Then, using case histories, we identify and study factors that have played key roles in many extinctions. We finish with a review of recovery efforts at the species and community levels.

## 60.1 Overview of the Biodiversity Crisis

### Learning Outcomes

1. Describe the history of extinction through time.
2. Explain the importance of hotspots to biodiversity conservation.

Extinction is a fact of life. Most species—probably all—become extinct eventually. More than 99% of species known to science (most from the fossil record) are now extinct. Current rates of extinction are alarmingly high, however. Taking into account the current rapid and accelerating loss of habitat, especially in the tropics, it has been calculated that as much as 20% of the world's biodiversity may be lost by the middle of this century. In addition, many of these species may be lost before we are even aware of their existence. Scientists estimate that no more than 15% of the world's eukaryotic organisms have been discovered and given scientific names, and this proportion is probably much lower for tropical species.

These losses will affect more than poorly known groups. As many as 50,000 species of the world's total of 250,000 species of plants, 4000 of the world's 20,000 species of butterflies, and nearly 2000 of the world's 8600 species of birds could be lost during this period. Considering that the human species has

been in existence for less than 200,000 years of the world's 4.5-billion-year history, and that our ancestors developed agriculture only about 10,000 years ago, this is an astonishing—and dubious—accomplishment.

### Prehistoric humans were responsible for local extinctions

A great deal can be learned about current rates of extinction by studying the past. In prehistoric times, members of *Homo sapiens* wreaked havoc whenever they entered a new area. For example, at the end of the last Ice Age, approximately 12,000 years ago, the fauna of North America was composed of a diversity of large mammals similar to those living in Africa today: mammoths and mastodons, horses, camels, giant ground sloths, saber-toothed cats, and lions, among others (figure 60.1).

Shortly after humans arrived, 74% to 86% of the mega-fauna (that is, animals weighing more than 100 lb) became extinct. These extinctions are thought to have been caused by hunting and, indirectly, by burning and clearing of forests. (Some scientists attribute these extinctions to climate change, but that hypothesis doesn't explain why the ends of earlier Ice Ages were not associated with mass extinctions, nor does it explain why extinctions occurred primarily among larger animals, with smaller species being relatively unaffected.)

Around the globe, similar results have followed the arrival of humans. Forty thousand years ago, Australia was occupied by a wide variety of large animals, including marsupials

**Figure 60.1 North America before human inhabitants.** Animals found in North America prior to the arrival of humans included birds and large mammals, such as the ancient North American camel, saber-toothed cat, giant ground sloth, and teratorn vulture.

similar in size and ecology to hippos and leopards, a kangaroo 9 ft tall, and a 20-ft-long monitor lizard. These all disappeared at approximately the same time as humans arrived.

Smaller islands have also been devastated. Madagascar has seen the extinction of at least 15 species of lemurs, including one the size of a gorilla; a pygmy hippopotamus; and the flightless elephant bird, *Aepyornis*, the largest bird to ever live (more than 3 m tall and weighing 450 kg). On New Zealand, 30 species of birds went extinct, including all 13 species of moas, another group of large, flightless birds. Interestingly, one continent that seems to have been spared these megafaunal extinctions is Africa. Scientists speculate that this lack of extinction in prehistoric Africa may have resulted because much of human evolution occurred in Africa. Consequently, African species had been coevolving with humans for several million years and thus had evolved counteradaptations to human predation.

### Extinctions have continued in historical time

Historical extinction rates are best known for birds and mammals because these species are conspicuous—that is, relatively large and well studied. Estimates of extinction rates for other species are much rougher. The data presented in table 60.1, based on the best available evidence, show recorded extinctions from 1600 to the present. These estimates indicate that about 85 species of mammals and 113 species of birds have become extinct since the year 1600. That is about 2.1% of known mammal species and 1.3% of known birds.

The majority of extinctions have occurred in the last 150 years: one species every year during the period from 1850 to 1950, and four species per year between 1986 and 1990. This increase in the rate of extinction is the heart of the biodiversity crisis.

Unfortunately, the situation is worsening. For example, the number of bird species recognized as “critically endangered” increased 8% from 1996 to 2000, and a recent report suggested that as many as half of Earth’s plant species may be threatened with extinction. Some researchers predict that two-thirds of all vertebrate species could perish by the end of this century.

The majority of historic extinctions—though by no means all of them—have occurred on islands. For example, of

the 85 species of mammals that have gone extinct in the last 400 years, 60% lived on islands. The particular vulnerability of island species probably results from a number of factors: Such species have often evolved in the absence of predators, and so have lost their ability to escape both humans and introduced predators such as rats and cats. In addition, humans have introduced competitors and diseases; malaria, for example, has devastated the bird fauna of the Hawaiian Islands. Finally, island populations are often relatively small, and thus particularly vulnerable to extinction, as we shall see later in this chapter.

In recent years, the extinction crisis has moved from islands to continents. Most species now threatened with extinction occur on continents, and these areas will bear the brunt of the extinction crisis in this century.

Some people have argued that we should not be concerned, because extinctions are a natural event and mass extinctions have occurred in the past. Indeed, mass extinctions have taken place several times over the past half-billion years (see figure 22.18). However, the current mass extinction event is notable in several respects. First, it is the only such event triggered by a single species (us!). Moreover, although species diversity usually recovers after a few million years (as discussed in chapter 22), this is a long time to deny our descendants the benefits and joys of biodiversity.

In addition, it is not clear that biodiversity will rebound this time. After previous mass extinctions, new species have evolved to utilize resources newly available due to extinctions of the species that previously used them. Today, however, such resources are unlikely to be available, because humans are destroying the habitats and taking the resources for their own use.

### Endemic species hotspots are especially threatened

A species found naturally in only one geographic area and no place else is said to be endemic to that area. The area over which an endemic species is found may be very large. For example, the black cherry tree (*Prunus serotina*) is endemic to all of temperate North America. More typically, however, endemic species occupy restricted ranges. The Komodo dragon (*Varanus*

**TABLE 60.1** Recorded Extinctions Since 1600

Taxon	RECORDED EXTINCTIONS				Approximate Number of Species	Percent of Taxon Extinct
	Mainland	Island	Ocean	Total		
Mammals	30	51	4	85	4,000	2.1
Birds	21	92	0	113	8,600	1.3
Reptiles	1	20	0	21	6,300	0.3
Fish	22	1	0	23	24,000	0.1
Invertebrates*	49	48	1	98	1,000,000+	0.01
Flowering plants	245	139	0	384	250,000	0.2

\*Number of extinct invertebrates is probably greatly underestimated due to lack of knowledge for many species (other groups are probably underestimated to a lesser extent for the same reason).

*komodoensis*) lives only on a few small islands in the Indonesian archipelago, and the Mauna Kea (*Argyroxiphium sandwicense*) and Haleakala silverswords (*A. s. macrocephalum*) each lives in a single volcano crater on the island of Hawaii (figure 60.2). Isolated geographic areas, such as oceanic islands, lakes, and mountain peaks, often have high percentages of endemic species, many in significant danger of extinction.

The number of endemic plant species can vary greatly from one place to another. In the United States, for example, 379 plant species are found in Texas and nowhere else, whereas New York has only one endemic plant species. California, with its varied array of habitats, including deserts, mountains, sea-coast, old-growth forests, and grasslands, is home to more endemic plant species than any other state.

### Species hotspots

Worldwide, notable concentrations of endemic species occur in particular regions. Conservationists have recently identified areas, termed hotspots, that have high endemism and are disappearing at a rapid rate. Such hotspots include Madagascar, a variety of tropical rain forests, the eastern Himalayas, areas with Mediterranean climates such as California, South Africa, and Australia, and several other areas (figure 60.3 and table 60.2). Overall, 25 such hotspots have been identified,

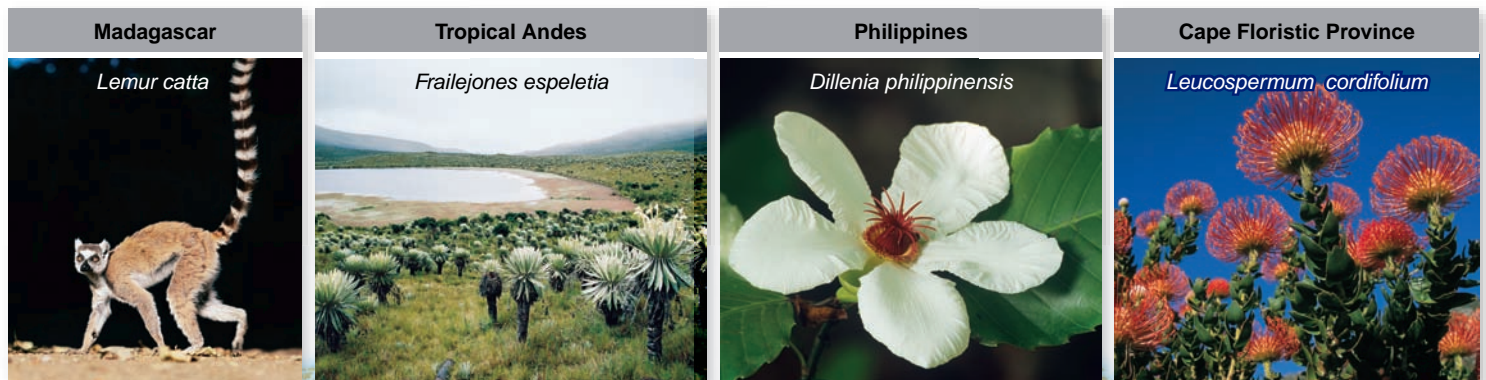

**Figure 60.2** Mauna Kea silversword (*Argyroxiphium sandwicense*). Many species of silverswords are endemic to very small areas. This photo illustrates two stages in the plant's life cycle.

which in total contain nearly half of all the terrestrial species in the world.

Why these areas contain so many endemic species is a topic of active scientific research. Some of these hotspots occur in areas of high species diversity; for these hotspots, the explanations for high species diversity in general, such as high productivity, probably apply (see chapter 58). In addition, some hotspots occur

**Figure 60.3** Hotspots of high endemism. These areas are rich in endemic species under threat of imminent extinction.

**TABLE 60.2**

**Numbers of Endemic Species in Some Hotspot Areas**

Region	Mammals	Reptiles	Amphibians	Plants
Atlantic coastal forest (Brazil)	160	60	253	6,000
South American Chocó	60	63	210	2,250
Philippines	115	159	65	5,832
Tropical Andes	68	218	604	20,000
Southwestern Australia	7	50	24	4,331
Madagascar	84	301	187	9,704
Cape region (South Africa)	9	19	19	5,682
California Floristic Province	30	16	17	2,125
New Caledonia	6	56	0	2,551
South-Central China	75	16	51	3,500

on isolated islands, such as New Zealand, New Caledonia, and the Hawaiian Islands, where evolutionary diversification over long periods has resulted in rich biotas composed of plant and animal species found nowhere else in the world.

**Human population growth in hotspots**

Because of the great number of endemic species that hotspots contain, conserving their biological diversity must be an important component of efforts to safeguard the world's biological

heritage. Or, to look at it another way, by protecting just 1.4% of the world's land surface, 44% of the world's vascular plants and 35% of its terrestrial vertebrates can be preserved.

Unfortunately, hotspots contain not only many endemic species, but also growing human populations. In 1995, these areas contained 1.1 billion people—20% of the world's population—sometimes at high densities (figure 60.4*a*). More important, human populations were growing in all but one of these hotspots both because birth rates are much higher than

**Figure 60.4**  
**Human populations in hotspots.**

**Inquiry question**

**?** Why do population density and growth rates differ among hotspots?

*a.*

*b.*

death rates and because rates of immigration into these areas are often high. Overall, the rate of growth exceeded the global average in 19 hotspots (figure 60.4b). In some hotspots, the rate of growth is nearly twice that of the rest of the world.

Not surprisingly, many of these areas are experiencing high rates of habitat destruction as land is cleared for agriculture, housing, and economic development. More than 70% of the original area of each hotspot has already disappeared, and in 14 hotspots, 15% or less of the original habitat remains. In Madagascar, it is estimated that 90% of the original forest has already been lost—this on an island where 85% of the species are found nowhere else in the world. In the forests of the Atlantic coast of Brazil, the extent of deforestation is even higher: 95% of the original forest is gone.

Population pressure is not the only cause of habitat destruction in hotspots. Commercial exploitation to meet the demands of more affluent people in the developed world also plays an important role. For example, large-scale logging of tropical rain forests occurs in countries around the world to provide lumber, most of which ends up in the United States, western Europe, and Japan. Similarly, many forests in Central and South America are cleared to make way for cattle ranches that produce cheap meat for fast-food restaurants. Hotspots in more affluent countries are often at risk because they occur in areas where land has great value for real estate and commercial purposes, such as in Florida and California in the United States.

### Learning Outcomes Review 60.1

The most recent losses of biodiversity have resulted from human activities, in both prehistoric and historical times. Endemic species are found in only a single region on Earth; regions with a high number of endemic species, known as hotspots, are particularly threatened by human encroachment and their preservation is critical.

- Why does so much resource exploitation occur in areas that are biodiversity hotspots?

## 60.2 The Value of Biodiversity

### Learning Outcomes

1. Distinguish between the direct and indirect economic value of biodiversity.
2. Explain what is meant by the aesthetic value of biodiversity.

Why should we worry about loss of biodiversity? The reason is that biodiversity is valuable to us in a number of ways:

- *Direct economic value* of products we obtain from species of plants, animals, and other groups
- *Indirect economic value* of benefits produced by species without our consuming them
- *Ethical and aesthetic values*

## The direct economic value of biodiversity includes resources for our survival

Many species have direct value as sources of food, medicine, clothing, biomass (for energy and other purposes), and shelter. Most of the world's food crops, for example, are derived from a small number of plants that were originally domesticated from wild plants in tropical and semiarid regions. As a result, many of our most important crops, such as corn, wheat, and rice, contain relatively little genetic variation (equivalent to a founder effect; see chapter 20), whereas their wild relatives have great diversity.

In the future, genetic variation from wild strains of these species may be needed if we are to improve yields or find a way to breed resistance to new pests. In fact, recent agricultural breeding experiments have illustrated the value of conserving wild relatives of common crops. For example, by breeding commercial varieties of tomato with a small, oddly colored wild tomato species from the mountains of Peru, scientists were able to increase crop yields by 50%, while increasing both nutritional content and color.

About 70% of the world's population depends directly on wild plants as their source of medicine. In addition, about 40% of the prescription and nonprescription drugs used today have active ingredients extracted from plants or animals. Aspirin, the world's most widely used drug, was first extracted from the leaves of the tropical willow, *Salix alba*. The rosy periwinkle from Madagascar has yielded potent drugs for combating childhood leukemia (figure 60.5), and drugs effective in treating

a.

b.

### Figure 60.5 Plants of pharmaceutical importance.

a. Two drugs extracted from the rosy periwinkle (*Catharanthus roseus*), vinblastine and vincristine, effectively treat common forms of childhood leukemia, increasing chances of survival from 20% to over 95%. b. Cancer-fighting drugs, such as taxol, have been developed from the bark of the Pacific yew (*Taxus brevifolia*).

several forms of cancer and other diseases have been produced from the Pacific yew. Overall, 62% of cancer drugs were developed from products derived from plants and animals.

Only recently have biologists perfected the techniques that make possible the transfer of genes from one species to another. We are just beginning to use genes obtained from other species to our advantage (see chapter 15). So-called “gene prospecting” of the genomes of plants and animals for useful genes has only begun. We have been able to examine only a minute proportion of the world’s organisms to see whether any of their genes have useful properties for humans.

By conserving biodiversity, we maintain the option of finding useful benefits in the future. Unfortunately, many of the most promising species occur in habitats, such as tropical rain forests, that are being destroyed at an alarming rate.

### Indirect economic value is derived from ecosystem services

Diverse biological communities are of vital importance to healthy ecosystems. They help maintain the chemical quality of natural water, buffer ecosystems against storms and drought, preserve soils and prevent loss of minerals and nutrients, moderate local and regional climate, absorb pollution, and promote the breakdown of organic wastes and the cycling of minerals.

In chapter 58, we discussed the evidence that the stability and productivity of ecosystems is related to species richness. By destroying biodiversity, we are creating conditions of instability and lessened productivity and promoting desertification, water-logging, mineralization, and many other undesirable outcomes throughout the world.

#### The value of intact habitats

Economists have recently been able to compare the societal value, in monetary terms, of intact habitats compared with the value of destroying those habitats. Surprisingly, in most studies conducted so far, intact ecosystems are more valuable than the products derived by destroying them. In Thailand, as one example, coastal mangrove habitats are commonly cleared so that shrimp farms can be established. Although the shrimp produced are valuable, their value is vastly outweighed by the benefits in timber, charcoal production, offshore fisheries, and storm protection provided by the mangroves (figure 60.6a).

Similarly, intact tropical rain forest in Cameroon, West Africa, provides fruit and other forest materials. Clearing the forest for agriculture or palm plantations leads to stream-polluting erosion as well as increased flooding. Combining all the costs and benefits of the three options, maintaining intact forests has the highest economic value (figure 60.6b).

#### Case study: New York City watersheds

Probably the most famous example of the value of intact ecosystems is provided by the watersheds of New York City. Ninety percent of the water for the New York area’s 9 million residents comes from the Catskill Mountains and the nearby headwaters of the Delaware River (figure 60.7). Water that runs off from over 4000 km<sup>2</sup> of rural, mountainous areas is collected into reservoirs and then transported by aqueduct more than 136.8 km to New York City at a rate of 4.9 billion liters per day.

a.

b.

**Figure 60.6** The economic value of maintaining habitats. *a.* Mangroves in Thailand are more valuable than shrimp farms. *b.* Rain forests in Cameroon provide more economic benefits if they are left standing than if they are destroyed and the land used for other purposes.

#### Inquiry question

? If shrimp farms established on cleared mangrove habitats make money, how can clearing mangroves not be an economic plus?

**Figure 60.7 New York City's water source.** New York gets its water from distant rain catchments. Preserving the ecological integrity of these areas is cheaper than building new water treatment plants.

In the 1990s, New York City faced a dilemma. New federal water regulations were requiring ever cleaner water, even as development and pollution in the source areas of the water were threatening to compromise water quality. The city had two choices: either work to protect the functioning ecosystem so that it could produce clean water, or construct filtration plants to clean it on arrival. Economic analysis made the choice clear: Building the plants would cost \$6 billion, with annual operating costs of \$300 million, whereas spending a billion dollars over 10 years could preserve the ecosystem and maintain water purity. The decision was easy.

### Economic trade-offs

These examples provide some idea of the value of the services that ecosystems provide. But maintaining ecosystems is not always more valuable than converting them to other uses. Certainly, when the United States was being settled and land was plentiful, ecosystem conversion was beneficial. Even today, habitat destruction sometimes is economically desirable. Nonetheless, we still have only a rudimentary knowledge of the many ways intact ecosystems provide services. Often, it is not until they are lost that the value becomes clear, as unexpected negative effects, such as increased flooding and pollution, decreased rainfall, or vulnerability to hurricanes become apparent.

The same argument can be made for preserving particular species within ecosystems. Given how little we know about the biology of most species, particularly in the tropics, it is impossible to predict all the consequences of removing a species.

Imagine taking a parts list for an airplane and randomly changing a digit in one of the part numbers. You might change a seat cushion into a roll of toilet paper—or you might just as easily change a key bolt holding up a wing into a pencil. By removing biodiversity, we are gambling with the future of the ecosystems on which we depend and whose functioning we understand very little.

In recent years, the field of ecological economics has developed to study how the societal benefits provided by species and ecosystems can be appropriately valued. The problem is twofold. First, until recently, we have not had a good estimate of the monetary value of services provided by ecosystems, a situation which, as you've just seen, is now changing.

The second problem, however, is that the people who gain the benefits of environmental degradation are often not the same as the people who pay the costs. For instance, in the Thai mangrove example, the shrimp farmers reap the financial rewards, while the local people bear the costs. The same is true of factories that produce air or water pollution. Environmental economists are devising ways to appropriately value and regulate the use of the environment in ways that maximize the benefits relative to the costs to society as a whole.

## Ethical and aesthetic values are based on our conscience and our consciousness

Many people believe that preserving biodiversity is an ethical issue because every species is of value in its own right, even if humans are not able to exploit or benefit from it. These people feel that along with the power to exploit and destroy other species comes responsibility: As the only organisms capable of eliminating large numbers of species and entire ecosystems, and as the only organisms capable of reflecting on what we are doing, humans should act as guardians or stewards for the diversity of life around us.

Almost no one would deny the aesthetic value of biodiversity—a wild mountain range, a beautiful flower, or a noble elephant—but how do we place a value on beauty or on the renewal many of us feel when we are in natural surroundings? Perhaps the best we can do is to consider the deep sense of loss we would feel if it no longer existed.

### Learning Outcomes Review 60.2

The direct value of biodiversity includes resources for our survival, such as natural products and medicines that enhance our lives and can be used in a sustainable way. Indirect value includes economic benefits provided by healthy ecosystems, such as availability of clean water and recreational benefits. The aesthetic value of biodiversity refers to our sense of beauty and peace when experiencing a natural environment.

- **What arguments could you use to convince shrimp farmers to stop operations and remediate the area they are using?**

## 60.3 Factors Responsible for Extinction

### Learning Outcomes

1. List the major causes of habitat destruction.
2. Explain how these causes can interact to bring about extinction.

A variety of causes, independently or in concert, are responsible for extinctions (table 60.3). Historically, overexploitation was the major cause of extinction; although it is still a factor, habitat loss is the major problem for most groups today, and introduced species rank second. Many other factors can contribute to species extinctions as well, including disruption of ecosystem interactions, pollution, loss of genetic variation, and catastrophic disturbances, either natural or human-caused.

More than one of these factors may affect a species. In fact, a chain reaction is possible in which the action of one factor predisposes a species to be more severely affected by another factor. For example, habitat destruction may lead to decreased birth rates and increased mortality rates. As a result, populations become smaller and more fragmented, making them more vulnerable to disasters such as floods or forest fires, which may eliminate populations. Also, as the habitat becomes more fragmented, populations become isolated, so that genetic interchange ceases and areas devastated by disasters are not recolonized. Finally, as populations become very small, inbreeding increases, and genetic variation is lost through genetic drift, further decreasing population fitness. Which factor acts as the final coup de grace may be irrelevant; many factors, and the interactions between them, may have contributed to a species' eventual extinction.

**Figure 60.8 An extinct species.** A breeding assemblage of the golden toad (*Bufo periglenes*) which was last seen in the wild in 1989.

### Amphibians are on the decline: A case study

In 1963, herpetologist Jay Savage was hiking through pristine cloud forest in Costa Rica. Reaching a windswept ridge, he couldn't believe his eyes. Before him was a huge aggregation of breeding toads. What was so amazing was the color of the toads: bright, eye-dazzling orange, unlike anything he had ever seen before (figure 60.8).

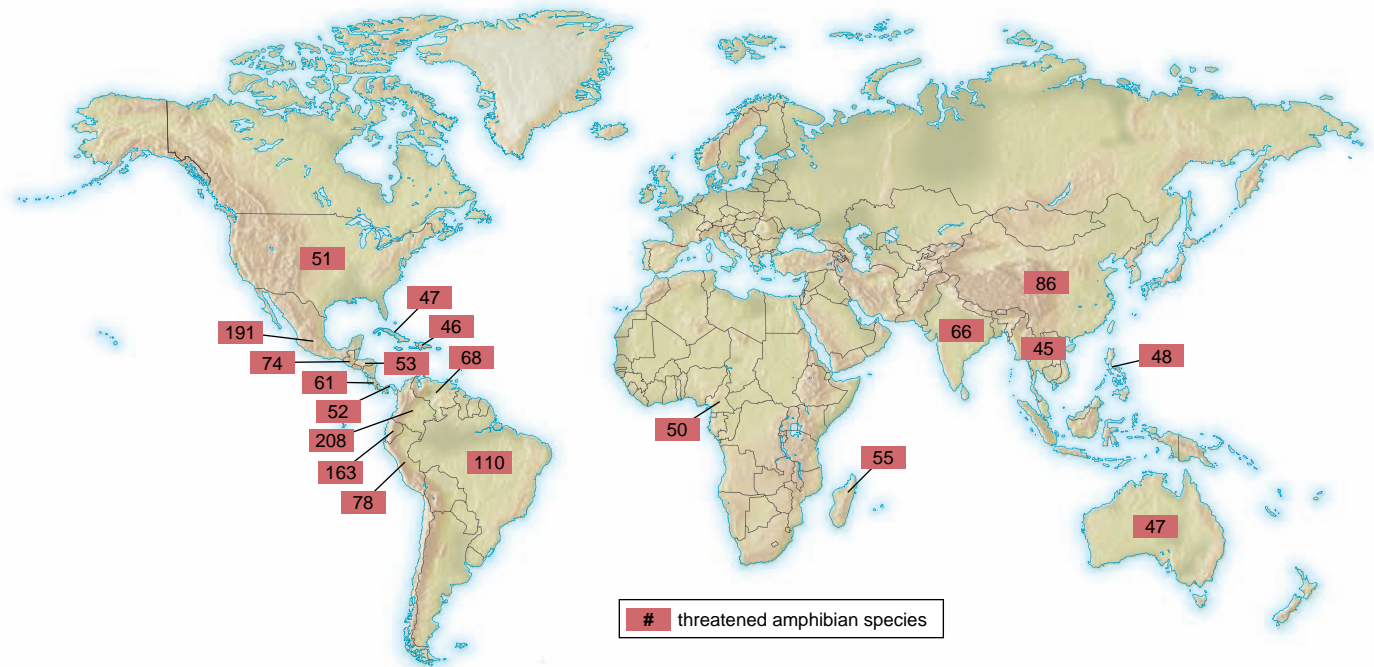

The color of the toads was so amazing and unexpected that Savage briefly considered the possibility that his colleagues had played a practical joke, getting to the clearing before him and somehow coloring normal toads orange. Realizing that this could not be, he went on to study the toads, eventually describing a species new to science, the golden toad, *Bufo periglenes*.

For the next 24 years, large numbers of toads were seen during the breeding season each spring. Their home was legally recognized as the Monteverde Cloud Forest Reserve, a well-protected, intact, and functioning ecosystem, seemingly

**TABLE 60.3** Causes of Extinctions

\*Some species may be influenced by more than one factor; thus, some rows may exceed 100%.

**Figure 60.9 Amphibian extinction crisis.** Boxes indicate the number of threatened species around the world. These numbers are rapidly being revised upward as scientists focus their attention on little-known species, many of which turn out to be in grave danger.

a successful model of conservation. Then, in 1988, few toads were seen, and in 1989, only a single male was observed. Since then, despite exhaustive efforts, no more golden toads have been found.

Despite living in a well-protected ecosystem, with no obvious threats from pollution, introduced species, overexploitation, or any other factor, the species appears to have gone extinct, right under the eyes of watchful scientists and conservationists. How could this happen?

### Frogs in trouble

At the first World Herpetological Congress in 1989 in Canterbury, England, frog experts from around the world met to discuss conservation issues relating to frogs and toads. At this meeting, it became clear that the golden toad story was not unique. Experts reported case after case of similar losses: Frog populations that had once been abundant were now decreasing or entirely gone.

Since then, scientists have devoted a great deal of time and effort to determining whether frogs and other amphibian species truly are in trouble and, if so, why. Unfortunately, the situation appears to be even worse than originally suspected. Amphibian experts recently reported that 43% of all amphibian

species have experienced decreases in population size, and one third of all amphibian species are threatened with extinction in countries as different as Ecuador, Venezuela, Australia, and the United States (figure 60.9).

Moreover, these numbers are probably underestimates; little information exists from many areas of the world, such as Southeast Asia and central Africa. Indeed researchers think that as many as 100 species from the island nation of Sri Lanka have recently gone extinct, perhaps not surprisingly because 95% of that nation's rain forests have also disappeared in recent times.

### Cause for concern

Amphibian declines are worrisome for several reasons. First, many of the species—including the golden toad—have declined in pristine, well-protected habitats. If species are becoming extinct in such areas, it brings into question our ability to preserve global biological diversity.

Second, many amphibian species are particularly sensitive to the state of the environment because of their moist skin, which allows chemicals from the environment to pass into the body, and their use of aquatic habitats for larval stages, which requires unpolluted water. In other words, amphibians may be analogous to the canaries formerly used in coal mines to detect

problems with air quality: If the canaries keeled over, the miners knew they had to get out.

Third, no single cause for amphibian declines is apparent. Although a single cause would be of concern, it would also suggest that a coordinated global effort could reverse the trend, as happened with chlorofluorocarbons and decreasing ozone levels (see chapter 59). However, different species are afflicted by different problems, including habitat destruction, the effects of global warming, pollution, decreased stratospheric ozone levels, disease epidemics, and introduced species.

The implication is that the global environment is deteriorating in many different ways. Could amphibians be global “canaries,” serving as indicators that the world’s environment is in serious trouble?

## Habitat loss devastates species richness

As table 60.3 indicates, habitat loss is the most important cause of modern-day extinction. Given the tremendous amounts of ongoing destruction of all types of habitat, from rain forest to ocean floor, this should come as no surprise. Natural habitats may be adversely affected by humans in four ways:

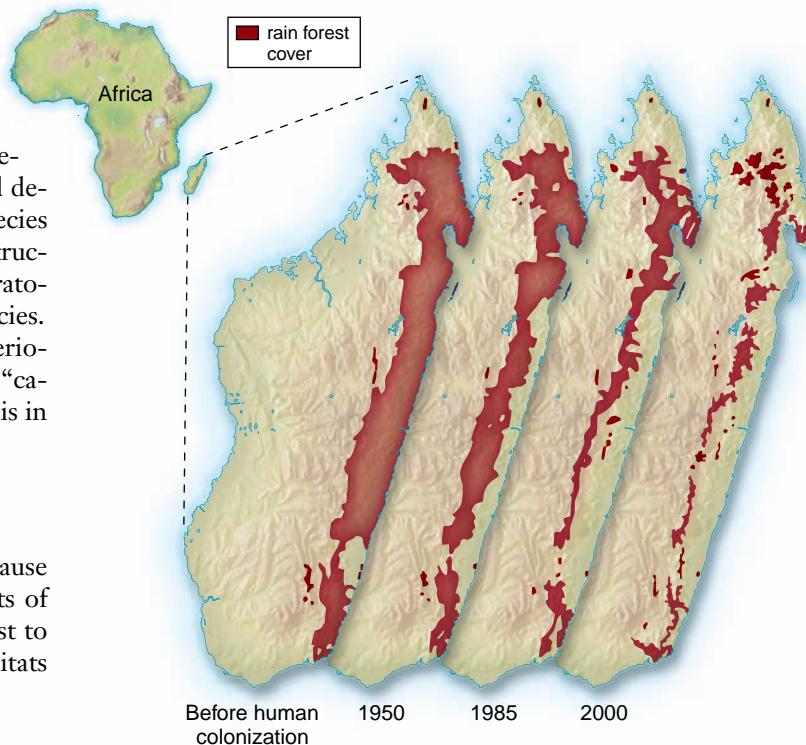

1. **destruction,**
2. **pollution,**
3. **disruption, and**
4. **habitat fragmentation.**

In addition to these causes, global climate change, discussed in the previous chapter, is an insidious threat that combines many of these factors. As climate changes, habitats will change—or disappear entirely, as is the case for polar bears (*Thalartos maritimus*), which require ice floes on which to hunt their seal prey. Some studies estimate that as many as 30% of all species may be imperiled by global warming.

### Destruction of habitat

A proportion of the habitat available to a particular species may simply be destroyed. This destruction is a common occurrence in the “clear-cut” harvesting of timber, in the burning of tropical forest to produce grazing land, and in urban and industrial development. Deforestation has been, and continues to be, by far the most pervasive form of habitat disruption (figure 60.10). Many tropical forests are being cut or burned at a rate of 1% or more per year.

To estimate the effect of reductions in habitat available to a species, biologists often use the well-established observation that larger areas support more species (see figure 58.22). Although this relationship varies according to geographic area, type of organism, and type of area, in general a 10-fold increase in area leads to approximately a doubling in the number of species. This relationship suggests, conversely, that if the area of a habitat is reduced by 90%, so that only 10% remains, then half of all species will be lost. Evidence for this hypothesis comes from a study in Finland of extinction rates of birds on habitat islands (that is, islands of a particular type of habitat surrounded by unsuitable habitat) where the population extinction rate was found to be inversely proportional to island size (figure 60.11).

**Figure 60.10 Extinction and habitat destruction.**

The rain forest covering the eastern coast of Madagascar, an island off the coast of East Africa, has been progressively destroyed and fragmented as the island’s human population has grown. Ninety percent of the eastern coast’s original forest cover is now gone. Many species have become extinct, and many others are threatened, including 16 of Madagascar’s 31 primate species.

**Figure 60.11 Extinction and island area.** The data present percent extinction rates for populations as a function of habitat area for birds on a series of Finnish habitat islands. Smaller islands experience far greater extinction rates.

### Inquiry question

Why does extinction rate increase with decreasing island size?

**Figure 60.12 Fragmentation of woodland habitat.** From the time of settlement of Cadiz Township, Wisconsin, the forest has been progressively reduced from a nearly continuous cover to isolated woodlots covering less than 1% of the original area.

### Pollution

Habitat may be degraded by pollution to the extent that some species can no longer survive there. Degradation occurs as a result of many forms of pollution, from acid rain to pesticides. Aquatic environments are particularly vulnerable; for example, many northern lakes in both Europe and North America have been essentially sterilized by acid rain (see chapter 59).

### Disruption

Human activities may disrupt a habitat enough to make it untenable for some species. For example, visitors to caves in Alabama and Tennessee caused significant population declines in bats over an 8-year period, some as great as 100%. When visits were fewer than one per month, less than 20% of bats were lost, but caves having more than four visits per month suffered population declines of 86% to 95%.

More generally, humans often alter the interactions that occur among species, such as the predator-prey or symbiotic relationships discussed in chapter 57. These disruptions can have far-ranging effects throughout an ecosystem. For example, when pollinating insects are killed off by insecticides, many plants do not reproduce, thus affecting all the animals that depend on the plants and their seeds for food.

### Habitat fragmentation

Loss of habitat by a species frequently results not only in lowered population numbers, but also in fragmentation of the population into unconnected patches (figure 60.12). A habitat also may become fragmented in nonobvious ways, as when roads and habitation intrude into forest. The effect is to carve the populations living in the habitat into a series of smaller populations, often with disastrous consequences because of the relationship between range size and extinction rate. Although detailed data

are not available, fragmentation of wildlife habitat in developed temperate areas is thought to be very substantial.

As habitats become fragmented and shrink in size, the relative proportion of the habitat that occurs on the boundary, or edge, increases. **Edge effects** can significantly degrade a population's chances of survival. Changes in microclimate (such as temperature, wind, humidity) near the edge may reduce appropriate habitat for many species more than the physical fragmentation suggests. In isolated fragments of rain forest, for example, trees on the edge are exposed to direct sunlight. As a result, these trees experience hotter and drier conditions than those normally encountered in the cool, moist forest interior, leading to negative effects on their survival and growth. In one study, the biomass of trees within 100 m of the forest edge decreased by 36% in the first 17 years after fragment isolation.

Also, increasing habitat edges opens up opportunities for some parasite and predator species that are more effective at edges. As fragments decrease in size, the proportion of habitat that is distant from any edge decreases, and consequently, more and more of the habitat is within the range of these species. Habitat fragmentation is blamed for local extinctions in a wide range of species.

The impact of habitat fragmentation can be seen clearly in a study conducted in Manaus, Brazil, where the rain forest was commercially logged. Landowners agreed to preserve patches of rain forest of various sizes, and censuses of these patches were taken before the logging started, while they were still part of a continuous forest. After logging, species began to disappear from the now-isolated patches (figure 60.13). First to go were the monkeys, which have large home ranges. Birds that prey on the insects flushed out by marching army ants followed, disappearing from patches too small to maintain enough army ant colonies to support them. As expected, the

**Figure 60.13 A study of habitat fragmentation.**

Landowners in Manaus, Brazil, agreed to preserve patches of rain forest of different sizes to examine the effect of patch size on species extinction. Biodiversity was monitored in the isolated patches before and after logging. Fragmentation led to significant species loss within patches. Army ants were one of the species that disappeared from smaller patches.

extinction rate was negatively related to patch size, but even the largest patches (100 hectares) lost half of their bird species in less than 15 years.

Because some species, such as monkeys, require large patches, large fragments are indispensable if we wish to preserve high levels of biodiversity. The take-home lesson is that preservation programs will need to provide suitably large habitat fragments to avoid this effect.

### Case study: Songbird declines

Every year since 1966, the U.S. Fish and Wildlife Service has organized thousands of amateur ornithologists and birdwatchers in an annual bird count called the Breeding Bird Survey. In recent years, a shocking trend has emerged. While year-round residents that prosper around humans, such as robins, starlings, and blackbirds, have increased their numbers and distribution over the last 30 years, forest songbirds have declined severely. The decline has been greatest among long-distance migrants such as thrushes, orioles, tanagers, vireos, buntings, and warblers. These birds nest in northern forests in the summer, but spend their winters in South or Central America or the Caribbean Islands.

In many areas of the eastern United States, more than three-quarters of the tropical migrant bird species have declined significantly. Rock Creek Park in Washington, D.C., for example, has lost 90% of its long-distance migrants in the past 20 years. Nationwide, American redstarts declined about 50% in the single decade of the 1970s. Studies of radar images from National Weather Service stations in Texas and Louisiana indicate that only about half as many birds fly over the Gulf of Mexico each spring as did in the 1960s. This suggests a total loss of about half a billion birds.

The culprit responsible for this widespread decline appears to be habitat fragmentation and loss. Fragmentation of breeding habitat and nesting failures in the summer nesting grounds of the United States and Canada have had a major negative effect on the breeding of woodland songbirds. Many of the most threatened species are adapted to deep woods and need an area of 25 acres or more per pair to breed and raise their young. As woodlands are broken up by roads and developments, it is becoming increasingly difficult for them to find enough contiguous woods to nest successfully.

A second and perhaps even more important factor is the availability of critical winter habitat in Central and South America. Studies of the American redstart clearly indicate that birds with better winter habitat have a superior chance of successfully migrating back to their breeding grounds in the spring. In a recent study, scientists were able to determine the quality of the habitat that particular birds used during the winter by examining levels of the stable carbon isotope  $^{13}\text{C}$  in their blood. Plants growing in the best habitats in Jamaica and Honduras (mangroves and wetland forests) have low levels of  $^{13}\text{C}$ , and so do the redstarts that feed on the insects that live in them. Of these wet-forest birds, 65% maintained or gained weight over the winter.

By contrast, plants growing in substandard dry scrub have high levels of  $^{13}\text{C}$ , and so do the redstarts that feed in those habitats. Scrub-dwelling birds lost up to 11% of their body mass over the winter. Now here's the key: Birds that winter in

the substandard scrub leave later in the spring on the long flight to northern breeding grounds, arrive later at their summer homes, and have fewer young (figure 60.14).

The proportion of  $^{13}\text{C}$  in birds arriving in New Hampshire breeding grounds increases as spring wears on and scrub-overwintering stragglers belatedly arrive. Thus, loss of mangrove habitat in the neotropics is having a quantifiable negative influence. As the best habitat disappears, overwintering birds fare poorly, and this leads to decreased reproduction and population declines.

Unfortunately, the Caribbean lost about 10% of its mangroves in the 1980s, and continues to lose about 1% per year. This loss of key habitat appears to be a driving force in the looming extinction of some songbirds.

### Overexploitation wipes out species quickly

Species that are hunted or harvested by humans have historically been at grave risk of extinction, even when the species is initially very abundant. A century ago, the skies of North America were darkened by huge flocks of passenger pigeons, but after being hunted as free and tasty food, they were driven to extinction. The bison that used to migrate in enormous herds

**Figure 60.14** The American redstart (*Setophaga ruticilla*) a migratory songbird. The numbers of this species are in serious decline. The graph presents data on the ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$  in male redstarts arriving at summer breeding grounds. Early arrivals, which have higher reproductive success, have lower proportions of  $^{13}\text{C}$  to  $^{12}\text{C}$ , indicating they wintered in more favorable mangrove-wetland forest habitats.

across the central plains of North America only narrowly escaped the same fate.

### Commercial motivation for exploitation

The existence of a commercial market often leads to overexploitation of a species. The international trade in furs, for example, has severely reduced the numbers of chinchilla, vicuña, otter, and many cat species. The harvesting of commercially valuable trees provides another example: Almost all West Indies mahogany trees (*Swietenia mahogani*) have been logged, and the extensive cedar forests of Lebanon, once widespread at high elevations, now survive in only a few isolated groves.

A particularly telling example of overexploitation is the commercial harvesting of fish in the North Atlantic. During the 1980s, fishing fleets continued to harvest large amounts of cod off the coast of Newfoundland, even as the population numbers declined precipitously. By 1992, the cod population had dropped to less than 1% of its original numbers. The American and Canadian governments have closed the fishery, but no one can predict whether the fish populations will recover. The Atlantic bluefin tuna has experienced a 90% population decline in the past 10 years. The swordfish has declined even further. In both cases, the drop has led to even more intense fishing of the remaining populations.

### Case study: Whales

Whales, the largest living animals that ever evolved, are rare in the world's oceans today, their numbers driven down by commercial whaling. Before the advent of cheap, high-grade oils manufactured from petroleum in the early 20th century, oil made from whale blubber was an important commercial product in the worldwide marketplace. In addition, the fine, lattice-like structure termed "baleen" used by baleen whales to filter-feed plankton from seawater was used in women's undergarments. Because a whale is such a large animal, each individual captured is of significant commercial value.

In the 18th century, right whales were the first to bear the brunt of commercial whaling. They were called "right" whales because they were slow, easy to capture, did not sink when killed and provided up to 150 barrels of blubber oil and abundant baleen, making them the right whale for a commercial whaler to hunt.

As the right whale declined, whalers turned to the gray, humpback, and bowhead whales. As their numbers declined, whalers turned to the blue, the largest of all whales, and when those were decimated, to the fin, then the Sei, and then the sperm whales. As each species of whale became the focus of commercial whaling, its numbers began a steep decline (figure 60.15).

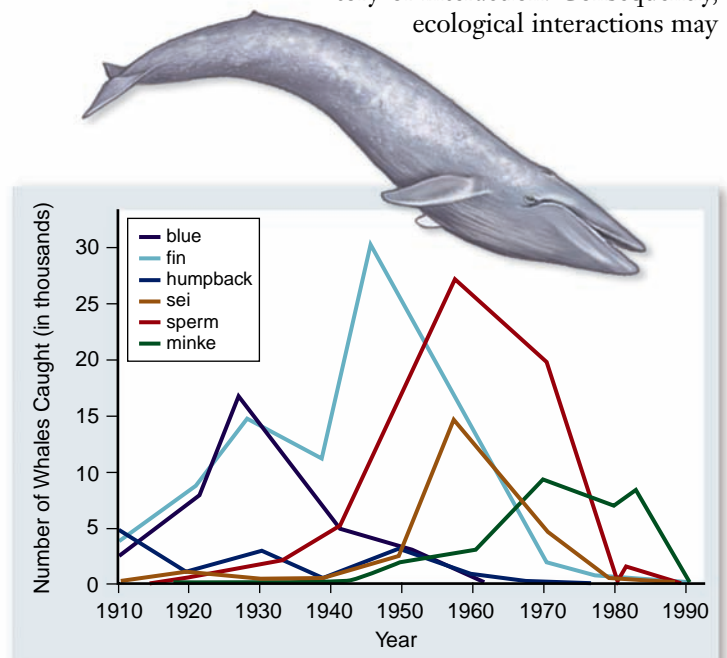

Hunting of right whales was made illegal in 1935. By then, they had been driven to the brink of extinction, their numbers less than 5% of what they had been. Although protected ever since, their numbers have not recovered in either the North Atlantic or the North Pacific. By 1946, several other whale species faced imminent extinction, and whaling nations formed the International Whaling Commission (IWC) to regulate commercial whale hunting. Like a fox guarding the henhouse, the IWC for decades did little to limit whale harvests, and whale numbers continued to decline steeply.

Finally, in 1974, when the numbers of all but the small minke whales had been driven down, the IWC banned hunting of blue, gray, and humpback whales, and instituted partial bans on other species. The rule was violated so often, however, that the IWC in 1986 instituted a worldwide moratorium on all commercial killing of whales. Although some commercial whaling continues, often under the guise of harvesting for scientific studies, annual whale harvests have dropped dramatically in the last 20 years.

Some species appear to be recovering, but others are not. Humpback numbers have more than doubled since the early 1960s, increasing nearly 10% annually, and Pacific gray whales have fully recovered to their previous numbers of about 20,000 animals, after having been hunted to fewer than 1000. Right, sperm, fin, and blue whales have not recovered, and no one knows whether they ever will.

### Introduced species threaten native species and habitats

Colonization, a natural process by which a species expands its geographic range, occurs in many ways: A flock of birds gets blown off course, a bird eats a fruit and defecates its seed miles away, or lowered sea levels connect two previously isolated landmasses, allowing species to freely move back and forth. Such events—particularly those leading to successful establishment of a new population—probably occur rarely, but when they do, the resulting change to natural communities can be large. The reason is that colonization brings together species with no history of interaction. Consequently, ecological interactions may

**Figure 60.15** World catch of some whale species in the 20th century. Each species is hunted in turn until its numbers fall so low that hunting it becomes commercially unprofitable.

### Inquiry question

Why might whale populations fail to recover once hunting is stopped?

**Figure 60.16** Zebra mussels (*Dreissena polymorpha*) clogging a pipe. These mussels were introduced from Europe, and are now a major problem in North American rivers.

be particularly strong because the species have not evolved ways of adjusting to the presence of one another, such as adaptations to avoid predation or to minimize competitive effects.

The paleontological record documents many cases in which geologic changes brought previously isolated species together, such as when the Isthmus of Panama emerged above the sea approximately 3 MYA, connecting the previously isolated fauna and flora of North and South America. In some cases, the result has been an increase in species diversity, but in other cases, invading species have led to the extinction of natives.

### Human influence on colonization

Unfortunately, what was naturally a rare process has become all too common in recent years, thanks to the actions of humans. Species introductions due to human activities occur in many ways, sometimes intentionally, but usually not. Plants and animals can be transported in the ballast of large ocean vessels; in nursery plants; as stowaways in boats, cars, and planes; as beetle larvae within wood products—even as seeds or spores in the mud stuck to the bottom of a shoe. Overall, some researchers estimate that as many as 50,000 species have been introduced into the United States.

**Figure 60.17** The akiapolaau (*Hemignathus munroi*) and the Palila (*Loxioides bailleui*), endangered Hawaiian birds. More than two-thirds of Hawaii's native bird species are now extinct or have been greatly reduced in population size. Bird faunas on islands around the world have experienced similar declines after human arrival.

The effects of introductions on humans have been enormous. In the United States alone, nonnative species cost the economy an estimated \$140 billion per year. For example, dozens of foreign weeds in Colorado have covered more than a million acres. Just three of these species cost wheat farmers tens of millions of dollars. At the same time, leafy spurge, a plant from Europe, outcompetes native grasses, ruining rangeland for cattle at a price tag of \$144 million per year.

The zebra mussel, a mollusk native to the Black Sea region, is a huge problem throughout much of the eastern and central United States, where it can attain densities as high as 700,000/m<sup>2</sup>, clogging pipes, including those for water and power plants, and causing an estimated \$3 to \$5 billion damage a year (figure 60.16).

Introduced species can also affect human health. For example, West Nile fever was probably introduced from Africa or the Middle East to the United States in the late 1990s.

The effect of species introductions on native ecosystems is equally dramatic. Islands have been particularly affected. For example, as mentioned in chapter 57, a single lighthouse keeper's cat wiped out an entire species, the Stephens Island wren. Rats had a devastating effect throughout the South Pacific where bird species nested on the ground and had no defense against the voracious predators to which they were evolutionarily naive. More recently, the brown tree snake, introduced to the island of Guam, essentially eliminated all species of forest birds.

In Hawaii, the problem has been slightly different: Introduced mosquitoes brought with them malaria, to which the native species had evolved no resistance. The result is that more than 100 species (>70% of the native fauna) either became extinct or are now restricted to higher and cooler elevations where the mosquitoes don't occur (figure 60.17).

The effects of introduced species are not always direct, but instead may reverberate throughout an ecosystem. For example, the Argentine ant has spread through much of the southern United States, greatly reducing populations of most native ant species with which it comes in contact. The extinction of these ant species has had a dramatic negative effect on the coast horned lizard (*Phrynosoma coronatum*), which feeds on the larger native species. In their absence, the lizards have shifted to less-preferred prey species. In addition, the native ant species consume seeds, and in the process, play an important

role in seed dispersal. Argentine ants, by contrast, do not eat seeds. In South Africa, where the Argentine ant has also appeared, at least one plant species has experienced decreased reproductive success due to the loss of its dispersal agent.

The most dramatic effects of introduced species, however, occur when entire ecosystems are transformed. Some plant species can completely overrun a habitat, displacing all native species and turning the area into a monoculture (that is, an area occupied by a single species). In California, the yellow star thistle now covers 4 million hectares of what was once highly productive grassland. In Hawaii, a small tree native to the Canary Islands, *Myrica faya*, has spread widely. Because it is able to fix nitrogen at high rates, it has caused a 90-fold increase in the nitrogen content of the soil, thus allowing other, nitrogen-requiring species to invade.

### **Efforts to combat introduced species**

Once an introduced species becomes established, eradicating it is often extremely difficult, expensive, and time-consuming. Some efforts—such as the removal of goats and rabbits from certain small islands—have been successful, but many other efforts have failed. The best hope for stopping the ravages of introduced species is to prevent them from being introduced in the first place. Although easier said than done, government agencies are now working strenuously to put into place procedures that can intercept species in transit, before they have the opportunity to become established.

### **Case study: Lake Victoria cichlids**

Lake Victoria, an immense, shallow, freshwater sea about the size of Switzerland in the heart of equatorial East Africa, used to be home to an incredibly diverse collection of over 300 species of cichlid fishes (see figure 22.15). These small, perchlike fish range from 5 to 13 cm in length, with males having endless varieties of color. Today, most of these cichlid species are threatened, endangered, or extinct.

What happened to bring about the abrupt loss of so many endemic cichlid species? In 1954, the Nile perch, a commercial fish with a voracious appetite, was purposely introduced on the Ugandan shore of Lake Victoria. Nile perch, which grow to over a meter in length, were to form the basis of a new fishing industry (figure 60.18). For decades, these perch did not seem to have a significant effect; over 30 years later, in 1978, Nile perch still made up less than 2% of the fish harvested from the lake.

Then something happened to cause the Nile perch population to explode and to spread rapidly through the lake, eating their way through the cichlids. By 1986, Nile perch constituted nearly 80% of the total catch of fish from the lake and the endemic cichlid species were virtually gone. Over 70% of cichlid species disappeared, including all open-water species.

So what happened to kick-start the mass extinction of the cichlids? The trigger seems to have been eutrophication. Before 1978, Lake Victoria had high oxygen levels at all depths, down to the bottom layers more than 60 m deep. However, by 1989 high inputs of nutrients from agricultural runoff and sewage from towns and villages had led to algal blooms that severely depleted oxygen levels in deeper parts of the lake. Cichlids feed on algae, and initially their population numbers are thought to

**Figure 60.18 Nile perch (*Lates niloticus*).** This predatory fish, which can reach a length of 2 m and a mass of 200 kg, was introduced into Lake Victoria as a potential food source. It is responsible for the virtual extinction of hundreds of species of cichlid fishes.

have risen in response to this increase in their food supply, but unlike the conditions during similar algal blooms of the past, the Nile perch was present to take advantage of the situation. With a sudden increase in its food supply (cichlids), the numbers of Nile perch exploded, and they simply ate all available cichlids.

Since 1990, the situation has been compounded by the introduction into Lake Victoria of a floating water weed from South America, the water hyacinth *Eichhornia crassipes*. Reproducing quickly under eutrophic conditions, thick mats of water hyacinth soon covered entire bays and inlets, choking off the coastal habitats of non-open-water cichlids.

### **Disruption of ecosystems can cause an extinction cascade**

Species often become vulnerable to extinction when their web of ecological interactions becomes seriously disrupted. Because of the many relationships linking species in an ecosystem (see chapter 58), human activities that affect one species can have ramifications throughout an ecosystem, ultimately affecting many other species.

A recent case in point involves the sea otters that live in the cold waters off Alaska and the Aleutian Islands. Otter populations have declined sharply in recent years. In a 500-mile stretch of coastline, otter numbers have dropped from 53,000 in the 1970s to an estimated 6000, a plunge of nearly 90%. Investigating this catastrophic decline, marine ecologists uncovered a chain of interactions among the species of the ocean and kelp forest ecosystems, a falling-domino series of lethal effects that illustrates the concepts of both top-down and bottom-up trophic cascades discussed in chapter 58.

### **Case study: Alaskan near-shore habitat**

The first in a series of events leading to the sea otter's decline seems to have been the heavy commercial harvesting of whales,

described earlier in this chapter. Without whales to keep their numbers in check, ocean zooplankton thrived, leading in turn to proliferation of a species of fish called pollock that feeds on the abundant zooplankton. Given this ample food supply, the pollock proved to compete very successfully with other northern Pacific fish, such as herring and ocean perch, so that levels of these other fish fell steeply in the 1970s.

Then the falling chain of dominoes began to accelerate. The decline in the nutritious forage fish led to an ensuing crash in Alaskan populations of sea lions and harbor seals, for which pollock did not provide sufficient nourishment. This decline may also have been hastened by orcas (also called killer whales) switching from feeding on the less-available whales to feeding on seals and sea lions; the numbers of these pinniped species have fallen precipitously since the 1970s.

When pinniped numbers crashed, some orcas, faced with a food shortage, turned to the next best thing: sea otters. In one bay where the entrance from the sea was too narrow and shallow for orcas to enter, only 12% of the sea otters have disappeared, while in a similar bay that orcas could enter easily, two-thirds of the otters disappeared in a year's time.

Without otters to eat them, the population of sea urchins exploded, eating the kelp and thus “deforesting” the kelp forests and denuding the ecosystem (figure 60.19). As a result, fish species that live in the kelp forest, such as sculpins and greenlings, are declining.

### Loss of keystone species

As discussed in chapter 57, a keystone species is a species that exerts a greater influence on the structure and functioning of an ecosystem than might be expected solely on the basis of its abundance. The sea otters of figure 60.19 are a keystone species of the kelp forest ecosystem, and their removal can have disastrous consequences.

No hard-and-fast line allows us to clearly identify keystone species. Rather, it is a qualitative concept, a statement that indicates a species plays a particularly important role in its community. Keystone species are usually characterized by the strength of their effect on their community.

### Case study: Flying foxes

The severe decline of many species of “flying foxes,” a type of bat (figure 60.20), in the Old World tropics is an example of how the loss of a keystone species can dramatically affect the other species living within an ecosystem, sometimes even leading to a cascade of further extinctions.

These bats have very close relationships with important plant species on the islands of the Pacific and Indian Oceans. The family Pteropodidae contains nearly 200 species, approximately one-quarter of them in the genus *Pteropus*, and is widespread on the islands of the South Pacific, where they are the most important—and often the only—pollinators and seed dispersers.

**Figure 60.19 Disruption of the kelp forest ecosystem.** Overharvesting by commercial whalers altered the balance of fish in the ocean ecosystem, inducing killer whales to feed on sea otters, a keystone species of the kelp forest ecosystem.

**1. Whales**  
Overharvesting of plankton-eating whales may have caused an increase in plankton-eating pollock populations.

**2. Nutritious fish**  
Populations of nutritious fish like ocean perch and herring declined, likely due to competition with pollock.

**3. Sea lions and harbor seals**  
Sea lion and harbor seal populations drastically declined in Alaska, probably because the less-nutritious pollock could not sustain them.

**4. Killer whales**  
With the decline in their prey populations of sea lions and seals, killer whales turned to a new source of food: sea otters.

**5. Sea otters**  
Sea otter populations declined so dramatically that they disappeared in some areas.

**6. Sea urchins**  
Usually the preferred food of sea otters, sea urchin populations now exploded and fed on kelp.

**7. Kelp forests**  
Severely thinned by the sea urchins, the kelp beds no longer support a diversity of fish species, which may lead to a decline in populations of eagles that feed on the fish.

**Figure 60.20 The importance of keystone species.**

Flying foxes, a type of fruit-eating bat, are keystone species on many Old World tropical islands. It pollinates many plants and is a key disperser of seeds. Its elimination due to hunting and habitat loss is having a devastating effect on the ecosystems of many South Pacific Islands.

A study in Samoa found that 80% to 100% of the seeds landing on the ground during the dry season were deposited by flying foxes, which eat the fruits and defecate the seeds, often moving them great distances in the process. Many species are entirely dependent on these bats for pollination. Some have evolved features such as night-blooming flowers that prevent any other potential pollinators from taking over the role of the fruit bats.

In Guam, the two local species of flying fox have recently been driven extinct or nearly so, with a substantial impact on the ecosystem. Botanists have found that some plant species are not fruiting or are doing so only marginally, producing fewer fruits than normal. Fruits are not being dispersed away from parent plants, so seedlings are forced to compete, usually unsuccessfully, with adult trees.

Flying foxes are being driven to extinction by human hunters who kill them for food and for sport, and by orchard farmers who consider them pests. Flying foxes are particularly vulnerable because they live in large and obvious groups of up to a million individuals. Because they move in regular and predictable patterns and can be easily tracked to their home roost, hunters can easily kill thousands at a time.

Programs aimed at preserving particular species of flying foxes are only just beginning. One particularly successful example is the program to save the Rodrigues fruit bat, *Pteropus rodricensis*, which occurs only on Rodrigues Island in the Indian Ocean near Madagascar. The population dropped from about 1000 individuals in 1955 to fewer than 100 by 1974, largely due to the loss of the fruit bat's forest habitat to farming. Since 1974, the species has been legally protected, and the forest area of the island is being increased through a tree-planting program. Eleven captive-breeding colonies have been established, and the bat population is now increasing rapidly. The combination of legal protection, habitat restoration, and captive breeding has in this instance produced a very effective preservation program.

**Small populations are particularly vulnerable**

Because of the factors just discussed, populations of many species are fragmented and reduced in size. Such populations are particularly prone to extinction.

**Demographic factors**

Small populations are vulnerable to events that decrease survival or reproduction. For example, by nature of their size, small populations are ill-equipped to withstand catastrophes, such as a flood, forest fire, or disease epidemic. One example is provided by the history of the heath hen. Although the species was once common throughout the eastern United States, hunting pressure in the 18th and 19th centuries eventually eliminated all but one population, on the island of Martha's Vineyard near Cape Cod, Massachusetts. Protected in a nature preserve, the population was increasing in number until a fire destroyed most of the preserve's habitat. The small surviving population was then ravaged the next year by an unusual congregation of predatory birds, followed shortly thereafter by a disease epidemic. The last sighting of a heath hen, a male, was in 1932 (figure 60.21a).

When populations become extremely small, bad luck can spell the end. For example, the dusky seaside sparrow (figure 60.21b), a now-extinct subspecies that was found on the east coast of Florida, dwindled to a population of five individuals, all of which happened to be males. In a large population, the probability that all individuals will be of one sex is infinitesimal. But in small populations, just by the luck of the draw, it is possible that 5 or 10 or even 20 consecutive births will all be individuals of one sex, and that can be enough to send a species to extinction. In addition, when populations are small, individuals may have trouble finding each other (the Allee effect discussed in chapter 56), thus leading the population into a downward spiral toward extinction.

**Figure 60.21 Alive no more.** a. A museum specimen of the heath hen (*Tympanuchus cupido cupido*) which went extinct in 1932. b. This male was one of the last dusky seaside sparrows (*Ammodramus maritimus nigrescens*).

### Lack of genetic variability

Small populations face a second dilemma. Because of their low numbers, such populations are prone to the loss of genetic variation as a result of genetic drift (figure 60.22). Indeed, many small populations contain little or no genetic variability. The result of such genetic homogeneity can be catastrophic. Genetic variation is beneficial to a population both because of heterozygote advantage (see chapter 20) and because genetically variable individuals tend not to have two copies of deleterious recessive alleles. Populations lacking variation are often composed of sickly, unfit, or sterile individuals. Laboratory groups of rodents and fruit flies that are maintained at small population sizes often perish after a few generations as each generation becomes less robust and fertile than the preceding one.

Although it is difficult to demonstrate that a species has gone extinct because of lack of genetic variation, studies of both zoo and natural populations clearly reveal that more genetically variable individuals have greater fitness. Furthermore, in the longer term, populations with limited genetic variation have diminished ability to adapt to changing environments.

### Interaction of demographic and genetic factors

As populations decrease in size, demographic and genetic factors combine to cause what has been termed an “extinction vortex.” That is, as a population gets smaller, it becomes more vulnerable to demographic catastrophes. In turn, genetic variation starts to be lost, causing reproductive rates to decline and population numbers to decline even further, and so on. Eventually, the population disappears entirely, but attributing its demise to one particular factor would be misleading.

### Case study: Prairie chickens

The greater prairie chicken, a close relative of the now-extinct heath hen, is a showy, 2-lb bird renowned for its flamboyant mating rituals (figure 60.23). Abundant in many midwestern states, the prairie chickens in Illinois have in the past six decades undergone a population collapse.

**Figure 60.22 Loss of genetic variability in small populations.** The percentage of genes that are polymorphic in isolated populations of the tree *Halocarpus bidwillii* in the mountains of New Zealand is a sensitive function of population size.

### Inquiry question

? Why do small populations lose genetic variation?

**Figure 60.23 A mating ritual.** The male greater prairie chicken (*Tympanuchus cupido pinnatus*) inflates bright orange air sacs, part of his esophagus, into balloons on each side of his head. As air is drawn into the sacs, it creates a three-syllable low frequency “boom-boom-boom” that can be heard for kilometers.

Once, enormous numbers of birds occurred throughout the state, but with the 1837 introduction of the steel plow, the first that could slice through the deep, dense root systems of prairie grasses, the Illinois prairie began to be replaced by farmland. By the turn of the 20th century, the prairie had all but vanished, and by 1931, the heath hen had become locally extinct in Illinois. The greater prairie chicken fared little better, its numbers falling to 25,000 statewide in 1933 and then to 2000 by 1962. In surrounding states with less intensive agriculture, it continued to prosper.

In 1962 and 1967, sanctuaries were established in Illinois to attempt to preserve the greater prairie chicken. But privately owned grasslands kept disappearing, along with their prairie chickens, and by the 1980s the birds were extinct in Illinois except for two preserves, and even there, their numbers kept falling. By 1990, the egg hatching rate, which at one time had averaged between 91% and 100%, had dropped to an extremely low 38%. By the mid-1990s, the count of males had dropped to as low as six in each sanctuary.

What was wrong with the sanctuary populations? One suggestion was that because of very small population sizes and a mating ritual whereby one male may dominate a flock, the Illinois prairie chickens had lost so much genetic variability as to create serious genetic problems. To test this idea, biologists at the University of Illinois compared DNA from frozen tissue samples of birds that had died in Illinois between 1974 and 1993, and found that in recent years Illinois birds had indeed become genetically less diverse.

The researchers then extracted DNA from tissue in the roots of feathers from stuffed birds collected in the 1930s from the same population. They found that Illinois birds had lost fully one-third of the genetic diversity of birds living in the same place before the population collapse of the 1970s. By contrast, prairie chicken populations in other states still contained much of the genetic variation that had disappeared from Illinois populations.

Now the stage was set to halt the Illinois prairie chicken's race toward extinction in Illinois. Wildlife managers began to

transplant birds from genetically diverse populations of Minnesota, Kansas, and Nebraska to Illinois. Between 1992 and 1996, a total of 518 out-of-state prairie chickens were brought in to interbreed with the Illinois birds, and hatching rates were back up to 94% by 1998. It looks as though the prairie chickens have been saved from extinction in Illinois.

The key lesson here is the importance of not allowing things to go too far—not to drop down to a single isolated population. Without the outlying genetically different populations, the prairie chickens in Illinois could not have been saved. When the last population of the dusky seaside sparrow lost its last female, there was no other source of females, and the subspecies went extinct.

### Learning Outcomes Review 60.3

Habitat factors responsible for extinction include habitat destruction, pollution, disruption, and fragmentation. Overexploitation can reduce populations to low levels or eliminate them entirely. Introduced species can wreak havoc on native communities. Finally, small populations have less ability to rebound from catastrophes and are vulnerable to loss of genetic variation. Interaction of all these factors can hasten species' decline into extinction.

- Does it make sense to take endangered species out of the wild to preserve them if their habitat is allowed to disappear? Explain.

## 60.4 Approaches for Preserving Endangered Species and Ecosystems

### Learning Outcomes

1. Distinguish between restoration of species and restoration of ecosystem functioning.
2. List the strategies for habitat restoration.
3. Explain the rationale for captive breeding programs.

Once the cause of a species' endangerment is known, it becomes possible to design a recovery plan. If the cause is commercial overharvesting, regulations can be issued to restrict harvesting and protect the threatened species. If the cause is habitat loss, plans can be instituted to restore the habitat. Loss of genetic variability in isolated subpopulations can be countered by transplanting individuals from genetically different populations. Populations in immediate danger of extinction can be captured, introduced into a captive-breeding program, and later reintroduced to other suitable habitat.

All of these solutions are extremely expensive. But as Bruce Babbitt, Secretary of the Interior in the Clinton administration, noted, it is much more economical to prevent “environmental trainwrecks” from occurring than to clean them up afterward. Preserving ecosystems and monitoring species before they are threatened is the most effective means of protecting the environment and preventing extinctions.

## Destroyed habitats can sometimes be restored

Conservation biology typically concerns itself with preserving populations and species in danger of decline or extinction. Conservation, however, requires that there be something left to preserve; in many situations, conservation is no longer an option. Species, and in some cases whole communities, have disappeared or been irretrievably modified. The clear-cutting of the temperate forests of Washington State leaves little behind to conserve, as does converting a piece of land into a wheat field or an asphalt parking lot. Redeeming these situations requires restoration rather than conservation.

Three quite different sorts of habitat restoration programs might be undertaken, depending on the cause of the habitat loss.

### Pristine restoration

In ecosystems where all species have been effectively removed, conservationists might attempt to restore the plants and animals that are the natural inhabitants of the area, if these species can be identified. When abandoned farmland is to be restored to prairie, as in figure 60.24, how would conservationists know what to plant?

a.

b.

**Figure 60.24 Habitat restoration.** The University of Wisconsin–Madison Arboretum has pioneered restoration ecology. *a.* The restoration of the prairie was at an early stage in November 1935. *b.* The prairie as it looks today. This picture was taken at approximately the same location as the 1935 photograph.

Although it is in principle possible to reestablish each of the original species in their original proportions, rebuilding a community requires knowing the identities of all the original inhabitants and the ecologies of each of the species. We rarely have this much information, so no restoration is ever truly pristine.

Increasingly, restoration biologists are working on restoring the functioning of an ecosystem, rather than trying to recreate the same community composition. This approach shifts the focus from restoring species to reconstructing the processes that operated in the natural habitat.

### Removing introduced species

Sometimes the habitat has been destroyed by a single introduced species. In such a case, habitat restoration involves removing the introduced species. Restoration of the once-diverse cichlid fishes to Lake Victoria will require more than breeding and restocking the endangered species. The introduced water hyacinth and Nile perch populations will have to be brought under control or removed, and eutrophication will have to be reversed.

It is important to act quickly if an introduced species is to be removed. When aggressive African bees (the so-called “killer bees”) were inadvertently released in Brazil, they remained confined to the local area for only one season. Now they occupy much of the western hemisphere.

### Cleanup and rehabilitation

Habitats seriously degraded by chemical pollution cannot be restored until the pollution is cleaned up. The successful restoration of the Nashua River in New England is one example of how a concerted effort can succeed in restoring a heavily polluted habitat to a relatively pristine condition.

Once so heavily polluted by chemicals from dye manufacturing plants that it was different colors in different places, the river is now clean and used for many recreational activities.

## Captive breeding programs have saved some species

Recovery programs, particularly those focused on one or a few species, must sometimes involve direct intervention in natural populations to avoid an immediate threat of extinction.

### Case study: The peregrine falcon

American populations of birds of prey, such as the peregrine falcon, began an abrupt decline shortly after World War II. Of the approximately 350 breeding pairs east of the Mississippi River in 1942, all had disappeared by 1960. The culprit proved to be the chemical pesticide DDT (Chapter 59).

The use of DDT was banned by federal law in 1972, causing levels in the eastern United States to fall quickly. However, no peregrine falcons were left in the eastern United States to reestablish a natural population. Falcons from other parts of the country were used to establish a

captive-breeding program at Cornell University in 1970, with the intent of reestablishing the peregrine falcon in the eastern United States by releasing offspring of these birds. By the end of 1986, over 850 birds had been released in 13 eastern states, producing an astonishingly strong recovery (figure 60.25).

### Case study: The California condor

The number of California condors (*Gymnogyps californianus*), a large, vulture-like bird with a wingspan of nearly 3 m, has been declining gradually for the past 200 years. By 1985, condor numbers had dropped so low that the bird was on the verge of extinction. Six of the remaining 15 wild birds disappeared in that year alone. The entire breeding population of the species consisted of the birds remaining in the wild and an additional 21 birds in captivity.

In a last-ditch attempt to save the condor from extinction, the remaining birds were captured and placed in a captive-breeding population. The breeding program was set up in zoos, with the goal of releasing offspring on a large, 5300-hectare ranch in prime condor habitat. Birds were isolated from human contact as much as possible, and closely related individuals were prevented from breeding.

By early 2009, the captive population of California condors had reached over 160 individuals. After extensive pre-release training to avoid power poles and people, captive-reared condors have been released successfully in California at two sites in the mountains north of Los Angeles, as well as at the Grand Canyon. Many of the released birds are doing well, and the wild population now numbers nearly 200 birds. Biologists are particularly

**Figure 60.25 Success of captive breeding.** The peregrine falcon (*Falco peregrinus*) has been reestablished in the eastern United States by releasing captive-bred birds over a period of 10 years.

excited by breeding activities that resulted in the first-ever offspring produced in the wild by captive-reared parents in both California and Arizona.

### Case study: Yellowstone wolves

The ultimate goal of captive-breeding programs is not simply to preserve interesting species, but rather to restore ecosystems to a balanced, functional state. Yellowstone Park has been an ecosystem out of balance, due in large part to the systematic extermination of the gray wolf (*Canis lupus*) in the park early in the 20th century. Without these predators to keep their numbers in check, herds of elk and deer expanded rapidly, damaging vegetation so that the elk themselves starve in time of scarcity.

In an attempt to restore the park's natural balance, two complete wolf packs from Canada were released into the park in 1995 and 1996. The wolves adapted well, breeding so successfully that by 2002 the park contained 16 free-ranging packs and more than 200 wolves.

Although ranchers near the park have been unhappy about the return of the wolves, little damage to livestock has been noted, and the ecological equilibrium of Yellowstone Park seems well on the way to being regained. Elk are congregating in larger herds and are avoiding areas near rivers where they are vulnerable. As a result, riverside trees such as willows are increasing in number, in turn providing food for beavers, whose dams lead to the creation of ponds, a habitat type that had become rare in Yellowstone. This newly restored habitat, in turn, has led to increases in some species of birds such as the redstart that had been in decline for decades or disappeared entirely.

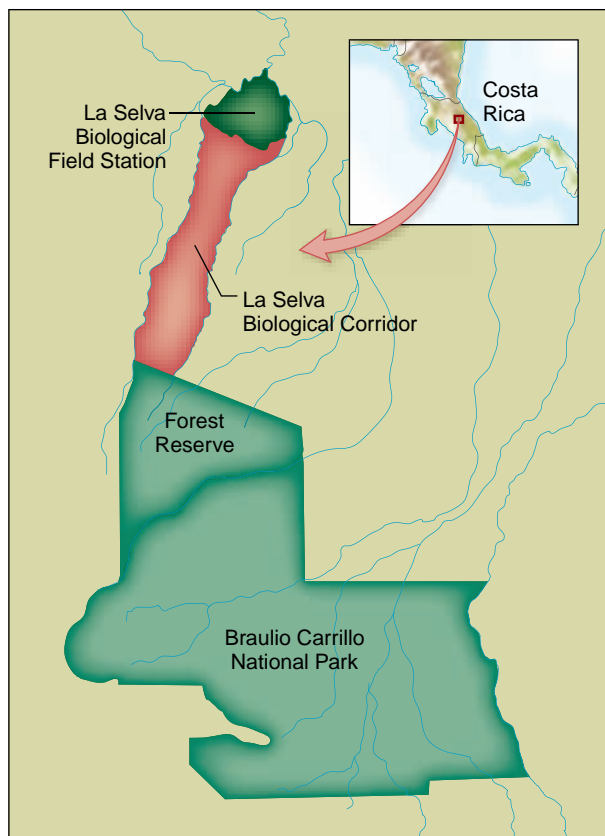

## Current conservation approaches are multidimensional

Historically, conservationists strived to solve the problems of habitat fragmentation by focusing solely on preserving as much land as possible in a pristine state in national parks and reserves. Increasingly, however, it has become apparent that the amount of land that can be preserved in such a state is limited; moreover, many areas that are not completely protected nonetheless provide suitable habitat for many species.

As a result, conservation plans are becoming multidimensional, including not only pristine areas, but also surrounding areas in which some level of human disturbance is permitted. As discussed previously, isolated patches of habitat lose species far more rapidly than large preserves do. By including these other, less pristine areas, the total amount of area available for many species is increased.

The key to managing such large tracts of land successfully over a long time is to operate them in a way compatible with local land use. For example, although no economic activity is allowed in the core pristine area, the remainder of the land may be used for nondestructive harvesting of resources. Even areas in which hunting of some species is allowed provide protection for many other species.

Corridors of dispersal are also being provided that link the pristine areas, thus effectively increasing population sizes and allowing recolonization if a population disappears in one area due to a catastrophe. Corridors can also provide protection to species that move over great distances during the course of a year. Corridors in East Africa have protected the migration routes of ungulates. In Costa Rica, a corridor linking the lowland rain forest at the La Selva Biological Station to the montane rain forest in Braulio Carrillo National Park permits the altitudinal migration of many species of birds, mammals, and butterflies (figure 60.26).

**Figure 60.26** Corridor connecting two reserves. *a.* The Organization of Tropical Studies' La Selva Biological Station in Costa Rica is connected to Braulio Carrillo National Park. *b.* The corridor allows migration of birds, mammals, butterflies, and other animals from La Selva at 35 m above sea level to mountainous habitats up to 2900 m elevation.

In addition to this focus on maintaining large enough reserves, in recent years conservation biologists also have recognized that the best way to preserve biodiversity is to focus on preserving intact ecosystems, rather than particular species. For this reason, attention in many cases is turning to identifying those ecosystems most in need of preservation and devising the means to protect not only the species within the ecosystem, but the functioning of the ecosystem itself. This entails making sure that reserves are not only large enough, but also that they protect elements such as watersheds so that activities outside the reserve won't threaten the ecosystem within it.

## Learning Outcomes Review 60.4

Restoration of species may prevent extinction, but only if restoration of habitat or an entire ecosystem is also undertaken. Removal of introduced species and cleanup of pollutants are primary strategies for habitat restoration. In cases where extinction appears imminent, removal of individuals from the wild and preservation in captive breeding programs may be necessary while habitat is restored.

- *Can habitat restoration ever approach a pristine state? Why or why not?*

## Chapter Review

### 60.1 Overview of the Biodiversity Crisis

#### *Prehistoric humans were responsible for local extinctions.*

Shortly after humans arrived in North America after the last Ice Age, at least 75% of large mammals became extinct. The same pattern has been observed in other parts of the world.

#### *Extinctions have continued in historical time.*

The majority of historical extinctions have occurred within the last 150 years and on islands. The current mass extinction is the only such event triggered by one species, *Homo sapiens*, and the only one in which resources will not be widely available for evolutionary recovery afterward.

#### *Endemic species hotspots are especially threatened.*

Endemic species are found in one restricted range and are thus vulnerable to extinction. Hotspots are areas with many endemic species; many hotspots are the site of large human population growth and high rates of extinction.

### 60.2 The Value of Biodiversity

#### *The direct economic value of biodiversity includes resources for our survival.*

Many products are obtained from different species and ecosystems, including food, materials for clothing and shelter, and medicines.

#### *Indirect economic value is derived from ecosystem services.*

Intact ecosystems provide services such as maintaining water quality, preserving soils and nutrients, moderating local climates, and recycling nutrients. The value of intact ecosystems is often not apparent until they are lost.

#### *Ethical and aesthetic values are based on our conscience and our consciousness.*

Humans can and should make ethical decisions to protect the esthetic, ecological, and economic values of ecosystems.

### 60.3 Factors Responsible for Extinction

#### *Amphibians are on the decline: A case study.*

Almost half of all amphibian species have experienced decreases in population size. No single cause has been identified, which implies that global environmental changes may be responsible.

#### *Habitat loss devastates species richness.*

Habitat may be destroyed, polluted, disrupted, or fragmented. As habitats become more fragmented, the relative proportion of the

remaining habitat that occurs on the boundary or edge increases rapidly, exposing species to parasites, nonnative invasive species, and predators (see figure 60.11).

#### *Overexploitation wipes out species quickly.*

Hunting and harvesting of wild species pose a risk of extinction. The collapse of the cod fisheries of the North Atlantic and the decline of whale species are only two of many examples.

#### *Introduced species threaten native species and habitats.*

Natural or accidental introductions of new species results in large and often negative changes to a community because of lack of checks and balances on introduced species' growth in the form of species interactions.

#### *Disruption of ecosystems can cause an extinction cascade.*

Extinction cascades may occur either top-down or bottom-up through the trophic levels. Loss of a keystone species may increase competition and greatly alter ecosystem structure and function.

#### *Small populations are particularly vulnerable.*

Catastrophes, lack of mates, and loss of genetic variability all make reduced populations more likely to become extinct (see figure 60.22).

### 60.4 Approaches for Preserving Endangered Species and Ecosystems

#### *Destroyed habitats can sometimes be restored.*

Restoration by removal of introduced species is very difficult and is most successful if done very soon after a new species is introduced. Severely polluted or damaged habitats sometimes cannot be restored to original conditions, but they may be restored to provide different environmental services.

#### *Captive breeding programs have saved some species.*

Species may be bred in captivity and returned to the wild when the factors that caused their endangerment are no longer a threat. Preservation of habitat may be a key in successful reintroduction.

#### *Current conservation approaches are multidimensional.*

The best way to preserve biodiversity is to preserve intact ecosystems rather than individual species. The key to management of large tracts of land is to operate them in a way compatible with local human needs.

Corridors of dispersal can link habitat fragments with one another and with larger habitats, allowing for increased population size, genetic exchange, and recolonization.

## Review Questions

### UNDERSTAND

1. Conservation hotspots are best described as
    - a. areas with large numbers of endemic species, in many of which species are disappearing rapidly.
    - b. areas where people are particularly active supporters of biological diversity.
    - c. islands that are experiencing high rates of extinction.
    - d. areas where native species are being replaced with introduced species.
  2. The economic value of indirect ecosystem services
    - a. is unlikely to exceed the economic value derived from uses after ecosystem conversion.
    - b. has never been carefully determined.
    - c. can greatly exceed the value derived after ecosystem conversion.
    - d. is entirely aesthetic.
  3. The amphibian decline is best described as
    - a. global disappearance of amphibian populations due to the pervasiveness of local habitat destruction.
    - b. global shrinkage of amphibian populations due to global climate change.
    - c. the unexplained disappearance of golden toads in Costa Rica.
    - d. None of the above
  4. Habitat fragmentation can negatively affect populations by
    - a. restricting gene flow among areas that were previously continuous.
    - b. increasing the relative amount of edge in suitable habitat patches.
    - c. creating patches that are too small to support a breeding population.
    - d. all of the above.
  5. When populations are drastically reduced in size, genetic diversity and heterozygosity
    - a. are likely to increase, enhancing the probability of extinction.
    - b. are likely to decrease, enhancing the probability of extinction.
    - c. are usually not factors that influence the probability of extinction.
    - d. automatically respond in a way that protects populations from future changes.
  6. A captive-breeding program followed by release to the wild
    - a. is very likely, all by itself, to save a species threatened by extinction.
    - b. is only likely to succeed when genetic variation of wild populations is very low.
    - c. may be successful when combined with proper regulations and habitat restoration.
    - d. None of the above
- a. Island populations are usually smaller than mainland populations.
  - b. All of the above
2. Ninety-nine percent of all the species that ever existed have gone extinct,
    - a. serving as evidence that current extinction rates are not higher than normal.
    - b. but most of these losses have occurred in the last 400 years.
    - c. which argues that the world just had too many species.
    - d. None of the above
  3. To effectively address the biodiversity crisis, the protection of individual species
    - a. must be used in concert with a principle of ecosystem management and restoration.
    - b. is a sufficient management approach that merely needs to be expanded to more species.
    - c. has no role to play in addressing the biodiversity crisis.
    - d. usually conflicts with the principle of ecosystem management.
  4. The introduction of a non-native predator to an ecosystem could cause extinction by
    - a. causing a top-down trophic cascade (see chapter 58).
    - b. outcompeting a native carnivore (see chapter 57).
    - c. transmitting parasites to which the native species are not adapted.
    - d. all of the above.

### SYNTHESIZE

1. If 99% of the species that ever existed are now extinct, why is there such concern over the extinction rates over the last several centuries?
2. Ecosystem conversion always has a cost and a benefit. Usually the benefit flows to a segment of society (a business or one group of people, for instance), but the costs are borne by all of society. That is what makes decisions about how and when to convert ecosystems difficult. However, is that a problem unique to conversion of ecosystems in the way we understand it today (for example, the conversion of the mangrove to a shrimp farm)? Are there other examples we can look to for guidance in how to make these decisions?
3. There is concern and evidence that amphibian populations are declining worldwide as a consequence of factors acting globally. Given that we know that species extinction is a natural process, how do we determine if there is a global decline that is different from normal species extinction?
4. Given what you learned in chapter 57 about interactions between species and in chapter 58 about interactions among trophic levels, how can the extinction of one species have far-ranging effects on an ecosystem? Is it possible to predict which species would be particularly likely to affect many other species if they were to go extinct?
5. All populations become small before going extinct. Is small population size really a cause of extinction, or just something that happens as a result of other factors that cause extinction?

### APPLY

1. Historically, island species have tended to become extinct faster than species living on a mainland. Which of the following reasons can be used to explain this phenomenon?
  - a. Island species have often evolved in the absence of predators and have no natural avoidance strategies.
  - b. Humans have introduced diseases and competitors to islands, which negatively affect island populations.

*This page intentionally left blank*

# Answer Key

## CHAPTER 1

### LEARNING OUTCOME QUESTIONS

**1.1** No. The study of biology encompasses information/tools from chemistry, physics, geology, literally all of the “natural sciences.”

**1.2** A scientific theory has been tested by experimentation. A(n) hypothesis is a starting point to explain a body of observations. When predictions generated using the hypothesis have been tested it gains the confidence associated with a theory. A theory still cannot be “proved” however as new data can always force us to re-evaluate a theory.

**1.3** No. Natural selection explains the patterns of living organisms we see at present, and allows us to work back in time, but it is not intended to explain how life arose. This does not mean that we can never explain this, but merely that natural selection does not do this.

**1.4** Viruses do not fit well into our definition of living systems. It is a matter of controversy whether viruses should be considered “alive.” They lack the basic cellular machinery, but they do have genetic information. Some theories for the origin of cells view viruses as being a step from organic molecules to cell, but looking at current organisms, they do not fulfill our definition of life.

### INQUIRY QUESTIONS

**Page 10** Reducing the factor by which the geometric progression increases (lowering the value of the exponent) reduces the difference between numbers of people and amount of food production. It can be achieved by lowering family size or delaying childbearing.

**Page 11** A snake would fall somewhere near the bird, as birds and snakes are closely related.

### UNDERSTAND

### APPLY

1. d 2. d 3. c 4. d 5. d 6. d 7. a

### SYNTHESIZE

- For something to be considered living it would demonstrate organization, possibly including a cellular structure. The organism would gain and use energy to maintain homeostasis, respond to its environment, and to grow and reproduce. These latter properties would be difficult to determine if the evidence of life from other planets comes from fossils. Similarly, the ability of an alien organism to evolve could be difficult to establish.
- The variables that were held the same between the two experiments include the broth, the flask, and the sterilization step.
  - The shape of the flask influences the experiment because any cells present in the air can enter the flask with the broken neck, but they are trapped in the neck of the other flask.
  - If cells can arise spontaneously, then cell growth will occur in both flasks. If cells can only arise from preexisting cells (cells in the air), then only the flask with the broken neck will grow cells. Breaking the neck exposes the broth to a source of cells.
  - If the sterilization step did not actually remove all cells, then growth would have occurred in both flasks. This result would seem to support the hypothesis that life can arise spontaneously.

## CHAPTER 2

### LEARNING OUTCOME QUESTIONS

**2.1** If the number of proton exceeds neutrons, there is no effect on charge; if the number of protons exceeds electrons, then the charge is (+).

**2.2** Atoms are reactive when their outer electron shell is not filled with electrons. The noble gases have filled outer electrons shells, and are thus unreactive.

**2.3** An ionic bond results when there is a transfer of electrons resulting in positive and negative ions that are attracted to each other. A covalent bond is the result of two atoms sharing electrons. Polar covalent bonds involve unequal sharing of electrons. This produces regions of partial charge, but not ions.

**2.4** C and H have about the same electronegativity, and thus form nonpolar covalent bonds. This would not result in a cohesive or adhesive fluid.

**2.5** Since ice floats, a lake will freeze from the top down, not the bottom up. This means that water remains fluid on the bottom of the lake allowing living things to overwinter.

**2.6** Since pH is a log scale, this would be a change of 100 fold in  $[H^+]$ .

### INQUIRY QUESTION

**Page 30** The buffer works over a broad range because it ionizes more completely as pH increases; in essence, there is more acid to neutralize the greater amount of base you are adding. At pH4 none of the buffer is ionized. Thus below that pH, base raises the pH without the ameliorating effects of the ionization of the buffer.

### UNDERSTAND

1. b 2. d 3. b 4. a 5. c 6. d 7. b

### APPLY

1. c 2. b 3. a 4. c 5. d 6. Chemical reactions involve changes in the electronic configuration of atoms. Radioactive decay involves the actual decay of the nucleus producing another atom and emitting radiation.

### SYNTHESIZE

- A cation is an element that tends to lose an electron from its outer energy level, leaving behind a net positive charge due to the presence of the protons in the atomic nucleus. Electrons are only lost from the outer energy level if that loss is energetically favorable, that is, if it makes the atom more stable by virtue of obtaining a filled outer energy level (the octet rule). You can predict which elements are likely to function as cations by calculating which of the elements will possess one (or two) electrons in their outer energy level. Recall that each orbital surrounding an atomic nucleus can only hold two electrons. Energy level K is a single *s* orbital and can hold two electrons. Energy level L consists of another *s* orbital plus three *p* orbitals—holding a total of eight electrons. Use the atomic number of each element to predict the total number of electrons present. Examples of other cations would include: hydrogen (H), lithium (Li), magnesium (Mg), and beryllium (Be).
- Silicon has an atomic number of 14. This means that there are four unpaired electrons in its outer energy level (comparable to carbon). Based on this fact, you can conclude that silicon, like carbon, could form four covalent bonds. Silicon also falls within the group of elements with atomic masses less than 21, a property of the elements known to participate in the formation of biologically important molecules. Interestingly, silicon is much more prevalent than carbon on Earth. Although silicon dioxide is found in the cell walls of plants and single-celled organisms called diatoms, silicon-based life has not been identified on this planet. Given the abundance of silicon on Earth you can conclude that some other aspect of the chemistry of this atom makes it incompatible with the formation of molecules that make up living organisms.
- Water is considered to be a critical molecule for the evolution of life on Earth. It is reasonable to assume that water on other planets could play a similar role. The key properties of water that would support its role in the evolution of life are:
  - The ability of water to acts as a solvent. Molecules dissolved in water could move and interact in ways that would allow for the formation of larger, more complex molecules such as those found in living organisms.
  - The high specific heat of water. Water can modulate and maintain its temperature, thereby protecting the molecules or organisms within it from temperature extremes—an important feature on other planets.

- The difference in density between ice and liquid water. The fact that ice floats is a simple, but important feature of water environments since it allows living organisms to remain in a liquid environment protected under a surface of ice. This possibility is especially intriguing given recent evidence of ice-covered oceans on Europa, a moon of the planet Jupiter.

## CHAPTER 3

### LEARNING OUTCOME QUESTIONS

**3.1** Hydrolysis is the reverse reaction of dehydration. Dehydration is a synthetic reaction involving the loss of water and hydrolysis is cleavage by addition of water.

**3.2** Starch and glycogen are both energy storage molecules. Their highly branched nature allows the formation of droplets, and the similarity in the bonds holding adjacent glucoses together mean that the enzyme we have to break down glycogen allow us to break down starch. The same enzymes do not allow us to break down cellulose. The structure of cellulose leads to the formation of tough fibers.

**3.3** The sequence of bases would be complementary. Wherever there is an A in the DNA there would be a U in the RNA, wherever there is a G in the DNA there would be a C in the RNA.

**3.4** If an unknown protein has sequence similarity to a known protein, we can infer its function is also similar. If an unknown protein has known functional domains or motifs we can also use these to help predict function.

**3.5** Phospholipids have a charged group replacing one of the fatty acids in a triglyceride. This leads to an amphipathic molecule that has both hydrophobic and hydrophilic regions. This will spontaneously form bilayer membranes in water.

### UNDERSTAND

1. b 2. a 3. d 4. c 5. b 6. b 7. c 8. b

### APPLY

1. c 2. d 3. b 4. d 5. b 6. b 7. d

### SYNTHESIZE

1. The four biological macromolecules all have different structure and function. In comparing carbohydrates, nucleic acids and proteins, we can think of these as being polymers with different monomers. In the case of carbohydrates, the polymers are all polymers of the simple sugar glucose. These are energy storage molecules (with many C-H bonds) and structural molecules such as cellulose that make tough fibers.

Nucleic acids are formed of nucleotide monomers, each of which consists of ribose, phosphate, and a nitrogenous base. These molecules are informational molecules that encode information in the sequence of bases. The bases interact in specific ways: A base pairs with T and G base pairs with C. This is the basis for their informational storage.

Proteins are formed of amino acid polymers. There are 20 different amino acids, and thus an incredible number of different proteins. These can have an almost unlimited number of functions. These functions arise from the amazing flexibility in structure of protein chains.

2. **Nucleic Acids**—Hydrogen bonds are important for complementary base-pairing between the two strands of nucleic acid that make up a molecule of DNA. Complementary base-pairing can also occur within the single nucleic acid strand of a RNA molecule.

**Proteins**—Hydrogen bonds are involved in both the secondary and tertiary levels of protein structure. The  $\alpha$  helices and  $\beta$ -pleated sheets of secondary structure are stabilized by hydrogen bond formation between the amino and carboxyl groups of the amino acid backbone. Hydrogen bond formation between R-groups helps stabilize the three-dimensional folding of the protein at the tertiary level of structure.

**Carbohydrates**—Hydrogen bonds are less important for carbohydrates; however, these bonds are responsible for the formation of the fibers of cellulose that make up the cell walls of plants.

**Lipids**—Hydrogen bonds are not involved in the structure of lipid molecules. The inability of fatty acids to form hydrogen bonds with water is key to their hydrophobic nature.

3. We have enzymes that can break down glycogen. Glycogen is formed from alpha-glucose subunits. Starch is also formed from alpha-glucose units, but cellulose is formed from beta-glucose units. The enzymes that break the alpha-glycosidic linkages cannot break the beta-glycosidic linkages. Thus we can degrade glycogen and starch but not cellulose.

## CHAPTER 4

### LEARNING OUTCOME QUESTIONS

**4.1** The statement about all cells coming from preexisting cells might need to be modified. It would really depend on whether these Martian life forms were based on a similar molecular/cellular basis as terrestrial life.

**4.2** Bacteria and archaea both tend to be single cells that lack a membrane-bounded nucleus, and extensive internal endomembrane systems. They both have a cell wall, although the composition is different. They do not undergo mitosis, although the proteins involved in DNA replication and cell division are not similar.

**4.3** Part of what gives different organs their unique identities are the specialized cell types found in each. That does not mean that there will not be some cell types common to all (epidermal cells for example) but that organs tend to have specialized cell types.

**4.4** They don't!

**4.5** The nuclear genes that encode organellar proteins moved from the organelle to the nucleus. There is evidence for a lot of "horizontal gene transfer" across domains; this is an example of how that can occur.

**4.6** It provides structure and support for larger cells, especially in animal cells that lack a cell wall.

**4.7** Microtubules and microfilaments are both involved in cell motility, and in movement of substance around cells. Intermediate filaments do not have this dynamic role, but are more structural.

**4.8** Cell junctions help to put together cells into higher level structures that are organized and joined in different ways. Different kinds of junctions can be used for different functional purposes.

### INQUIRY QUESTIONS

**Page 64** Stretch, dent, convolute, fold, add more than one nuclei, anything which would increase the amount of diffusion between the cytoplasm and the external environment.

**Page 75** Both the cristae of mitochondria and the thylakoids of chloroplasts, where many of the reactions take place leading to the production of ATP, are highly folded. The convolutions allow for a large surface area increasing the efficiency of the mechanisms of oxidative phosphorylation.

**Page 80** Ciliated cell in the trachea help to remove particulate matter from the respiratory tract where it can be expelled or swallowed and processed in the digestive tract.

### UNDERSTAND

1. d 2. d 3. c 4. a 5. c 6. d 7. b

### APPLY

1. c 2. b 3. b 4. b 5. c 6. b 7. a

### SYNTHESIZE

1. Your diagram should start at the SER and then move to the RER, Golgi apparatus, and finally to the plasma membrane. Small transport vesicles are the mechanism that would carry a phospholipids molecule between two membrane compartments. Transport vesicles are small "membrane bubbles" composed of a phospholipid bilayer.
2. If these organelles were free-living bacteria, they would have the features found in bacteria. Mitochondria and chloroplasts do both have DNA but no nucleus, and they lack the complex organelles found in eukaryotes. At first glance, the cristae may seem to be an internal membrane system, but they are actually infoldings of the inner membrane. If endosymbiosis occurred, this would be the plasma membrane of the endosymbiont, and the outer membrane would be the plasma membrane of the engulfing cell. Another test would be to compare DNA in these organelles with current bacteria. This has actually shown similarities that make us confident of the identity of the endosymbionts.
3. The prokaryotic and eukaryotic flagella are examples of an analogous trait. Both flagella function to propel the cell through its environment by converting chemical energy into mechanical force. The key difference is in the structure of the flagella. The bacterial flagellum is composed of a single protein emerging from a basal body anchored within the cell's plasma membrane and using the potential energy of a proton gradient to cause a rotary movement. In contrast, the flagellum of the eukaryote is composed of

many different proteins assembled into a complex axoneme structure that uses ATP energy to cause an undulating motion.

- Eukaryotic cells are distinguished from prokaryotic cells by the presence of a system of internal membrane compartments and membrane-bounded organelles such as mitochondria and chloroplasts. As outlined in Figure 4.19, the first step in the evolution of the eukaryotic cell was the infolding of the plasma membrane to create separate internal membranes such as the nuclear envelope and the endoplasmic reticulum. The origins of mitochondria and chloroplasts are hypothesized to be the result of a bit of cellular “indigestion” where aerobic or photosynthetic prokaryotes were engulfed, but not digested by the larger ancestor eukaryote. Given this information, there are two possible scenarios for the origin of *Giardia*. In the first scenario, the ancestor of *Giardia* split off from the eukaryotic lineage after the evolution of the nucleus, but before the acquisition of mitochondria. In the second scenario, the ancestor of *Giardia* split off after the acquisition of mitochondria, and subsequently lost the mitochondria. At present, neither of these two scenarios can be rejected. The first case was long thought to be the best explanation, but recently it has been challenged by evidence for the second case.

## CHAPTER 5

### LEARNING OUTCOME QUESTIONS

- Cells would not be able to control their contents. Nonpolar molecules would be able to cross the membrane by diffusion, as would small polar molecules, but without proteins to control the passage of specific molecules, it would not function as a semipermeable membrane.
- No. The nonpolar interior of the bilayer would not be soluble in the solvent. The molecules will organize with their nonpolar tails in the solvent, but the negative charge on the phosphates would repel other phosphates.
- Transmembrane domains anchor protein in the membrane. They associate with the hydrophobic interior, thus they must be hydrophobic as well. If they slide out of the interior, they are repelled by water.
- The concentration of the IV will be isotonic with your blood cell. If it were hypotonic, your blood cells would take on water and burst; if it were hypertonic, your blood cells would lose water and shrink.
- Channel proteins are aqueous pores that allow facilitated diffusion. They cannot actively transport ions. Carrier proteins bind to their substrates and couple transport to some form of energy for active transport.
- In all cases, there is recognition and specific binding of a molecule by a protein. In each case this binding is necessary for biological function.

### INQUIRY QUESTIONS

**Page 94** As the name suggests for the fluid mosaic model, cell membranes have some degree of fluidity. The degree of fluidity varies with the composition of the membrane, but in all membranes, phospholipids are able to move about within the membrane. Also, due to the hydrophobic and hydrophilic opposite ends of phospholipid molecules, phospholipid bilayers form spontaneously. Therefore, if stressing forces happen to damage a membrane, adjacent phospholipids automatically move to fill in the opening.

**Page 95** Integral membrane proteins are those that are embedded within the membrane structure and provide passageways across the membrane. Because integral membrane proteins must pass through both polar and nonpolar regions of the phospholipid bilayer, the protein portion held within the nonpolar fatty acid interior of the membrane must also be nonpolar. The amino acid sequence of an integral protein would have polar amino acids at both ends, with nonpolar amino acids comprising the middle portion of the protein.

### SYNTHESIZE

- Since the membrane proteins become intermixed in the absence of the energy molecule, ATP, one can conclude that chemical energy is not required for their movement. Since the proteins do not move and intermix when the temperature is cold, one can also conclude that the movement is temperature-sensitive. The passive diffusion of molecules also depends on tempera-

ture and does not require chemical energy; therefore, it is possible to conclude that membrane fluidity occurs as a consequence of passive diffusion.

- The inner half of the bilayer of the various endomembranes becomes the outer half of the bilayer of the plasma membrane.
- Lipids can be inserted into one leaflet to produce asymmetry. When lipids are synthesized in the SER, they can be assembled into asymmetric membranes. There are also enzymes that can flip lipids from one leaflet to the other.

## CHAPTER 6

### LEARNING OUTCOME QUESTIONS

- At the bottom of the ocean, light is not an option as it does not penetrate that deep. However, there is a large source of energy in the form of reduced minerals, such as sulfur compounds, that can be oxidized. These are abundant at hydrothermal vents found at the junctions of tectonic plates. This supports whole ecosystems dependent on bacteria that oxidize reduced minerals available at the hydrothermal vents.
- In a word: No. Enzymes only alter the rate of a reaction; they do not change the thermodynamics of the reaction. The action of an enzyme does not change the  $\Delta G$  for the reaction.
- In the text, it stated that the average person turns over approximately their body weight in ATP per day. This gives us enough information to determine approximately the amount of energy released:

$$\begin{aligned} 100 \text{ kg} &= 1.0 \times 10^5 \text{ g} \\ (1.0 \times 10^5 \text{ g}) / (507.18 \text{ g/mol}) &= 197.2 \text{ mol} \\ (197.2 \text{ mol}) (7.3 \text{ kcal/mol}) &= 1,439 \text{ kcal} \end{aligned}$$

- This is a question that cannot be definitely answered, but we can give some reasonable conjectures. First, DNA's location is in the nucleus and not the cytoplasm, where most enzymes are found. Second, the double stranded structure of DNA is works well for information storage, but would not necessarily function well as an enzyme. Each base interacts with a base on the opposite strand, which makes for a very stable linear molecule, but does not encourage folding into the kind of complex 3-D shape found in enzymes.
- Feedback inhibition is common in pathways that synthesize metabolites. In these anabolic pathways, when the end product builds up, it feeds back to inhibit its own production. Catabolic pathways are involved in the degradation of compounds. Feedback inhibition makes less biochemical sense in a pathway that degrades compounds as these are usually involved in energy metabolism, or recycling or removal of compounds. Thus the end product is destroyed or removed and cannot feed back.

### INQUIRY QUESTION

**Page 113** If ATP hydrolysis supplies more energy than is needed to drive the endergonic reaction, the overall process is exergonic. The reactions result in a net release of energy, so the  $\Delta G$  for the overall process is therefore negative.

### APPLY

1. b 2. c 3. d 4. c 5. c 6. c

### SYNTHESIZE

- At 40°C the enzyme is at its optimum. The rate of the reaction is at its highest level.
  - Temperature is a factor that influences enzyme function. This enzyme does not appear to function at either very cold or very hot temperatures. The shape of the enzyme is affected by temperature, and the enzyme's structure is altered enough at extreme temperatures that it no longer binds substrate. Alternatively, the enzyme may be denatured—that is a complete loss of normal three-dimensional shape at extreme temperatures. Think about frying an egg: What happens to the proteins in the egg?
  - Everyone's body is slightly different. If the temperature optimum was very narrow, then the cells that make up a body would be vulnerable. Having a broad range of temperature optimums keeps the enzyme functioning.
- The reaction rate would be slow because of the low concentration of the substrate ATP. The rate of reaction depends on substrate concentration.

- b. ATP acts like a noncompetitive, allosteric inhibitor when ATP levels are very high. If ATP binds to the allosteric site, then the reaction should slow down.
- c. When ATP levels are high, the excess ATP molecules bind to the allosteric site and inhibit the enzyme. The allosteric inhibitor functions by causing a change in the shape of the active site in the enzyme. This reaction is an example of feedback regulation because ATP is a final product of the overall series of reactions associated with glycolysis. The cell regulates glycolysis by regulating this early step catalyzed by phosphofructokinase; the allosteric inhibitor is the “product” of glycolysis (and later stages) ATP.

## CHAPTER 7

### LEARNING OUTCOME QUESTIONS

**7.1** Cells require energy for a wide variety of functions. The reactions involved in the oxidation of glucose are complex and linking these to the different metabolic functions that require energy would be inefficient. Thus cells make and use ATP as a reusable source of energy.

**7.2** The location of glycolysis does not argue for or against the endosymbiotic origin of mitochondria. It could have been located in the mitochondria previously and moved to the cytoplasm, or could have always been located in the cytoplasm in eukaryotes.

**7.3** For an enzyme like pyruvate decarboxylase the complex reduces the distance for the diffusion of substrates for the different stages of the reaction. If there are any unwanted side reactions they are prevented. Finally the reactions occur within a single unit and thus can be controlled in a coordinated fashion. The main disadvantage is that since the enzymes are all part of a complex their evolution is more constrained than if they were independent.

**7.4** At the end of the Krebs cycle, the electrons removed from glucose are all carried by soluble electron carriers. Most of these are in NADH and a few are in FADH<sub>2</sub>. All of these are all fed into the electron transport chain under aerobic conditions where they are used to produce a proton gradient.

**7.5** A hole in the outer membrane would allow protons in the intermembrane space to leak out. This would destroy the proton gradient across the inner membrane, stopping the phosphorylation of ADP by ATP synthase.

**7.6** The inner membrane actually allows a small amount of leakage of protons back into the matrix, reducing the yield per NADH. The proton gradient can also be used to power other functions, such as the transport of pyruvate. The actual yield is also affected by the relative concentrations ADP, Pi, and ATP as the equilibrium constant for this reaction depends on this.

**7.7** Glycolysis, which is the starting point for respiration from sugars is regulated at the enzyme phosphofructokinase. This enzyme is just before the 6-C skeleton is split into two 3-C molecules. The allosteric effectors for this enzyme include ATP and citrate. Thus the “end product” ATP, and an intermediate from the Krebs cycle, both feedback to inhibit the first part of this process.

**7.8** The first obvious point is that the most likely type of ecosystem would be one where oxygen is nonexistent or limiting. This includes marine, aquatic, and soil environments. Any place where oxygen is in short supply is expected to be dominated by anaerobic organisms and respiration produces more energy than fermentation.

**7.9** The short answer is no. The reason is two-fold. First the oxidation of fatty acids feeds acetyl units into the Krebs cycle. The primary output of the Krebs cycle is electrons that are fed into the electron transport chain to eventually produce ATP by chemiosmosis. The second reason is that the process of beta-oxidation that produces the acetyl units is oxygen dependent as well. This is because beta-oxidation uses FAD as a cofactor for an oxidation, and the FADH<sub>2</sub> is oxidized by the electron transport chain.

**7.10** The evidence for the origins of metabolism is indirect. The presence of O<sub>2</sub> in the atmosphere is the result of photosynthesis, so the record of when we went from a reducing to an oxidizing atmosphere chronicles the rise of oxygenic photosynthesis. Glycolysis is a universal pathway that is found in virtually all types of cells. This indicates that it is an ancient pathway that likely evolved prior to other types of energy metabolism. Nitrogen fixation probably evolved in the reducing atmosphere that preceded oxygenic photosynthesis as it is poisoned by oxygen, and aided by the reducing atmosphere.

### INQUIRY QUESTION

**Page 142** During the catabolism of fats, each round of 2-oxidation uses one molecule of ATP and generates one molecule each of FADH<sub>2</sub> and NADH. For a 16-carbon fatty acid, seven rounds of 2-oxidation would convert the fatty acid into eight molecules of acetyl-CoA. The oxidation of each acetyl-CoA in the Krebs

cycle produces 10 molecules of ATP. The overall ATP yield from a 16-carbon fatty acid would be: a net gain of 21 ATP from 7 rounds of 2-oxidation [gain of 4 ATP per round minus 1 per round to prime reactions] + 80 ATP from the oxidation of 8 acetyl-CoAs = 101 molecules of ATP.

### SYNTHESIZE

- 1.

Molecules	Glycolysis	Cellular Respiration
Glucose	<i>Is the starting material for the reaction</i>	<i>Does not directly use glucose; however, does use pyruvate derived from glucose</i>
Pyruvate	<i>The end product of glycolysis</i>	<i>The starting material for cellular respiration</i>
Oxygen	<i>Not required</i>	<i>Required for aerobic respiration, but not for anaerobic respiration</i>
ATP	<i>Produced through substrate-level phosphorylation</i>	<i>Produced through oxidative phosphorylation. More produced than in glycolysis</i>
CO <sub>2</sub>	<i>Not produced</i>	<i>Produced during pyruvate oxidation and Krebs cycle</i>

2. The electron transport chain of the inner membrane of the mitochondria functions to create a hydrogen ion concentration gradient by pumping protons into the intermembrane space. In a typical mitochondrion, the protons can only diffuse back down their concentration gradient by moving through the ATP synthase and generating ATP. If protons can move through another transport protein then the potential energy of the hydrogen ion concentration gradient would be “lost” as heat.
3. If brown fat persists in adults, then the uncoupling mechanism to generate heat described above could result in weight loss under cold conditions. There is now some evidence to indicate that this may be the case.

## CHAPTER 8

### LEARNING OUTCOME QUESTIONS

**8.1** Both chloroplasts and mitochondria have an outer membrane and an inner membrane. The inner membrane in both forms an elaborate structure. These inner membrane systems have electron transport chains that move protons across the membrane to allow for the synthesis of ATP by chemiosmosis. They also both have a soluble compartment in which a variety of enzymes carry out reactions.

**8.2** All of the carbon in your body comes from carbon fixation by autotrophs. Thus, all of the carbon in your body was once CO<sub>2</sub> in the atmosphere, before it was fixed by plants.

**8.3** The action spectrum for photosynthesis refers to the most effective wavelengths. The absorption spectrum for an individual pigment shows how much light is absorbed at different wavelengths.

**8.4** Before the discovery of photosystems, we assumed that each chlorophyll molecule absorbed photons resulting in excited electrons.

**8.5** Without a proton gradient, synthesis of ATP by chemiosmosis would be impossible. However, NADPH could still be synthesized because electron transport would still occur as long as photons were still being absorbed to begin the process.

**8.6** A portion of the Calvin cycle is the reverse of glycolysis (the reduction of 3-phosphoglycerate to glyceraldehyde-3-phosphate).

**8.7** Both C<sub>4</sub> plants and CAM plants fix carbon by incorporating CO<sub>2</sub> into the 4-carbon malate, then use this to produce high local levels of CO<sub>2</sub> for the Calvin cycle. The main difference is that in C<sub>4</sub> plants, this occurs in different cells, and in CAM plants this occurs at different times.

### INQUIRY QUESTIONS

**Page 150** Light energy is used in light-dependent reactions to reduce NADP<sup>+</sup> and to produce ATP. Molecules of chlorophyll absorb photons of light energy, but only within narrow energy ranges (specific wavelengths of light). When all chloro-

phyll molecules are in use, no additional increase in light intensity will increase the rate at which they can absorb light energy.

**Page 154** Saturation levels should be higher when light intensity is greater, up to a maximum level. If it were possible to minimize the size of photosystems by reducing the number of chlorophyll molecules in each, then the saturation level would also increase.

**Page 157** You could conclude that the two photosystems do not function sequentially.

## UNDERSTAND

## APPLY

1. d 2. b 3. c 4. c 5. d 6. b 7. a 8. a

## SYNTHESIZE

1. In  $C_3$  plants  $CO_2$  reacts with ribulose 1,5-bisphosphate (RuBP) to yield 2 molecules of PGA. This reaction is catalyzed by the enzyme rubisco. Rubisco also catalyzes the oxidation of RuBP. Which reaction predominates depends on the relative concentrations of reactants. The reactions of the Calvin cycle reduce the PGA to G3P, which can be used to make a variety of sugars including RuBP. In  $C_4$  and CAM plants, an initial fixation reaction incorporates  $CO_2$  into malate. The malate then can be decarboxylated to pyruvate and  $CO_2$  to produce locally high levels of  $CO_2$ . The high levels of  $CO_2$  get around the oxidation of RuBP by rubisco. In  $C_4$  plants malate is produced in one cell, then shunted into an adjacent cell that lacks stomata to produce high levels of  $CO_2$ . CAM plants fix carbon into malate at night when their stomata are open, then use this during the day to fuel the Calvin cycle. Both are evolutionary innovations that have arisen in hot dry climates that allow plants to more efficiently fix carbon and prevent desiccation.
2. Figure 8.19 diagrams this relationship. The oxygen produced by photosynthesis is used as a final electron acceptor for electron transport in respiration. The  $CO_2$  that results from the oxidation of glucose (or fatty acids) is incorporated into organic compounds via the Calvin cycle. Respiration also produces water, while photosynthesis consumes water.
3. Yes. Plants use their chloroplasts to convert light energy into chemical energy. During light reactions ATP and NADPH are created, but these molecules are consumed during the Calvin cycle and are not available for the cell's general use. The G3P produced by the Calvin cycle stores the chemical energy from the light reactions within its chemical bonds. Ultimately, this energy is stored in glucose and retrieved by the cell through the process of glycolysis and cellular respiration.

## CHAPTER 9

### LEARNING OUTCOME QUESTIONS

- 9.1** Ligands bind to receptors based on complementary shapes. This interaction based on molecular recognition is similar to how enzymes interact with their ligands.
- 9.2** Hydrophobic molecule can cross the membrane and are thus more likely to have an internal receptor.
- 9.3** Intracellular receptors have direct effects on gene expression. This generally leads to effects with longer duration.
- 9.4** Ras protein occupies a central role in signaling pathways involving growth factors. A number of different kinds of growth factors act through Ras. So it is not surprising that this is mutated in a number of different cancers.
- 9.5** GPCRs are a very ancient and flexible receptor/signaling pathway. The genes encoding these receptors have been duplicated and then have diversified over evolutionary time so now there are many members of this gene family.

## UNDERSTAND

## APPLY

1. b 2. c 3. b 4. d 5. d 6. c

## SYNTHESIZE

1. All signaling events start with a ligand binding to a receptor. The receptor initiates a chain of events that ultimately leads to a change in cellular

behavior. In some cases the change is immediate—for example, the opening of an ion channel. In other cases the change requires more time before it occurs, such as when the MAP kinase pathway becomes activated multiple different kinases become activated and deactivated. Some signals only affect a cell for a short time (the channel example), but other signals can permanently change the cell by changing gene expression, and therefore the number and kind of proteins found in the cell.

2. a. This system involves *both* autocrine and paracrine signaling because Netrin-1 can influence the cells within the crypt that are responsible for its production and the neighboring cells.  
b. The binding of Netrin-1 to its receptor produces the signal for cell growth. This signal would be strongest in the regions of the tissue with the greatest amount of Netrin-1—that is, in the crypts. A concentration gradient of Netrin-1 exists such that the levels of this ligand are lowest at the tips of the villi. Consequently, the greatest amount of cell death would occur at the villi tips.  
c. Tumors occur when cell growth goes unregulated. In the absence of Netrin-1, the Netrin-1 receptor can trigger cell death—controlling the number of cells that make up the epithelial tissue. Without this mechanism for controlling cell number, tumor formation is more likely.

## CHAPTER 10

### LEARNING OUTCOME QUESTIONS

- 10.1** The concerted replication and segregation of chromosomes works well with one small chromosome, but would likely not work as well with many chromosomes.
- 10.2** No.
- 10.3** The first irreversible step is the commitment to DNA replication.
- 10.4** Loss of cohesins would mean that the products of DNA replication would not be kept together. This would make normal mitosis impossible, and thus lead to aneuploid cells and probably be lethal.
- 10.5** The segregation of chromatids that lose cohesin would be random as they could not longer be held at metaphase attached to opposite poles. This would likely lead to gain and loss of this chromosome in daughter cells due to improper partitioning.
- 10.6** Tumor suppressor genes are genetically recessive, while proto-oncogenes are dominant. Loss of function for a tumor suppressor gene leads to cancer while inappropriate expression or gain of function lead to cancer with proto-oncogenes.

## UNDERSTAND

## APPLY

1. d 2. a 3. c 4. b 5. d 6. c 7. d

## SYNTHESIZE

1. If Wee-1 were absent then there would be no way for the cell to phosphorylate Cdk. If Cdk is not phosphorylated, then it cannot be inhibited. If Cdk is not inhibited, then it will remain active. If Cdk remains active, then it will continue to signal the cell to move through the  $G_2/M$  checkpoint, but now in an unregulated manner. The cells would undergo multiple rounds of cell division without the growth associated with  $G_2$ . As a consequence, the daughter cells will become smaller and smaller with each division—hence the name of the protein!
2. Growth factor = ligand
  1. Ligand binds to receptor (the growth factor will bind to a growth factor receptor).
  2. A signal is transduced (carried) into the cytoplasm.
  3. A signal cascade is triggered. Multiple intermediate proteins or second messengers will be affected.
  4. A transcription factor will be activated to bind to a specific site on the DNA.
  5. Transcription occurs and the mRNA enters the cytoplasm.
  6. The mRNA is translated and a protein is formed.
  7. The protein functions within the cytoplasm—possibly triggering S phase. If you study Figure 10.22 you will see a similar pathway for the formation of S phase proteins following receptor–ligand binding by a growth factor. In this diagram various proteins in the signaling pathway become phosphorylated

and then dephosphorylated. Ultimately, the Rb protein that regulated the transcription factor E2F becomes phosphorylated. This releases the E2F and allows it to bind to the gene for S phase proteins and cyclins.

- Proto-oncogenes tend to encode proteins that function in signal transduction pathways that control cell division. When the regulation of these proteins is aberrant, or they are stuck in the “on” state by mutation, it can lead to cancer. Tumor suppressor genes, on the other hand, tend to be in genes that encode proteins that suppress instead of activate cell division. Thus loss of function for a tumor suppressor gene leads to cancer.

## CHAPTER 11

### LEARNING OUTCOME QUESTIONS

- 11.1** Stem cells divide by mitosis to produce one cell that can undergo meiosis, and another stem cell.
- 11.2** No. Keeping sister chromatids together at the first division is key to this is reductive division. Homologues segregate at the first division, reducing the number of chromosomes by half.
- 11.3** An improper disjunction at anaphase I would result in 4 aneuploid gametes: 2 with an extra chromosome and 2 that are missing a chromosome. Nondisjunction at anaphase II would result in 2 normal gametes and 2 aneuploid gametes: 1 with an extra chromosome and 1 missing a chromosome.
- 11.4** The independent alignment of homologous pairs at metaphase I and the process of crossing over. The first shuffles the genome at the level of entire chromosomes, and the second shuffles the genome at the level of individual chromosomes.

### INQUIRY QUESTION

**Page 217** No, at the conclusion of meiosis I each cell has a single copy of each homologue. So, even if the attachment of sister chromatids were lost after a meiosis I division, the results would not be the same as mitosis.

### UNDERSTAND

1. c 2. d 3. a 4. b 5. b 6. a 7. b

### APPLY

1. c 2. b 3. b 4. d 5. b 6. a

### SYNTHESIZE

- Compare your figure with Figure 11.8.
  - There would be three homologous pairs of chromosomes for an organism with a diploid number of six.
  - For each pair of homologues, you should now have a maternal and paternal pair.
  - Many possible arrangements are possible. The key to your image is that it must show the homologues aligned pairwise—not single-file along the metaphase plate. The maternal and paternal homologues *do not* have to align on the same side of the cell. Independent assortment means that the pairs can be mixed.
  - A diagram of metaphase II would not include the homologous pairs. The pairs have separated during anaphase of meiosis I. Your picture should diagram the haploid number of chromosomes, in this case three, aligned single-file along the metaphase plate. Remember that meiosis II is similar to mitosis.
- The diploid chromosome number of a mule is 63. The mule receives 32 chromosomes from its horse parent (diploid 64: haploid 32) and another 31 chromosomes from its donkey parent (diploid 61: haploid 31).  $32 + 31 = 63$ . The haploid number for the mule would be one half the diploid number  $63 \div 2 = 31.5$ . Can there be a 0.5 chromosome? Even if the horse and donkey chromosomes can pair (no guarantee of that) there will be one chromosome without a partner. This will lead to aneuploid gametes that are not viable.
- Independent assortment involves the random distribution of maternal versus paternal homologues into the daughter cells produced during meiosis I. The number of possible gametes is equal to  $2^n$ , where  $n$  is the haploid number of chromosomes. Crossing over involves the physical exchange of genetic material between homologous chromosomes, creating new combinations of genes on a single chromosome. Crossing over is a relatively rare event that affects large blocks of genetic material, so independent assortment likely has the greatest influence on genetic diversity.
- Aneuploid gametes are cells that contain the wrong number of chromosomes. Aneuploidy occurs as a result of *nondisjunction*, or lack of separation of the chromosomes during either phase of meiosis.

- Nondisjunction occurs at the point when the chromosomes are being pulled to opposite poles. This occurs during anaphase.
  - Use an image like Figure 11.8 and illustrate nondisjunction at anaphase I versus anaphase II
- Anaphase I nondisjunction:

## CHAPTER 12

### LEARNING OUTCOME QUESTIONS

- 12.1** Both had an effect, but the approach is probably the most important. In theory, his approach would have worked for any plant, or even animal he chose. In practice, the ease of both cross and self-fertilization was helpful.
- 12.2**  $\frac{1}{3}$  of tall  $F_2$  plants are true-breeding.
- 12.3** The events of meiosis I are much more important in explaining Mendel's laws. During anaphase I homologues separate and are thus segregated, and the alignment of different homologous pairs at metaphase I is independent.
- 12.4** Assuming independent assortment of all three genes, the cross is  $Aa Bb Cc \times Aa Bb Cc$  and the  $\text{prob}(A\_ B\_ C\_)=\left(\frac{3}{4}\right) \left(\frac{3}{4}\right) \left(\frac{3}{4}\right)=27/64$ .
- 12.5** 1:1:1:1 dom dom:dom rec:rec dom:rec rec.
- 12.6**  $6/16$ .

### INQUIRY QUESTIONS

- Page 223** The ability to control whether the plants self-fertilized or cross-fertilized was of paramount importance in Mendel's studies. Results due to cross-fertilization would have had confounding influences on the predicted number of offspring with a particular phenotype.
- Page 227** Each of the affected females in the study had one unaffected parent, which means that each is heterozygous for the dominant trait. If each female marries an unaffected (recessive) male, each could produce unaffected offspring. The chance of having unaffected offspring is 50% in each case.
- Page 228** Genetic defects that remain hidden or dormant as heterozygotes in the recessive state are more likely to be revealed in homozygous state among closely related individuals.
- Page 235** Almost certainly, differences in major phenotypic traits of twins would be due to environmental factors such as diet.

### SYNTHESIZE

- The approach to solving this type of problem is to identify the possible gametes. Separate the possible gamete combinations into the boxes along the top and side. Fill in the Punnet square by combining alleles from each parent.
  - A monohybrid cross between individuals with the genotype  $Aa$  and  $Aa$

	$A$	$a$
$A$	$AA$	$Aa$
$a$	$aA$	$aa$

Phenotypic ratio: 3 dominant to 1 recessive

b. A dihybrid cross between two individuals with the genotype *AaBb*

	<i>AB</i>	<i>Ab</i>	<i>aB</i>	<i>ab</i>
<i>AB</i>	<i>AABB</i>	<i>AABb</i>	<i>AaBB</i>	<i>AaBb</i>
<i>Ab</i>	<i>AAbB</i>	<i>AAbb</i>	<i>AabB</i>	<i>Aabb</i>
<i>aB</i>	<i>aABB</i>	<i>aABb</i>	<i>aaBB</i>	<i>aaBb</i>
<i>ab</i>	<i>aAbB</i>	<i>aAbb</i>	<i>aabB</i>	<i>aabb</i>

Phenotypic ratio: 9 dominant dominant to 3 dominant recessive to 3 recessive dominant to 1 recessive recessive

Using Product Rule:  $\text{Prob}(A\_B\_) = (3/4)(3/4) = 9/16$   
 $\text{Prob}(A\_bb) = (3/4)(1/4) = 3/16$   
 $\text{Prob}(aaB\_) = (1/4)(3/4) = 3/16$   
 $\text{Prob}(aabb) = (1/4)(1/4) = 1/16$

c. A dihybrid cross between individuals with the genotype *AaBb* and *aabb*

	<i>AB</i>	<i>Ab</i>	<i>aB</i>	<i>ab</i>
<i>ab</i>	<i>aAbB</i>	<i>aAbb</i>	<i>aabB</i>	<i>aabb</i>

Using Product Rule:  $\text{Prob}(A\_B\_) = (1/4)(1) = 1/16$   
 $\text{Prob}(A\_bb) = (1/4)(1) = 1/16$   
 $\text{Prob}(aaB\_) = (1/4)(1) = 1/16$   
 $\text{Prob}(aabb) = (1/4)(1) = 1/16$

- The segregation of different alleles for any gene occurs due to the pairing of homologous chromosomes, and the subsequent separation of these homologues during anaphase I. The independent assortment of traits, more accurately the independent segregation of different allele pairs, is due to the independent alignment of chromosomes during metaphase I of meiosis.
- There seems to be the loss of a genotype as there are only 3 possible outcomes (2 yellow and 1 black). If the yellow gene has a dominant effect on coat color, but also causes lethality when homozygous, then this could explain the observations. So, a yellow mouse is heterozygous and crossing two yellow mice yields 1 homozygous yellow (dead):2 heterozygous (appears yellow):1 black. You could test this by crossing the yellow to homozygous black. You should get 1 yellow:1 black, and all black offspring should be true breeding, and all yellow should behave as above.
- There are two genes involved, one of which is epistatic to the other. At one gene, there are two alleles: black and brown; at the other gene, there are two alleles: albino and colored. The albino gene is epistatic to the brown gene so when you are homozygous recessive for albino, you are albino regardless of whether you are black or brown at the other locus. This leads to the 4 albino in a Mendelian kind of crossing scheme.

## CHAPTER 13

### LEARNING OUTCOME QUESTIONS

- 13.1** Females would be all wild type; males would be all white eyed.
- 13.2** Yes, should be viable and appear female.
- 13.3** The mt-DNA could be degraded by a nuclease similar to how bacteria deal with invading viruses. Alternatively, the mt-containing mitochondria could be excluded from the zygote.
- 13.4** No, not by genetic crosses.
- 13.5** Yes. First division nondisjunction yields four aneuploid gametes while second division yields only two aneuploid gametes.

### INQUIRY QUESTIONS

- Page 244** There would probably be very little if any recombination so the expected assortment ratios would have been skewed from the expected 9:3:3:1.
- Page 247** About 10% of the progeny would have been recombinants, based on the relationship of 1 cM (map unit or centimorgan) equals 1% recombination frequency. When gene loci are separated by greater distances, the frequency of recombination between them increases to the extent that the number of recombinant gametes roughly equals the number of parental gametes. In that instance, the genes would exhibit independent assortment. With a recombination frequency of only 10%, it is doubtful that it would have led Mendel to the concept of independent assortment.

**Page 250** What has changed is the mother's age. The older the woman, the higher the risk she has of nondisjunction during meiosis. Thus, she also has a much greater risk of producing a child with Down syndrome.

**Page 251** XY egg is fertilized by an X sperm. A normal X egg is fertilized by an XY sperm.

**Page 253** Advanced maternal age, a previous child with birth defects, or a family history of birth defects.

- Theoretically, 25% of the children from this cross will be color blind. All of the color blind children will be male and 50% of the males will be color blind.
- Parents of heterozygous plant were: green wrinkled X yellow round  
 Frequency of recombinants is  $36+29/1300=0.05$   
 Map distance = 5 cM
- Male calico cats are very rare. The coloration that is associated with calico cats is the product of X inactivation. X inactivation only occurs in females as a response to dosage levels of the X-linked genes. The only way to get a male calico is to be heterozygous for the color gene and to be the equivalent of a Klinefelters male (XXY).

## CHAPTER 14

### LEARNING OUTCOME QUESTIONS

- 14.1** The 20 different amino acid building blocks offers chemical complexity. This appears to offer informational complexity as well.
- 14.2** The proper tautomeric forms are necessary for proper base pairing, which is critical to DNA structure.
- 14.3** Prior to replication in light N there would be only one band. After one round of replication, there would be two bands with denatured DNA: one heavy and one light.
- 14.4** The 5' to 3' activity is used to remove RNA primers. The 3' to 5' activity is used to removed mispaired bases (proofreading).
- 14.5** A shortening of chromosome ends would eventually affect DNA that encodes important functions.
- 14.6** No. The number of DNA damaging agents, in addition to replication errors, would cause lethal damage (this has been tested in yeast).

### INQUIRY QUESTIONS

- Page 262** Because adenine always forms bonds with only thymine, and guanine forms bonds with only cytosine, adenine and thymine will always have the same proportions, and likewise with guanine and cytosine.
- Page 265** The covalent bonds create a strong backbone for the molecule making it difficult to disrupt. Individual hydrogen bonds are more easily broken allowing enzymes to separate the two strands without disrupting the inherent structure of the molecule.
- Page 269** DNA ligase is important in connecting Okazaki fragments during DNA replication. Without it, the lagging strand would not be complete.
- Page 273** The linear structure of chromosomes creates the end problem discussed in the text. It is impossible to finish the ends of linear chromosomes using unidirectional polymerases that require RNA primers. The size of eukaryotic genomes also means that the time necessary to replicate the genome is much greater than in prokaryotes with smaller genomes. Thus the use of multiple origins of replication.
- Page 275** Cells have a variety of DNA repair pathways that allow them to restore damaged DNA to its normal constitution. If DNA repair pathways are compromised, the cell will have a higher mutation rate. This can lead to higher rates of cancer in a multicellular organism such as humans.

## APPLY

1.c 2.b 3.c 4.c 5.a 6.b 7.d 8.c

## SYNTHESIZE

- If both bacteria are heat-killed, then the transfer of DNA will have no effect since pathogenicity requires the production of proteins encoded by the DNA. Protein synthesis will not occur in a dead cell.
  - The nonpathogenic cells will be transformed to pathogenic cells. Loss of proteins will not alter DNA.
  - The nonpathogenic cells remain nonpathogenic. If the DNA is digested, it will not be transferred and no transformation will occur.
- The region could be an origin of replication. Origins of replication are adenine- and thymine-rich regions since only these nucleotides form two hydrogen bonds versus the three hydrogen bonds formed between guanine and cytosine, making it easier to separate the two strands of DNA.

The RNA primer sequences would be 5'-ACUUAUUGCUUUUAUA-3'.

The sequence is antiparallel to the DNA sequence (review Figure 14.16) meaning that the 5' end of the RNA is matching up with the 3' end of the DNA. It is also important to remember that in RNA the thymine nucleotide is replaced by uracil (U). Therefore, the adenine in DNA will form a complementary base-pair with uracil.

- DNA gyrase* functions to relieve torsional strain on the DNA. If *DNA gyrase* were not functioning, the DNA molecule would undergo supercoiling, causing the DNA to wind up on itself, preventing the continued binding of the polymerases necessary for replication.
  - DNA polymerase III* is the primary polymerase involved in the addition of new nucleotides to the growing polymer and in the formation of the phosphodiester bonds that make up the sugar-phosphate backbone. If this enzyme were not functioning, then no new DNA strand would be synthesized and there would be no replication.
  - DNA ligase* is involved in the formation of phosphodiester bonds between Okazaki fragments. If this enzyme was not functioning, then the fragments would remain disconnected and would be more susceptible to digestion by nucleases.
  - DNA polymerase I* functions to remove and replace the RNA primers that are required for *DNA polymerase III* function. If *DNA polymerase I* was not available, then the RNA primers would remain and the replicated DNA would become a mix of DNA and RNA.

## CHAPTER 15

### LEARNING OUTCOME QUESTIONS

**15.1** There is no molecular basis for recognition between amino acids and nucleotides. The tRNA is able to interact with nucleic acid by base pairing and an enzyme can covalently attach amino acids to it.

**15.2** There would be no specificity to the genetic code. Each codon must specify a single amino acid, although amino acids can have more than one codon.

**15.3** Transcription translation coupling cannot exist in eukaryotes where the two processes are separated in both space and time.

**15.4** No. This is a result of the evolutionary history of eukaryotes but is not necessitated by genome complexity.

**15.5** Alternative splicing offers flexibility in coding information. One gene can encode multiple proteins.

**15.6** This tRNA would be able to “read” STOP codons. This could allow nonsense mutations to be viable, but would cause problems making longer than normal proteins. Most bacterial genes actually have more than one STOP at the end of the gene.

**15.7** Attaching amino acids to tRNAs, bringing charged tRNAs to the ribosome, and ribosome translocation all require energy.

**15.8** No. It depends on where the breakpoints are that created the inversion, or duplication. For duplications it also depends on the genes that are duplicated.

### INQUIRY QUESTIONS

**Page 281** One would expect higher amounts of error in transcription over DNA replication. Proofreading is important in DNA replication because errors in DNA replication will be passed on to offspring as mutations. However, RNAs have very short life spans in the cytoplasm therefore mistakes are not permanent.

**Page 284** The very strong similarity among organisms indicates a common ancestry of the code.

**Page 285** The promoter acts a binding site for RNA polymerase. The structure of the promoter provides information as to both where to bind, but also the direction of transcription. If the two sites were identical, the polymerase would need some other cue for the direction of transcription.

**Page 289** Splicing can produce multiple transcripts from the same gene.

**Page 297** Wobble not only explains the number of tRNAs that are observed due to the increased flexibility in the 5' position, it also accounts for the degeneracy that is observed in the Genetic Code. The degenerate base is the one in the wobble position.

## UNDERSTAND

1.d 2.c 3.d 4.b 5.c 6.b 7.c

## APPLY

1.d 2.c 3.b 4.b 5.c 6.b 7.b

## SYNTHESIZE

- the predicted sequence of the mRNA for this gene  
5'-GCAAUGGGCUCGGCAUGCAAUCC-3'  
the predicted amino acid sequence of the protein  
5'-GCA AUG GGC UCG GCA UGC UAA UCC-3'  
Met-Gly-Ser-Ala-Cys-STOP
- A frameshift essentially turns the sequence of bases into a “random” sequence. If you consider the genetic code, 3 of the 64 codons are STOP, so the probability of hitting a STOP in a random sequence is 3/64 or about 1 every 20 codons.
- mRNA = 5'-GCA AUG GGC UCG GCA UUG CUA AUC C-3'  
The amino acid sequence would then be: Met-Gly-Ser-Ala-Leu-Leu-Iso-. There is no stop codon. This is an example of a frameshift mutation. The addition of a nucleotide alters the “reading frame,” resulting in a change in the type and number of amino acids in this protein.
  - mRNA = 5'-GCA AUG GGC UAG GCA UGC UAA UCC-3'  
The amino acid sequence would then be: Met-Gly-STOP.  
This is an example of a nonsense mutation. A single nucleotide change has resulted in the early termination of protein synthesis by altering the codon for Ser into a stop codon.
  - mRNA = 5'-GCA AUG GGC UCG GCA AGC UAA UCC -3'  
The amino acid sequence would then be: Met-Gly-Ser-Ala-Ser-STOP.  
This base substitution has affected the codon that would normally encode Cys (UGC) and resulted in the addition of Ser (AGC).
- The split genes of eukaryotes offers the opportunity to control the splicing process, which does not exist in prokaryotes. This is also true for polyadenylation in eukaryotes. In prokaryotes, transcription/translation coupling offers the opportunity for the process of translation to have an effect on transcription.

## CHAPTER 16

### LEARNING OUTCOME QUESTIONS

**16.1** The control of gene expression would be more like humans (fellow eukaryote) than *E. coli*.

**16.2** The two helices both interact with DNA, so the spacing between the helices is important for both to be able to bind to DNA.

**16.3** The operon would be on all of the time (constitutive expression).

**16.4** The loss of a general transcription factor would likely be lethal as it would affect all transcription. The loss of a specific factor would affect only those genes controlled by the factor.

**16.5** These genes are necessary for the ordinary functions of the cell. That is, the role of these genes is in ordinary housekeeping and not in any special functions.

**16.6** RNA interference offers a way to specifically affect gene expression using drugs made of siRNAs.

**16.7** As there are many proteins in a cell doing a variety of functions, uncontrolled degradation of proteins would be devastating to the cell.

### INQUIRY QUESTIONS

**Page 308** The presence more than one gene in the operon allows for increased control over the elements of the pathway and therefore the product. A single regulatory system can regulate several adjacent genes.

**Page 315** Regulation occurs when various genes have the same regulatory sequences, which bind the same proteins.

**Page 324** Ubiquitin is added to proteins that need to be removed because they are nonfunctional or those that are degraded as part of a normal cellular cycle.

## UNDERSTAND

1. c 2. d 3. a 4. c 5. b 6. c 7. b

## APPLY

1. c 2. c 3. b 4. d 5. c 6. a 7. c

## SYNTHESIZE

1. Mutations that affect binding sites for proteins on DNA will control the expression of genes covalently linked to them. Introducing a wild type binding site on a plasmid will not affect this. We call this being cis-dominant. Mutations in proteins that bind to DNA would be recessive to a wild type gene introduced on a plasmid.
2. Negative control of transcription occurs when the ability to initiate transcription is reduced. Positive control occurs when the ability to initiate transcription is enhanced. The *lac* operon is regulated by the presence or absence of lactose. The proteins encoded within the operon are specific to the catabolism (breakdown) of lactose. For this reason, operon expression is only required when there is lactose in the environment. Allolactose is formed when lactose is present in the cell. The allolactose binds to a repressor protein, altering its conformation and allowing RNA polymerase to bind. In addition to the role of lactose, there is also a role for the activator protein CAP in regulation of *lac*. When cAMP levels are high then CAP can bind to DNA and make it easier for RNA polymerase to bind to the promoter. The *lac* operon is an example of both positive and negative control.

The *trp* operon encodes protein manufacture of tryptophan in a cell. This operon must be expressed when cellular levels of tryptophan are low. Conversely, when tryptophan is available in the cell, there is no need to transcribe the operon. The tryptophan repressor must bind tryptophan before it can take on the right shape to bind to the operator. This is an example of negative control.

3. Forms that control gene expression that are unique to eukaryotes include alternative splicing, control of chromatin structure, control of transport of mRNA from the nucleus to the cytoplasm, control of translation by small RNAs, and control of protein levels by ubiquitin- directed destruction. Of these, most are obviously part of the unique features of eukaryotic cells. The only mechanisms that could work in prokaryotes would be translational control by small RNAs and controlled destruction of proteins.
4. Mutation is a permanent change in the DNA. Regulation is a short-term change controlled by the cell. Like mutations, regulation can alter the number of proteins in a cell, change the size of a protein, or eliminate the protein altogether. The key difference is that gene regulation can be reversed in response to changes in the cell's environment. Mutations do not allow for this kind of rapid response.

## CHAPTER 17

### LEARNING OUTCOME QUESTIONS

**17.1** *EcoRI* is a restriction enzyme that can be used to cut DNA at specific places. Ligase is used to “glue” together pieces of DNA that have been cut with the same restriction enzyme. The two enzymes make it possible to add foreign DNA into an *E. coli* plasmid.

**17.2** A cDNA library is constructed from mRNA. Unlike the gene itself, cDNA does not include the introns or regulatory elements.

**17.3** Multiple rounds of DNA replication allow for an exponential increase in copies of the DNA. A heat-stable DNA polymerase makes this possible.

**17.4** The gene coding for a functional protein must be mutated. Recombination allows for the “knockout” gene to be specifically targeted.

**17.5** The protein must be completely pure so that the patient does not have an immune response to proteins from another organism.

It is important that the protein have exactly the same structure when it is produced in a bacterial cell as in a human cell. Because post-translational modification is specific to eukaryotes, the human DNA may need to be modified before it is inserted in a bacterial genome to ensure the protein structure is identical to the human protein.

The protein may not be produced in every cell in a human. It is difficult to target the manufactured protein to only the cells where it is produced or needed. The protein could have unintended consequences in other cells in the patient's body.

**17.6** The pollen from the plant with the recombinant gene might fertilize a closely related wild plant. If the offspring are viable, the recombinant gene will be introduced into the wild population.

## INQUIRY QUESTIONS

**Page 331** A bacterial artificial chromosome or a yeast artificial chromosome would be the best way to go as a plasmid vector only can stably hold up to 10 kb.

**Page 332** No, cDNA is created using mRNA as a template, therefore, intron sequences would not be expressed.

**Page 340** Yes, if you first used reverse transcriptase to make cDNA to amplify. This is called RT PCR.

## SYNTHESIZE

1. Genes coding for each of the subunits would need to be inserted into different plasmids that are integrated into different bacteria. The cultures would need to be grown separately and the different protein subunits would then need to be isolated and purified. If the subunits can self assemble in vitro, then the protein could be functional. It could be difficult to establish just the right conditions for the assembly of the multiple subunits.
2. 5'-CTGATAGTCAGCTG-3'

## CHAPTER 18

### LEARNING OUTCOME QUESTIONS

**18.1** Banding sites on karyotypes depend on dyes binding to the condensed DNA that is wrapped around protein. The dyes bind to some regions, but not all and are therefore not evenly spaced along the genome in the way that sequential base-pairs are evenly spaced.

**18.2** Sequencing is not a perfect process and a small number of errors would occur. Also, the number of base-pairs that can be sequenced in an individual sequencing reaction is limited. Multiple copies of the genome need to be cut in different places and sequenced so that the overlapping pieces can be assembled into an overall genome sequence. If there were not multiple, overlapping sequences, it would not be possible to determine the order of the smaller pieces that are sequenced.

**18.3** One possibility is that transposable elements can move within the genome and create new genetic variability, subject to natural selection.

**18.4** From the transcriptome, it is possible to predict the proteins that may be translated and available for use in part of an organism at a specific time in development.

**18.5** Yes. Additional protein could enhance the nutritional value of the potato for human consumption. One caveat would be that the increased level of protein not change the texture or flavor of potatoes that a consumer is expecting.

## INQUIRY QUESTIONS

**Page 354** Repetitive elements are one of the main obstacles to assembling the DNA sequences in proper order. There is one copy of *bcr* (see with green probe) and one copy of *abl* (seen with red probe).

The other *bcr* and *abl* genes are fused and the yellow color is the result of red plus green fluorescence combined).

**Page 361** Repetitive elements are one of the main obstacles to assembling the DNA sequences in proper order because it is difficult to determine which sequences are overlapping.

**Page 366** Proteins exhibit post-translational modification and the formation of protein complexes. Additionally a single gene can code for multiple proteins using alternative splicing.

**Page 367** A proteome is all the proteins coded for by the genome, and the transcriptome is all the RNA present in a cell or tissue at a specific time.

**Page 369** You may be able to take advantage of synteny between the rice and corn genome (see Figure 18.14). Let's assume that a drought-tolerance gene has already been identified and mapped in rice. Using what is known about synteny between the rice and corn genomes, you could find the region of the corn genome that corresponds to the rice drought-tolerance gene. This would narrow down the region of the corn genome that you might want to sequence to find your gene. A subsequent step might be to modify the corn gene that corresponds to the rice gene to see if you can increase drought tolerance.

### SYNTHESIZE

- The STSs represent unique sequences in the genome. They can be used to align the clones into one contiguous sequence of the genome based on the presence or absence of an STS in a clone. The contig, with aligned clones, would look like this:

- The anthrax genome has been sequenced. Investigators would look for differences in the genome between existing natural strains and those collected from a suspected outbreak. The genome of an infectious agent can be modified, or “weaponized,” to make it more deadly. Also, single-nucleotide polymorphisms could be used to identify the source of the anthrax. In the case of the Florida anthrax outbreak it was determined that the source was a research laboratory.

## CHAPTER 19

### LEARNING OUTCOME QUESTIONS

- 19.2** The early cell divisions are very rapid and do not involve an increase in size between divisions. Interphase is greatly reduced allowing very fast cell divisions.
- 19.3** This requires experimentation to isolate cell from contact, which would prevent induction, or to follow a particular cells lineage.
- 19.4** The nucleus must be reprogrammed. What this means exactly on the molecular level is not clear, but probably involves changes in chromatin structure and methylation patterns.
- 19.5** Homeotic genes seem to have arisen very early in the evolutionary history of bilaterians. These have been duplicated and they have diversified with increasing morphological complexity.
- 19.6** Cell death can be a patterning mechanism. Your fingers were sculpted from a paddle-like structure by cell death.

### INQUIRY QUESTION

**Page 378** The *macho-1* gene product is a transcription factor that can activate the expression of several muscle-specific genes. Whether or not the fibroblast growth factor (FGF) signal is received from underlying endoderm precursor cells in the embryo determines how *macho-1* acts. If the FGF signal is present, it activates a Ras/MAP kinase pathway which, together with *macho-1*, either suppresses muscle genes or activates the transcription of mesenchyme genes. Without the FGF signal, *macho-1* alone triggers the transcription of muscle genes.

### UNDERSTAND

1. b 2. d 3. c 4. d 5. b 6. c 7. b

### APPLY

1. d 2. a 3. b 4. a 5. c 6. c 7. c

### SYNTHESIZE

- The horizontal lines of the fate map represent cell divisions. Starting with the egg, four cell divisions are required to establish a population of cells that will become nervous tissue. It takes another eight to nine divisions to produce the final number of cells that will make up the nervous system of the worm. It takes seven to eight rounds of cell division to generate the population of cells that will become the gonads. Once established, another seven to eight cell divisions are required to produce the actual gonad cells.
- Not every cell in a developing embryo will survive. The process of apoptosis is responsible for eliminating cells from the embryo. In *C. elegans*, the process of apoptosis is regulated by three genes: *ced-3*, *ced-4*, and *ced-9*. Both *ced-3* and *ced-4* encode proteases, enzymes that degrade proteins. Interestingly, the *ced-3* protease functions to activate gene expression of the *ced-4* protease. Together, these proteases will destroy the cell from the inside-out. The *ced-9* gene functions to repress the activity of the protease-encoding genes, thereby preventing apoptosis.
- N-cadherin plays a specific role in differentiating cells of the nervous system from ectodermal cells. Ectodermal cells express E-cadherin, but neural cells express N-cadherin. The difference in cell-surface cadherins means that the neural cells lose their contact with the surrounding ectodermal cells and establish new contacts with other neural cells. In the absence of N-cadherin, the nervous system would not form. If you assume that E-cadherin expression is also lost (as would occur normally in development) then these cells would lose all cell-cell contacts and would probably undergo apoptosis.
  - Integrins mediate the connection between a cell and its surrounding environment, the extracellular matrix (ECM). The loss of integrins would result in the loss of cell adhesion to the ECM. These cells would not be able to move and therefore, gastrulation and other developmental processes would be disrupted.
  - Integrins function by linking the cell's cytoskeleton to the ECM. This connection is critical for cell movement. The deletion of the cytoplasmic domain of the integrin would not affect the ability of integrin to attach to the ECM, but it would prevent the cytoskeleton from getting a “grip.” This deletion would likely result in a disruption of development similar to the complete loss of integrin.
- Adult cells from the patient would be cultured with factors that reprogram the nucleus into pluripotent cells. These cells would then be grown in culture with factors necessary to induce differentiation into a specific cell type that could be transplanted into the patient. This would be easiest for tissue like a liver that regenerates, but could in theory be used for a variety of cell types.

## CHAPTER 20

### LEARNING OUTCOME QUESTIONS

- 20.1** Natural selection occurs when some individuals are better suited to their environment than others. These individuals live longer and reproduce more, leaving more offspring with the traits that enabled their parents to thrive. In essence, genetic variation within a population provides the raw material on which natural selection can act.
- 20.2** To determine if a population is in Hardy Weinberg equilibrium, one would first need to determine the actual allele frequencies, which can be calculated based on the actual genotype frequencies. After assigning variables  $p$  and  $q$  to the actual allele frequencies, one would then use the Hardy Weinberg equation,  $p^2 + 2pq + q^2 = 1$  in order to determine the expected genotype frequencies. If the actual and expected genotype frequencies are the same (or, at least not significantly different) then it is safe to say that the population is in Hardy Weinberg equilibrium.
- 20.3** There are five mechanisms of evolution—natural selection, mutation, gene flow (migration), genetic drift, and nonrandom mating. Any of these mechanisms can alter allele frequencies within a population, although usually a change in allele frequency results from more than one mechanism working in concert (for example, mutation will introduce a beneficial new allele into the population, and natural selection will select for that allele such that its frequency increases over the course of two or more generations). Natural selection, the first mechanism and probably the most influential in bringing about evolutionary change, is also the only mechanism to produce adaptive change, that is, change that results in the population being better adapted to its environment. Mutation is the only way in which new alleles can

be introduced—it is the ultimate source of all variation. Because it is a relatively rare event, mutation by itself is not a strong agent of allele frequency change; however, in concert with other mechanisms, especially natural selection, it can drastically change the allele frequencies in a population. Gene flow can introduce new alleles into a population from another population of the same species, thus changing the allele frequency within both the recipient and donor populations. Genetic drift is the random, chance factor of evolution—while the results of genetic drift can be negligible in a large population, small populations can see drastic changes in allele frequency due to this agent. Finally, nonrandom mating results in populations varying from Hardy Weinberg equilibrium not by changing allele frequencies but by changing genotype frequencies—nonrandom mating reduces the proportion of heterozygotes in a population.

**20.4** Reproductive success relative to other individuals within an organism's population is referred to as that organism's fitness. Its fitness is determined by its longevity, mating frequency, and the number of offspring it produces for each mating. None of these factors is always the most important in determining reproductive success—instead it is the cumulative effects of all three factors that determines an individual's reproductive success. For example, an individual that has a very long life span but mates only infrequently might have lower fitness than a conspecific that lives only half as long but mates more frequently and with greater success. As seen with the water strider example in this section, traits that are favored for one component of fitness, say, for example, longevity, may be disadvantageous for other components of fitness, say, lifetime fecundity.

**20.5** The dynamics among the different evolutionary mechanisms are very intricate, and it is often difficult, if not impossible, to discern which direction each process is operating within a population—it is much easier to simply see the final cumulative effects of the various agents of evolutionary change. However, there are cases in which more than one evolutionary process will operate in the same direction, with the resulting population changing, or evolving, more rapidly than it would have under only one evolutionary mechanism. For example, mutation may introduce a beneficial allele into a population; gene flow could then spread the new allele to other populations. Natural selection will favor this allele within each population, resulting in relatively rapid evolutionary adaptation of a novel phenotype.

**20.6** In a population wherein heterozygotes had the lowest fitness, natural selection should favor both homozygous forms. This would result in disruptive selection, and a bimodal distribution of traits within the population. Over enough time, it could lead to a speciation event.

**20.7** Directional selection occurs when one phenotype has an adaptive advantage over other phenotypes in the population, regardless of its relative frequency within the population. Frequency-dependent selection, on the other hand, results when either a common (positive frequency-dependent selection) or rare (negative frequency-dependent selection) has a selective advantage simply by virtue of its commonality or rarity. In other words, if a mutation introduces a novel allele into a population, directional selection may result in evolution because the allele is advantageous, not because it is rare.

**20.8** Wild guppies have to balance natural selection, which, in the presence of a predator such as the pike cichlid, would tend to favor drab coloration, with sexual selection, wherein females prefer brightly colored males. Thus, in low-predation environments the male guppies tend to be brightly colored whereas in high-predation environments they are drably colored. Background color matching is a form of camouflage used by many species to avoid predation; again, however, in many cases this example of natural selection runs counter to sexual selection—males want to be inconspicuous to predators but attractive to potential mates. For example, to test the effects of predation on background color matching in a species of butterfly, one might raise captive populations of butterflies with a normal variation in coloration. After a few generations, add natural predators to half of the enclosures. After several generations, one would expect the butterflies in the predatory environment to have a high degree of background color matching in order to avoid predation, while the non-predatory environment would have promoted brightly-colored individuals where color would correlate with mating success.

**20.9** Pleiotropic effects occur with many genes; in other words, a single gene has multiple effects on the phenotype of the individual. Whereas natural selection might favor a particular aspect of the pleiotropic gene, it might select against another aspect of the same gene; thus, pleiotropy often limits the degree to which a phenotype can be altered by natural selection. Epistasis occurs when the expression of one gene is controlled or altered by the existence or expression of another gene. Thus, the outcome of natural selection will depend not just on the genotype of one gene, but the other genotype as well.

## INQUIRY QUESTIONS

**Page 399** In the example of Figure 20.3, the frequency of the recessive white genotype is 0.16. The remaining 84 cats (out of 100) in the population are ho-

mozygous or heterozygous black. If the 16 white cats died, they will not contribute recessive white genes to the next generation. Only heterozygous black cats will produce white kittens in a 3:1 ratio of black to white. Homozygous  $\times$  homozygous black and homozygous  $\times$  heterozygous black cats will have all black kittens. Since there are 36 homozygous black cats and 48 heterozygous black cats, with a new total of 84 cats, the new frequency of homozygous black cats is  $36/84$  or 43%, with the heterozygous black cats now comprising 57% of the population. If  $p^2 = 0.43$ , then  $p = 0.65$  (approximately), then  $1-p = q$ , and  $q = 0.35$ . The frequency of white kittens in the next generation,  $q^2$ , is 0.12 or 12%.

**Page 405** Differential predation might favor brown toads over green toads, green toads might be more susceptible to disease, or green toads might be less able to tolerate variations in climate, among other possibilities.

**Page 406** Since the intermediate-sized water strider has the highest level of fitness, it would be expected that the intermediate size would become more prevalent in the population. If the number of eggs laid per day was not affected by body size, the small water striders would be favored because of their tendency to live longer than their larger counterparts.

**Page 407** Yes. The frequency of copper tolerance will decrease as distance from the mine increases.

**Page 411** The proportion of flies moving toward light (positive phototropism) would again begin to increase in successive generations.

**Page 411** The distribution of birth weights in the human population would expand somewhat to include more babies of higher and lower birth weights.

**Page 413** Guppy predators evidently locate their prey using visual cues. The more colorful the guppy, the more likely it is to be seen and thus the more likely it will become prey.

**Page 414** Thoroughbred horse breeders have been using selective breeding for certain traits over many decades, effectively removing variation from the population of thoroughbred horses. Unless mutation produces a faster horse, it remains unlikely that winning speeds will improve.

## UNDERSTAND

1. a 2. b 3. d 4. a 5. d 6. a 7. d

## APPLY

1. d 2. d 3. a

## SYNTHESIZE

- The results depend on coloration of guppies increasing their conspicuousness to predators such that an individual's probability of survival is lower than if it was a drab morph. In the laboratory it may be possible to conduct trials in simulated environments; we would predict, based on the hypothesis of predation, that the predator would capture more of the colorful morph than the drab morph when given access to both. Design of the simulated environment would obviously be critical, but results from such an experiment, if successful, would be a powerful addition to the work already accomplished.
- On the large lava flows, where the background is almost entirely black, those individuals with black coloration within a population will have a selective advantage because they will be more cryptic to predators. On the other hand, on small flows, which are disrupted by light sand and green plants, dark individuals would be at an adaptive disadvantage for the same reason. You can read more about this in chapter 21 (21.2); the black peppered moths had an advantage on the trees lacking lichen, but a disadvantage on lichen-covered trees.
- Ultimately, genetic variation is produced by the process of mutation. However, compared with the speed at which natural selection can reduce variation in traits that are closely related to fitness, mutation alone cannot account for the persistence of genetic variation in traits that are under strong selection. Other processes can account for the observation that genetic variation can persist under strong selection. They include gene flow. Populations are often distributed along environmental gradients of some type. To the extent that different environments favor slightly different variants of phenotypes that have a genetic basis, gene flow among areas in the habitat gradient can introduce new genetic variation or help maintain existing variation. Similarly, just as populations frequently encounter different selective environments across their range (think of the guppies living above and below the waterfalls in Trinidad), a single population also encounters variation in selective environments across time (oscillating selection). Traits favored this year may not be the same as those favored next year, leading to a switching of natural selection and the maintenance of genetic variation.

## CHAPTER 21

### LEARNING OUTCOME QUESTIONS

**21.1** No. If eating hard seeds caused individuals to develop bigger beaks, then the phenotype is a result of the environment, not the genotype. Natural selection can only act upon those traits with a genetic component. Just as a body builder develops large muscles in his or her lifetime but does not have well-muscled offspring, birds that develop large beaks in their lifetime will not necessarily have offspring with larger beaks.

**21.2** An experimental design that would test this hypothesis could be as simple as producing enclosures for the moths and placing equal numbers of both morphs into each enclosure and then presenting predatory birds to each enclosure. One enclosure could be used as a control. One enclosure would have a dark background while the other would have a light background. After several generations, measuring the phenotype frequency of the moths should reveal very clear trends—the enclosure with the dark background should consist of mostly dark moths, the enclosure with the light background mostly light moths, and the neutral enclosure should have an approximately equal ratio of light to dark moths.

**21.3** If the trait that is being artificially selected for is due to the environment rather than underlying genotype, then the individuals selected that have that trait will not necessarily pass it on to their offspring.

**21.4** The major selective agent in most cases of natural selection is the environment; thus, climatic changes, major continental shifts, and other major geological changes would result in dramatic changes in selective pressure; during these times the rate and direction of evolutionary change would likely be affected in many, if not most, species. On the other hand, during periods of relative environmental stability, the selective pressure does not change and we would not expect to see many major evolutionary events.

**21.5** The only other explanation that could be used to explain homologous characteristics and vestigial structures could be mutation. Especially in the case of vestigial structures, if one resulted from a mutation that had pleiotropic effects, and the other effects of the genetic anomaly were selected for, then the vestigial structure would also be selected for, much like a rider on a Congressional Bill.

**21.6** Convergence occurs when distantly related species experience similar environmental pressures and respond, through natural selection, in similar ways. For example, penguins (birds), sharks (fish), sea lions (mammals) and even the extinct ichthyosaur (reptile) all exhibit the fusiform shape. Each of these animals has similar environmental pressures in that they are all aquatic predators and need to be able to move swiftly and agilely through the water. Clearly their most recent common ancestor does not have the fusiform body shape; thus the similarities are due to convergence (environment) rather than homology (ancestry). However, similar environmental pressures will not always result in convergent evolution. Most importantly, in order for a trait to appear for the first time in a lineage, there must have been a mutation; however, mutations are rare events, and even rarer is a beneficial mutation. There may also be other species that already occupy a particular niche; in these cases it would be unlikely that natural selection would favor traits that would increase the competition between two species.

**21.7** It is really neither a hypothesis nor a theory. Theories are the building blocks of scientific knowledge, they have withstood the most rigorous testing and review. Hypotheses, on the other hand, are tentative answers to a question. Unfortunately, a good hypothesis must be testable and falsifiable, and stating that humans came from Mars is not realistically testable or falsifiable; thus, it is, in the realm of biological science, a nonsense statement.

### INQUIRY QUESTIONS

**Page 419** The figure demonstrates that the beak depth of offspring can be predicted by the average beak depth of the parent's bills. Thus, one would expect the offspring to have the same beak depth if their parents' mean beak depth is the same. This is only correct if males and females do not differ in beak depth. In species for which the sexes differ (such as height in humans), then one would need to know both the depth and the sex of the parents and the calculation would be more complicated.

**Page 421** Such a parallel trend would suggest that similar processes are operating in both localities. Thus, one would conduct a study to identify similarities. In this case, both areas have experienced coincident reductions in air pollution, which most likely is the cause of the parallel evolutionary trends.

**Page 422** Assuming that small and large individuals would breed with each other, then middle-sized offspring would still be born (the result of matings between small and large flies). Nonetheless, there would also be many small and large individuals (the result of small  $\times$  small and large  $\times$  large matings). Thus, the

frequency distribution of body sizes would be much broader than the distributions in the figures.

**Page 426** This evolutionary decrease could occur for many reasons. For example, maybe *Nannippus* adapted to forested habitats and thus selection favored smaller size, as it had in the ancestral horses, before horses moved into open, grassland habitats. Another possibility is that there were many species of horses present at that time, and different sized horses ate different types of food. By evolving small size, *Nannippus* may have been able to eat a type of food not eaten by the others.

### APPLY

1. a 2. d 3. d

### SYNTHESIZE

- Briefly, they are:
  - There must be variation among individuals within a population.
  - Variation among individuals must be related to differences among individuals in their success in producing offspring over their lifetime.
  - Variation related to lifetime reproductive success must have a genetic (heritable) basis.
- Figure 21.2a shows in an indirect way that beak depth varies from year to year. Presumably this is a function of variation among individuals in beak size. However, the most important point of 21.2a is that it shows the result of selection. That is, if the three conditions hold, we might expect to see average beak depth change accordingly as precipitation varies from year to year. Figure 21.2b is more directly relevant to the conditions noted for natural selection to occur. The figure shows that beak size varies among individuals, and that it tends to be inherited.
- The relationship would be given by a cloud of points with no obvious linear trend in any direction different from a zero slope. In other words, it would be a horizontal line through an approximately circular cloud of points. Such data would suggest that whether a parent(s) has a large or small beak has no bearing on the beak size of its offspring.
- Assuming that small and large individuals would breed with each other, then middle-sized offspring would still be born (the result of matings between small and large flies). Nonetheless, there would also be many small and large individuals (the result of small  $\times$  small and large  $\times$  large matings). Thus, the frequency distribution of body sizes would be much broader than the distributions in the figures. In some experiments, reproductive isolation evolves in which small and large individuals evolve mating preferences that prevent them from interbreeding, leading to the production of two different-sized species. This would be a laboratory example of sympatric speciation. Most studies, however, have failed to produce such reproductive isolation; rather, a single population remains through time with great variation.
- The evolution of horses was not a linear event; instead it occurred over 55 million years and included descendants of 34 different genera. By examining the fossil record, one can see that horse evolution did not occur gradually and steadily; instead several major evolutionary events occurred in response to drastic changes in environmental pressures. The fossil record of horse evolution is remarkably detailed, and shows that while there have been trends toward certain characteristics, change has not been fluid and constant over time, nor has it been entirely consistent across all of the horse lineages. For example, some lineages experienced rapid increases in body size over relatively short periods of geological time, while other lineages actually saw decreases in body size.

## CHAPTER 22

### LEARNING OUTCOME QUESTIONS

**22.1** The Biological Species Concept states that different species are capable of mating and producing viable, fertile offspring. If sympatric species are unable to do so, they will remain reproductively isolated and thus distinct species. Along the same lines, gene flow between populations of the same species allow for homogenization of the two populations such that they remain the same species.

**22.2** In order for reinforcement to occur and complete the process of speciation, two populations must have some reproductive barriers in place prior to sympatry. In the absence of this initial reproductive isolation we would expect rapid exchange

of genes and thus homogenization resulting from gene flow. On the other hand, if two populations are already somewhat reproductively isolated (due to hybrid infertility or a prezygotic barrier such as behavioral isolation), then we would expect natural selection to continue improving the fitness of the non-hybrid offspring, eventually resulting in speciation.

**22.3** Reproductive isolation that occurs due to different environments is a factor of natural selection; the environmental pressure favors individuals best suited for that environment. As isolated populations continue to develop, they accumulate differences due to natural selection that eventually will result in two populations so different that they are reproductively isolated. Reinforcement, on the other hand, is a process that specifically relates to reproductive isolation. It occurs when natural selection favors non-hybrids because of hybrid infertility or are simply less fit than their parents. In this way, populations that may have been only partly reproductively isolated become completely reproductively isolated.

**22.4** Polyploidy occurs instantaneously; in a single generation, the offspring of two different parental species may be reproductively isolated; however, if it is capable of self-fertilization then it is, according to the Biological Species Concept, a new species. Disruptive selection, on the other hand, requires many generations as reproductive barriers between the two populations must evolve and be reinforced before the two would be considered separate species.

**22.5** In the archipelago model, adaptive radiation occurs as each individual island population adapts to its different environmental pressures. In sympatric speciation resulting from disruptive selection, on the other hand, traits are selected for that are not necessarily best suited for a novel environment but are best able to reduce competition with other individuals. It is in the latter scenario wherein adaptive radiation due to a key innovation is most likely to occur.

**22.6** It depends on what species concept you are using to define a given species. Certainly evolutionary change can be punctuated, but in times of changing environmental pressures we would expect adaptation to occur. The adaptations, however, do not necessarily have to lead to the splitting of a species—instead one species could simply change in accordance with the environmental changes to which it is subjected. This would be an example of non-branching, as opposed to branching, evolution; but again, whether the end-result organism is a different species from its ancestral organism that preceded the punctuated event is subject to interpretation.

**22.7** Unlike the previous major mass extinction events, the current mass extinction is largely attributable to human activity, including but not limited to habitat degradation, pollution, and hunting.

## INQUIRY QUESTIONS

**Page 447** Speciation can occur under allopatric conditions because isolated populations are more likely to diverge over time due to drift or selection. Adaptive radiation tends to occur in places inhabited by only a few other species or where many resources in a habitat are unused. Different environmental conditions typical of adaptive radiation tend to favor certain traits within a population. Allopatric conditions would then generally favor adaptive radiation.

In character displacement, natural selection in each species favors individuals able to use resources not used by the other species. Two species might have evolved from two populations of the same species located in the same environment (sympatric species). Individuals at the extremes of each population are able to use resources not used by the other group. Competition for a resource would be reduced for these individuals, possibly favoring their survival and leading to selection for the tendency to use the new resource. Character displacement tends to compliment sympatric speciation.

**Page 452** If one area experiences an unfavorable change in climate, a mobile species can move to another area where the climate was like it was before the change. With little environmental change to drive natural selection within that species, stasis would be favored.

## UNDERSTAND

1. a 2. c 3. a 4. b 5. a 6. a 7. d 8. b

## APPLY

1. b 2. a 3. d 4. a 5. b 6. b

## SYNTHESIZE

1. If hybrids between two species have reduced viability or fertility, then natural selection will favor any trait that prevents hybrid matings. The reason is that individuals that don't waste time, energy, or resources on such matings will have greater fitness if they instead spend the time, energy, and resources on mating with members of their own species. For this reason, natural selection

will favor any trait that decreases the probability of hybridization. By contrast, once hybridization has occurred, the time, energy, and resources have already been expended. Thus, there is no reason that less fit hybrids would be favored over more fit ones. The only exception is for species that invest considerable time and energy in incubating eggs and rearing the young; for those species, selection may favor reduced viability of hybrids because parents of such individuals will not waste further time and energy on them.

2. The biological species concept, despite its limitations, reveals the continuum of biological processes and the complexity and dynamics of organic evolution. At the very least, the biological species concept provides a mechanism for biologists to communicate about taxa and know that they are talking about the same thing! Perhaps even more significantly, discussion and debate about the meaning of "species" fuels a deeper understanding about biology and evolution in general. It is unlikely that we will ever have a single unifying concept of species given the vast diversity of life, both extinct and extant.
3. The principle is the same as in character displacement. In sympatry, individuals of the two species that look alike may mate with each other. If the species are not completely interfertile, then individuals hybridizing will be at a selective disadvantage. If a trait appears in one species that allows that species to more easily recognize members of its own species and thus avoid hybridization, then individuals bearing that trait will have higher fitness and that trait will spread through the population.
4. I would expect the two species to have more similar morphology when they are found alone (allopatry) than when they are found together (sympatry), assuming that food resources were the same from one island to the next. This would be the result of character displacement expected under a hypothesis of competition for food when the two species occur in sympatry. A species pair that is more distantly related might not be expected to show the pattern of character displacement since they show greater differences in morphology (and presumably in ecology and behavior as well), which should reduce the potential for competition to drive character divergence.

## CHAPTER 23

### LEARNING OUTCOME QUESTIONS

**23.1** Because of convergent evolution; two distantly related species subjected to the same environmental pressures may be more phenotypically similar than two species with different environmental pressures but a more recent common ancestor. Other reasons for the possible dissimilarity between closely related species include oscillating selection and rapid adaptive radiations in which species rapidly adapt to a new available niche.

**23.2** In some cases wherein characters diverge rapidly relative to the frequency of speciation, it can be difficult to construct a phylogeny using cladistics because the most parsimonious phylogeny may not be the most accurate. In most cases, however, cladistics is a very useful tool for inferring phylogenetic relationships among groups of organisms.

**23.3** Yes, in some instances this is possible. For example, assume two populations of a species become geographically isolated from one another in similar environments, and each population diverges and speciation occurs, with one group retaining its ancestral traits and the other deriving new traits. The ancestral group in each population may be part of the same biological species but would be considered polyphyletic because to include their common ancestor would also necessitate including the other, more derived species (which may have diverged enough to be reproductively isolated).

**23.4** Not necessarily; it is possible that the character changed since the common ancestor and is present in each group due to convergence. While the most recent common ancestor possessing the character is the most parsimonious, and thus the most likely, explanation, it is possible, especially for small clades, that similar environmental pressures resulted in the emergence of the same character state repeatedly during the course of the clade's evolution.

**23.5** Hypothetically it is possible; however, the viral analyses and phylogenetic analyses have provided strong evidence that HIV emergence was the other way around; it began as a simian disease and mutated to become a human form, and that this has occurred several times.

### INQUIRY QUESTIONS

**Page 461** In parsimony analyses of phylogenies, the least complex explanation is favored. High rates of evolutionary change and few character states complicate matters. High rates of evolutionary change, such as occur when mutations arise in noncoding portions of DNA, can be misleading when constructing phylogenies. Mutations arising in noncoding DNA are not eliminated by natural selection in

the same manner as mutations in coding (functional) DNA. Also, evolution of new character states can be very high in nonfunctional DNA and this can lead to genetic drift. Since DNA has only four nucleotides (four character states) it is highly likely that two species could evolve the same derived character at a particular base position. This leads to a violation of the assumptions of parsimony—that the fewest evolutionary events lead to the best hypothesis of phylogenetic relationships—and resulting phylogenies are inaccurate.

**Page 462** The only other hypothesis is that the most recent common ancestor of birds and bats was also winged. Of course, this scenario is much less parsimonious (and thus much more unlikely) than the convergence hypothesis, especially given the vast number of reptiles and mammals without wings. Most phylogenies are constructed based on the rule of parsimony; in the absence of fossil evidence of other winged animals and molecular data supporting a closer relationship between birds and bats than previously thought, there is no way to test the hypothesis that bird and bat wings are homologous rather than analogous.

**Page 471** If the victim had contracted HIV from a source other than the patient, the most recent common ancestor of the two strains would be much more distant. As it is, the phylogeny shows that the victim and patient strains share a relatively recent ancestor, and that the victim's strain is derived from the patient's strain.

1. d 2. b 3. a 4. b 5. a 6. d 7. b 8. c

## APPLY

1. c 2. d 3. d 4. a

## SYNTHESIZE

1. Naming of groups can be variable; names provided here are just examples. Jaws—shark, salamander, lizard, tiger, gorilla, human (jawed vertebrates); lungs—salamander, lizard, tiger, gorilla, human (terrestrial tetrapods); amniotic membrane—lizard, tiger, gorilla, human (amniote tetrapods); hair—tiger, gorilla, human (mammals); no tail—gorilla, human (humanoid primate); bipedal—human (human).
2. It would seem to be somewhat of a conundrum, or potentially circular; choosing a closely related species as an outgroup when we do not even know the relationships of the species of interest. One way of guarding against a poor choice for an outgroup is to choose several species as outgroups and examine how the phylogenetic hypothesis for the group of interest changes as a consequence of using different outgroups. If the choice of outgroup makes little difference, then that might increase one's confidence in the phylogenetic hypotheses for the species of interest. On the other hand, if the choice makes a big difference (different phylogenetic hypotheses result when choosing different outgroups), that might at least lead to the conclusion that one cannot be confident in inferring a robust phylogenetic hypothesis for the group of interest without collecting more data.
3. Recognizing that birds are reptiles potentially provides insight to the biology of both birds and reptiles. For example, some characteristics of birds are clearly of reptilian origin, such as feathers (modified scales), nasal salt secreting glands, and strategies of osmoregulation/excretion (excreting nitrogenous waste products as uric acid) representing ancestral traits, that continue to serve birds well in their environments. On the other hand, some differences from other reptiles (again, feathers) seem to have such profound significance biologically, that they overwhelm similarities visible in shared ancestral characteristics. For example, no extant nonavian reptiles can fly, or are endothermic and these two traits have created a fundamental distinction in the minds of many biologists. Indeed, many vertebrate biologists prefer to continue to distinguish birds from reptiles rather than emphasize their similarities even though they recognize the power of cladistic analysis in helping to shape classification. Ultimately, it may be nothing much more substantial than habit which drives the preference of some biologists to traditional classification schemes.
4. In fact, such evolutionary transitions (the loss of the larval mode, and the re-evolution of a larval mode from direct development) are treated with equal weight under the simplest form of parsimony. However, if it is known from independent methods (for example, developmental biology) that one kind of change is less likely than another (loss versus a reversal), these should and can be taken into account in various ways. The simplest way might be to assign weights based on likelihoods; two transitions from larval development to direct development is equal to one reversal from direct development back to a larval mode. In fact, there are such methods, and they are similar in spirit to the statistical approaches used to build specific models of evolutionary change rather than rely on simple parsimony.

5. The structures are both homologous, as forelimbs, and convergent, as wings. In other words, the most recent common ancestor of birds, pterosaurs and bats had a forelimb similar in morphology to that which these organisms possess—it has similar bones and articulations. Thus, the forelimb itself among these organisms is homologous. The wing, however, is clearly convergent; the most recent common ancestor surely did not have wings (or all other mammals and reptiles would have had to have lost the wing, which violates the rule of parsimony). The wing of flying insects is purely convergent with the vertebrate wing, as the forelimb of the insect is not homologous with the vertebrate forelimb.
6. The biological species concept focuses on processes, in particular those which result in the evolution of a population to the degree that it becomes reproductively isolated from its ancestral population. The process of speciation as utilized by the biological species concept occurs through the interrelatedness of evolutionary mechanisms such as natural selection, mutation, and genetic drift. On the other hand, the phylogenetic species concept focuses not on process but on history, on the evolutionary patterns that led to the divergence between populations. Neither species concept is more right or more wrong; species concepts are, by their very nature, subjective and potentially controversial.

## CHAPTER 24

### LEARNING OUTCOME QUESTIONS

**24.1** There should be a high degree of similarity between the two genomes because they are relatively closely related. There could be differences in the relative amounts of non-coding DNA. Genes that are necessary for bony skeletal development might be found in the bony fish. The cartilaginous fish might lack those genes or have substantial sequences in the genes needed for skeletal development in bony fish.

**24.2** There would now be three copies of the chromosome from the same species. This would cause a problem for the cell during meiosis I as there would not be an even number of homologs of the chromosome to pair up and segregate.

**24.3** Compare the sequence of the pseudogene with other species. If, for example, it is a pseudogene of an olfactory gene that is found in mice or chimps, the sequences will be much more similar than in a more distantly related species. If horizontal gene transfer explains the origins of the gene, there may not be a very similar gene in closely related species. You might use the BLAST algorithm discussed in chapter 18 to identify similar sequences and then construct a phylogenetic tree to compare the relationships among the different species.

**24.4** A SNP can change a single amino acid in the coded peptide. If the new R group is very different, the protein may fold in a different way and not function effectively. SNPs in the *FOXP2* gene may, in part, explain why humans have speech and chimps do not. Other examples that you may remember from earlier in the text include cystic fibrosis and sickle cell anemia.

**24.5** One approach would be to create a mutation in the non-coding gene and ask whether or not this changes the phenotype. You would need to be sure that both copies of the nonprotein-coding gene were “knocked out.”

**24.6** Much of the non-coding DNA could contain retrotransposons that replicate and insert the new DNA into the genome, enlarging the genome. Since the number of genes does not change, polyploidy is not a good explanation.

**24.7** An effective drug might bind only to the region of the pathogen protein that is distinct from the human protein. The drug could render the pathogen protein ineffective without making the human ill. If the seven amino acids that differ are scattered throughout the genome, they might have a minimal effect on the protein and it would be difficult to develop a drug that could detect small differences. It's possible that the drug could inadvertently affect other areas of the protein as well.

**24.8** One approach would be to create transgenic soy with additional protein coding genes.

### INQUIRY QUESTIONS

**Page 478** Meiosis in a 3n cell would be impossible because three sets of chromosomes cannot be divided equally between two cells. In a 3n cell, all three homologous chromosomes would pair in prophase I, then align during anaphase I. As the homologous chromosomes separate, two of a triplet might go to one cell while the third chromosome would go to the other cell. The same would be true for each set of homologues. Daughter cells would have an unpredictable number of chromosomes.

**Page 479** Polyploidization seems to induce the elimination of duplicated genes. Duplicate genes code for the same gene product. It is reasonable that duplicate genes would be eliminated to decrease the redundancy arising from the translation of several copies of the same gene.

**Page 484** Ape and human genomes show very different patterns of gene transcription activity, even though genes encoding proteins are over 99% similar between chimps and humans. Different genes would be transcribed when comparing apes with humans, and the levels of transcription would vary widely.

## UNDERSTAND

1. c 2. d 3. d 4. b 5. b 6. a

## APPLY

1. a 2. d 3. d 4. a

## SYNTHESIZE

1. The two amino acid difference between the FOXP2 protein in humans and closely related primates must alter the way the protein functions in the brain. The protein affects motor function in the brain allowing coordination of larynx, mouth and brain for speech in humans. For example, if the protein affects transcription, there could be differences in the genes that are regulated by FOXP2 in humans and chimps.
2. Human and chimp DNA is close to 99% similar, yet our phenotypes are conspicuously different in many ways. This suggests that a catalogue of genes is just the first step to identifying the mechanisms underlying genetically influenced diseases like cancer or cystic fibrosis. Clearly, gene expression, which might involve the actions of multiple noncoding segments of the DNA and other potentially complex regulatory mechanics, are important sources of how phenotypes are formed, and it is likely that many genetically determined diseases result from such complex underlying mechanisms, making the gene identification of genomics just the first step; a necessary but not nearly sufficient strategy. What complete genomes do offer is a starting point to correlating sequence differences among humans with genetic disease, as well as the opportunity to examine how multiple genes and regulatory sequences interact to cause disease.
3. Phylogenetic analysis usually assumes that most genetic and phenotypic variation arises from descent with modification (vertical inheritance). If genetic and phenotypic characteristics can be passed horizontally (that is, not vertically through genetic lineages) then using patterns of shared character variation to infer genealogical relationships will be subject to potentially significant error. We might expect that organisms with higher rates of HGT will have phylogenetic hypotheses that are less reliable or at least are not resolved as a neatly branching tree.

## CHAPTER 25

### LEARNING OUTCOME QUESTIONS

**25.1** A change in the promoter of a gene necessary for wing development might lead to the repression of wing development in a second segment of a fly in a species that has double wings.

**25.2** No. This cichlid would need to reproduce and over time give rise to a line of cichlid's with extra-long jaws. Perhaps they would populate a different part of the lake and not reproduce with other cichlids. Over time they could become a new species. The extra-long jaw would have to offer some selective advantage or the trait would not persist in the population.

**25.3** Yes, although this is not the only explanation. The coding regions could be identical but the promoter or other regulatory regions could have been altered by mutation, leading to altered patterns of gene expression. To test this hypothesis, the *pitx1* gene should be sequenced in both fish and compared.

**25.4** The pectoral fins are homoplastic because sharks and whales are only distantly related and pectoral fins are not found in whales' more recent ancestors.

**25.5** The duplication could persist if a mutation in the duplicated gene prevented its expression or altered the coding region, and either a regulatory or a coding change could lead to a new function.

**25.6** A phylogenetic analysis of paleoAP3 and its gene duplicates demonstrated that the presence of AP3 correlates with petal formation. The specific domain of AP3 that is necessary for petal development was identified by making gene constructs of the AP3 gene where the C terminus of the protein was eliminated or was replaced with the C terminus from the duplicate gene. The C terminus was shown to be essential for petal formation.

**25.7** There is no need for eyes in the dark. Perhaps the fish expend less energy when eyes are not produced and that offered a selective advantage in cavefish. In a habitat with light, a mutation that resulted in a functional Pax6 would likely be

selected for and over time more of the fish would have eyes. Keep in mind that the probability of a mutation restoring Pax6 function is very low, but real.

## INQUIRY QUESTIONS

**Page 495** Because there is a stop codon located in the middle of the CAL (cauliflower) gene coding sequence, the wild-type function of CAL must be concerned with producing branches rather than leaves. The wild type of *Brassica oleracea* consists of compact plants that add leaves rather than branches; branches are typical of the flowering heads of broccoli and cauliflower. Additional evolutionary events possibly include large flower heads, unusual head coloration, protective leaves covering flower heads, or head size variants, among other possibilities.

**Page 501** Functional analysis involves the use of a variety of experiments designed to test the function of a specific gene in different species. By mixing and matching parts of the *AP3* and *PI* genes and introducing them into *ap3* mutant plants, it was found that the C terminus sequence of the *AP3* protein is essential for specifying petal function. Without the 3' region of the *AP3* gene, the *Arabidopsis* plant cannot make petals.

## UNDERSTAND

1. c 2. b 3. a 4. a 5. b 6. d 7. b 8. c 9. c 10. d

## APPLY

1. b 2. a 3. d 4. b

## SYNTHESIZE

1. Mutations in the promoter region of other genes allowed them to be recognized by Tbx5, which led to transcriptional control of these genes by Tbx5.
2. Development is a highly conserved and constrained process; small perturbations can have drastic consequences, and most of these are negative. Given the thousands or hundreds of thousands of variables that can change in even a simple developmental pathway, most perturbations lead to negative outcomes. Over millions of years, some of these changes will arise under the right circumstances to produce a benefit. In this way, developmental perturbations are not different from what we know about mutations in general. Beneficial mutations are rare, but with enough time they will emerge and spread under specific circumstances.

Not all mutations provide a selective advantage. For example, reduced body armor increases the fitness of fish in freshwater, but it was not selected for in a marine environment where the armor was important for protection from predators. The new trait can persist at low levels for a very long time until a change in environmental conditions results in an increase in fitness for individuals exhibiting the trait.

3. The latter view represents our current understanding. There are many examples of small gene families (such as, *Hox*, *MADS*) whose apparent role in generating phenotypic diversity among major groupings of organisms is in altering the expression of other genes. Alterations in timing (heterochrony) or spatial pattern of expression (homeosis) can lead to shifts in developmental events, giving rise to new phenotypes. Many examples are presented in the chapter, such as the developmental variants of two species of sea urchins, one with a normal larval phase, and another with direct development. In this case the two species do not have different sets of developmental genes, rather the expression of those genes differ. Another example that makes the same point is the evolution of an image forming eye. Recent studies suggest, in contrast to the view that eyes across the animal kingdom evolved independently multiple times, that image-forming eyes from very distantly related taxa (such as, insects and vertebrates) may trace back to the common origin of the *Pax6* gene. If that view is correct, then genes controlling major developmental patterns would seem to be highly conserved across long periods of time, with expression being the major form of variation.
4. Unless the Pax6 gene was derived multiple times, it is difficult to hypothesize multiple origins of eyes. Pax6 initiates eye development in many species. The variation in eyes among animals is a result of which genes are expressed and when after Pax6 initiates eye development.
5. Maize relies on paleoAP3 and PI for flower development while tomato has three genes because of a duplication of paleoAP3. This duplication event in the ancestor of tomato, but not maize, is correlated with independent petal origin.
6. The direct developing sea urchin has an ancestor that had one or more mutations in genes that were needed to regulate the expression of other genes needed for larval stage development. When those genes were not expressed, there was no larval development and the genes necessary for adult development were expressed.

## CHAPTER 26

### LEARNING OUTCOME QUESTIONS

**26.1** The evidence would be that the organism reproduces and passes a system to pass on information from generation to generation (heredity), regulates its internal processes and can maintain homeostasis, grows and develops, has some sort of cellular organization, and can respond to some stimuli.

**26.2** You can infer that both a squirrel and fox are in the class Mammalia but are in different orders. Thus they share many, but not all traits. They likely shared a common ancestor. However the taxonomic hierarchy does not show the evolutionary relationships among organisms the way a phylogeny would.

**26.3** The viral genome would now be part of the infected cell's genome and the viral genes could be expressed. One example of this is the chicken pox virus.

**26.4** Without atmospheric oxygen, organisms would still be anaerobic. There would be no cellular respiration and no mitochondria in cells. Organisms would not be as effective at producing energy and they may not have evolved to be as large as some life forms today because they couldn't meet the energy demands of the cells.

**26.5** Insect vectors might carry DNA from moss to a flowering plant.

**26.6** Closely related living organisms might have diverged from a common ancestor millions of years ago. Even though they are the closest living relatives, much evolutionary change could have occurred during the intervening years.

### INQUIRY QUESTIONS

**Page 515** A clade is an evolutionary unit consisting of a common ancestor and all of its descendants. Evidence suggests that the Archaea are very different from all other organisms, which justifies including the Archaea in a separate domain. Phylogenetically, each domain forms a clade.

**Page 522** Comparisons of a single gene could result in an inaccurate phylogenetic tree because it fails to take into account the effects of horizontal gene transfer. For example, the clade of *Amborella trichopoda* is a sister clade to all other flowering plants, but roughly 2/3 of its mitochondrial genes are present due to horizontal gene transfer from other land plants, including more distantly-related mosses.

**Page 522** To determine if a moss gene had a function you would employ functional analysis, using a variety of experiments, to test for possible functions of the moss gene in *Amborella*.

### UNDERSTAND

1. b 2. c 3. c 5. The protists are a bit of a catchall and are not monophyletic. Organisms that were clearly eukarotic but did not fit with plants, fungi, or animals were placed in the protists 6. c 7. c 8. d

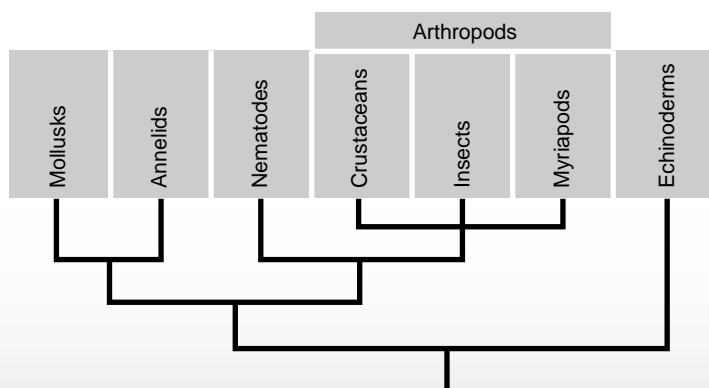

### APPLY

1. Kingdom Fungi because some fungi have flagella and cell walls made of chitin. Fungi lack a nervous system 2. a 3. c 4. d 5. b 6. d

### SYNTHESIZE

1. If the life is biochemically the same on one of these moons and Earth, then it is possible that life originated in one place and was moved to the other location by the action of meteorites and comets. As you have seen with convergent evolution, panspermia would still not be proven by such a finding. However, if the life was biochemically different it would suggest that life originated independently on the moons and Earth.

2.

3. The most logical choice would be a species from the domain Archae. These are considered to be the oldest forms of life on our planet, and are known to have evolved to survive harsh environmental condition.

4. Morphology may be influenced by processes such as convergent evolution. However, DNA acts as a molecular record of a species' past. Combining what is being learned from both morphological and molecular data leads to more robust evolutionary hypotheses.

## CHAPTER 27

### LEARNING OUTCOME QUESTIONS

**27.1** Viruses use cellular machinery for replication. They do not make all of the proteins necessary for complete replication.

**27.2** A prophage carrying such a mutation could not be induced to undergo the lytic cycle.

**27.3** This therapy, at present, does not remove all detectable viruses. This cannot be considered a true cure.

**27.4** In addition to a high mutation rate, the influenza genome consists of multiple RNA segments that can recombine during infection. This causes the main antigens for the immune system to shift rapidly.

**27.5** Prions carry information in their three-dimensional structure. This 3-D information is different from the essentially one-dimensional genetic information in DNA.

### UNDERSTAND

1. c 2. b 3. c 4. d 5. b 6. d 7. b

### APPLY

1. c 2. b 3. c 4. d 5. b 6. c 7. c 8. a

### SYNTHESIZE

1. A set of genes that are involved in the response to DNA damage are normally induced by the same system. The protein involved destroys a repressor that keeps DNA repair genes unexpressed. Lambda has evolved to use this system to its advantage.
2. Since viruses require the replication machinery of a host cell to replicate, it is unlikely that they existed before the origin of the first cells.
3. This is a complex situation. Factors that act include the high mutation rate of the virus and the fact that the virus targets the very cells that mount an immune response. The influenza virus also requires a new vaccine every year due to rapid changes in the virus. The smallpox virus was a DNA virus that had antigenic determinants that did not change rapidly making a vaccine possible.
4. Emerging viruses are those that jump species and thus are new to humans. Recent examples include SARS and Ebola.
5. If excision of the lambda prophage is imprecise, then the phage produced will carry *E. coli* genes adjacent to the integration site.

## CHAPTER 28

### LEARNING OUTCOME QUESTIONS

**28.1** Evidence would take the form of microfossils, evidence for altered isotopic ratios, or biomarkers such as hydrocarbons that do not arise by abiotic processes.

**28.2** Archaea have ether linked instead of ester linked phospholipids; their cell wall is made of unique material.

**28.3** Compare their DNA. The many metabolic tests we have used for years have been supplanted by DNA analysis.

**28.4** Transfer of genetic information in bacteria is directional: from donor to recipient and does not involve fusion of gametes.

**28.5** Prokaryotes do not have a lot of morphological features, but do have diverse metabolic functions.

**28.6** Pathogens tend to evolve to be less virulent. If they are too good at killing, their lifestyle is an evolutionary dead end.

**28.7** Rotating a crop that has a symbiotic association with nitrogen fixing bacteria will return nitrogen to the soil depleted by other plants.

## INQUIRY QUESTION

**Page 562** The simplest explanation is that the two STDs are occurring in different populations, and one population has rising levels of sexual activity, while the other has falling levels. However, the rise in incidence of an STD can reflect many parameters other than level of sexual activity. The virulence or infectivity of one or both disease agents may be changing, for example, or some aspect of exposed people may be changing in such a way as to alter susceptibility. Only a thorough public health study can sort this out.

## UNDERSTAND

1. b 2. a 3. c 4. c 5. d 6. a 7. b

## APPLY

1. c 2. b 3. b 4. c 5. d 6. b 7. a

## SYNTHESIZE

1. The study of carbon signatures in rocks using isotopic data assumes that ancient carbon fixation involves one of two pathways that each show a bias towards incorporation of carbon 12. If this bias were not present, it is not possible to infer early carbon fixation by this pathway. This pathway could have arisen even earlier and we would have no way to detect it.
2. The heat killing of the virulent S strain of *Streptococcus* released the genome of the virulent smooth strain into the environment. These strains of *Streptococcus* bacteria are capable of natural transformation. At least some of the rough strain cells took up smooth strain genes that encoded the polysaccharide coat from the environment. These genes entered into the rough strain genome by recombination, and then were expressed. These transformed cells were now smooth bacteria.
3. The multiple antibiotics are not a bad idea if all of the bacteria are killed. In the case of some persistent infections, this is an effective strategy. However, it does provide very strong selective pressure for rare genetic events that produce multiple resistances in a single bacteria species. For this reason, it is not a good idea for it to be the normal practice. The more bacteria that undergo this selection for multiple resistance, the more likely it will arise. This is helped by patients not taking the entire course as bacteria may survive by chance and proliferate with each generation providing the opportunity for new mutations. This is also complicated by the horizontal transfer of resistance via resistance plasmids, and the existence of transposable genetic elements that can move genes from one piece of DNA to another.
4. Most species on the planet are incapable of fixing nitrogen without the assistance of bacteria. Without nitrogen, amino acids and other compounds cannot be synthesized. Thus a loss of the nitrogen fixing bacteria due to increased UV radiation levels would reduce the ability of plants to grow, severely limiting the food sources of the animals.

## CHAPTER 29

### LEARNING OUTCOME QUESTIONS

**29.1** Mitochondria and chloroplasts contain their own DNA. Mitochondrial genes are transcribed within the mitochondrion, using mitochondrial ribosomes that are smaller than those of eukaryotic cells and quite similar to bacterial ribosomes. Antibiotics that inhibit protein translation in bacteria also inhibit protein translation in mitochondria. Also, both chloroplasts and mitochondria divide using binary fission like bacteria.

**29.2** There are distinct clades in the Protista that do not share a common ancestor. The group of organisms commonly referred to as protists are actually a collection of a number of monophyletic clades.

Pseudopodia provide a large surface area and substantial traction for stable movement.

**29.3** Undulating membranes would be effective on surfaces with curvature that may not always be smooth, including intestinal walls.

**29.4** Contractile vacuoles collect and remove excess water from within the *Euglena*.

**29.5** The *Plasmodium* often becomes resistant to new poisons and drugs.

**29.6** While the gametophytes are often much smaller than the sporophytes, you could be most confident in your answer if you counted the chromosomes in the cells of each. The diploid sporophyte will have twice as many chromosomes as the haploid gametophyte.

**29.7** Both the red and green algae obtained their chloroplasts through endosymbiosis, possibly of the same lineage of photosynthetic bacteria. The red and green algae had diverged before the endosymbiotic events and the history recorded in their nuclear DNA is a different evolutionary history than that recorded in the plastids derived through endosymbiosis.

**29.8** Comparative genomic studies of choanoflagellates and sponges would be helpful. Considering the similarities among a broader range of genes than just the conserved tyrosine kinase receptor would provide additional evidence.

**29.9** It is unlikely that cellular and plasmodial slime molds are closely related. They both appear in the last section of this chapter because they have yet to be assigned to clades. The substantial differences in their cell biology are inconsistent with a close phylogenetic relationship.

## INQUIRY QUESTION

**Page 570** Red and green algae obtained chloroplasts by engulfing photosynthetic bacteria by primary endosymbiosis; chloroplasts in these cells have two membranes. Brown algae obtained chloroplasts by engulfing cells of red algae through secondary endosymbiosis; chloroplasts in cells of brown algae have four membranes. Counting the number of cell membranes of chloroplasts indicates primary or secondary endosymbiosis.

## UNDERSTAND

1. b 2. a 3. b 4. c 5. d 6. b 7. a 8. c 9. b, c 10. a, d 11. d 12. a

## APPLY

1. d 2. a 3. a

## SYNTHESIZE

1. Cellular and plasmodial slime molds both exhibit group behavior and can produce mobile slime mold masses. However, these two groups are very distantly related phylogenetically.
2. The development of a vaccine, though challenging, will be the most promising in the long run. It is difficult to eradicate all the mosquito vectors and many eradication methods can be harmful to the environment. Treatments to kill the parasites are also difficult because the parasite is likely to become resistant to each new poison or drug. A vaccine would provide long-term protection without the need to use harmful pesticides or drugs where drug resistance is a real possibility.
3. For the first experiment, plate the cellular slime molds on a plate that has no bacteria. Spot cyclic-AMP and designated places on the plate and determine if the bacteria aggregate around the cAMP.

For the second experiment, repeat the first experiment using plates that have a uniform coating of bacteria as well as plates with no bacteria. If the cellular slime molds aggregate on both plates, resource scarcity is not an issue. If the cells aggregate only in the absence of bacteria, you can conclude that the attraction to cAMP occurs only under starvation conditions.

## CHAPTER 30

### LEARNING OUTCOME QUESTIONS

**30.1** Make sections and examine them under the microscope to look for tracheids. Only the tracheophytes will have tracheids.

Gametes in plants are produced by mitosis. Human gametes are produced directly by meiosis.

**30.2** Chlorophytes have chloroplasts which are not found in choanoflagellates.

The lack of water is the major barrier for sperm that move through water to reach the egg. It is more difficult for sperm to reach the egg on land.

**30.3** Moss are extremely desiccation tolerant and can withstand the lack of water. Also, freezing temperatures at the poles are less damaging when moss have a low water content.

**30.4** The sporophyte generation has evolved to be the larger generation and therefore an effective means to transporting water and nutrients over greater distances would be advantageous.

**30.5** There was substantial climate change during that time period. Glaciers had spread, then melted and retreated. Drier climates could have contributed to the extinction of large club mosses. Refer to chapter 26 for more information on changes in Earth's climate over geological time.

- 30.6** The silica can increase the strength of the hollow-tube stems and would also deter herbivores.
- 30.7** The pollen tube grows towards the egg, carrying the sperm within the pollen tube.
- 30.8** The ovule rests, exposed on the scale (a modified leaf).
- 30.9** Animals that consume the fruit disperse the seed over longer distances than wind can disperse seed. The species can colonize a larger territory more rapidly.

## INQUIRY QUESTIONS

**Page 592** The diploid sporophyte of *Ulva* produces sporangia in which meiosis occurs. The resultant haploid spores develop into either plus or minus strains of multicellular gametophytes which, in turn, produce haploid gametangia. The gametangia produce haploid gametes. Meiosis is involved in the formation of *Ulva* gametes, but not directly.

**Page 596** Tracheophytes developed vascular tissue, enabling them to have efficient water- and food-conducting systems. Vascular tissue allowed tracheophytes to grow larger, possibly then able to out-compete smaller, nonvascular land plants. A protective cuticle and stomata that can close during dry conditions also conferred a selective advantage.

**Page 610** Endosperm provides nutrients for the developing embryo in most flowering plants. The embryo cannot derive nutrition from soil prior to root development, therefore without endosperm, the embryo is unlikely to survive.

## UNDERSTAND

## APPLY

2. d 3. b 4. c 5. c 6. a 7. b 8. a 9. a

## SYNTHESIZE

- Moss has a dominant gametophyte generation while lycophytes have a dominant sporophyte generation. Perhaps a comparison of the two genomes would provide insight into the genomic differences associated with the evolutionary shift from dominant gametophyte to dominant sporophyte.
- Answers to this question may vary. However, gymnosperms are defined as “naked” seed plants. Therefore, an ovule that is not completely protected by sporophyte tissue would be characteristic of a gymnosperm. To be classified as an angiosperm, evidence of flower structures and double fertilization are key characteristics, although double fertilization has been observed in some gnetophytes.
- The purpose of pollination is to bring together the male and female gametes for sexual reproduction. Sexual reproduction is designed to increase the genetic variability of a species. If a plant allows self-pollination, then the amount of genetic diversity will be reduced, but this is a better alternative than not reproducing at all. This would be especially useful in species in which the individuals are widely dispersed.
- The benefit is that by developing a relationship with a specific pollinator, the plant species increases the chance that its pollen will be brought to another member of its species for pollination. If the pollinator is a generalist, then the pollinator might not travel to another member of the same species, and pollination would not occur. The drawback is that if something happens to the pollinator (extinction or drop in population size) then the plant species would be left with either a reduced or nonexistent means of pollination.

## CHAPTER 31

### LEARNING OUTCOME QUESTIONS

- 31.1** In fungi mitosis results in duplicated nuclei, but the nuclei remain within a single cell. This lack of cell division following mitosis is very unusual in animals. Hyphae are protected by chitin, which is not digested by fungal enzymes.
- 31.2** Microsporidians lack mitochondria which are found in *Plasmodium*.
- 31.3** Blastocladiomycetes are free-living and have mitochondria. Microsporidians are obligate parasites and lack mitochondria.
- 31.4** Zygosporangia are more likely to be produced when environmental conditions are not favorable. Sexual reproduction increases the chances of offspring with new combinations of genes that will have an advantage in a changing environment. Also, the zygospore can stay dormant until conditions improve.

**31.5** Parasitism is a subset of symbiotic relationships. Symbiotic relationships refer to two or more organisms of different species living in close relationship to each other to the benefit of one, both or neither. In parasitism, only one member of the symbiosis benefits and that is at the expense of the other.

**31.6** A dikaryotic cell has two nuclei, each with a single set of chromosomes. A diploid cell has a single nucleus with two sets of chromosomes.

**31.7** Preventing the spread of the fungal infection using fungicides and good cultivation practices could help. If farmworkers must tend to infected fields, masks that filter out the spores could protect the workers.

**31.8** The fungi that ants consumed may have originally been growing on leaves. Over evolutionary time, mutations that altered ant behavior so the ants would bring leaves to a stash of fungi would have been favored and the tripartite symbiosis evolved.

**31.9** Wind can spread spores over large distances, resulting in the spread of fungal disease.

## UNDERSTAND

1. c 2. d 3. a 4. d 5. b 6. d 7. d

## APPLY

1. d 2. b 3. a 4. c 5. d

## SYNTHESIZE

- Fungi possess cell walls. Although the composition of these cell walls differs from that of the plants, cell walls are completely absent in animals. Fungi are also immobile (except for chytrids), and mobility is a key characteristic of the animals.
- The mycorrhizal relationships between the fungi and plants allow plants to make use of nutrient poor soil. Without the colonization of land by plants, it is unlikely that animals would have diversified to the level they have achieved today. Lichens are important organisms in the colonization of land. Early land masses would have been composed primarily of barren rock, with little or no soil for plant colonization. As lichens colonize an area they begin the process of soil formation, which allows other plant
- Antibiotics are designed to combat prokaryotic organisms and fungi are eukaryotic. In addition, fungi possess a cell wall that has a different chemical constitution (chitin) from that of prokaryotes.

## CHAPTER 32

### LEARNING OUTCOME QUESTIONS

**32.1** The rules of parsimony state that the simplest phylogeny is most likely the true phylogeny. As there are living organisms that are both multicellular and unicellular, it stands to reason that the first organisms were unicellular, and multicellularity followed. Animals are also all heterotrophs; if they were the first type of life to have evolved, there would not have been any autotrophs on which they could feed.

**32.2** Cephalization, the concentration of nervous tissue in a distinct head region, is intrinsically connected to the onset of bilateral symmetry. Bilateral symmetry promotes the development of a central nerve center, which in turn favors the nervous tissue concentration in the head. In addition, the onset of both cephalization and bilateral symmetry allows for the marriage of directional movement (bilateral symmetry) and the presence of sensory organs facing the direction in which the animal is moving (cephalization).

**32.3** This allows systematists to classify animals based solely on derived characteristics. Using features that have only evolved once implies that the species that have that characteristic are more closely related to each other than they are to species that do not have the characteristic.

**32.4** One hypothesis is that the rapid diversification in body plan was a biological response to the evolution of predation—the adaptation of traits that enabled predators to better find prey and prey to better elude predators. Another hypothesis is that the explosion of new body forms resulted from changes in the physical environment such as oxygen and mineral build up in the oceans.

## UNDERSTAND

## APPLY

1. d 2. b 3. Determinate development indicates that it is a protostome and the fact that it molts places it within the Ecdysozoa. The presence of jointed appendages makes it an arthropod.

## SYNTHESIZE

1. The tree should contain platyhelminthes and nemetera on one branch, a second branch should contain nematodes, and a third branch should contain the annelids and the hemichordates. This does not coincide with the information in Figure 32.4. Therefore, some of the different types of body cavities have evolved multiple times, and the body cavities are not good characteristics to infer phylogenetic relationships.
2. Answers may vary depending on the classification used. Many students will place the Echinoderms near the Cnidaria due to radial symmetry; others will place them closer to the Annelids.

## CHAPTER 33

### LEARNING OUTCOME QUESTIONS

**33.1** The cells of a truly colonial organism, such as a colonial protist, are all structurally and functionally identical; however, sponge cells are differentiated and these cells coordinate to perform functions required by the whole organism. Unlike all other animals, however, sponges do appear much like colonial organisms in that they are not comprised of true tissues, and the cells are capable of differentiating from one type to another.

**33.2** The importance of triploblasty relates to the placement of ctenophores on the animal phylogenetic tree. Until recently, ctenophores have been considered diploblasts, with platyhelminthes as the first triploblasts. New evidence, however, indicates that ctenophores are actually triploblastic. In addition, molecular evidence suggests that this phylum belongs at the base of the animal phylogeny—thus implying that the ancestor to all animals was triploblastic.

**33.3** Tapeworms are parasitic platyhelminthes that live in the digestive system of their host. Tapeworms have a scolex, or head, with hooks for attaching to the wall of their host's digestive system. Another way in which the anatomy of a tapeworm relates to its way of life is their dorsoventrally flattened body and corresponding lack of a digestive system. Tapeworms live in their food; as such they absorb their nutrients directly through the body wall, and their flat bodies facilitate this form of nutrient delivery.

**33.4** *Ascaris lumbricoides*, the intestinal roundworm, infects humans when the human swallows food or water contaminated with roundworm eggs. The most effective ways of preventing the spread of intestinal roundworms is to increase sanitation, especially those in food handling, education, and cease using human feces as fertilizer. Not surprisingly, infection by these parasites is most common in areas without modern plumbing.

### UNDERSTAND

1. c 2. a 3. b 4. b 5. d 6. d 7. c

### APPLY

1. c 2. c 3. d

### SYNTHESIZE

1. Answers may vary. Phylum Acoela represents a reclassification of the platyhelminthes and phylum Cyclophora represents an entirely new kingdom. Since we have most likely not discovered all of the noncoelomate invertebrate species on the planet, and we are utilizing new molecular tools to examine the relationships of existing phyla, it is unlikely that the modern phylogeny presented in section 33.2 is complete.
2. Since the population size of a parasitic species may be very small (just a few individuals), possessing both male and female reproductive structures would allow the benefits of sexual reproduction.
3. Answers may vary. However, it is known that the tapeworm is not the ancestral form of platyhelminthes; instead it has lost its digestive tract due to its role as an intestinal parasite. As an intestinal parasite, the tapeworm relies on the digestive system of its host to break down nutrients into their building blocks for absorption.

## CHAPTER 34

### LEARNING OUTCOME QUESTIONS

**34.1** Cephalopods are the most active of all mollusks, and this increased level of activity necessitates a more efficient oxygen delivery system. The extensive series of blood vessels, and thus more efficient gas exchange, in the cephalopod circulatory system allows the animal to move more rapidly and over longer periods of time.

**34.2** With a flow-through digestive tract, food moves in only one direction. This allows for specialization within the tract; sections may be specialized for

mechanical and chemical digestion, some for storage, and yet others for absorption. Overall, the specialization yields greater efficiency than does a gastrovascular cavity.

**34.3** The main advantage is coordination. A nervous system that serves the entire body allows for coordinated movement and coordinated physiological activities such as reproduction and excretion, even if those systems themselves are segmented. Likewise, a body-wide circulatory system enables efficient oxygen delivery to all of the body cells regardless of the nature of the organism's individual segments.

**34.4** Lophophorates are sessile suspension-feeding animals. Much of their body also remains submerged in the ocean floor. Thus, a traditional tubular digestive system would require either the mouth or the anus to be inaccessible to the water column—meaning the animal either could not feed or would have to excrete waste into a closed environment. The U-shaped gut allows them to both acquire nutrients from and excrete waste into their environment.

**34.5** One of the defining features of the arthropods is the presence of a chitinous exoskeleton. As arthropods increase in size, the exoskeleton must increase in thickness disproportionately, in order to bear the pull of the animal's muscles. This puts a limit on the size a terrestrial arthropod can reach, as the increased bulk of the exoskeleton would prohibit the animal's ability to move. Water is denser than air and thus provides more support; for this reason aquatic arthropods are able to be larger than terrestrial arthropods.

**34.6** Bilateral symmetry evolved relatively early in animal phylogeny, with the platyhelminthes. Echinoderms clearly branched off later in evolutionary history, as evidenced by their deuterostome development, and yet, as adults they exhibit radial (or, more accurately, pentaradial) symmetry. This might be a confusing factor when determining the phylogeny of animals, if not for the bilateral form the echinoderm larvae take. The bilaterally symmetrical larvae suggest that the echinoderm ancestor is in fact bilaterally symmetrical, rather than radially symmetrical.

### UNDERSTAND

1. c 2. b 3. a 4. d 5. d 6. b 7. c 8. d 9. d 10. a 11. a

### APPLY

1. b 2. c 3. d 4. a

### SYNTHESIZE

1. Clams and scallops are bivalves, which are filter feeders that siphon large amounts of water through their bodies to obtain food. They act as natural pollution-control systems for bays and estuaries. A loss of bivalves (from overfishing, predation, or toxic chemicals) would upset the aquatic ecosystem and allow pollution levels to rise.
2. Chitin is an example of convergent evolution since these organisms do not share a common chitin-equipped ancestor. Chitin is often used in structures that need to withstand the rigors of stress (chaetae, exoskeletons, zoecium, etc.).

## CHAPTER 35

### LEARNING OUTCOME QUESTIONS

**35.1** Chordates have a truly internal skeleton (an endoskeleton), compared to the endoskeleton on echinoderms, which is functionally similar to the exoskeleton of arthropods. Whereas an echinoderm uses tube feet attached to an internal water vascular system for locomotion, a chordate has muscular attachments to its endoskeleton. Finally, chordates have a suite of four characteristics that are unique to the phylum—a nerve chord, a notochord, pharyngeal slits, and a postanal tail.

**35.2** While mature and immature lancelets are similar in form, the tadpole-like tunicate larvae are markedly different from the sessile, vase-like adult form. Both tunicates and lancelets are chordates, but they differ from vertebrates in that they do not have vertebrae or internal bony skeletons.

**35.3** The functions of an exoskeleton include protection and locomotion—arthropod exoskeletons, for example, provide a fulcrum to which the animals' muscles attach. In order to resist the pull of increasingly large muscles, the exoskeleton must dramatically increase in thickness as the animal grows larger. There is thus a limit on the size of an organism with an exoskeleton—if it gets too large it will be unable to move due to the weight and heft of its exoskeleton.

**35.4** Lobe-finned fish are able to move their fins independently, whereas ray-finned fish must move their fins simultaneously. This ability to “walk” with their fins indicates that lobe-finned fish are most certainly the ancestors of amphibians.

**35.5** The challenges of moving onto land were plentiful for the amphibians. First, amphibians needed to be able to support their body weight and locomote on land; this challenge was overcome by the evolution of legs. Second, amphibians needed to be able to exchange oxygen with the atmosphere; this was accomplished

by the evolution of more efficient lungs than their lungfish ancestors as well as cutaneous respiration. Third, since movement on land requires more energy than movement in the water, amphibians needed a more efficient oxygen delivery system to supply their larger muscles; this was accomplished by the evolution of double-loop circulation and a partially divided heart. Finally, the first amphibians needed to develop a way of staying hydrated in a non-aquatic environment, and these early amphibians developed leathery skin that helped prevent desiccation.

**35.6** Amphibians remain tied to the water for their reproduction; their eggs are jelly-like and if laid on the land will quickly desiccate. Reptile eggs, on the other hand, are amniotic eggs—they are watertight and contain a yolk, which nourishes the developing embryo, and a series of four protective and nutritive membranes.

**35.7** There are two primary traits shared between birds and reptiles. First, both lay amniotic eggs. Second, they both possess scales (which cover the entire reptile body but solely the legs and feet of birds). Birds also share characteristics only with one group of reptiles—the crocodylians, such as a four-chambered heart.

**35.8** The most striking convergence between birds and mammals is endothermy, the ability to regulate body temperature internally. Less striking is flight; found in most birds and only one mammal, the ability to fly is another example of convergent evolution.

**35.9** Only the hominids comprise a monophyletic group. Prosimians, monkeys, and apes are all paraphyletic—they include the common ancestor but not all descendants: the clade that prosimians share with the common prosimian ancestor excludes all anthropoids, the clade that monkeys share with the common monkey ancestor excludes hominoids, and the clade that apes share with the common ape ancestor excludes hominids.

## UNDERSTAND

1. c 2. c 3. a 4. c 5. a 6. d 7. a 8. d

## APPLY

1. c 2. c 3. b

## SYNTHESIZE

1. Increased insulation would have allowed birds to become endothermic and thus to be active at times that ectothermic species could not be active. High body temperature may also allow flight muscles to function more efficiently.
2. Birds evolved from one type of dinosaurs. Thus, in phylogenetic terms, birds are a type of dinosaur.
3. Like the evolution of modern day horses, the evolution of hominids was not a straight and steady progression to today's *Homo sapiens*. Hominid evolution started with an initial radiation of numerous species. From this group, there was an evolutionary trend of increasing size, similar to what is seen in the evolution of horses. However, like in horse evolution, there are examples of evolutionary decreases in body size as seen in *Homo floresiensis*. Hominid evolution also reveals the coexistence of related species, as seen with *Homo neanderthalensis* and *Homo sapiens*. Hominid evolution, like horse evolution, was not a straight and steady progression to the animal that exists today.

## CHAPTER 36

### LEARNING OUTCOME QUESTIONS

**36.1** Primary growth contributes to the increase in plant height, as well as branching. Secondary growth makes substantial contributions to the increase in girth of the plant, allowing for a much larger sporophyte generation.

**36.2** Vessels transport water and are part of the xylem. The cells are dead with only the walls remaining. Cylinders of stacked vessels move water from the roots to the leaves of plants. Sieve tube members are part of the phloem and transport nutrients. Sieve tube members are living cells, but they lack a nucleus. They rely on neighboring companion cells to carry out some metabolic functions. Like vessels, sieve tube members are stacked to form a cylinder.

**36.3** The energy of the cell is used primarily to elongate the cell. It would be difficult for a root hair to form in the region of elongation because its base would be pulled apart by the elongation of the cell wall.

**36.4** Roots are constantly growing through soil where cells are damaged and sloughed off. The tips of stems do not encounter the same barriers and do not require the additional protection.

**36.5** Both sides of the leaf are equally exposed to sunlight. In contrast, horizontal leaves have a top and a bottom. Palisade layers are tightly packed with minimum airspace between the cells which maximizes photosynthetic surface area.

## INQUIRY QUESTION

**Page 736** Three dermal tissue traits that are adaptive for a terrestrial lifestyle include: guard cells, trichomes, and root hairs. Guard cells flank an epidermal opening called a stoma and regulate its opening and closing. Stomata are closed when water is scarce, thus conserving water. Trichomes are hairlike outgrowths of the epidermis of stems, leaves, and reproductive organs. Trichomes help to cool leaf surfaces and reduce evaporation from stomata. Root hairs are epidermal extensions of certain cells in young roots and greatly increase the surface area for absorption.

## UNDERSTAND

## APPLY

1. a 2. c 3. d 4. c

## SYNTHESIZE

1. Roots lack leaves with axillary buds at nodes, although there may be lateral roots that originated from deep within the root. The vascular tissue would have a different pattern in roots and stems. If there is a vascular stele at the core with a pericycle surrounded by a Casparian strip, you are looking at a root.
2. Lenticels increase gas exchange. In wet soil, the opportunity for gas exchange decreases. Lenticels could compensate for decreased gas exchange, which would be adaptive.
3. The tree is likely to die because the phloem and vascular cambium is located near the surface. Removing a ring of bark results in the loss of the vascular cambium and phloem, leading to starvation and death.

## CHAPTER 37

### LEARNING OUTCOME QUESTIONS

**37.1** Only angiosperms have an endosperm which results from double fertilization. The endosperm is the nutrient source in angiosperms. Gymnosperm embryos rely on megagametophytic tissue sources for nutrients.

**37.2** These seeds might be sensitive to temperature and require a period of cold before germinating.

**37.3** Fruits with fleshy coverings, often shiny black or bright blue or red, normally are favored by birds or other vertebrates.

**37.4** Retaining the seed in the ground might provide greater stability for the seedling until its root system is established.

## INQUIRY QUESTIONS

**Page 758** The root meristem never forms, although the shoot meristem is fully functional. This plant is missing the HOBBIT protein which normally allows auxin to induce the expression of a gene or genes needed for correct cell division to make a root meristem. Without the correct cell divisions, the meristem fails to form.

**Page 758** The *MONOPTEROS* (*MP*) gene product cannot act as a transcription factor when it is bound by its repressor. With a *MP* protein that can no longer bind to its repressor, *MP* acts as a transcription factor and activates a root development gene. The phenotype of a plant with a mutation in the *MP* gene has roots.

**Page 761** A monocot has a solitary cotyledon. Two cotyledons are illustrated here, thus the embryo is a eudicot.

**Page 762** The prior sporophyte generation, as part of the ovary, is diploid. The degenerating gametophyte generation is haploid. The next sporophyte generation, the embryo, is diploid.

## APPLY

1. c 2. c 3. b 4. d 5. c

## SYNTHESIZE

1. Place *Fucus* zygotes on a screen and shine a light from the bottom. If light is more important, the rhizoid will form towards the light, even though that is the opposite direction gravity would dictate. If gravity is more important, the rhizoid will form away from the direction of the light.
2. The endosperm has three times as many copies of each gene. If transcription occurs at a constant rate in both nutritive tissues, more will be produced in the endosperm because of the extra copies of the genes.

- The seeds may need to be chilled before they can germinate. You can store them in the refrigerator for several weeks or months and try again. The surface of the seed may need to be scarified (damaged) before it can germinate. Usually this would happen from the effects of weather or if the seed goes through the digestive track of an animal where the seed coat is weakened by acid in the gut of the animal. You could substitute for natural scarification by rubbing your seeds on sand paper before germinating them. It is possible that your seed needs to be exposed to light or received insufficient water when you first planted it. You may need to soak your seed in water for a bit to imbibe it. Exposing the imbibed seed to sunlight might also increase the chances of germination.

## CHAPTER 38

### LEARNING OUTCOME QUESTIONS

**38.1** Physical pressures include gravity and transpiration, as well as turgor pressure as an expanding cell presses against its cell wall. Increases in turgor pressure and other physical pressures are associated with increases water potential. Solute concentration determines whether water enters or leaves a cell via osmosis. The smallest amount of pressure on the side of the cell membrane with the greater solute concentration that is necessary to stop osmosis is the solute potential. Water potential is the sum of the pressure from physical forces and from the solute potential.

**38.2** Proteins in the cell membrane allow diffusion to be selective. Other protein channels are involved in active transport across the membrane. Water moves through channels called aquaporins. For a review of membrane properties, see chapter 5.

**38.3** The driving force for transpiration is the gradient between 100% humidity inside the leaf and the external humidity. When the external humidity is low, the rate of transpiration is high, limited primarily by the amount of water available for uptake through the root system.

The minerals are used for metabolic activities. Some minerals can move into the phloem and be transported to metabolically active areas of the plants, but others, including calcium, cannot be relocated after they leave the xylem.

**38.4** Once carbon dioxide is dissolved in water, it can be transported to photosynthetically active cells where it is used in carbon fixation in the Calvin Cycle (see chapter 8 for a review of photosynthesis).

**38.5** Physical changes in the roots in response to oxygen deprivation may prevent further transport of water in the xylem. Although the leaves may be producing oxygen, it is not available to the roots.

**38.6** Phloem liquid is rich in organic compounds including sucrose and plant hormones dissolved in water. Fluid in the xylem consists of minerals dissolved in water.

### INQUIRY QUESTIONS

**Page 773** Before equilibrium, the solute potential of the solution is  $-0.5$  MPa, and that of the cell is  $-0.2$  MPa. Since the solution contains more solute than does the cell, water will leave the cell to the point that the cell is plasmolyzed. Initial turgor pressure ( $\Psi_p$ ) of the cell =  $0.05$  MPa, while that of the solution is  $0$  MPa. At equilibrium, both the solution and the cell will have the same  $\Psi_w$ .  $\Psi_{\text{cell}} = -0.2$  MPa +  $0.5$  MPa =  $0.3$  MPa before equilibrium is reached. At equilibrium,  $\Psi_{\text{cell}} = \Psi_{\text{solution}} = -0.5$  MPa, thus  $\Psi_{w(\text{cell})} = -0.5$  MPa. At equilibrium, the plasmolyzed cell  $\Psi_p = 0$  MPa. Finally, using the relationship  $\Psi_{w(\text{cell})} = \Psi_p + \Psi_s$  and  $\Psi_{w(\text{cell})} = -0.5$  MPa,  $\Psi_{p(\text{cell})} = 0$  MPa, then  $\Psi_{s(\text{cell})} = -0.5$  MPa.

**Page 775** The fastest route for water movement through cells has the least hindrance, and thus is the symplast route. The route that exerts the most control over what substances enter and leave the cell is the transmembrane route, which is then the best route for moving nutrients into the plant.

**Page 777** If a mutation increases the radius,  $r$ , of a xylem vessel threefold, then the movement of water through the vessel would increase 81-fold ( $r^4 = 3^4 = 81$ ). A plant with larger diameter vessels can move much more water up its stems.

### UNDERSTAND

1. a 2. c 3. d 4. a 5. c 6. d 7. b 8. a 9. b 10. b

### APPLY

1. b 2. c 3. b 4. c 5. b

### SYNTHESIZE

- The solute concentration outside the root cells is greater than inside the cells. Thus the solute potential is more negative outside the cell and water moves out of the root cells and into the soil. Without access to water, your plant wilts.
- Look for wilted plants since the rate of water movement across the membrane would decrease in the aquaporin mutants.

- At the level of membrane transport, plants and animals are very similar. Plant cell walls allow plant cells to take up more water than most animal cells, which rupture without the supportive walls. At the level of epidermal cells there is substantial variation among animals. Amphibians exchange water across the skin. Plants have waterproof epidermal tissue but lose water through stomata. Humans sweat, but dogs do not. Some animals have adaptations for living in aquatic or high saline environment, as do plants. Vascular plants move vast amounts of water through the plant body via the xylem, using evaporation to fuel the transport. Animals with closed circulatory systems can move water throughout the organism and also excrete excess water through the urinary system, which is responsible for osmoregulation.
- The rate of transpiration is greater during the day than the night. Since water loss first occurs in the upper part of the tree where more leaves with stomata are located, the decrease in water volume in the xylem would first be observed in the upper portion, followed by the lower portion of the tree.
- Spring year 1—The new carrot seedling undergoes photosynthesis in developing leaves and the sucrose moves towards the growing tip.  
Summer year 1—The developing leaves are sources of carbohydrate, which now moves to the developing root and also the growing young tip.  
Fall year 1—The carrot root is now the sink for all carbohydrates produced by the shoot.  
Spring year 2—Stored carbohydrate in the root begins to move upwards into the shoot.  
Summer year 2—The shoot is flowering and the developing flowers are the primary sink for carbohydrates from the root and also from photosynthesis in the leaves.  
Fall year 2—Seeds are developing and they are the primary sink. The root reserves have been utilized and any remaining carbohydrates from photosynthesis are transported to developing seeds.

## CHAPTER 39

### LEARNING OUTCOME QUESTIONS

**39.1** Alkaline soil can affect the availability of nutrients in the soil for uptake by a plant.

**39.2** Magnesium is found in the center of the chlorophyll molecule. Without sufficient magnesium, chlorophyll deficiencies will result in decreased photosynthesis and decreased yield per acre.

**39.3** Nitrogen is essential for all amino acids, the building blocks of protein. Without sufficient levels of proteins that function as enzymes, membrane transporters, transcription factors, and structural components, plant growth and reproduction will be limited.

**39.4** Increasing the amount of available nitrogen in the soil is one strategy. This can be accomplished with chemically produced ammonia for fertilizing, intercropping with nitrogen-fixing legumes, or using organic matter rich in nitrogen for enriching the soil. Efforts to reduce the relative amounts of atmospheric carbon dioxide would also be helpful.

**39.5** Large poplar trees that are not palatable to animals offer a partial solution. Fencing in areas that are undergoing phytoremediation is another possibility, but it would be difficult to isolate all animals, especially birds. Plants that naturally deter herbivores with secondary compounds, including some mustard species (*Brassica* species) could be effective for phytoremediation.

### INQUIRY QUESTION

**Page 797** At low and high temperature extremes, enzymes involved in plant respiration are denatured. Plants tend to acclimate to slower long-term changes in temperature, and rates of respiration are able to adjust. Short-term more dramatic changes might slow or halt respiration, especially if a temperature change is large enough to cause enzymes to denature.

### UNDERSTAND

### APPLY

1. c 2. a 3. a 4. d 5. The macronutrient potassium constitutes 0.5–6% of the dry weight. Let's assume that the potato is 90% water. The dry weight would be 10% of 1000 kg, or 100 kg. Next you calculate 0.5% of 100, which is 0.5 kg. You would do the same type of calculation for 6%.

The micronutrient problems would also use the estimate of 100 kg dry weight. The conversion you need to use is that 1 ppm is the same as 1 mg/kg. So, 4 ppm of copper is the same as 4 mg/kg. Multiply this by 100 kg of dry weight potato and

you have 400 mg of copper. Since there are 1000 mg in a gram,  $400 \text{ mg} \times 1 \text{ g}/1000 \text{ mg} = 0.4 \text{ g}$  of copper in a ton of potato. The other micronutrient problems would be calculated in a similar manner.

## SYNTHESIZE

1. Bacteria that are important for nitrogen fixation could be destroyed. Other microorganisms that make nutrients available to plants could also be destroyed.
2. Grow the tomatoes hydroponically in a complete nutrient solution minus boron and complete nutrient solution with varying concentrations of boron. Compare the coloration of the leaves, the rate of growth (number of new leaves per unit time), and number and size of fruits produced on plants in each treatment group. It would also be helpful to compare the dry weights of plants from each treatment group at the end of the study.
3. Other inputs include both the macronutrients and micronutrients. Nitrogen, potassium, and phosphorous are common macronutrients in fertilizers. Of course the plants also need to be watered.

## CHAPTER 40

### LEARNING OUTCOME QUESTIONS

- 40.1** The lipid-based compounds help to create a water impermeable layer on the leaves.
- 40.2** A drug prepared from a whole plant or plant tissue would contain a number of different compounds, in addition to the active ingredient. Chemically synthesized or purified substances contain one or more known substances in known quantities.
- 40.3** It is unlikely that wasps will kill all the caterpillars. When attacked by a caterpillar, the plant releases a volatile substance that attracts the wasp. But, the wasp has to be within the vicinity of the signal when the plant releases the signal. As a result, some caterpillars will escape detection by wasps.
- 40.4** The local death of cells creates a barrier between the pathogen and the rest of the plant.

### INQUIRY QUESTION

**Page 808** Ricin functions as a ribosome-binding protein that limits translation. A very small quantity of rice was injected into Markov's thigh from the modified tip of his assassin's umbrella. Without translation of proteins in cells, enzymes and other gene products are no longer produced, causing the victim's metabolism to shut down leading to death.

### UNDERSTAND

### APPLY

1. c 2. d 3. d 4. b 5. c 6. a

### SYNTHESIZE

1. Humans learn quickly and plants with toxins that made people ill would not become a dietary mainstay. If there was variation in the levels of toxin in the same species in different areas, humans would likely have continued to harvest plants from the area where plants had reduced toxin levels. As domestication continued, seeds would be collected from the plants with reduced toxin levels and grown the following year.
2. For parasitoid wasps to effectively control caterpillars, sufficiently large populations of wasps would need to be maintained in the area where the infestation occurred. As wasps migrate away from the area, new wasps would need to be introduced. The density of wasps is critical because the wasp has to be in the vicinity of the plant being attacked by the caterpillar when the plant releases its volatile signal. Maintaining sufficient density is a major barrier to success.
3. If a plant is flowering or has fruits developing, the systemin will move towards the fruit or flowers, providing protection for the developing seed. If the plant is a biennial, such as a carrot plant, in its first year of growth, systemin will likely be diverted to the root or other storage organ that will reserve food stores for the plant for the following year.

## CHAPTER 41

### LEARNING OUTCOME QUESTIONS

**41.1** Chlorophyll is essential for photosynthesis. Phytochromes regulate plant growth and development using light as a signal. Phytochrome mediated responses

align the plant with the light environment so photosynthesis is maximized which is advantageous for the plant.

**41.2** The plant would not have normal gravitropic responses. Other environmental signals, including light, would determine the direction of plant growth.

**41.3** Folding leaves can startle an herbivore that lands on the plant. The herbivore leaves and the plant is protected.

**41.4** During the winter months the leaves would cease photosynthesis except on a few warm days. If the weather warmed briefly, water would move into the leaves and photosynthesis would begin. Unfortunately, the minute the temperature dropped, the leaves would freeze and be permanently damaged. Come the spring, the leaves would not be able to function and the tree would die. It is to the trees advantage to shed its leaves and grow new, viable leaves in the spring when the danger of freezing is past.

**41.5** Abscisic acid could be isolated from root caps of several plants. The isolated abscisic acid could then be applied to the buds on stems of other plants of the same species. The growth of these buds (or lack of growth) could be compared with untreated controls to determine whether or not the abscisic acid had an effect.

### INQUIRY QUESTIONS

**Page 816** A number of red-light-mediated responses are linked to phytochrome action alone, including seed germination, shoot elongation, and plant spacing. Only some of the red-light-mediated responses leading to gene expression are dependent on the action of protein kinases. When phytochrome converts to the Pfr form, a protein kinase triggers phosphorylation that, in turn, initiates a signaling cascade that triggers the translation of certain light-regulated genes. Not all red-light-mediated responses are disrupted in a plant with a mutation in the protein kinase domain of phytochrome.

**Page 819** Auxin is involved in the phototropic growth responses of plants, including the bending of stems and leaves toward light. Auxin increases the plasticity of plants cells and signals their elongation. The highest concentration of auxin would most likely occur at the tips of stems where sun exposure is maximal.

**Page 827** A chemical substance, such as the hormone auxin, could trigger the elongation of cells on the shaded side of a stem, causing the stem to bend toward the light.

### UNDERSTAND

1. c 2. a 3. d 4. d 5. b 6. d

### APPLY

1. b 2. a 3. b 4. c 5. c 6. b 7. d

### SYNTHESIZE

1. You are observing etiolation. Etiolation is an energy conservation strategy to help plants growing in the dark reach the light before they die. They don't green up until light becomes available, and they divert energy to internode elongation. This strategy is useful for potato shoots. The sprouts will be long so they can get to the surface more quickly. They will remain white until exposed to sunlight which will signal the production of chlorophyll.
2. Tropism refers to the growth of an organism in response to an environmental signal such as light. Taxis refers to the movement of an organism in response to an environmental signal. Since plants cannot move, they will not exhibit taxis, but they do exhibit tropisms.
3. Auxin accumulates on the lower side of a stem in a gravitropism, resulting in elongation of cells on the lower side. If auxin or vesicles containing auxin responded to a gravitational field, it would be possible to have a gravitropic response without amyloplasts.
4. Farmers are causing a thigmotropic response. In response to touch, the internodes of the seedlings will increase in diameter. The larger stems will be more resistant to wind and rain once they are moved to the field. The seedlings will be less likely to snap once they are moved to the more challenging environment.

## CHAPTER 42

### LEARNING OUTCOME QUESTIONS

**42.1** Without flowering in angiosperms, sexual reproduction is not possible and the fitness of a plant drops to zero.

**42.2** Set up an experiment in a controlled growth chamber with a day/night light regimen that promotes flowering. Then interrupt the night length with a brief exposure to light. If day length is the determining factor, the brief flash of light will

not affect flowering. If night length is the determining factor, the light flash may affect the outcome. For example, if the plant requires a long night, interrupting the night will prevent flowering. If the plant flowers whether or not you interrupt the night with light, it may be a short night plant. In that case, you would want to set up a second experiment where you lengthen the night length. That should prevent the plant from flowering.

**42.3** Flowers can attract pollinators, enhancing the probability of reproduction.

**42.4** No because the gametes are formed by meiosis which allows for new combinations of alleles to combine. You may want to review Mendel's law of independent assortment.

**42.5** When conditions are uniform and the plant is well adapted to those constant conditions, genetic variation would not be advantageous. Rather, vegetative reproduction will ensure that the genotypes that are well adapted to the current conditions are maintained.

**42.6** A biennial life cycle allows an organism to store up substantial reserves to be used to support reproduction during the second season. The downside to this strategy is that the plant might not survive the winter between the two growing seasons and its fitness would be reduced to zero.

### INQUIRY QUESTIONS

**Page 843** Strict levels of CONSTANS (CO) gene protein are maintained according to the circadian clock. Phytochrome, the pigment that perceives photoperiod, regulates the transcription of CO. By examining posttranslational regulation of CO, it might be possible to determine whether protein levels are modulated by means other than transcription. An additional level of control might be needed to ensure that the activation of floral meristem genes coincides with the activation of genes that code for individual flower organs.

**Page 846** Flower production employs up to four genetically-regulated pathways. These pathways ensure that the plant flowers when it has reached adult size, when temperature and light regimes are optimal, and when nutrition is sufficient to support flowering. All of these factors combine to ensure the success of flowering and the subsequent survival of the plant species.

**Page 846** Once vernalization occurred and nutrition was optimal, flowering could occur in the absence of flower-repressing genes, even if the plant had not achieved adult size. Thus flowering might occur earlier than normal.

### UNDERSTAND

1.a 2.c 3.a 4.d 5.d 6.c 7.d 8.c 9.b 10.c 11.a

### APPLY

1.b 2.c 3.b 4.d 5.b

### SYNTHESIZE

1. Pointsettias are short day plants. The lights from the cars on the new highway interrupt the long night and prevent flowering.
2. Spinach is a long day plant and you want to harvest the vegetative, not the reproductive parts of the plant. Spinach will flower during the summer as the days get longer. Only leaves will be produced during the spring. If you grow and harvest your spinach in the early spring, you will be able to harvest the leaves before the plant flowers and begins to senesce.
3. Cross-pollination increases the genetic diversity of the next generation. But, self-pollination is better than no pollination. The floral morphology of columbine favors cross-pollination, but self-pollination is a backup option. Should this backup option be utilized, there is still one more opportunity for cross-pollination to override self-pollination because the pollen tube from the other plant can still grow through the style more rapidly than the pollen tube from the same plant.
4. Potatoes grown from true seed take longer to produce new potatoes than potatoes grown from tubers. Seeds are easier to store between growing seasons and require much less storage space than whole potatoes. The seed-grown potatoes will have greater genetic diversity than the asexually propagated potato tubers. If environmental conditions vary from year to year, the seed grown potatoes may have a better yield because different plants will have an advantage under different environmental conditions. The tuber-grown potatoes will be identical. If conditions are optimal for that genotype, the tuber-grown potatoes will outperform the more variable seed-grown potatoes. But, if conditions are not optimal for the asexually propagated potatoes, the seed-grown potatoes may have the higher yield.

## CHAPTER 43

### LEARNING OUTCOME QUESTIONS

- 43.1** Organs may be made of multiple tissue types. For example, the heart contains muscle, connective tissue and epithelial tissue.
- 43.2** The epithelium in glandular tissue produces secretions, the epithelium has microvilli on the apical surface that increase surface area for absorption.
- 43.3** Blood is a form of connective tissue because it contains abundant extracellular material: the plasma.
- 43.4** The function of heart cell requires their being electrically connected. The gap junctions allow the flow of ions between cells.
- 43.5** Neurons may be a meter long, but this is a very thin projection that still can allow diffusion of materials along its length. They do require specialized transport along microtubules to move proteins from the cell body to the synapse.
- 43.6** The organ systems may overlap. Consider the respiratory and circulatory systems. These systems are interdependent.
- 43.7** Yes.
- 43.8** The distinction should be between the ability to generate metabolic heat to modulate temperature, and the lack of that ability. Thus ectotherms and endotherms have replaced cold-blooded and warm-blooded.

### INQUIRY QUESTIONS

**Page 880** After two minutes of shivering, the thoracic muscles have warmed up enough to engage in full contractions. The muscle contractions that allow the full range of motion of the wings utilize kinetic energy in the movement of the wings, rather than releasing the energy as heat, which occurred in the shivering response.

**Page 882** Small mammals, with a proportionately larger surface area, dissipate heat readily, which is helpful in a warm environment, but detrimental in a cold environment. In cold conditions, small mammals must seek shelter or have adaptations, such as insulating hair, to maintain body temperature. Because of a greater volume and proportionately less surface area, large mammals are better adapted to cold environments since it takes much longer for them to lose body heat. Hot environments pose a greater challenge for them for the same reason.

### UNDERSTAND

### APPLY

1.b 2.b 3.c 4.c 5.d 6.a 7.c

### SYNTHESIZE

1. Yes, both the gut and the skin include epithelial tissue. A disease that affects epithelial cells could affect both the digestive system and the skin. For example, cystic fibrosis affects the ion transport system in epithelial membranes. It is manifested in the lungs, gut, and sweat glands.
2. The digestive, circulatory, and respiratory systems are grouped together because they all provide necessary nutrients for the body. The digestive system is responsible for the acquisition of nutrients from food; the respiratory system provides oxygen and removes waste (carbon monoxide). The circulatory system transports nutrients to the cells of the body and removes metabolic wastes.
3. Hunger is a negative feedback stimulus. Hunger stimulates an individual to eat which in turn causes a feeling of fullness that removes hunger. Hunger is the stimulus; eating is the response that removes the stimulus.
4. The internal environment is constantly changing. As you move through your day, muscle activity raises your body temperature, but when you sit down to eat or rest, your temperature cools. The body must constantly adjust to changes in activity or the environment.

## CHAPTER 44

### LEARNING OUTCOME QUESTIONS

- 44.1** The somatic nervous system is under conscious control.
- 44.2** A positive current inwards (influx of  $\text{Na}^+$ ) depolarizes the membrane while a positive current outward (efflux of  $\text{K}^+$ ) repolarizes the membrane.
- 44.3** Tobacco contains the compound nicotine, which can bind some acetylcholine receptors. This leads to the classic symptoms of addiction due to underlying habituation involving changes to receptor numbers and responses.

**44.4** Reflex arcs allow you to respond to a stimulus that is damaging before the information actually arises at your brain.

**44.5** These two systems work in opposition. This may seem counterintuitive, but is the basis for much of homeostasis.

## UNDERSTAND

## APPLY

1. d 2. b 3. c 4. a 5. a 6. c 7. d

## SYNTHESIZE

1. TEA blocks  $K^+$  channels so that they will not permit the passage of  $K^+$  out of the cell, thereby not allowing the cell to return to the resting potential. Voltage-gated  $Na^+$  channels would still be functional and  $Na^+$  would still flow into the cell but there would be no repolarization.  $Na^+$  would continue to flow into the cell until an electrochemical equilibrium was reached for  $Na^+$ , which is +60 mV. After the membrane potential reached +60 mV, there would be no net movement of  $Na^+$ , but the membrane would also not be able to repolarize back to the resting membrane potential. The neuron would no longer be able to function.

The effects on the postsynaptic cell would be somewhat similar if TEA were applied to the presynaptic cell. The presynaptic cell would depolarize and would continue to release neurotransmitter until it had exhausted its store of synaptic vesicles. As a result, the postsynaptic cell would be bombarded with neurotransmitters and would be stimulated continuously until the stores of presynaptic neurotransmitter were depleted. The postsynaptic cell however would recover, being able to repolarize its membrane, and return to the resting membrane potential.

2. Rising:  $Na^+$  gates open,  $K^+$  closed  
Falling:  $Na^+$  inactivation gate closes,  $K^+$  open  
Undershoot:  $Na^+$  activation gate closed, inactivation gate open,  $K^+$  gate closing.
3. Action potential arrives at the end of the axon.  
 $Ca^{2+}$  channels open.  
 $Ca^{2+}$  causes synaptic vesicles to fuse with the axon membrane at the synapse. Synaptic vesicles release their neurotransmitter.  
Neurotransmitter molecules diffuse across synaptic cleft.  
Postsynaptic receptor proteins bind neurotransmitter.  
Postsynaptic membrane depolarizes.  
If this were an inhibitory synapse, the binding of receptor protein and neurotransmitter would cause the postsynaptic membrane to hyperpolarize.
4. Cells exposed to a stimulus repeatedly may lose their ability to respond. This is known as habituation. Karen's postsynaptic cells may have decreased the number of receptor proteins they produce because the stimulatory signal is so abundant. The result is that it now takes more stimuli to achieve the same result.

## CHAPTER 45

### LEARNING OUTCOME QUESTIONS

**45.1** When the log values of the intensity of the stimulus and the frequency of the resulting action potentials are plotted against each other, a straight line results; this is referred to as a logarithmic relationship.

**45.2** Proprioceptors detect the stretching of muscles and subsequently relay information about the relative position and movement of different parts of the organism's body to the central nervous system. This knowledge is critical for the central nervous system; it must be able to respond to these data by signaling the appropriate muscular responses, allowing for balance, coordinated locomotion, and reflexive responses.

**45.3** The lateral line system supplements the sense of hearing in fish and amphibian larvae by allowing the organism to detect minute changes in the pressure and vibrations of its environment. This is facilitated by the density of water; without an aquatic environment the adult, terrestrial amphibian will no longer be able to make use of this system. On land, sound waves are more easily detectable by the sense of hearing than are vibratory or pressure waves by the similar structures of a lateral line.

**45.4** Many insects, such as the housefly, have chemoreceptors on their feet with which they can detect the presence of edible materials as they move through their environment. These insects can thus "taste" what they are walking on, and when they encounter an edible substrate they can then descend their proboscis and consume the food.

**45.5** Individuals with complete red-green color blindness (those who have no red cones or no green cones, as opposed to those who lack only some red or green cones) would be highly unlikely to be able to learn to distinguish these colors. In order for an individual to perceive the colors in the red-green area of the spectrum, both red and green cones are required; without both cones there is no reference point by which individuals could compare the signals between the retina and the brain. If there are other cues available, such as color saturation or object shape and size, individuals with a less severe form of color blindness may be able to learn to distinguish these colors. In the absence of other references, however, it would be very difficult for individuals with even partial red-green color blindness to distinguish these colors.

**45.6** The body temperature of an ectothermic organism is not necessarily the same as the ambient temperature; for example, other reptiles may bask in the sun, wherein on a chilly day the sun may warm the animal's body temperature above the ambient temperature. In this situation, the heat-sensing organs of, for example, a pit viper would still be effective in hunting as it would be able to distinguish the differences between the environment and its ectothermic prey.

## INQUIRY QUESTIONS

**Page 921** As the injured fish thrashed around, it would produce vibrations, rapid changes in the pressure of the water. The lateral line system in fish consists of canals filled with sensory cells that send a signal to the brain in response to the changes in water pressure.

**Page 927** Both taste and smell utilize chemoreceptors as sensory receptors, wherein the binding of specific proteins to the receptor induces an action potential which is sent as a sensory signal to the brain. The chemicals detected by both systems must first be dissolved in extracellular fluid before they can be detected. One major difference between the two systems is that the olfactory system does not route a signal through the thalamus; instead, action potentials are routed directly to the olfactory cortex. Another difference is that olfactory receptors occur in larger numbers—tens of millions, as opposed to tens or hundreds of thousands for taste receptors.

**Page 929** In humans, the ganglion cells attach to the front of the retinal cells, thus forcing the optic nerve to disrupt the continuity of the retina, leading to the formation of a "blind spot". In mollusks, however, the ganglion cells attach to the back of the retina and thus the retina is uninterrupted, eliminating the blind spot.

## APPLY

1. c 2. a 3. c 4. b

## SYNTHESIZE

1. When blood pH becomes acidic, chemoreceptors in the circulatory and the nervous systems notify the brain and the body responds by increasing the breathing rate. This causes an increase in the release of carbon dioxide through the lungs. Decreased carbon dioxide levels in the blood cause a decrease in carbonic acid, which, in turn, causes the pH to rise.
2. In order to reach the retina and generate action potentials on the optic nerve, light must first pass through the ganglion and bipolar cells to reach the rods and cones that synapse with the bipolar cells. The bipolar cells then synapse with ganglion cells. These in turn send action potentials to the brain. Because the retina comprises three layers, with the rods and cones located farthest from the pupil, light must travel to the deepest level to set off reactions that move up through the more superficial levels and result in optic signals.
3. Without gravity to force the otoliths down toward the hair cells, the otolith organ will not function properly. The otolith membrane would not rest on the hair cells and would not move in response to movement of the body parallel or perpendicular to the pull of gravity. Consequently, the hair cell would not bend and so would not produce receptor potentials. Because the astronauts can see, they would have an impression of motion—they can see themselves move in relation to objects around them—but with their eyes closed, they would not know if they were moving in relation to their surroundings. Because their proprioceptors would still function, they would be able to sense when they moved their arms or legs, but they would not have the sensation of their enter body moving through space.

The semicircular canals would not function equally well in zero-gravity conditions. Although the fluid in the semicircular canals is still able to move around, some sensation of angular movement would most likely occur, but the full function of the semicircular canals requires the force of gravity to aid in the directional movement of the fluid in the canals.

## CHAPTER 46

### LEARNING OUTCOME QUESTIONS

- 46.1** Neurotransmitters are released at a synapse and act on the post synaptic membrane. Hormones enter the circulatory system and are thus delivered to the entire body.
- 46.2** The response of a particular tissue depends first on the receptors on its surface, and second on the response pathways active in a cell. There can be different receptor subtypes that bind the same hormone, and the same receptor can stimulate different response pathways.
- 46.3** This might lower the amount of GH in circulation. As a treatment, it may have unwanted side effects.
- 46.4** With two hormones that have antagonistic effects, the body can maintain a fine level of blood sugar.
- 46.5** Reducing blood volume should also reduce blood pressure.

### UNDERSTAND

1. b 2. d 3. c 4. b 5. d 6. b 7. a

### APPLY

1. a 2. c 3. c 4. b 5. b 6. b 7. b

### SYNTHESIZE

1. If the target cell for a common hormone or paracrine becomes cancerous, it may become hypersensitive to the messenger. This may in turn cause over production of cells, which would result in tumor formation. By blocking the production of the hormone specific to that tissue (for example, breast or prostate tissue and sex steroids), it would be possible to slow the growth rate and decrease the size of the tumor.
2. The same hormone can affect two different organs in different ways because the second messengers triggered by the hormone have different targets inside the cell because the cells have different functions. Epinephrine affects the cells of the heart by increasing metabolism so that their contractions are faster and stronger. However, liver cells do not contract and so the second messenger in liver cells triggers the conversion of glycogen into glucose. That is why hormones are so valuable but also economical to the body. One hormone can be produced, one receptor can be made, and one second-messenger system can be used, but there can be two different targets inside the cell.
3. With hormones such as thyroxine, whose effects are slower and have a broader range of activity, a negative feedback system using one hormone adequately controls the system. However, for certain parameters that have a very narrow range and change constantly within that range, a regulatory system that uses up-and-down regulation is desirable. Too much or too little  $\text{Ca}^{2+}$  or glucose in the blood can have devastating effects on the body and so those levels must be controlled within a very narrow range. To rely on negative feedback loops would restrict the quick “on” and “off” responses needed to keep the parameters in a very narrow range.

## CHAPTER 47

### LEARNING OUTCOME QUESTIONS

- 47.1** There are three limitations terrestrial invertebrates experience due to an exoskeleton. First, animals with an exoskeleton can only grow by shedding, or molting, the exoskeleton, leaving them vulnerable to predation. Second, muscles that act upon the exoskeleton cannot strengthen and grow as they are confined within a defined space. Finally, the exoskeleton, in concert with the respiratory system of many terrestrial invertebrates, limits the size to which these animals can grow. In order for the exoskeleton of a terrestrial animal to be strong, it has to have a sufficient surface area, and thus it has to increase in thickness as the animal gets larger. The weight of a thicker exoskeleton would impose debilitating constraints on the animal's ability to move.
- 47.2** Vitamin D is important for the absorption of dietary calcium as well as the deposition of calcium phosphate in bone. Children undergo a great deal of skeletal growth and development; without sufficient calcium deposition their bones can become soft and pliable, leading to a condition known as rickets, which causes a bending or bowing of the lower limbs. In the elderly, bone remodeling without adequate mineralization of the bony tissue can lead to brittle bones, a condition known as osteoporosis.
- 47.3** First, unlike the chitinous exoskeleton, a bony endoskeleton is made of living tissue; thus, the endoskeleton can grow along with the organism. Second, because the muscles that act upon the bony endoskeleton are not confined within a rigid structure, they are able to strengthen and grow with increased use. Finally, the size limitations imposed by a heavy exoskeleton that covers the entire organism

are overcome by the internal bony skeleton, which can support a greater size and weight without itself becoming too cumbersome.

**47.4** Slow-twitch fibers are found primarily in muscles adapted for endurance rather than strength and power. Myoglobin provides oxygen to the muscles for the aerobic respiration of glucose, thus providing a higher ATP yield than anaerobic respiration. Increased mitochondria also increases the ATP productivity of the muscle by increasing availability of cellular respiration and thus allows for sustained aerobic activity.

**47.5** Locomotion via alternation of legs requires a greater degree of nervous system coordination and balance; the animal needs to constantly monitor its center of gravity in order to maintain stability. In addition, a series of leaps will cover more ground per unit time and energy expenditure than will movement by alternation of legs.

### INQUIRY QUESTIONS

**Page 969** The idea is very similar; both quadrupeds and insects such as grasshoppers have flexors and extensors that exert antagonistic control over many of their muscles. The main difference is in the structure rather than function—in a grasshopper, the muscles are covered by the skeletal elements, while in organisms with an endoskeleton, the muscles overlie the bony skeleton.

**Page 974** Increasing the frequency of stimulation to a maximum rate will yield the maximum amplitude of a summated muscle contraction. The strength of a contraction increases because little or no relaxation time occurs between successive twitches.

**Page 974** A rough estimate of the composition of calf muscle could be obtained by measuring the amount of time the calf muscle takes to reach maximum tension and compare that amount with the contraction speed of muscles of known fiber composition. Alternatively, a small sample of muscle could be extracted and examined for histological differences in fiber composition.

### UNDERSTAND

1. d 2. b 3. c 4. a 5. c 6. a 7. b 8. a

### APPLY

1. d 2. b 3. d 4. b 5. b 6. b

### SYNTHESIZE

1. Although a hydrostatic skeleton might have advantages in terms of ease of transport and flexibility of movement, the exoskeleton would probably do a better job at protecting the delicate instruments within. This agrees with our observations of these support systems on Earth. Worms and marine invertebrates use hydrostatic skeletons, although arthropods (“hard bodies”) use an exoskeleton. Worms are very flexible, but easily crushed.
2. The first 90 seconds of muscle activity are anaerobic in which the cells utilize quick sources of energy (creatine phosphate, lactic acid fermentation) to generate ATP. After that, the respiratory and circulatory systems will catch up and begin delivering more oxygen to the muscles which allows them to use aerobic respiration, which is a much more efficient method of generating ATP from glucose.
3. If acetylcholinesterase is inhibited, acetylcholine will continue to stimulate muscles to contract. As a result, muscle twitching, and eventually paralysis, will occur. In March 1995, canisters of Sarin were released into a subway system in Tokyo. Twelve people were killed and hundreds injured.
4. Natural selection is not goal-oriented. In other words, evolution does not anticipate environmental pressures and the structures that result from evolution by natural selection are those most well-suited the previous generations' environment. Since vertebral wing development occurred several times during evolution, it is probable that the animals in question—birds, pterosaurs, and bats—all encountered different evolutionary pressures during wing evolution.

## CHAPTER 48

### LEARNING OUTCOME QUESTIONS

**48.1** The cells and tissues of a one-way digestive system are specialized such that ingestion, digestion, and elimination can happen concurrently, making it more efficient in terms of food processing and energy utilization. With a gastrovascular cavity, however, all of the cells are exposed to all aspects of digestion.

**48.2** Voluntary processes include bringing food into the mouth (food capture), mastication, and the initiation of swallowing. Salivation and the swallowing reflex are involuntary.

**48.3** The sandwich represents carbohydrate (bread), protein (chicken), and fat (mayonnaise). The breakdown of carbohydrates begins with salivary amylase in the mouth. The breakdown of proteins begins in the stomach with pepsinogen, and the emulsification of fats begins in the duodenum with the introduction of bile. So—it is the chicken that will begin its breakdown in the stomach.

**48.4** Fats are broken down, by emulsification, into fatty acids and monoglycerides, both of which are nonpolar molecules. Nonpolar molecules are able to enter the epithelial cells by simple diffusion.

**48.5** The success of any mutation depends upon the selective pressures that species is subjected to. Thus, if two different species are subjected to similar environmental conditions and undergo the same mutation, then, yes, the mutation should be similarly successful. If two species undergo the same mutation but are under different selective pressures, then the mutation may not be successful in both species.

**48.6** The sight, taste, and, yes, smell of food are the triggers the digestive system needs to release digestive enzymes and hormones. The saliva and gastric secretions that are required for proper digestion and are triggered by the sense of smell would be affected by anosmia.

**48.7** Any ingested compounds that might be dangerous are metabolized first by the liver, thus reducing the risk to the rest of the body.

**48.8** Even with normal leptin levels, individuals with reduced sensitivity in the brain to the signaling molecule may still become obese.

## INQUIRY QUESTIONS

**Page 985** If the epiglottis does not properly seal off the larynx and trachea, food can accidentally become lodged in the airway, causing choking.

**Page 986** The digestive system secretes a mucus layer that helps to protect the delicate tissues of the alimentary canal from acidic secretions.

**Page 992** The amino acid sequences for lysozyme evolved convergently among ruminants and langur monkeys. Thus, if a phylogeny was constructed using solely the lysozyme molecular data, these species—ruminants and langur monkeys—would be adjacent to each other on the phylogenetic tree.

**Page 997** GIP and CCK send inhibitory signals to the hypothalamus upon food intake. If the hypothalamus sensors did not work properly, leptin levels would increase; increased leptin levels would result in a loss of appetite.

## UNDERSTAND

1. b 2. c 3. c 4. b 5. d 6. d 7. c

## APPLY

1. d 2. b 3. c 4. c

## SYNTHESIZE

1. Birds feed their young with food they acquire from the environment. The adult bird consumes the food but stores it in her crop. When she returns to the nest, she regurgitates the food into the mouths of the fledglings. Mammals on the other hand feed their young with milk that is produced in the mother's mammary glands. Young feed by latching onto the mother's nipples and sucking the milk. Mammals have no need for a crop in their digestive system because they don't feed their young in the same way as birds.
2. Leptin is produced by the adipose cells and serves as a signal for feeding behavior. Since low blood leptin levels signal the brain to initiate feeding, a treatment for obesity would need to raise leptin levels, thereby decreasing appetite.
3. The liver plays many important roles in maintaining homeostasis. Two of those roles are detoxifying drugs and chemicals and producing plasma proteins. A drop in plasma protein levels is indicative of liver disease, which in turn could be caused by abuse of alcohol or other drugs.
4. The selective pressures that guide the adaptation of mutated alleles within a population were the same in these two groups of organisms. Both ruminants and langur monkeys eat tough, fibrous plant materials which are broken down by intestinal bacteria. The ruminants and langurs then absorb the nutrients from the cellulose by digesting those bacteria; this is accomplished through the use of these adapted lysozymes. Normal lysozymes, found in saliva and other secretions, work in a relatively neutral pH environment. These intestinal lysozymes, however, needed to adapt to an acidic environment, which explains the level of convergence.
5. Whereas mammalian dentition is adapted to process different food types, birds are able to process different types of food by breaking up food particles

in the gizzard. Bird diets are comparably diverse to mammalian diets; some birds are carnivores, others are insectivores or frugivores, still others omnivores.

## CHAPTER 49

### LEARNING OUTCOME QUESTIONS

**49.1** Fick's law states that the rate of diffusion ( $R$ ) can be increased by increasing the surface area of a respiratory surface, increase the concentration difference between respiratory gases, and decreasing the distance the gases must diffuse:  $R = \frac{DA \Delta p}{d}$ . Continually beating cilia increase the concentration difference ( $\Delta p$ ).

**49.2** Countercurrent flow systems maximize the oxygenation of the blood by increasing  $\Delta p$ , thus maintaining a higher oxygen concentration in the water than in the blood throughout the entire diffusion pathway. The lamellae, found within a fish's gill filaments, facilitate this process by allowing water to flow in only one direction, counter to the blood flow within the capillary network in the gill.

**49.3** Birds have a more efficient respiratory system than other terrestrial vertebrates. Birds that live or fly at high altitudes are subjected to lower oxygen partial pressure and thus have evolved a respiratory system that is capable of maximizing the diffusion and retention of oxygen in the lungs. In addition, efficient oxygen exchange is crucial during flight; flying is more energetically taxing than most forms of locomotion and without efficient oxygen exchange birds would be unable to fly even short distances safely.

**49.4** There are both structural and functional differences in bird and mammalian respiration. Both mammals and birds have lungs, but only birds also have air sacs, which they use to move air in and out of the respiratory system, while only mammals have a muscular diaphragm used to move air in and out of the lungs. Mammalian lungs are pliable, and gas exchange occurs within small closed-ended sacs in the mammalian lung called alveoli. In contrast, bird lungs are rigid, and gas exchange occurs in the unidirectional parabronchi. In addition, because air flow in mammals is bi-directional, there is a mixing of oxygenated and deoxygenated air, while the unidirectional air flow in birds increases the purity of the oxygen entering the capillaries. Mammalian respiration is less efficient than avian respiration; birds transfer more oxygen with each breath than do mammals. Finally, mammals only have one respiratory cycle whereas birds have two complete cycles.

**49.5** Most oxygen is transported in the blood bound to hemoglobin (forming oxyhemoglobin) while only a small percentage is dissolved in the plasma. Carbon dioxide, on the other hand, is predominantly transported as bicarbonate (having first been combined with water to form carbonic acid and then dissociated into bicarbonate and hydrogen ions). Carbon dioxide is also transported dissolved in the plasma and bound to hemoglobin.

## INQUIRY QUESTIONS

**Page 1002** Capillaries, the tiniest of the cardiovascular vessels, are located near every cell of the body. Because of their small size and large number, the surface area for gas exchange through them is maximized. This capillary arrangement also works well with the tiny alveoli of the lungs which also provide a large surface area for gas exchange. Since capillaries are in intimate contact with alveoli, rapid gas exchange is enhanced.

**Page 1012** Fick's law of diffusion states that for a dissolved gas, the rate of diffusion is directly proportional to the pressure difference between the two sides of the membrane and to the area over which the diffusion occurs. In emphysema, alveolar walls break down and alveoli increase in size, effectively reducing the surface area for gas exchange. Emphysema thus reduces the diffusion of gases.

**Page 1013** Most veins have a bluish color and function to return oxygen-depleted blood to the heart. The pulmonary veins, however, are bright red because they return fully oxygenated blood from the lungs to the left atrium of the heart.

**Page 1013** The difference in oxygen content between arteries and veins during rest and exercise shows how much oxygen was unloaded to the tissues.

**Page 1014** Not really. A healthy individual still has a substantial oxygen reserve in the blood even after intense exercise.

**Page 1014** It increases it. At any pH or temperature, the percentage of  $O_2$  saturation falls (e.g. more  $O_2$  is delivered to tissues) as pressure increases.

## UNDERSTAND

1. c 2. d 3. d 4. d 5. b 6. a 7. d 8. c

## APPLY

1. d 2. c 3. a 4. c 5. a 6. c

## SYNTHESIZE

1. Fish gills have not only a large respiratory surface area but also a countercurrent flow system, which maintains an oxygen concentration gradient throughout the entire exchange pathway, thus providing the most efficient system for the oxygenation of blood. Amphibian respiratory systems are not very efficient. They practice positive pressure breathing. Bird lungs are quite effective, in that they have a large surface area and one-way air flow; mammals, on the other hand, have only a large surface area but no mechanism to ensure the maintenance of a strong concentration gradient.
2. During exercise, cellular respiration increases the amount of carbon dioxide released, thus decreasing the pH of the blood. In addition, the increased cellular respiration increases temperature, as heat is released during glucose metabolism. Decreased pH and increased temperature both facilitate an approximately 20% increase in oxygen unloading in the peripheral tissues.
3. Unicellular prokaryotic organisms, protists, and many invertebrates are small enough such that gas exchange can occur over the body surface directly from the environment. Only larger organisms, where most cells are not in direct contact with the environment with which gases must be exchanged, require specialized structures for gas exchange.

## CHAPTER 50

### LEARNING OUTCOME QUESTIONS

- 50.1** Following an injury to a vessel, vasoconstriction is followed by the accumulation of platelets at the site of injury and the subsequent formation of a platelet plug. This triggers a positive feedback enzyme cascade, attracting more platelets, clotting factors, and other chemicals, each of which continually attract additional clotting molecules until the clot is formed. The enzyme cascade also causes fibrinogen to come out of solution as fibrin, forming a fibrin clot that will eventually replace the platelet plug.
- 50.2** When the insect heart contracts, it forces hemolymph out through the vessels and into the body cavities. When it relaxes, the resulting negative pressure gradient, combined with muscular contractions in the body, draws the blood back to the heart.
- 50.3** The primary advantage of having two ventricles rather than one is the separation of oxygenated from deoxygenated blood. In fish and amphibians, oxygenated and deoxygenated blood mix, leading to less oxygen being delivered to the body's cells.
- 50.4** The delay following auricular allows the atrioventricular valves to close prior to ventricular contraction. Without that delay, the contraction of the ventricles would force blood back up through the valves into the atria.
- 50.5** During systemic gas exchange, only about 90% of the fluid that diffuses out of the capillaries returns to the blood vessels; the rest moves into the lymphatic vessels, which then return the fluid to the circulatory system via the left and right subclavian veins.
- 50.6** Breathing rate is regulated to ensure ample oxygen is available to the body. However, the heart rate must be regulated to ensure efficient delivery of the available oxygen to the body cells and tissues. For example, during exertion, respiratory rates will increase in order to increase oxygenation and allow for increased aerobic cellular respiration. But simply increasing the oxygen availability is not enough—the heart rate must also increase so that the additional oxygen can be quickly delivered to the muscles undergoing cellular respiration.

### INQUIRY QUESTION

**Page 1021** Erythropoietin is a hormone that stimulates the production of erythrocytes from the myeloid stem cells. If more erythrocytes are produced, the oxygen-carrying capacity of the blood is increased. This could potentially enhance athletic performance and is why erythropoietin is banned from use during the Olympics and other sporting events.

### UNDERSTAND

### APPLY

1. a 2. b 3. a 4. c 5. a

## SYNTHESIZE

1. Antidiuretic hormone (ADH) is secreted by the posterior pituitary but has its target cells in the kidney. In response to the presence of ADH, the kidneys increase the amount of water reabsorbed. This water eventually returns to the plasma where it causes an increase in volume and subsequent increase in blood pressure. Another hormone, aldosterone, also causes an increase in blood pressure by causing the kidney to retain  $\text{Na}^+$ , which sets up a concentration gradient that also pulls water back into the blood.
2. Blood includes plasma (comprised primarily of water with dissolved proteins) and formed elements (red blood cells, white blood cells, and platelets). Lymph is comprised of interstitial fluid and found only within the lymphatic vessels and organs. Both blood and lymph are found in organisms with closed circulatory systems. Hemolymph is both the circulating fluid and the interstitial fluid found in organisms with open circulatory systems.
3. Many argue that the evolution of endothermy was less an adaptation to maintain a constant internal temperature and more an adaptation to function in environments low in oxygen. If this is the case, then yes, it makes sense that the evolution of the four-chambered heart, an adaptation that increases the availability of oxygen in the body tissues and which would be highly beneficial in an oxygen-poor environment, and the evolution of endothermy were related. These two adaptations can also be looked at as related in that the more efficient heart would be able to provide the oxygen necessary for the increased metabolic activity that accompanies endothermy.
4. The SA node acts as a natural pacemaker. If it is malfunctioning, one would expect a slow or irregular heartbeat or irregular electrical activity between the atria and the ventricles.

## CHAPTER 51

### LEARNING OUTCOME QUESTIONS

- 51.1** Water moves towards regions of higher osmolarity.
- 51.2** They are both involved in water conservation.
- 51.3** This may have arisen independently in both the mammalian and avian lineages, or lost from the reptilian lineage.
- 51.4** Nitrogenous waste is a problem because it is toxic, and it is a result of degrading old proteins.
- 51.5** This would increase the osmolarity within the tubule system, and thus increase decrease reabsorption of water. This would lead to loss of water.
- 51.6** Blocking aquaporin channels would prevent reabsorption of water from the collecting duct.

### UNDERSTAND

1. d 2. a 3. c 4. c 5. d 6. d 7. d

### APPLY

1. d 2. c 3. b 4. b 5. c 6. b

### SYNTHESIZE

- 1a. Antidiuretic hormone (ADH) is produced in the hypothalamus and is secreted by the posterior pituitary. ADH targets the collecting duct of the nephron and stimulates the reabsorption of water from the urine by increasing the permeability of water in the walls of the duct. The primary stimulus for ADH secretion is an increase in the osmolarity of blood.
- 1b. Aldosterone is produced and secreted by the adrenal cortex in response to a drop in blood  $\text{Na}^+$  concentration. Aldosterone stimulates the distal convoluted tubules to reabsorb  $\text{Na}^+$ , decreasing the excretion of  $\text{Na}^+$  in the urine. The reabsorption of  $\text{Na}^+$  is followed by  $\text{Cl}^-$  and water, and so aldosterone has the net effect of retaining both salt and water. Aldosterone secretion however, is not stimulated by a decrease in blood osmolarity, but rather by a decrease in blood volume. A group of cells located at the base of the glomerulus, called the juxtaglomerular apparatus, detect drops in blood volume that then stimulates the renin-angiotensin-aldosterone system.
- 1c. Atrial natriuretic hormone (ANH) is produced and secreted by the right atrium of the heart, in response to an increase in blood volume. The secretion of ANH results in the reduction of aldosterone secretion. With the secretion of ANH, the distal convoluted tubules reduce the amount of  $\text{Na}^+$  that is reabsorbed, and likewise reduces the amount of  $\text{Cl}^-$  and water that is reabsorbed. The final result is the reduction in blood volume.

His normal renal blood flow rate would be 21% of cardiac output, or  $7.2 \text{ L/min} \times 0.21 = 1.5 \text{ L/min}$ .  
If John's kidneys are not affected by his circulatory condition, his renal blood flow rate should be about 1.5 L/min.

## CHAPTER 52

### LEARNING OUTCOME QUESTIONS

- 52.1** No, innate immunity shows some specificity for classes of molecules common to pathogens.
- 52.2** Hematopoietic stem cells.
- 52.3** T-cell receptors are rearranged to generate a large number of different receptors with specific binding abilities. Toll-like receptors are not rearranged, and recognize specific classes of molecules, not specific molecules.
- 52.4** Ig receptors are rearranged to generate many different specificities. TLR innate receptors are not rearranged and bind to specific classes of molecules.
- 52.5** Allergies are a case of the immune system overreacting while autoimmune disorders involve the immune system being compromised.
- 52.6** Diagnostic kits use monoclonal antibodies because they are against a single specific epitope of an antigen. They also use cells that can be grown in culture, and do not require immunizing an animal, bleeding them and then isolating the antibodies from their sera.
- 52.7** The main difference between Polio and influenza is the rate at which the viruses can change. The Polio virus is a RNA virus with a genome that consists of a single RNA. The viral surface proteins do not change rapidly allowing immunity via a vaccine. Influenza is an RNA virus with a high mutation rate, which means that surface proteins change rapidly. Influenza has a genome that consists of multiple RNAs, which allows recombination of the different viral RNAs during infection with different strains.

### INQUIRY QUESTIONS

- Page 1059** The viruses would be liberated into the body where they could infect numerous additional cells.
- Page 1063** The antigenic properties of the two viruses must be similar enough that immunity to cowpox also enables protection against smallpox.
- Page 1074** The common structure and mechanism of formation of B cell immunoglobulins (Igs) and T-cell receptors (TCRs) suggests a common ancestral form of adaptive immunity gave rise to the two cell lines existing today.
- Page 1078** A high level of HCG in a urine sample will block the binding of the antibody to HCG-coated particles and prevent any agglutination.
- Page 1079** Influenza frequently alters its surface antigens making it impossible to produce a vaccine with a long-term effect. Smallpox virus has a considerably more stable structure.

### UNDERSTAND

### APPLY

1. d 2. c 3. c 4. a. b., then d., then c 5. c 6. b 7. a

### SYNTHESIZE

- It would be difficult to advertise this lotion as immune-enhancing. The skin serves as a barrier to infection because it is oily and acidic. Applying a lotion that is watery and alkaline will dilute the protective effects of the skin secretions, thereby inhibiting the immune functions. Perhaps it is time to look for another job.
- The scratch has caused an inflammatory response. Although it is very likely that some pathogens entered her body through the broken skin, the response is actually generated by the injury to her tissue. The redness is a result of the increased dilation of blood vessels caused by the release of histamine. This also increases the temperature of the skin by bringing warm blood closer to the surface. Leakage of fluid from the vessels causes swelling in the area of the injury, which can cause pressure on the pain sensors in the skin. All of these serve to draw defensive cells and molecules to the injury site, thereby helping to defend her against infection.
- There are a number of ways that this could be done. However, one method would be to show that viral genetic material never appears within the cells of those who claim immunity. Another method would involve testing for the presence of interferon, which is released by cells in response to viral infection.

- These data imply that innate immunity is a very ancient defense mechanism. The presence of these proteins in Cnidarians indicates that they arose soon after multicellularity.

## CHAPTER 53

### LEARNING OUTCOME QUESTIONS

- 53.1** Genetic sex determination essentially guarantees equal sex ratios; when sex ratios are not equal, the predominant sex is selected against because those individuals have more competition for mates. Temperature-dependent sex-determination can result in skewed sex ratios in which one sex or the other is selected against. Genetic sex determination, on the other hand, can provide much greater stability within the population, and consequently the genetic characteristics that provide that stability are selected for.
- 53.2** Estrous cycles occur in most mammals, and most mammalian species have relatively complex social organizations and mating behaviors. The cycling of sexual receptivity allows for these complex mating systems. Specifically, in social groups where male infanticide is a danger, synchronized estrous among females may be selected for as it would eliminate the ability of the male to quickly impregnate the group females. Physiologically, estrous cycles result in the maturation of the egg accompanying the hormones that promote sexual receptivity.
- 53.3** In mating systems where males compete for mates, sperm competition, a form of sexual selection, is very common. In these social groups, multiple males may mate with a given female, and thus those individuals who produced the highest number of sperm would have a reproductive advantage—a higher likelihood of siring the offspring.
- 53.4** The answer varies depending upon the circumstances. In a species that is very r-selected, in other words, one that reproduces early in life and often but does not invest much in the form of parental care, multiple offspring per pregnancy would definitely be favored by natural selection. In K-selected species where parental care is very high, on the other hand, single births might be favored because the likelihood of offspring survival is greater if the parental resources are not divided among the offspring.
- 53.5** The birth control pill works by hormonally controlling the ovulation cycle in women. By releasing progesterone continuously the pill prevents ovulation. Ovulation is a cyclical event and under hormonal control, thus it is easy for the process to be controlled artificially. In addition, the female birth control pill only has to halt the release of a single ovum. An analogous male birth control pill, on the other hand, would have to completely cease sperm production (and men produce millions of sperm each day), and such hormonal upheaval in the male could lead to infertility or other intolerable side effects.

### INQUIRY QUESTIONS

- Page 1085** The ultimate goal of any organism is to maximize its relative fitness. Small females are able to reproduce but once they become very large they would be better able to maximize their reproductive success by becoming male, especially in groups where only a few males mate with all of the females. Protandry might evolve in species where there is a limited supply of mates and relatively little space; a male of such a species in close proximity to another male would have higher reproductive success by becoming female and mating with the available male than by waiting for a female (and then having to compete for her with the other male).
- Page 1088** The evolutionary progression from oviparity to viviparity is a complex process; requiring the development of a placenta or comparable structure. Once a complex structure evolves, it is rare for an evolutionary reversal to occur. Perhaps more importantly, there are several advantages to viviparity over oviparity, especially in cold environments where eggs are vulnerable to mortality due to cold weather (and predation). In aquatic reptiles such as sea snakes, viviparity allows the female to remain at sea and avoid coming ashore, where both she and her eggs would be exposed to predators.
- Page 1094** Under normal circumstances, the testes produce hormones, testosterone and inhibin, which exert negative feedback inhibition on the hormones produced and secreted by the anterior pituitary (luteinizing hormone and follicle-stimulating hormone). Following castration, testosterone and inhibin are no longer produced and thus the brain will overproduce LH and FSH. For this reason, hormone therapy is usually prescribed following castration.

### APPLY

1. a 2. b 3. d 4. a

## SYNTHESIZE

1. A mutation that makes *SRY* nonfunctional would mean that the embryo would lack the signal to form male structures during development. Therefore, the embryo would have female genitalia at birth.
2. Amphibians and fish that rely on external fertilization also have access to water. Lizards, birds, and mammals have adaptations that allow them to reproduce away from a watery environment. These adaptations include eggs that have protective shells or internal development, or both.
3. FSH and LH are produced by the anterior pituitary in both males and females. In both cases they play roles in the production of sex hormones and gametogenesis. However, FSH stimulates spermatogenesis in males and oogenesis in females, whereas LH promotes the production of testosterone in males and estradiol in females.
4. It could indeed work. The hormone hCG is produced by the zygote to prevent menstruation, which would in turn prevent implantation in the uterine lining. Blocking the hormone receptors would prevent implantation and therefore pregnancy.
5. Parthenogenic species reproduce from gametes that remain diploid. Sperm are haploid, whereas eggs do not complete meiosis (becoming haploid) until after fertilization. Therefore, only eggs could develop without DNA from an outside source. In addition, only eggs have the cellular structures needed for development. Therefore only females can undergo parthenogenesis.

## CHAPTER 54

### LEARNING OUTCOME QUESTIONS

**54.1**  $\text{Ca}^{2+}$  ions act as second messengers and bring about changes in protein activity that result in blocking polyspermy and increasing the rate of protein synthesis within the egg.

**54.2** In a mammal, the cells at the four-cell stage are still uncommitted and thus separating them will still allow for normal development. In frogs, on the other hand, yolk distribution results in displaced cleavage; thus, at the four-cell stage the cells do not each contain a nucleus which contains the genetic information required for normal development.

**54.3** The cellular behaviors necessary for gastrulation differ across organisms; however, some processes are necessary for any gastrulation to occur. Specifically, cells must rearrange and migrate throughout the developing embryo.

**54.4** No—neural crest cell fate is determined by its migratory pathway.

**54.5** Marginal zone cells in both the ventral and dorsal regions express bone morphogenetic protein 4 (BMP4). The fate of these cells is determined by the number of receptors on the cell membrane to bind to BMP4; greater BMP4 binding will induce a ventral mesodermal fate. The organizer cells, which previously were thought to activate dorsal development, have been found to actually inhibit ventral development by secreting one of many proteins that block the BMP4 receptors on the dorsal cells.

**54.6** Most of the differentiation of the embryo, in which the initial structure formation occurs, happens during the first trimester; the second and third trimesters are primarily times of growth and organ maturation, rather than the actual development and differentiation of structures. Thus, teratogens are most potent during this time of rapid organogenesis.

### INQUIRY QUESTION

**Page 1127** High levels of estradiol and progesterone in the absence of pregnancy would still affect the body in the same way. High levels of both hormones would inhibit the release of FSH and LH, thereby preventing ovulation. This is how birth control pills work. The pills contain synthetic forms of either both estradiol and progesterone or just progesterone. The high levels of these hormones in the pill trick the body into thinking that it is pregnant and so the body does not ovulate.

### APPLY

1. c 2. b 3. a 4. a 5. d 6. b 7. c

### SYNTHESIZE

1. By starting with a series of embryos at various stages, you could try removing cells at each stage. Embryos that failed to compensate for the removal (evidenced by missing structures at maturity) would be those that lost cells after they had become committed; that is, when their fate has been determined.

2. Homeoboxes are sequences of conserved genes that play crucial roles in development of both mammals (Fifi) and *Drosophila* (the fruit fly). In fact, we know that they are more similar than dissimilar; research has demonstrated that both groups use the same transcription factors during organogenesis. The major difference between them is in the genes that are transcribed. Homeoboxes in mammals turn on genes that cause the development of mammalian structures, and those in insects would generate insect structures.
3. After fertilization, the zygote produces hCG, which inhibits menstruation and maintains the corpus luteum. At 10 weeks gestation, the placenta stops releasing hCG but it does continue to release estradiol and progesterone, which maintain the uterine lining and inhibit the pituitary production of FSH and LH. Without FSH and LH no ovulation and no menstruation occur.
4. Spemann and Mangold removed cells from the dorsal lip of one amphibian embryo and transplanted them to a different location on a second embryo. The transplanted cells caused cells that would normally form skin and belly to instead form somites and the structures associated with the dorsal area. Because of this and because the secondary dorsal structures contained both host and transplanted cells, Spemann and Mangold concluded that the transplanted cells acted as organizers for dorsal development.

## CHAPTER 55

### LEARNING OUTCOME QUESTIONS

**55.1** Just as with morphological characteristics that enhance an individual's fitness, behavioral characteristics can also affect an individual's survivability and reproductive success. Understanding the evolutionary origins of many behaviors allows biologists insights into animal behavior, including that of humans.

**55.2** A male songbird injected with testosterone prior to the usual mating season would likely begin singing prior to the usual mating season. However, since female mating behavior is largely controlled by hormones (estrogen) as well, most likely that male will not have increased fitness (and may actually have decreased fitness, if the singing stops before the females are ready to mate, or if the energetic expenditure from singing for two additional weeks is compensated by reduced sperm production).

**55.3** The genetic control over pair-bonding in prairie voles has been fairly well-established. The fact that males sometimes seek extra-pair copulations indicates that the formation of pair-bonds is under not only genetic control but also behavioral control.

**55.4** In species where males travel farther from the nest (and thus have larger range sizes), there should be significant sex differences in spatial memory. However, in species without sexual differences in range sizes should not express sex differences in spatial memory. To test the hypothesis you could perform maze tests on males and females of species with sex differences in range size as well as those species without range size differences between the sexes. (NOTE: such experiments have been performed and do support the hypothesis that there is a significant correlation between range size and spatial memory, so in species with sex differences in range size there are indeed sex differences in spatial memory. See Jones, CM et al., 2003. "The Evolution of Sex Differences in Spatial Ability." *Behavioral Neuroscience*. 117(3): 403-411)

**55.5** Although there may be a link between IQ and genes in humans, there is most certainly also an environmental component to IQ. The danger of assigning a genetic correlation to IQ lies in the prospect of selective "breeding" and the emergence of "designer babies."

**55.6** One experiment that has been implemented in testing counting ability among different primate and bird species is to present the animal with a number and have him match the target number to one of several arrays containing that number of objects. In another experiment, the animal may be asked to select the appropriate number of individual items within an array of items that equals the target number.

**55.7** Butterflies and birds have extremely different anatomy and physiology and thus most likely use very different navigation systems. Birds generally migrate bi-directionally; moving south during the cold months and back north during the warmer months. Usually, then, migrations are multi-generational events and it could be argued that younger birds can learn migratory routes from older generations. Butterflies, on the other hand, fly south to breed and die. Their offspring must then fly north having never been there before.

**55.8** In addition to chemical reproductive barriers, many species also employ behavioral and morphological reproductive barriers, such that even if a female moth is attracted by the pheromones of a male of another species, the two may be behaviorally or anatomically incompatible.

**55.9** The benefits of territorial behavior must outweigh the potential costs, which may include physical danger due to conflict, energy expenditure, and the loss of foraging or mating time. In a flower that is infrequently encountered, the

honeycreeper would lose more energy defending the resource than it could gain by utilizing the resource. On the other hand, there is usually low competitive pressure for highly abundant resources, thus the bird would expend unnecessary energy defending a resource to which its access is not limited.

**55.10** The males should exhibit mate choice, as they are the sex with the greater parental investment and energy expenditure; thus, like females of most species, they should be the “choosier” sex.

**55.11** Generally, reciprocal behaviors are low-cost while behaviors due to kin selection may be low- or high-cost. Protecting infants from a predator is definitely a high-risk / potentially high-cost behavior; thus it would seem that the behavior is due to kin selection. The only way to truly test this hypothesis, however, is to conduct genetic tests or, in a particularly well-studied population, consult a pedigree.

Living in a group is associated with both costs and benefits. The primary cost is increased competition for resources, while the primary benefit is protection from predation. Altruism toward kin is considered selfish because helping individuals closely related to you will directly affect your inclusive fitness. Most armies more closely resemble insect societies than vertebrate societies. Insect societies consist of multitudes of individuals congregated for the purpose of supporting and defending a select few individuals. One could think of these few protected and revered individuals as the society the army is charged with protecting. These insect societies, like human armies, are composed of individuals each “assigned” to a particular task. Most vertebrate societies, on the other hand, are less altruistic and express increased competition and aggression between group members. In short, vertebrate societies are comprised of individuals whose primary concern is usually their own fitness, while insect societies are comprised of individuals whose primary concern is the colony itself.

## INQUIRY QUESTIONS

**Page 1135** Selection for learning ability would cease, and thus change from one generation to the next in maze learning ability; would only result from random genetic drift.

**Page 1136** Normal *fosB* alleles produce a protein that in turn affects enzymes that affect the brain. Ultimately, these enzymes trigger maternal behavior. In the absence of the enzymes, normal maternal behavior does not occur.

**Page 1140** Peter Marler’s experiments addressed this question and determined that both instinct and learning are instrumental in song development in birds.

**Page 1148** Many factors affect the behavior of an animal other than its attempts to maximize energy intake. For example, avoiding predation is also important. Thus, it may be that larger prey take longer to subdue and ingest, thus making the crabs more vulnerable to predators. Hence, the crabs may trade off decreased energy gain for decreased vulnerability for predators. Many other similar explanations are possible.

**Page 1150** A question that is the subject of much current research. Ideas include the possibility that males with longer tails are in better condition (because males in poor condition couldn’t survive the disadvantage imposed by the tail). The advantage to a female mating with a male in better condition might be either that the male is less likely to be parasitized, and thus less likely to pass that parasite on to the female, or the male may have better genes, which in turn would be passed on to the offspring. Another possibility is the visual system for some reason is better able to detect males with long tails, and thus long-tailed males are preferred by females simply because the longer tails are more easily detected and responded to.

**Page 1151** Yes, the larger the male, the larger the prenuptial gift, which provides energy that the female converts into egg production.

**Page 1158** If more birds are present, then each one can spend less time watching for predators, and thus have more time for foraging.

## APPLY

1. Presumably, the model is basic, taking into account only size and energetic value of mussels. However, it may be that larger mussels are in places where shore crabs would be exposed to higher levels of predation or greater physiological stress. Similarly, it could be that the model underestimated time costs or energy returns as a function of mussel size. In the case of large mussels being in a place where shore crabs are exposed to costs not considered by the model, one could test the hypothesis in several ways. First, how are the sizes of mussels distributed in space? If they are completely interspersed that would tend to reject the hypothesis. Alternatively, if the mussels were differentially distributed such that the hypothesis was

reasonable, mussels could be experimentally relocated (change their distribution in space) and the diets would be expected to shift to match more closely the situation predicted by the model.

2. The four new pairs may have been living in surrounding habitat that was of lower quality, or they may have been individuals that could not compete for a limited number of suitable territories for breeding. Often, the best territories are won by the most aggressive or largest or otherwise best competitors, meaning that the new territory holders would likely have been less fierce competitors. If new residents were weaker competitors (due to aggression or body size), then the birds not removed would have been able to expand their territories to acquire even more critical resources.
3. The key here is that if the tail feathers are a handicap, then by reducing the handicap in these males should enhance their survival compared with males with naturally shorter tail feathers. The logic is simple. If the male with long tail feathers is superior such that it can survive the negative effect of the long tail feathers, then that superior phenotype should be “exposed” with the removal or reduction of the tail feathers. Various aspects of performance could be measured since it is thought that the tail feathers hinder flying. Can males with shorter tails fly faster? Can males with shorter tails turn better? Ultimately, whether males with shorter tails survive better than males with un-manipulated tails can be measured.
4. Both reciprocity and kin selection explain the evolution of altruistic acts by examining the hidden benefits of the behavior. In both cases, altruism actually *benefits* the individual performing the act in terms of its fitness effects. If it didn’t, it would be very hard to explain how such behavior could be maintained because actions that reduce the fitness of an individual should be selected against. Definition of the behavior reflects the apparent paradox of the behavior because it focuses on the cost and not the benefit that also accrues to the actor.

## SYNTHESIZE

1. The best experiment for determining whether predatory avoidance of certain coloration patterns would involve rearing a predator without an opportunity to learn avoidance and subsequently presenting the predator with prey with different patterns. If the predator avoids the black and yellow coloration more frequently than expected then the avoidance is most likely innate. If the predator does not express any preference but upon injury from a prey with the specific coloration does begin to express a preference, then the avoidance is most likely learned. In this case, the learning would be operant conditioning; the predator has learned to associate the coloration with pain and thus subsequently avoids prey with that coloration. To measure the adaptive significance of black and yellow coloration, both poisonous (or stinging) and harmless prey species with the coloration and without the coloration pattern could be presented to predators; if predators avoid both the harmful and the harmless prey, the coloration is evolutionary significant.
2. In many cases the organisms in question are unavailable for or unrealistic to study in a laboratory setting. Model organisms allow behavioral geneticists to overcome this obstacle by determining general patterns and then applying these patterns and findings to other, similar organisms. The primary disadvantage of the model system is, of course, the vast differences that are usually found between groups of taxa; however, when applying general principles, in particular those of genetic behavioral regulation, the benefits of using a model outweigh the costs. Phylogenetic analysis is the best way to determine the scale of applicability when using model organisms.
3. Extra-pair copulations and mating with males that are outside a female’s territory are, by and large, more beneficial than costly to the female. By mating with males outside her territory, she reduces the likelihood that a male challenging the owner of her territory would target her offspring; males of many species are infanticidal but would not likely attack infants that could be their own. Historical data have actually shown that in many cases, females are more attracted to infanticidal males if those males win territory prior to their infanticidal behavior.

## CHAPTER 56

### LEARNING OUTCOME QUESTIONS

**56.1** It depends upon the type of species in question. Conformers are able to adapt to their environment by adjusting their body temperature and making other physiological adjustments. Over a longer period of time, individuals within a non-conforming species might not adjust to the changing environment but we would expect the population as a whole to adapt due to natural selection.

**56.2** If the populations in question comprised a source-sink metapopulations, then the lack of immigration into the sink populations would, most likely, eventually result in the extinction of those populations. The source populations would likely then increase their geographic ranges.

**56.3** It depends upon the initial sizes of the populations in question; a small population with a high survivorship rate will not necessarily grow faster than a large population with a lower survivorship rate.

**56.4** A species with high levels of predation would likely exhibit an earlier age at first reproduction and shorter inter-birth intervals in order to maximize its fitness under the selective pressure of the predation. On the other hand, species with few predators have the luxury of waiting until they are more mature before reproducing and can increase the inter-birth interval (and thus invest more in each offspring) because their risk of early mortality is decreased.

**56.5** Many different factors might affect the carrying capacity of a population. For example, climate changes, even on a relatively small scale, could have large effects on carrying capacity by altering the available water and vegetation, as well as the phenology and distribution of the vegetation. Regardless of the type of change in the environment, however, most populations will move toward carrying capacity; thus, if the carrying capacity is lowered, the population should decrease, and if the carrying capacity is raised, the population should increase.

**56.6** A given population can experience both positive and negative density-dependent effects, but not at the same time. Negative density-dependent effects, such as low food availability or high predation pressure, would decrease the population size. On the other hand, positive density-dependent effects, such as is seen with the Allee effect, results in a rapid increase in population size. Since a population cannot both increase and decrease at the same time, the two cannot occur concurrently. However, the selective pressures on a population are on a positive-negative continuum, and the forces shaping population size can not only vary in intensity but can also change direction from negative to positive or positive to negative.

**56.7** The two are closely tied together, and both are extremely important if the human population is not to exceed the Earth's carrying capacity. As population growth increases, the human population approaches the planet's carrying capacity; as consumption increases, the carrying capacity is lowered—thus, both trends must be reversed.

## INQUIRY QUESTIONS

**Page 1164** Very possibly. How fast a lizard runs is a function of its body temperature. Researchers have shown that lizards in shaded habitats have lower temperatures and thus lower maximal running speeds. In such circumstances, lizards often adopt alternative escape tactics that rely less on rapidly running away from potential predators.

**Page 1169** Because of their shorter generation times, smaller species tend to reproduce more quickly, and thus would be able to respond more quickly to increased resources in the environment.

**Page 1171** Based on the survivorship curve of meadow grass, the older the plant, the less likely it is to survive. It would be best to choose a plant that is very young to ensure the longest survival as a house plant. A survivorship curve that is shaped like a Type I curve, in which most individuals survive to an old age and then die would also lead you to select a younger plant. A type III survivorship curve, in which only a few individuals manage to survive to an older age, would suggest the selection of a middle-aged plant that had survived the early stages of life since it would also be more likely to survive to old age.

**Page 1172** It depends on the situation. If only large individuals are likely to reproduce (as is the case in some territorial species, in which only large males can hold a territory), then a few large offspring would be favored; alternatively, if body size does not affect survival or reproduction, then producing as many offspring as possible would maximize the representation of an individual's genes in subsequent generations. In many cases, intermediate values are favored by natural selection.

**Page 1174** Because when the population is below carrying capacity, the population increases in size. As it approaches the carrying capacity, growth rate slows down either from increased death rates, decreased birthrates, or both, becoming zero as the population hits the carrying capacity. Similarly, populations well above the carrying capacity will experience large decreases in growth rate, resulting either from low birthrates or high death rates, that also approach zero as the population hits the carrying capacity.

**Page 1175** There are many possible reasons. Perhaps resources become limited, so that females are not able to produce as many offspring. Another possibility is that space is limited so that, at higher populations, individuals spend more time in interactions with other individuals and squander energy that otherwise could be invested in producing and raising more young.

**Page 1176** The answer depends on whether food is the factor regulating population size. If it is, then the number of young produced at a given population size would increase and the juvenile mortality rate would decrease. However, if other factors, such as the availability of water or predators, regulated population size, then food supplementation might have no effect.

**Page 1177** If hare population levels were kept high, then we would expect lynx populations to stay high as well because lynx populations respond to food availability. If lynx populations were maintained at a high level, we would expect hare populations to remain low because increased reproduction of hares would lead to increased food for the lynxes.

**Page 1179** If human populations are regulated by density-dependent factors, then as the population approaches the carrying capacity, either birthrates will decrease or death rates will increase, or both. If populations are regulated by density-independent factors, then if environmental conditions change, then either both rates will decline, death rates will increase, or both.

**Page 1179** The answer depends on whether age-specific birth and death rates stay unchanged. If they do, then the Swedish distribution would remain about the same. By contrast, because birthrates are far outstripping death rates, the Kenyan distribution will become increasingly unbalanced as the bulge of young individuals enter their reproductive years and start producing even more offspring.

**Page 1181** Both are important causes and the relative importance of the two depends on which resource we are discussing. One thing is clear: The world cannot support its current population size if everyone lived at the level of resource consumption of people in the United States.

## APPLY

1. d 2. c 3. b 4. c

## SYNTHESIZE

1. The genetic makeup of isolated populations will change over time based on the basic mechanisms of evolutionary change; for example, natural selection, mutation, assortative mating, and drift. These same processes affect the genetic makeup of populations in a metapopulation, but the outcomes are likely to be much more complicated. For example, if immigration between a source and a sink population is very high, then local selection in a sink population may be swamped by the regular flow of individuals carrying alleles of lower fitness from a source population where natural selection may not be acting against those alleles; divergence might be slowed or even stopped under some circumstances. On the other hand, if sinks go through repeated population declines such that they often are made up of a very small number of individuals, then they may lose considerable genetic diversity due to drift. If immigration from source populations is greater than zero but not large, these small populations might begin to diverge substantially from other populations in the metapopulation due to drift. The difference is that in the metapopulation, such populations might actually be able to persist and diverge, rather than just going extinct due to small numbers of individuals and no ability to be rescued by neighboring sources.
2. The probability that an animal lives to the next year should decline with age (Note that in Figure 55.11, all the curves decrease with age) so the cost of reproduction for an old animal would, all else being equal, be lower than for a young animal. The reason is that the cost of reproduction is measured by changes in fitness. Imagine a very old animal that has almost no chance in surviving to another reproductive event; it should spend all its effort on a current reproductive effort since its future success is likely to be zero anyway.
3. If offspring size does not affect offspring quality, then it is in the parent's interest to produce absolutely as many small offspring as possible. In doing so, it would be maximizing its fitness by increasing the number of related individuals in the next generation.
4. By increasing the mean generation time (increasing the age at which an individual can begin reproducing; age at first reproduction), keeping all else equal, one would expect that the population growth rate would be reduced. That comes simply from the fact of reducing the number of individuals that are producing offspring in the adult age classes; lower population birth rates would lead to a reduced population growth rate. As to which would have a larger influence, that is hard to say. If the change in generation time (increased age at first reproduction) had an overall larger effect on the total number of offspring an individual female had than a reduced fecundity at any age, then population growth rate would probably be more sensitive to the

change in generation time. Under different scenarios, the comparison of these two effects could become more complicated, however. Suffice it to say that population growth control can come from more than one source: fecundity and age at first reproduction.

## CHAPTER 57

### LEARNING OUTCOME QUESTIONS

- 57.1** The answer depends upon the habitat of the community in question. Some habitats are more hospitable to animals, and others to plants. The abundance of plants and animals in most habitats is also closely tied; thus the variation in abundance of one would affect the variation in abundance of the other.
- 57.2** It depends upon whether we are talking about fundamental niche or realized niche. Two species can certainly have identical fundamental niches and coexist indefinitely, because they could develop different realized niches within the fundamental niche. In order for two species with identical realized niches to coexist indefinitely, the resources within the niche must not be limited.
- 57.3** This is an example of Batesian mimicry, in which a non-poisonous species evolves coloration similar to a poisonous species.
- 57.4** In an ecosystem with limited resources and multiple prey species, one prey species could out-compete another to extinction in the absence of a predator. In the presence of the predator, however, the prey species that would have otherwise been driven to extinction by competitive exclusion is able to persist in the community. The predators that lower the likelihood of competitive exclusion are known as keystone predators.
- 57.5** Selective harvesting of individual trees would be preferable from a community point of view. According to the Intermediate Disturbance Hypothesis, moderate degrees of disturbance, as in selective harvesting, increase species richness and biodiversity more than severe disturbances, such as clear-cutting.

### INQUIRY QUESTIONS

**Page 1187** The different soil types require very different adaptations, and thus different species are adapted to each soil type.

**Page 1191** The kangaroo rats competed with all the other rodent species for resources, keeping the size of other rodent populations smaller. In the absence of competition when the kangaroo rats were removed, there were more resources available which allowed the other rodent populations to increase in size.

**Page 1192** This could be accomplished in a variety of ways. One option would be to provide refuges to give some *Paramecium* a way of escaping the predators. Another option would be to include predators of the *Didinium*, which would limit their populations (see Ecosystem chapter).

**Page 1201** By removing the kangaroo rats from the experimental enclosures and measuring the effects on both plants and ants. At first, the number of small seeds available to ants increases due to the absence of rodents. However, over time, plants that produce large seeds outcompete plants that produce small seeds, and thus fewer small seeds are produced and available to ants; hence, ant populations decline.

### UNDERSTAND

1. a 2. a 3. d 4. a 5. b 6. d 7. c 8. c

### APPLY

1. d 2. b 3. d 4. d 5. d

### SYNTHESIZE

1. Experiments are useful means to test hypotheses about ecological limitations, but they are generally limited to rapidly reproducing species that occur in relatively small areas. Alternative means of studying species' interactions include detailed studies of the mechanisms by which species might interact; sometimes, for long-lived species, instead of monitoring changes in population size, which may take a very long time, other indices can be measured, such as growth or reproductive rate. Another means of assessing interspecific interactions is to study one species in different areas, in only some of which a second species occurs. Such studies must be interpreted cautiously, however, because there may be many important differences between the areas in addition to the difference in the presence or absence of the second species.
2. Adding differentially preferred prey species might have the same effect as putting in a refuge for prey in the single species system. One way to think about it is that if a highly preferred species becomes rare due to removal by the predator, then a predator might switch to a less desirable species, even if it

doesn't taste as good or is harder to catch, simply because it is still provides a better return than chasing after a very rare preferred species. While the predator has switched, there might be enough time for the preferred species to rebound. All of these dynamics will depend upon the time it takes a predator to reduce the population size of its prey relative to the time it takes for those prey populations to rebound once the predator pressure is removed.

3. Although the mechanism might be known in this system, hidden interactions might affect interpretations in many ways because ecological systems are complex. For example, what if some other activity of the rodents besides their reduction of large seeds leading to an increase in the number of small seeds was responsible for the positive effect of rodents on ants? One way to test the specific mechanism would be to increase the abundance of small seeds experimentally independent of any manipulation of rodents. Under the current hypothesis, an increase in ant population size would be expected and should be sustained, unlike the initial increase followed by a decrease seen when rodents are removed.
4. By itself, the pattern shown in Figure 56.7 suggests character displacement, but alternative hypotheses are possible. For example, what if the distribution of seeds available on the two islands where the species are found alone is different from that seen where they are found in sympatry? If there were no large and small seeds seen on Los Hermanos or Daphne, just medium-sized ones, then it would be hard to conclude that the bill size on San Cristobal has diverged relative to the other islands just due to competition. This is a general criticism of inferring the process of character displacement with just comparing the size distributions in allopatry and sympatry. In this case, however, the Galápagos system has been very well studied. It has been established that the size distribution of seeds available is not measurably different. Furthermore, natural selection-induced changes seen in the bill size of birds on a single island, in response to drought-induced changes in seed size lend further support to the role of competition in establishing and maintaining these patterns.
5. It is possible, as the definition of an ecosystem depends upon scale. In some ecosystems, there may be other, smaller ecosystems operating within it. For example, within a rainforest ecosystem, there are small aquatic ecosystems, ecosystems within the soil, ecosystems upon an individual tree. Research seems to indicate that most species behave individually, but there are some instances where groups of species do depend upon one another and do function holistically. We would expect this kind of dual community structure especially in areas of overlap between distinct ecosystems, where ecotones exist.

## CHAPTER 58

### LEARNING OUTCOME QUESTIONS

**58.1** Yes, fertilization with natural materials such as manure is less disruptive to the ecosystem than is chemical fertilization. Many chemical fertilizers, for example, contain higher levels of phosphates than does manure and thus chemical fertilization has disrupted the natural global phosphorus cycle.

**58.2** Both matter and energy flow through ecosystems by changing form, but neither can be created or destroyed. Both matter and energy also flow through the trophic levels within an ecosystem. The flow of matter such as carbon atoms is more complex and multi-leveled than is energy flow, largely because it is truly a cycle. The atoms in the carbon cycle truly cycle through the ecosystem, with no clear beginning or end. The carbon is changed during the process of cycling from a solid to a gaseous state and back again. On the other hand, energy flow is unidirectional. The ultimate source of the energy in an ecosystem is the sun. The solar energy is captured by the primary producers at the first trophic level and is changed in form from solar to chemical energy. The chemical energy is transferred from one trophic level to another, until only heat, low quality energy, remains.

**58.3** Yes, there are certainly situations in ecosystems in which the top predators in one trophic chain affect the lower trophic levels, while within the same ecosystem the primary producers affect the higher trophic levels within another trophic chain.

**58.4** It depends on whether the amount of sunlight captured by the primary producers was affected. Currently, only approximately 1% of the solar energy in Earth's atmosphere is captured by primary producers for photosynthesis. If less sunlight reached Earth's surface, but a correlating increase in energy capture accompanied the decrease in sunlight, then the primary productivity should not be affected.

**58.5** The equilibrium model of island biogeography describes the relationship between species richness and not only island size but also distance from the mainland. A small island closer to the mainland would be expected to have more species than would a larger island that is farther from the mainland.

## INQUIRY QUESTIONS

**Page 1218** At each link in the food chain, only a small fraction of the energy at one level is converted into mass of organisms at the next level. Much energy is dissipated as heat or excreted.

**Page 1219** In the inverted pyramid, the primary producers reproduce quickly and are eaten quickly, so that at any given time, a small population of primary producers exist relative to the heterotroph population.

**Page 1220** Because the trout eat the invertebrates which graze the algae. With fewer grazers, there is more algae.

**Page 1220** The snakes might reduce the number of fish, which would allow an increase in damselflies, which would reduce the number of chironomids and increase the algae. In other words, lower levels of the food chain would be identical for the “snake and fish” and “no fish and no snake” treatments. Both would differ from the enclosures with only fish.

**Page 1222** Herbivores consume much of the algal biomass even as primary productivity increases. Increases in primary productivity can lead to increased herbivore populations. The additional herbivores crop the biomass of the algae even while primary productivity increases.

**Page 1222** More light means more photosynthesis. More plant material means more herbivores, which translates into more predator biomass.

**Page 1223** Introduce them yourself. For example, each spring, you could place a premeasured number of seeds of a particular invasive species in each plot. Such an experiment would have the advantage of more precisely controlling the opportunity for invasion, but also would be less natural, which is one of the advantages of the Cedar Creek study site: the plots are real ecosystems, interacting with their surrounding environment in natural ways.

**Page 1224** (a) Perhaps because an intermediate number of predators is enough to keep numbers of superior competitors down. (b) Perhaps because there are more habitats available and thus more different ways of surviving in the environment. (c) Hard to say. Possibly more stable environments permit greater specialization, thus permitting coexistence of more species.

1. d 2. a 3. d 4. d

## SYNTHESIZE

1. Because the length of food chains appears to be ultimately limited by the amount of energy entering a system, and the characteristic loss of usable energy (about 90%) as energy is transferred to each higher level, it would be reasonable to expect that the ectotherm-dominated food chains would be longer than the endotherm-dominated chains. In fact, there is some indirect evidence for this from real food chains, and it is also predicted by some advanced ecological models. However, whether in reality such is the case, is difficult to determine due to all of the complex factors that determine food chain length and structure. Moreover, there are many practical difficulties associated with measuring actual food chain length in natural systems.
2. It is critical to distinguish, as this chapter points out, between energy and mass transfer in trophic dynamics of ecosystems. The standing biomass of phytoplankton is not necessarily a reliable measure of the energy contained in the trophic level. If phytoplankton are eaten as quickly as they are produced, they may contribute a tremendous amount of energy, which can never be directly measured by a static biomass sample. The standing crop therefore, is an incomplete measure of the productivity of the trophic level.
3. As Figure 58.17 suggests, trophic structure and dynamics are interrelated and are primary determinants of ecosystem characteristics and behavior. For example, if a particularly abundant herbivore is threatened, energy that is abundant at the level of primary productivity in an ecosystem may be relatively unavailable to higher trophic levels (e.g., carnivores). That is, the herbivores are an important link in transducing energy through an ecosystem. Cascading effects, whether they are driven from the bottom up or from the top down are a characteristic of energy transfer in ecosystems, and that translates into the reality that effects on any particular species are unlikely to be limited to that species itself.
4. There are many ways to answer this question, but the obvious place to start is to think about the many ways plant structural diversity potentially affects animals that are not eating the plants directly. For example, plants may provide shelter, refuges, food for prey, substrate for nesting, among other

things. Therefore, increasing complexity might increase the ability of lizards to partition the habitat in more ways, allow more species to escape their predators or seek refuge from harsh physical factors (such as, cold or hot temperatures), provide a greater substrate for potential prey in terms of food resources, for instance. If we want to know the exact mechanisms for the relationship, we would need to conduct experiments to test specific hypotheses. For example, if we hypothesize that some species that require greater structural complexity in order to persist in a particular habitat, we could modify the habitat (reduce plant structure) and test whether species originally present were reduced in numbers or became unable to persist.

## CHAPTER 59

### LEARNING OUTCOME QUESTIONS

**59.1** If the Earth rotated in the opposite direction, the Coriolis Effect would be reversed. In other words, winds descending between 30° north or 30° south and the equator would still be moving more slowly than the underlying surface so it would be deflected; however, they would be deflected to the left in the northern hemisphere and to the right in the southern hemisphere. The pattern would be reversed between 30° and 60° because the winds would be moving more rapidly than the underlying surface, and would thus be deflected again in the opposite directions from normal—to the left in the northern hemisphere and to the right in the southern hemisphere. All of this would result in Trade Winds that blew from west to east and “Westerlies” that were actually “Easterlies,” blowing east to west.

**59.2** As with elevation, latitude is a primary determinant of climate and precipitation, which together largely determine the vegetational structure of a particular area, which in turn defines biomes.

**59.3** The spring and fall overturns that occur in freshwater lakes found in temperate climates result in the oxygen-poor water near the bottom of the lake getting re-mixed with the oxygen-rich water near the top of the lake, essentially eliminating, at least temporarily, the thermocline layer. In the tropics, there is less temperature fluctuation; thus the thermocline layer is more permanent and the oxygen depletion (and resulting paucity of animal life) is sustained.

**59.4** Regions affected by the ENSO, or El Niño Southern Oscillation events, experience cyclical warming events in the waters around the coastline. The warmed water lowers the primary productivity, which stresses and subsequently decreases the populations of fish, seabirds, and sea mammals.

**59.5** CFCs, or chlorofluorocarbons, are an example of point-source pollution. CFCs and other types of point-source pollutants are, in general, easier to combat because their sources are more easily identified and thus the pollutants more easily eliminated.

**59.6** Global climate change and ozone depletion may be interconnected. However, while climate change and ozone depletion are both global environmental concerns due to the impact each has on human health, the environment, economics, and politics, there are some different approaches to combating and understanding each dilemma. Ozone depletion results in an increase in the ultraviolet radiation reaching the earth's surface. Global climate change, on the other hand, results in long-term changes in sea level, ice flow, and storm activity.

## INQUIRY QUESTIONS

**Page 1232** Because of the tilt of the Earth's axis and the spherical shape of the planet, the light (and heat) from the sun hits the equator and nearby latitudes more directly than it does at the poles.

**Page 1236** Increased precipitation and temperature allows for the sustainability of a larger variety and biomass of vegetation, and primary productivity is a measure of the rate at which plants convert solar energy into chemical energy.

## APPLY

1. d 2. b 3. c 4. b

## SYNTHESIZE

1. The Earth is tilted on its axis such that regions away from the equator receive less incident solar radiation per unit surface area (because the angle of incidence is oblique). The northern and southern hemispheres alternate between angling towards vs. away from the Sun on the Earth's annual orbit. These two facts mean that the annual mean temperature will decline as you move away from the equator, and that variation in the mean temperatures of

the northern and southern hemispheres will be complementary to each other; when one is hot, the other will be cold.

2. Energy absorbed by the Earth is maximized at the equator because of the angle of incidence. Because there are large expanses of ocean at the equator, warmed air picks up moisture and rises. As it rises, equatorial air, now saturated with moisture, cools and releases rain, the air falling back to Earth's surface displaced north and south to approximately 30°. The air, warming as it descends, absorbs moisture from the land and vegetation below, resulting in desiccation in the latitudes around 30°.
3. Even though there have been global climate changes in the past, conservation biologists are concerned about the current warming trend for two reasons. First, the warming rate is rapid, thus the selective pressures on the most vulnerable organisms may be too strong for the species to adapt. Second, the natural areas that covered most of the globe during past climatic changes are now in much more limited, restricted areas, thus greatly impeding the ability of organisms to migrate to more suitable habitats.
4. Two characteristics can lead to a phenomenon known as biological magnification. First, if a pesticide actually persists in the bodies of target species (that is, it doesn't degrade after having its effect), then depending on its chemical composition, it might actually be sequestered in the bodies of animals that eat the target species. Because large numbers of prey are consumed at each trophic level (due to the 10% rate of transfer of energy), large amounts of the pesticide may be passed up the food chain. So, persistence and magnification can lead to toxic exposures at the top of food chains.

## CHAPTER 60

### LEARNING OUTCOME QUESTIONS

**60.1** Unfortunately, most of the Earth's biodiversity hotspots are also areas of the greatest human population growth; human population growth is accompanied by increased resource utilization and exploitation.

**60.2** I would tell the shrimp farmers that if they were to shut down the shrimp farm and remediate the natural mangrove swamp on which their property sits, other, more economically lucrative businesses could be developed, such as timber, charcoal production, and offshore fishing.

**60.3** Absolutely. The hope of conservation biologists is that even if a species is endangered to the brink of extinction due to habitat degradation, the habitat may someday be restored. The endangered species can be bred in captivity (which also allows for the maintenance of genetic diversity within the species) and either re-introduced to a restored habitat, or even introduced to another suitable habitat.

**60.4** It depends upon the reason for the degradation of the habitat in the first place, but yes, in some cases, habitat restoration can approach a pristine state. For example, the Nashua River in New England was heavily polluted, but habitat restoration efforts returned it to a relatively pristine state. However, because habitat degradation affects so many species within the ecosystem, and the depth and complexity of the trophic relationships within the ecosystem are difficult if not impossible to fully understand, restoration is rarely if ever truly pristine.

### INQUIRY QUESTIONS

**Page 1260** Many factors affect human population trends, including resource availability, governmental support for settlement in new areas or for protecting natural areas, and the extent to which governments attempt to manage population growth.

**Page 1262** The mangroves provide many economic services. For example, without them, fisheries become less productive and storm damage increases. However, because the people who benefit from these services do not own the mangroves, governmental action is needed to ensure that the value of what are economists call "common goods" is protected.

**Page 1266** On smaller islands, populations tend to be smaller. As we discuss later in this chapter, small populations are vulnerable to many problems, which individually or in concert can heighten the risk of extinction.

**Page 1269** As discussed in this chapter, populations that are small face many problems that can reinforce one another and eventually cause extinction.

**Page 1274** As we discussed in chapter 21, allele frequencies change randomly in a process called genetic drift. The smaller the population size, the greater these random fluctuations will be. Thus, small populations are particularly prone to one allele being lost from a population due to these random changes.

### UNDERSTAND

1. a 2. c 3. d 4. d 5. b 6. c

### APPLY

1. d 2. d 3. a 4. d

### SYNTHESIZE

1. Although it is true that extinction is a natural part of the existence of a species, several pieces of evidence suggest that current rates of extinction are much elevated over the natural background level and the disappearance is associated with human activities (which many of the most pronounced extinction events in the history of the Earth were not). It is important to appreciate the length of time over which the estimate of 99% is made. The history of life on Earth extends back billions of years. Certainly, clear patterns of the emergence and extinction of species in the fossil record extend back many hundreds of millions of years. Since the average time of species' existence is short relative to the great expanse of time over which we can estimate the percentage of species that have disappeared, the perception might be that extinction rates have always been high, when in fact the high number is driven by the great expanse of time of measurement. We have very good evidence that modern extinction rates (over human history) are considerably elevated above background levels. Furthermore, the circumstances of the extinctions may be very different because they are also associated with habitat and resource removal; thus potentially limiting the natural processes that replace extinct species.
2. The problem is not unique and not new. It represents a classic conflict that is the basic source of societal laws and regulations, especially in the management of resources. For example, whether or not to place air pollution scrubbers on the smoke stacks of coal-fired power plants is precisely the same issue. In this case, it is not ecosystem conversion, per se, but the fact that the businesses that run the power plants benefit from their operation, but the public "owns" and relies on the atmosphere is a conflict between public and private interests. Some of the ways to navigate the dilemma is for society to create regulations to protect the public interest. The problem is difficult and clearly does not depend solely on economic valuation of the costs and benefits because there can be considerable debate about those estimates. One only has to look at the global climate change problem to suggest how hard it will be to make progress in an expedient manner.
3. This is not a trivial undertaking, which is why, since the first concerns were raised in the late 1980s, it has taken nearly 15 years to collect evidence showing a decline is likely. Although progress has been made on identifying potential causes, much work remains to be done. Many amphibians are secretive, relatively long-lived, and subject to extreme population fluctuations. Given those facts about their biology, documenting population fluctuations (conducting censuses of the number of individuals in populations) for long periods of time is the only way to ultimately establish the likely fate of populations, and that process is time-consuming and costly.
4. Within an ecosystem, every species is dependent upon and depended upon by any number of other species. Even the smallest organisms, bacteria, are often specific about the species they feed upon, live within, parasitize, etc. So, the extinction of a single species anywhere in the ecosystem will affect not only the organisms it directly feeds upon and that directly feed upon it, but also those related more distantly. In the simplest terms, if, for example, a species of rodent goes extinct, the insects and vegetation upon which it feeds would no longer be under the same predation pressure and thus could grow out of control, outcompeting other species and leading to their demise. In addition, the predators of the rodent would have to find other prey, which would result in competition with those species' predators. And so on, and so on. The affects could be catastrophic to the entire ecosystem. By looking at the trophic chains in which a particular organism is involved, one could predict the affects its extinction would have on other species.
5. Population size is not necessarily a direct cause of extinction, but it certainly is an indirect cause. Smaller populations have a number of problems that themselves can lead directly to extinction, such as loss of diversity (and thus increased susceptibility to pathogens) and greater vulnerability to natural catastrophes.

## A

- ABO blood group** A set of four phenotypes produced by different combinations of three alleles at a single locus; blood types are A, B, AB, and O, depending on which alleles are expressed as antigens on the red blood cell surface.
- abscission** In vascular plants, the dropping of leaves, flowers, fruits, or stems at the end of the growing season, as the result of the formation of a layer of specialized cells (the abscission zone) and the action of a hormone (ethylene).
- absorption spectrum** The relationship of absorbance vs. wavelength for a pigment molecule. This indicates which wavelengths are absorbed maximally by a pigment. For example, chlorophyll *a* absorbs most strongly in the violet-blue and red regions of the visible light spectrum.
- acceptor stem** The 3' end of a tRNA molecule; the portion that amino acids become attached to during the tRNA charging reaction.
- accessory pigment** A secondary light-absorbing pigment used in photosynthesis, including chlorophyll *b* and the carotenoids, that complement the absorption spectrum of chlorophyll *a*.
- acoelomate** An animal, such as a flatworm, having a body plan that has no body cavity; the space between mesoderm and endoderm is filled with cells and organic materials.
- acetyl-CoA** The product of the transition reaction between glycolysis and the Krebs cycle. Pyruvate is oxidized to acetyl-CoA by NAD<sup>+</sup>, also producing CO<sub>2</sub> and NADH.
- achiasmata segregation** The lining up and subsequent separation of homologues during meiosis I without the formation of chiasmata between homologues; found in *Drosophila* males and some other species.
- acid** Any substance that dissociates in water to increase the hydrogen ion (H<sup>+</sup>) concentration and thus lower the pH.
- actin** One of the two major proteins that make up vertebrate muscle; the other is myosin.
- action potential** A transient, all-or-none reversal of the electric potential across a membrane; in neurons, an action potential initiates transmission of a nerve impulse.
- action spectrum** A measure of the efficiency of different wavelengths of light for photosynthesis. In plants it corresponds to the absorption spectrum of chlorophylls.
- activation energy** The energy that must be processed by a molecule in order for it to undergo a specific chemical reaction.
- active site** The region of an enzyme surface to which a specific set of substrates binds, lowering the activation energy required for a particular chemical reaction and so facilitating it.
- active transport** The pumping of individual ions or other molecules across a cellular membrane from a region of lower concentration to one of higher concentration (i.e., against a concentration gradient); this transport process requires energy, which is typically supplied by the expenditure of ATP.
- adaptation** A peculiarity of structure, physiology, or behavior that promotes the likelihood of an organism's survival and reproduction in a particular environment.
- adapter protein** Any of a class of proteins that acts as a link between a receptor and other proteins to initiate signal transduction.
- adaptive radiation** The evolution of several divergent forms from a primitive and unspecialized ancestor.
- adenosine triphosphate (ATP)** A nucleotide consisting of adenine, ribose sugar, and three phosphate groups; ATP is the energy currency of cellular metabolism in all organisms.
- adherens junction** An anchoring junction that connects the actin filaments of one cell with those of adjacent cells or with the extracellular matrix.
- ATP synthase** The enzyme responsible for producing ATP in oxidative phosphorylation; it uses the energy from a proton gradient to catalyze the reaction  $\text{ADP} + \text{P}_i \longrightarrow \text{ATP}$ .
- adenyl cyclase** An enzyme that produces large amounts of cAMP from ATP; the cAMP acts as a second messenger in a target cell.
- adhesion** The tendency of water to cling to other polar compounds due to hydrogen bonding.
- adipose cells** Fat cells, found in loose connective tissue, usually in large groups that form adipose tissue. Each adipose cell can store a droplet of fat (triacylglyceride).
- adventitious** Referring to a structure arising from an unusual place, such as stems from roots or roots from stems.
- aerenchyma** In plants, loose parenchymal tissue with large air spaces in it; often found in plants that grow in water.
- aerobic** Requiring free oxygen; any biological process that can occur in the presence of gaseous oxygen.
- aerobic respiration** The process that results in the complete oxidation of glucose using oxygen as the final electron acceptor. Oxygen acts as the final electron acceptor for an electron transport chain that produces a proton gradient for the chemiosmotic synthesis of ATP.
- aleurone** In plants, the outer layer of the endosperm in a seed; on germination, the aleurone produces  $\alpha$ -amylase that breaks down the carbohydrates of the endosperm to nourish the embryo.
- alga, pl. algae** A unicellular or simple multicellular photosynthetic organism lacking multicellular sex organs.
- allantois** A membrane of the amniotic egg that functions in respiration and excretion in birds and reptiles and plays an important role in the development of the placenta in most mammals.
- allele** One of two or more alternative states of a gene.
- allele frequency** A measure of the occurrence of an allele in a population, expressed as proportion of the entire population, for example, an occurrence of 0.84 (84%).
- allometric growth** A pattern of growth in which different components grow at different rates.
- allelopathy** The release of a substance from the roots of one plant that block the germination of nearby seeds or inhibits the growth of a neighboring plant.
- allopatric speciation** The differentiation of geographically isolated populations into distinct species.
- allopolyploid** A polyploid organism that contains the genomes of two or more different species.
- allosteric activator** A substance that binds to an enzyme's allosteric site and keeps the enzyme in its active configuration.
- allosteric inhibitor** A noncompetitive inhibitor that binds to an enzyme's allosteric site and prevents the enzyme from changing to its active configuration.
- allosteric site** A part of an enzyme, away from its active site, that serves as an on/off switch for the function of the enzyme.
- alpha ( $\alpha$ ) helix** A form of secondary structure in proteins where the polypeptide chain is wound into a spiral due to interactions between amino and carboxyl groups in the peptide backbone.
- alternation of generations** A reproductive cycle in which a haploid (*n*) phase (the gametophyte), gives rise to gametes, which, after fusion to form a zygote, germinate to produce a diploid (*2n*) phase (the sporophyte). Spores produced by meiotic division from the sporophyte give rise to new gametophytes, completing the cycle.
- alternative splicing** In eukaryotes, the production of different mRNAs from a single primary transcript by including different sets of exons.
- altruism** Self-sacrifice for the benefit of others; in formal terms, the behavior that increases the fitness of the recipient while reducing the fitness of the altruistic individual.
- alveolus, pl. alveoli** One of many small, thin-walled air sacs within the lungs in which the bronchioles terminate.
- amino acid** The subunit structure from which proteins are produced, consisting of a central carbon atom with a carboxyl group ( $-\text{COOH}$ ), an amino group ( $-\text{NH}_2$ ), a hydrogen, and a side group (*R* group); only the side group differs from one amino acid to another.

- aminoacyl-tRNA synthetase** Any of a group of enzymes that attach specific amino acids to the correct tRNA during the tRNA-charging reaction. Each of the 20 amino acids has a corresponding enzyme.
- amniocentesis** Indirect examination of a fetus by tests on cell cultures grown from fetal cells obtained from a sample of the amniotic fluid or tests on the fluid itself.
- amnion** The innermost of the extraembryonic membranes; the amnion forms a fluid-filled sac around the embryo in amniotic eggs.
- amniote** A vertebrate that produces an egg surrounded by four membranes, one of which is the amnion; amniote groups are the reptiles, birds, and mammals.
- amniotic egg** An egg that is isolated and protected from the environment by a more or less impervious shell during the period of its development and that is completely self-sufficient, requiring only oxygen.
- ampulla** In echinoderms, a muscular sac at the base of a tube foot that contracts to extend the tube foot.
- amyloplast** A plant organelle called a plastid that specializes in storing starch.
- anabolism** The biosynthetic or constructive part of metabolism; those chemical reactions involved in biosynthesis.
- anaerobic** Any process that can occur without oxygen, such as anaerobic fermentation or H<sub>2</sub>S photosynthesis.
- anaerobic respiration** The use of electron transport to generate a proton gradient for chemiosmotic synthesis of ATP using a final electron acceptor other than oxygen.
- analogous** Structures that are similar in function but different in evolutionary origin, such as the wing of a bat and the wing of a butterfly.
- anaphase** In mitosis and meiosis II, the stage initiated by the separation of sister chromatids, during which the daughter chromosomes move to opposite poles of the cell; in meiosis I, marked by separation of replicated homologous chromosomes.
- anaphase-promoting complex (APC)** A protein complex that triggers anaphase; it initiates a series of reactions that ultimately degrades cohesin, the protein complex that holds the sister chromatids together. The sister chromatids are then released and move toward opposite poles in the cell.
- anchoring junction** A type of cell junction that mechanically attaches the cytoskeleton of a cell to the cytoskeletons of adjacent cells or to the extracellular matrix.
- androecium** The floral whorl that comprises the stamens.
- aneuploidy** The condition in an organism whose cells have lost or gained a chromosome; Down syndrome, which results from an extra copy of human chromosome 21, is an example of aneuploidy in humans.
- angiosperms** The flowering plants, one of five phyla of seed plants. In angiosperms, the ovules at the time of pollination are completely enclosed by tissues.
- animal pole** In fish and other aquatic vertebrates with asymmetrical yolk distribution in their eggs, the hemisphere of the blastula comprising cells relatively poor in yolk.
- anion** A negatively charged ion.
- annotation** In genomics, the process of identifying and making note of “landmarks” in a DNA sequence to assist with recognition of coding and transcribed regions.
- anonymous markers** Genetic markers in a genome that do not cause a detectable phenotype, but that can be detected using molecular techniques.
- antenna complex** A complex of hundreds of pigment molecules in a photosystem that collects photons and feeds the light energy to a reaction center.
- anther** In angiosperm flowers, the pollen-bearing portion of a stamen.
- antheridium, pl. antheridia** A sperm-producing organ.
- anthropoid** Any member of the mammalian group consisting of monkeys, apes, and humans.
- antibody** A protein called immunoglobulin that is produced by lymphocytes in response to a foreign substance (antigen) and released into the bloodstream.
- anticodon** The three-nucleotide sequence at the end of a transfer RNA molecule that is complementary to, and base-pairs with, an amino-acid-specifying codon in messenger RNA.
- antigen** A foreign substance, usually a protein or polysaccharide, that stimulates an immune response.
- antiporter** A carrier protein in a cell’s membrane that transports two molecules in opposite directions across the membrane.
- anus** The terminal opening of the gut; the solid residues of digestion are eliminated through the anus.
- aorta** (Gr. *aeirein*, to lift) The major artery of vertebrate systemic blood circulation; in mammals, carries oxygenated blood away from the heart to all regions of the body except the lungs.
- apical meristem** In vascular plants, the growing point at the tip of the root or stem.
- apoplast route** In plant roots, the pathway for movement of water and minerals that leads through cell walls and between cells.
- apoptosis** A process of programmed cell death, in which dying cells shrivel and shrink; used in all animal cell development to produce planned and orderly elimination of cells not destined to be present in the final tissue.
- aposematic coloration** An ecological strategy of some organisms that “advertise” their poisonous nature by the use of bright colors.
- aquaporin** A membrane channel that allows water to cross the membrane more easily than by diffusion through the membrane.
- aquifers** Permeable, saturated, underground layers of rock, sand, and gravel, which serve as reservoirs for groundwater.
- archegonium, pl. archegonia** The multicellular egg-producing organ in bryophytes and some vascular plants.
- archenteron** The principal cavity of a vertebrate embryo in the gastrula stage; lined with endoderm, it opens up to the outside and represents the future digestive cavity.
- arteriole** A smaller artery, leading from the arteries to the capillaries.
- artificial selection** Change in the genetic structure of populations due to selective breeding by humans. Many domestic animal breeds and crop varieties have been produced through artificial selection.
- ascomycetes** A large group comprising part of the “true fungi.” They are characterized by separate hyphae, asexually produced conidiospores, and sexually produced ascospores within asci.
- ascus, pl. asci** A specialized cell, characteristic of the ascomycetes, in which two haploid nuclei fuse to produce a zygote that divides immediately by meiosis; at maturity, an ascus contains ascospores.
- asexual reproduction** The process by which an individual inherits all of its chromosomes from a single parent, thus being genetically identical to that parent; cell division is by mitosis only.
- A site** In a ribosome, the aminoacyl site, which binds to the tRNA carrying the next amino acid to be added to a polypeptide chain.
- assembly** The phase of a virus’s reproductive cycle during which the newly made components are assembled into viral particles.
- assortative mating** A type of nonrandom mating in which phenotypically similar individuals mate more frequently.
- aster** In animal cell mitosis, a radial array of microtubules extending from the centrioles toward the plasma membrane, possibly serving to brace the centrioles for retraction of the spindle.
- atom** The smallest unit of an element that contains all the characteristics of that element. Atoms are the building blocks of matter.
- atrial peptide** Any of a group of small polypeptide hormones that may be useful in treatment of high blood pressure and kidney failure; produced by cells in the atria of the heart.
- atrioventricular (AV) node** A slender connection of cardiac muscle cells that receives the heartbeat impulses from the sinoatrial node and conducts them by way of the bundle of His.
- atrium** An antechamber; in the heart, a thin-walled chamber that receives venous blood and passes it on to the thick-walled ventricle; in the ear, the tympanic cavity.
- autonomic nervous system** The involuntary neurons and ganglia of the peripheral nervous system of vertebrates; regulates the heart, glands, visceral organs, and smooth muscle.
- autopolyploid** A polyploid organism that contains a duplicated genome of the same species; may result from a meiotic error.
- autosome** Any eukaryotic chromosome that is not a sex chromosome; autosomes are present in the same number and kind in both males and females of the species.
- autotroph** An organism able to build all the complex organic molecules that it requires as its own food source, using only simple inorganic compounds.
- auxin** (Gr. *auxein*, to increase) A plant hormone that controls cell elongation, among other effects.
- auxotroph** A mutation, or the organism that carries it, that affects a biochemical pathway causing a nutritional requirement.
- avirulent pathogen** Any type of normally pathogenic organism or virus that utilizes host resources but does not cause extensive damage or death.
- axil** In plants, the angle between a leaf’s petiole and the stem to which it is attached.
- axillary bud** In plants, a bud found in the axil of a stem and leaf; an axillary bud may develop into a new shoot or may become a flower.
- axon** A process extending out from a neuron that conducts impulses away from the cell body.

## B

- b6-f* complex** See cytochrome *b6-f* complex.
- bacteriophage** A virus that infects bacterial cells; also called a *phage*.
- Barr body** A deeply staining structure, seen in the interphase nucleus of a cell of an individual with more than one X chromosome, that is a condensed and inactivated X. Only one X remains active in each cell after early embryogenesis.
- basal body** A self-reproducing, cylindrical, cytoplasmic organelle composed of nine triplets of microtubules from which the flagella or cilia arise.
- base** Any substance that dissociates in water to absorb and therefore decrease the hydrogen ion ( $H^+$ ) concentration and thus raise the pH.
- base-pair** A complementary pair of nucleotide bases, consisting of a purine and a pyrimidine.
- basidium**, pl. **basidia** A specialized reproductive cell of the basidiomycetes, often club-shaped, in which nuclear fusion and meiosis occur.
- basophil** A leukocyte containing granules that rupture and release chemicals that enhance the inflammatory response. Important in causing allergic responses.
- Batesian mimicry** A survival strategy in which a palatable or nontoxic organism resembles another kind of organism that is distasteful or toxic. Both species exhibit warning coloration.
- B cell** A type of lymphocyte that, when confronted with a suitable antigen, is capable of secreting a specific antibody protein.
- behavioral ecology** The study of how natural selection shapes behavior.
- biennial** A plant that normally requires two growing seasons to complete its life cycle. Biennials flower in the second year of their lives.
- bilateral symmetry** A single plane divides an organism into two structural halves that are mirror images of each other.
- bile salts** A solution of organic salts that is secreted by the vertebrate liver and temporarily stored in the gallbladder; emulsifies fats in the small intestine.
- binary fission** Asexual reproduction by division of one cell or body into two equal or nearly equal parts.
- binomial distribution** The distribution of phenotypes seen among the progeny of a cross in which there are only two alternative alleles.
- binomial name** The scientific name of a species that consists of two parts, the genus name and the specific species name, for example, *Apis mellifera*.
- biochemical pathway** A sequence of chemical reactions in which the product of one reaction becomes the substrate of the next reaction. The Krebs cycle is a biochemical pathway.
- biodiversity** The number of species and their range of behavioral, ecological, physiological, and other adaptations, in an area.
- bioenergetics** The analysis of how energy powers the activities of living systems.
- biofilm** A complex bacterial community comprising different species; plaque on teeth is a biofilm.
- biogeography** The study of the geographic distribution of species.

- biological community** All the populations of different species living together in one place; for example, all populations that inhabit a mountain meadow.
- biological species concept (BSC)** The concept that defines species as groups of populations that have the potential to interbreed and that are reproductively isolated from other groups.
- biomass** The total mass of all the living organisms in a given population, area, or other unit being measured.
- biome** One of the major terrestrial ecosystems, characterized by climatic and soil conditions; the largest ecological unit.
- bipolar cell** A specialized type of neuron connecting cone cells to ganglion cells in the visual system. Bipolar cells receive a hyperpolarized stimulus from the cone cell and then transmit a depolarization stimulus to the ganglion cell.
- biramous** Two-branched; describes the appendages of crustaceans.
- blade** The broad, expanded part of a leaf; also called the lamina.
- blastocoel** The central cavity of the blastula stage of vertebrate embryos.
- blastodisc** In the development of birds, a disclike area on the surface of a large, yolky egg that undergoes cleavage and gives rise to the embryo.
- blastomere** One of the cells of a blastula.
- blastopore** In vertebrate development, the opening that connects the archenteron cavity of a gastrula stage embryo with the outside.
- blastula** In vertebrates, an early embryonic stage consisting of a hollow, fluid-filled ball of cells one layer thick; a vertebrate embryo after cleavage and before gastrulation.
- Bohr effect** The release of oxygen by hemoglobin molecules in response to elevated ambient levels of  $CO_2$ .
- bottleneck effect** A loss of genetic variability that occurs when a population is reduced drastically in size.
- Bowman's capsule** In the vertebrate kidney, the bulbous unit of the nephron, which surrounds the glomerulus.
- $\beta$ -oxidation** The oxygen-dependent reactions where 2-carbon units of fatty acids are cleaved and combined with CoA to produce acetyl-CoA, which then enters the Krebs cycle. This occurs cyclically until the entire fatty acid is oxidized.
- $\beta$  sheet** A form of secondary structure in proteins where the polypeptide folds back on itself one or more times to form a planar structure stabilized by hydrogen bonding between amino and carboxyl groups in the peptide backbone. Also known as a  $\beta$ -pleated sheet.
- book lung** In some spiders, a unique respiratory system consisting of leaflike plates within a chamber over which gas exchange occurs.
- bronchus**, pl. **bronchi** One of a pair of respiratory tubes branching from the lower end of the trachea (windpipe) into either lung.
- bud** An asexually produced outgrowth that develops into a new individual. In plants, an embryonic shoot, often protected by young leaves; buds may give rise to branch shoots.
- buffer** A substance that resists changes in pH. It releases hydrogen ions ( $H^+$ ) when a base is added and absorbs  $H^+$  when an acid is added.

## C

- $C_3$  photosynthesis** The main cycle of the dark reactions of photosynthesis, in which  $CO_2$  binds to ribulose 1,5-bisphosphate (RuBP) to form two 3-carbon phosphoglycerate (PGA) molecules.
- $C_4$  photosynthesis** A process of  $CO_2$  fixation in photosynthesis by which the first product is the 4-carbon oxaloacetate molecule.
- cadherin** One of a large group of transmembrane proteins that contain a  $Ca^{2+}$ -mediated binding between cells; these proteins are responsible for cell-to-cell adhesion between cells of the same type.
- callus** Undifferentiated tissue; a term used in tissue culture, grafting, and wound healing.
- Calvin cycle** The dark reactions of  $C_3$  photosynthesis; also called the Calvin-Benson cycle.
- calyx** The sepals collectively; the outermost flower whorl.
- CAM plant** Plants that use  $C_4$  carbon fixation at night, then use the stored malate to generate  $CO_2$  during the day to minimize desiccation.
- Cambrian explosion** The huge increase in animal diversity that occurred at the beginning of the Cambrian period.
- cAMP response protein (CRP)** See catabolite activator protein (CAP)
- cancer** The unrestrained growth and division of cells; it results from a failure of cell division control.
- capillary** The smallest of the blood vessels; the very thin walls of capillaries are permeable to many molecules, and exchanges between blood and the tissues occur across them; the vessels that connect arteries with veins.
- capsid** The outermost protein covering of a virus.
- capsule** In bacteria, a gelatinous layer surrounding the cell wall.
- carapace** (Fr. from Sp. *carapacho*, shell) Shieldlike plate covering the cephalothorax of decapod crustaceans; the dorsal part of the shell of a turtle.
- carbohydrate** An organic compound consisting of a chain or ring of carbon atoms to which hydrogen and oxygen atoms are attached in a ratio of approximately 2:1; having the generalized formula  $(CH_2O)_n$ ; carbohydrates include sugars, starch, glycogen, and cellulose.
- carbon fixation** The conversion of  $CO_2$  into organic compounds during photosynthesis; the first stage of the dark reactions of photosynthesis, in which carbon dioxide from the air is combined with ribulose 1,5-bisphosphate.
- carotenoid** Any of a group of accessory pigments found in plants; in addition to absorbing light energy, these pigments act as antioxidants, scavenging potentially damaging free radicals.
- carpel** A leaflike organ in angiosperms that encloses one or more ovules.
- carrier protein** A membrane protein that binds to a specific molecule that cannot cross the membrane and allows passage through the membrane.
- carrying capacity** The maximum population size that a habitat can support.
- cartilage** A connective tissue in skeletons of vertebrates. Cartilage forms much of the skeleton of embryos, very young vertebrates, and some adult vertebrates, such as sharks and their relatives.

- Casparian strip** In plants, a band that encircles the cell wall of root endodermal cells. Adjacent cells' strips connect, forming a layer through which water cannot pass; therefore, all water entering roots must pass through cell membranes and cytoplasm.
- catabolism** In a cell, those metabolic reactions that result in the breakdown of complex molecules into simpler compounds, often with the release of energy.
- catabolite activator protein (CAP)** A protein that, when bound to cAMP, can bind to DNA and activate transcription. The level of cAMP is inversely related to the level of glucose, and CAP/cAMP in *E. coli* activates the *lac* (lactose) operon. Also called *cAMP response protein (CRP)*.
- catalysis** The process by which chemical subunits of larger organic molecules are held and positioned by enzymes that stress their chemical bonds, leading to the disassembly of the larger molecule into its subunits, often with the release of energy.
- cation** A positively charged ion.
- cavitation** In plants and animals, the blockage of a vessel by an air bubble that breaks the cohesion of the solution in the vessel; in animals more often called embolism.
- CD4<sup>+</sup> cell** A subtype of helper T cell that is identified by the presence of the CD4 protein on its surface. This cell type is targeted by the HIV virus that causes AIDS.
- cecum** In vertebrates, a blind pouch at the beginning of the large intestine.
- cell cycle** The repeating sequence of growth and division through which cells pass each generation.
- cell determination** The molecular "decision" process by which a cell becomes destined for a particular developmental pathway. This occurs before overt differentiation and can be a stepwise process.
- cell-mediated immunity** Arm of the adaptive immune system mediated by T cells, which includes cytotoxic cells and cells that assist the rest of the immune system.
- cell plate** The structure that forms at the equator of the spindle during early telophase in the dividing cells of plants and a few green algae.
- cell-surface marker** A glycoprotein or glycolipid on the outer surface of a cell's membrane that acts as an identifier; different cell types carry different markers.
- cell-surface receptor** A cell surface protein that binds a signal molecule and converts the extracellular signal into an intracellular one.
- cellular blastoderm** In insect embryonic development, the stage during which the nuclei of the syncytial blastoderm become separate cells through membrane formation.
- cellular respiration** The metabolic harvesting of energy by oxidation, ultimately dependent on molecular oxygen; carried out by the Krebs cycle and oxidative phosphorylation.
- cellulose** The chief constituent of the cell wall in all green plants, some algae, and a few other organisms; an insoluble complex carbohydrate formed of microfibrils of glucose molecules.
- cell wall** The rigid, outermost layer of the cells of plants, some protists, and most bacteria; the cell wall surrounds the plasma membrane.
- central nervous system (CNS)** That portion of the nervous system where most association occurs; in vertebrates, it is composed of the brain and spinal cord; in invertebrates, it usually consists of one or more cords of nervous tissue, together with their associated ganglia.
- central vacuole** A large, membrane-bounded sac found in plant cells that stores proteins, pigments, and waste materials, and is involved in water balance.
- centriole** A cytoplasmic organelle located outside the nuclear membrane, identical in structure to a basal body; found in animal cells and in the flagellated cells of other groups; divides and organizes spindle fibers during mitosis and meiosis.
- centromere** A visible point of constriction on a chromosome that contains repeated DNA sequences that bind specific proteins. These proteins make up the kinetochore to which microtubules attach during cell division.
- cephalization** The evolution of a head and brain area in the anterior end of animals; thought to be a consequence of bilateral symmetry.
- cerebellum** The hindbrain region of the vertebrate brain that lies above the medulla (brainstem) and behind the forebrain; it integrates information about body position and motion, coordinates muscular activities, and maintains equilibrium.
- cerebral cortex** The thin surface layer of neurons and glial cells covering the cerebrum; well developed only in mammals, and particularly prominent in humans. The cerebral cortex is the seat of conscious sensations and voluntary muscular activity.
- cerebrum** The portion of the vertebrate brain (the forebrain) that occupies the upper part of the skull, consisting of two cerebral hemispheres united by the corpus callosum. It is the primary association center of the brain. It coordinates and processes sensory input and coordinates motor responses.
- chaetae** Bristles of chitin on each body segment that help anchor annelid worms during locomotion.
- channel protein (ion channel)** A transmembrane protein with a hydrophilic interior that provides an aqueous channel allowing diffusion of species that cannot cross the membrane. Usually allows passage of specific ions such as K<sup>+</sup>, Na<sup>+</sup>, or Ca<sup>2+</sup> across the membrane.
- chaperone protein** A class of enzymes that help proteins fold into the correct configuration and can refold proteins that have been misfolded or denatured.
- character displacement** A process in which natural selection favors individuals in a species that use resources not used by other species. This results in evolutionary change leading to species dissimilar in resource use.
- character state** In cladistics, one of two or more distinguishable forms of a character, such as the presence or absence of teeth in amniote vertebrates.
- charging reaction** The reaction by which an aminoacyl-tRNA synthetase attaches a specific amino acid to the correct tRNA using energy from ATP.
- chelicera, pl. chelicerae** The first pair of appendages in horseshoe crabs, sea spiders, and arachnids—the chelicerates, a group of arthropods. Chelicerae usually take the form of pincers or fangs.
- chemical synapse** A close association that allows chemical communication between neurons. A chemical signal (neurotransmitter) released by the first neuron binds to receptors in the membrane of the second neurons.
- chemiosmosis** The mechanism by which ATP is generated in mitochondria and chloroplasts; energetic electrons excited by light (in chloroplasts) or extracted by oxidation in the Krebs cycle (in mitochondria) are used to drive proton pumps, creating a proton concentration gradient; when protons subsequently flow back across the membrane, they pass through channels that couple their movement to the synthesis of ATP.
- chiasma** An X-shaped figure that can be seen in the light microscope during meiosis; evidence of crossing over, where two chromatids have exchanged parts; chiasmata move to the ends of the chromosome arms as the homologues separate.
- chitin** A tough, resistant, nitrogen-containing polysaccharide that forms the cell walls of certain fungi, the exoskeleton of arthropods, and the epidermal cuticle of other surface structures of certain other invertebrates.
- chlorophyll** The primary type of light-absorbing pigment in photosynthesis. Chlorophyll *a* absorbs light in the violet-blue and the red ranges of the visible light spectrum; chlorophyll *b* is an accessory pigment to chlorophyll *a*, absorbing light in the blue and red-orange ranges. Neither pigment absorbs light in the green range, 500–600 nm.
- chloroplast** A cell-like organelle present in algae and plants that contains chlorophyll (and usually other pigments) and carries out photosynthesis.
- choanocyte** A specialized flagellated cell found in sponges; choanocytes line the body interior.
- chorion** The outer member of the double membrane that surrounds the embryo of reptiles, birds, and mammals; in placental mammals, it contributes to the structure of the placenta.
- chorionic villi sampling** A technique in which fetal cells are sampled from the chorion of the placenta rather than from the amniotic fluid; this less invasive technique can be used earlier in pregnancy than amniocentesis.
- chromatid** One of the two daughter strands of a duplicated chromosome that is joined by a single centromere.
- chromatin** The complex of DNA and proteins of which eukaryotic chromosomes are composed; chromatin is highly uncoiled and diffuse in interphase nuclei, condensing to form the visible chromosomes in prophase.
- chromatin-remodeling complex** A large protein complex that has been found to modify histones and DNA and that can change the structure of chromatin, moving or transferring nucleosomes.
- chromosomal mutation** Any mutation that affects chromosome structure.
- chromosome** The vehicle by which hereditary information is physically transmitted from one generation to the next; in a bacterium, the chromosome consists of a single naked circle of DNA; in eukaryotes, each chromosome consists of a single linear DNA molecule and associated proteins.

- chromosomal theory of inheritance** The theory stating that hereditary traits are carried on chromosomes.
- cilium** A short cellular projection from the surface of a eukaryotic cell, having the same internal structure of microtubules in a 9 + 2 arrangement as seen in a flagellum.
- circadian rhythm** An endogenous cyclical rhythm that oscillates on a daily (24-hour) basis.
- circulatory system** A network of vessels in coelomate animals that carries fluids to and from different areas of the body.
- cisterna** A small collecting vessel that pinches off from the end of a Golgi body to form a transport vesicle that moves materials through the cytoplasm.
- cisternal space** The inner region of a membrane-bounded structure. Usually used to describe the interior of the endoplasmic reticulum; also called the *lumen*.
- clade** A taxonomic group composed of an ancestor and all its descendents.
- cladistics** A taxonomic technique used for creating hierarchies of organisms that represent true phylogenetic relationship and descent.
- class** A taxonomic category between phyla and orders. A class contains one or more orders, and belongs to a particular phylum.
- classical conditioning** The repeated presentation of a stimulus in association with a response that causes the brain to form an association between the stimulus and the response, even if they have never been associated before.
- clathrin** A protein located just inside the plasma membrane in eukaryotic cells, in indentations called clathrin-coated pits.
- cleavage** In vertebrates, a rapid series of successive cell divisions of a fertilized egg, forming a hollow sphere of cells, the blastula.
- cleavage furrow** The constriction that forms during cytokinesis in animal cells that is responsible for dividing the cell into two daughter cells.
- climax vegetation** Vegetation encountered in a self-perpetuating community of plants that has proceeded through all the stages of succession and stabilized.
- cloaca** In some animals, the common exit chamber from the digestive, reproductive, and urinary system; in others, the cloaca may also serve as a respiratory duct.
- clone-by-clone sequencing** A method of genome sequencing in which a physical map is constructed first, followed by sequencing of fragments and identifying overlap regions.
- clonal selection** Amplification of a clone of immune cells initiated by antigen recognition.
- cloning** Producing a cell line or culture all of whose members contain identical copies of a particular nucleotide sequence; an essential element in genetic engineering.
- closed circulatory system** A circulatory system in which the blood is physically separated from other body fluids.
- coacervate** A spherical aggregation of lipid molecules in water, held together by hydrophobic forces.
- coactivator** A protein that functions to link transcriptional activators to the transcription complex consisting of RNA polymerase II and general transcription factors.
- cochlea** In terrestrial vertebrates, a tubular cavity of the inner ear containing the essential organs for hearing.
- coding strand** The strand of a DNA duplex that is the same as the RNA encoded by a gene. This strand is not used as a template in transcription, it is complementary to the template.
- codominance** Describes a case in which two or more alleles of a gene are each dominant to other alleles but not to each other. The phenotype of a heterozygote for codominant alleles exhibit characteristics of each of the homozygous forms. For example, in human blood types, a cross between an AA individual and a BB individual yields AB individuals.
- codon** The basic unit of the genetic code; a sequence of three adjacent nucleotides in DNA or mRNA that codes for one amino acid.
- coelom** In animals, a fluid-filled body cavity that develops entirely within the mesoderm.
- coenzyme** A nonprotein organic molecule such as NAD that plays an accessory role in enzyme-catalyzed processes, often by acting as a donor or acceptor of electrons.
- coevolution** The simultaneous development of adaptations in two or more populations, species, or other categories that interact so closely that each is a strong selective force on the other.
- cofactor** One or more nonprotein components required by enzymes in order to function; many cofactors are metal ions, others are organic coenzymes.
- cohesin** A protein complex that holds sister chromatids together during cell division. The loss of cohesins at the centromere allow the anaphase movement of chromosomes.
- collenchyma cell** In plants, the cells that form a supporting tissue called collenchyma; often found in regions of primary growth in stems and in some leaves.
- colloblast** A specialized type of cell found in members of the animal phylum Ctenophora (comb jellies) that bursts on contact with zooplankton, releasing an adhesive substance to help capture this prey.
- colonial flagellate hypothesis** The proposal first put forth by Haeckel that metazoans descended from colonial protists; supported by the similarity of sponges to choanoflagellate protists.
- commensalism** A relationship in which one individual lives close to or on another and benefits, and the host is unaffected; a kind of symbiosis.
- community** All of the species inhabiting a common environment and interacting with one another.
- companion cell** A specialized parenchyma cell that is associated with each sieve-tube member in the phloem of a plant.
- competitive exclusion** The hypothesis that two species with identical ecological requirements cannot exist in the same locality indefinitely, and that the more efficient of the two in utilizing the available scarce resources will exclude the other; also known as Gause's principle.
- competitive inhibitor** An inhibitor that binds to the same active site as an enzyme's substrate, thereby competing with the substrate.
- complementary** Describes genetic information in which each nucleotide base has a complementary partner with which it forms a base-pair.
- complementary DNA (cDNA)** A DNA copy of an mRNA transcript; produced by the action of the enzyme reverse transcriptase.
- complement system** The chemical defense of a vertebrate body that consists of a battery of proteins that become activated by the walls of bacteria and fungi.
- complete digestive system** A digestive system that has both a mouth and an anus, allowing unidirectional flow of ingested food.
- compound eye** An organ of sight in many arthropods composed of many independent visual units called ommatidia.
- concentration gradient** A difference in concentration of a substance from one location to another, often across a membrane.
- condensin** A protein complex involved in condensation of chromosomes during mitosis and meiosis.
- cone** (1) In plants, the reproductive structure of a conifer. (2) In vertebrates, a type of light-sensitive neuron in the retina concerned with the perception of color and with the most acute discrimination of detail.
- conidia** An asexually produced fungal spore.
- conjugation** Temporary union of two unicellular organisms, during which genetic material is transferred from one cell to the other; occurs in bacteria, protists, and certain algae and fungi.
- consensus sequence** In genome sequencing, the overall sequence that is consistent with the sequences of individual fragments; computer programs are used to compare sequences and generate a consensus sequence.
- conservation of synteny** The preservation over evolutionary time of arrangements of DNA segments in related species.
- contig** A contiguous segment of DNA assembled by analyzing sequence overlaps from smaller fragments.
- continuous variation** Variation in a trait that occurs along a continuum, such as the trait of height in human beings; often occurs when a trait is determined by more than one gene.
- contractile vacuole** In protists and some animals, a clear fluid-filled vacuole that takes up water from within the cell and then contracts, releasing it to the outside through a pore in a cyclical manner; functions primarily in osmoregulation and excretion.
- conus arteriosus** The anteriormost chamber of the embryonic heart in vertebrate animals.
- convergent evolution** The independent development of similar structures in organisms that are not directly related; often found in organisms living in similar environments.
- cork cambium** The lateral meristem that forms the periderm, producing cork (phellem) toward the surface (outside) of the plant and phelloderm toward the inside.
- cornea** The transparent outer layer of the vertebrate eye.
- corolla** The petals, collectively; usually the conspicuously colored flower whorl.
- corpus callosum** The band of nerve fibers that connects the two hemispheres of the cerebrum in humans and other primates.
- corpus luteum** A structure that develops from a ruptured follicle in the ovary after ovulation.

**cortex** The outer layer of a structure; in animals, the outer, as opposed to the inner, part of an organ; in vascular plants, the primary ground tissue of a stem or root.

**cotyledon** A seed leaf that generally stores food in dicots or absorbs it in monocots, providing nourishment used during seed germination.

**crassulacean acid metabolism (CAM)** A mode of carbon dioxide fixation by which CO<sub>2</sub> enters open leaf stomata at night and is used in photosynthesis during the day, when stomata are closed to prevent water loss.

**crista** A folded extension of the inner membrane of a mitochondrion. Mitochondria contain numerous cristae.

**cross-current flow** In bird lungs, the latticework of capillaries arranged across the air flow, at a 90° angle.

**crossing over** In meiosis, the exchange of corresponding chromatid segments between homologous chromosomes; responsible for genetic recombination between homologous chromosomes.

**ctenidia** Respiratory gills of mollusks; they consist of a system of filamentous projections of the mantle that are rich in blood vessels.

**cuticle** A waxy or fatty, noncellular layer (formed of a substance called cutin) on the outer wall of epidermal cells.

**cutin** In plants, a fatty layer produced by the epidermis that forms the cuticle on the outside surface.

**cyanobacteria** A group of photosynthetic bacteria, sometimes called the “blue-green algae,” that contain the chlorophyll pigments most abundant in plants and algae, as well as other pigments.

**cyclic AMP (cAMP)** A form of adenosine monophosphate (AMP) in which the atoms of the phosphate group form a ring; found in almost all organisms, cAMP functions as an intracellular second messenger that regulates a diverse array of metabolic activities.

**cyclic photophosphorylation** Reactions that begin with the absorption of light by reaction center chlorophyll that excites an electron. The excited electron returns to the photosystem, generating ATP by chemiosmosis in the process. This is found in the single bacterial photosystem, and can occur in plants in photosystem I.

**cyclin** Any of a number of proteins that are produced in synchrony with the cell cycle and combine with certain protein kinases, the cyclin-dependent kinases, at certain points during cell division.

**cyclin-dependent kinase (Cdk)** Any of a group of protein kinase enzymes that control progress through the cell cycle. These enzymes are only active when complexed with cyclin. The cdc2 protein, produced by the *cdc2* gene, was the first Cdk enzyme discovered.

**cytochrome** Any of several iron-containing protein pigments that serve as electron carriers in transport chains of photosynthesis and cellular respiration.

**cytochrome *b6-f* complex** A proton pump found in the thylakoid membrane. This complex uses energy from excited electrons to pump protons from the stroma into the thylakoid compartment.

**cytokinesis** Division of the cytoplasm of a cell after nuclear division.

**cytokine** Signaling molecules secreted by immune cells that affect other immune cells.

**cytoplasm** The material within a cell, excluding the nucleus; the protoplasm.

**cytoskeleton** A network of protein microfilaments and microtubules within the cytoplasm of a eukaryotic cell that maintains the shape of the cell, anchors its organelles, and is involved in animal cell motility.

**cytosol** The fluid portion of the cytoplasm; it contains dissolved organic molecules and ions.

**cytotoxic T cell** A special T cell activated during cell-mediated immune response that recognizes and destroys infected body cells.

## D

**deamination** The removal of an amino group; part of the degradation of proteins into compounds that can enter the Krebs cycle.

**deductive reasoning** The logical application of general principles to predict a specific result. In science, deductive reasoning is used to test the validity of general ideas.

**dehydration reaction** A type of chemical reaction in which two molecules join to form one larger molecule, simultaneously splitting out a molecule of water; one molecule is stripped of a hydrogen atom, and another is stripped of a hydroxyl group (—OH), resulting in the joining of the two molecules, while the H and —OH released may combine to form a water molecule.

**dehydrogenation** Chemical reaction involving the loss of a hydrogen atom. This is an oxidation that combines loss of an electron with loss of a proton.

**deletion** A mutation in which a portion of a chromosome is lost; if too much information is lost, the deletion can be fatal.

**demography** The properties of the rate of growth and the age structure of populations.

**denaturation** The loss of the native configuration of a protein or nucleic acid as a result of excessive heat, extremes of pH, chemical modification, or changes in solvent ionic strength or polarity that disrupt hydrophobic interactions; usually accompanied by loss of biological activity.

**dendrite** A process extending from the cell body of a neuron, typically branched, that conducts impulses toward the cell body.

**deoxyribonucleic acid (DNA)** The genetic material of all organisms; composed of two complementary chains of nucleotides wound in a double helix.

**dephosphorylation** The removal of a phosphate group, usually by a phosphatase enzyme. Many proteins can be activated or inactivated by dephosphorylation.

**depolarization** The movement of ions across a plasma membrane that locally wipes out an electrical potential difference.

**derived character** A characteristic used in taxonomic analysis representing a departure from the primitive form.

**dermal tissue** In multicellular organisms, a type of tissue that forms the outer layer of the body and is in contact with the environment; it has a protective function.

**desmosome** A type of anchoring junction that links adjacent cells by connecting their cytoskeletons with cadherin proteins.

**derepression** Seen in anabolic operons where the operon that encodes the enzymes for a biochemical pathway is repressed in the presence of the end product of the pathway and derepressed in the absence of the end product. This allows production of the enzymes only when they are necessary.

**determinate development** A type of development in animals in which each embryonic cell has a predetermined fate in terms of what kind of tissue it will form in the adult.

**deuterostome** Any member of a grouping of bilaterally symmetrical animals in which the anus develops first and the mouth second; echinoderms and vertebrates are deuterostome animals.

**diacylglycerol (DAG)** A second messenger that is released, along with inositol-1,4,5-trisphosphate (IP<sub>3</sub>), when phospholipase C cleaves PIP<sub>2</sub>. DAG can have a variety of cellular effects through activation of protein kinases.

**diaphragm** (1) In mammals, a sheet of muscle tissue that separates the abdominal and thoracic cavities and functions in breathing. (2) A contraceptive device used to block the entrance to the uterus temporarily and thus prevent sperm from entering during sexual intercourse.

**diapsid** Any of a group of reptiles that have two pairs of temporal openings in the skull, one lateral and one more dorsal; one lineage of this group gave rise to dinosaurs, modern reptiles, and birds.

**diastolic pressure** In the measurement of human blood pressure, the minimum pressure between heartbeats (repolarization of the ventricles). *Compare with* systolic pressure.

**dicer** An enzyme that generates small RNA molecules in a cell by chopping up double-stranded RNAs; dicer produces miRNAs and siRNAs.

**dicot** Short for dicotyledon; a class of flowering plants generally characterized as having two cotyledons, net-veined leaves, and flower parts usually in fours or fives.

**dideoxynucleotide** A nucleotide lacking —OH groups at both the 2' and 3' positions; used as a chain terminator in the enzymatic sequencing of DNA.

**differentiation** A developmental process by which a relatively unspecialized cell undergoes a progressive change to a more specialized form or function.

**diffusion** The net movement of dissolved molecules or other particles from a region where they are more concentrated to a region where they are less concentrated.

**dihybrid** An individual heterozygous at two different loci; for example *A/a B/b*.

**dihybrid cross** A single genetic cross involving two different traits, such as flower color and plant height.

**dikaryotic** In fungi, having pairs of nuclei within each cell.

**dioecious** Having the male and female elements on different individuals.

**diploid** Having two sets of chromosomes ( $2n$ ); in animals, twice the number characteristic of gametes; in plants, the chromosome number characteristic of the sporophyte generation; in contrast to haploid ( $n$ ).

**directional selection** A form of selection in which selection acts to eliminate one extreme from an array of phenotypes.

**disaccharide** A carbohydrate formed of two simple sugar molecules bonded covalently.

**disruptive selection** A form of selection in which selection acts to eliminate rather than favor the intermediate type.

**dissociation** In proteins, the reversible separation of protein subunits from a quaternary structure without altering their tertiary structure. Also refers to the dissolving of ionic compounds in water.

**disassortative mating** A type of nonrandom mating in which phenotypically different individuals mate more frequently.

**diurnal** Active during the day.

**DNA-binding motif** A region found in a regulatory protein that is capable of binding to a specific base sequence in DNA; a critical part of the protein's DNA-binding domain.

**DNA fingerprinting** An identification technique that makes use of a variety of molecular techniques to identify differences in the DNA of individuals.

**DNA gyrase** A topoisomerase involved in DNA replication; it relieves the torsional strain caused by unwinding the DNA strands.

**DNA library** A collection of DNAs in a vector (a plasmid, phage, or artificial chromosome) that taken together represent a complex mixture of DNAs, such as the entire genome, or the cDNAs made from all of the mRNA in a specific cell type.

**DNA ligase** The enzyme responsible for formation of phosphodiester bonds between adjacent nucleotides in DNA.

**DNA microarray** An array of DNA fragments on a microscope slide or silicon chip, used in hybridization experiments with labeled mRNA or DNA to identify active and inactive genes, or the presence or absence of particular sequences.

**DNA polymerase** A class of enzymes that all synthesize DNA from a preexisting template. All synthesize only in the 5'-to-3' direction, and require a primer to extend.

**DNA vaccine** A type of vaccine that uses DNA from a virus or bacterium that stimulates the cellular immune response.

**domain** (1) A distinct modular region of a protein that serves a particular function in the action of the protein, such as a regulatory domain or a DNA-binding domain. (2) In taxonomy, the level higher than kingdom. The three domains currently recognized are Bacteria, Archaea, and Eukarya.

**Domain Archaea** In the three-domain system of taxonomy, the group that contains only the Archaea, a highly diverse group of unicellular prokaryotes.

**Domain Bacteria** In the three-domain system of taxonomy, the group that contains only the Bacteria, a vast group of unicellular prokaryotes.

**Domain Eukarya** In the three-domain system of taxonomy, the group that contains eukaryotic organisms including protists, fungi, plants, and animals.

**dominant** An allele that is expressed when present in either the heterozygous or the homozygous condition.

**dosage compensation** A phenomenon by which the expression of genes carried on sex chromosomes is kept the same in males and females, despite a different number of sex chromosomes. In mammals, inactivation of one of the X chromosomes in female cells accomplishes dosage compensation.

**double fertilization** The fusion of the egg and sperm (resulting in a  $2n$  fertilized egg, the zygote) and the simultaneous fusion of the second male gamete with the polar nuclei (resulting in a primary endosperm nucleus, which is often triploid,  $3n$ ); a unique characteristic of all angiosperms.

**double helix** The structure of DNA, in which two complementary polynucleotide strands coil around a common helical axis.

**duodenum** In vertebrates, the upper portion of the small intestine.

**duplication** A mutation in which a portion of a chromosome is duplicated; if the duplicated region does not lie within a gene, the duplication may have no effect.

## E

**ecdysis** Shedding of outer, cuticular layer; molting, as in insects or crustaceans.

**ecdysone** Molting hormone of arthropods, which triggers when ecdysis occurs.

**ecology** The study of interactions of organisms with one another and with their physical environment.

**ecosystem** A major interacting system that includes organisms and their nonliving environment.

**ecotype** A locally adapted variant of an organism; differing genetically from other ecotypes.

**ectoderm** One of the three embryonic germ layers of early vertebrate embryos; ectoderm gives rise to the outer epithelium of the body (skin, hair, nails) and to the nerve tissue, including the sense organs, brain, and spinal cord.

**ectomycorrhizae** Externally developing mycorrhizae that do not penetrate the cells they surround.

**ectotherms** Animals such as reptiles, fish, or amphibians, whose body temperature is regulated by their behavior or by their surroundings.

**electronegativity** A property of atomic nuclei that refers to the affinity of the nuclei for valence electrons; a nucleus that is more electronegative has a greater pull on electrons than one that is less electronegative.

**electron transport chain** The passage of energetic electrons through a series of membrane-associated electron-carrier molecules to proton pumps embedded within mitochondrial or chloroplast membranes. *See* chemiosmosis.

**elongation factor (Ef-Tu)** In protein synthesis in *E. coli*, a factor that binds to GTP and to a charged tRNA to accomplish binding of the charged tRNA to the A site of the ribosome, so that elongation of the polypeptide chain can occur.

**embryo** A multicellular developmental stage that follows cell division of the zygote.

**embryonic stem cell (ES cell)** A stem cell derived from an early embryo that can develop into different adult tissues and give rise to an adult organism when injected into a blastocyst.

**emergent properties** Novel properties arising from the way in which components interact. Emergent properties often cannot be deduced solely from knowledge of the individual components.

**emerging virus** Any virus that originates in one organism but then passes to another; usually refers to transmission to humans.

**endergonic** Describes a chemical reaction in which the products contain more energy than the reactants, so that free energy must be put into the reaction from an outside source to allow it to proceed.

**endocrine gland** Ductless gland that secretes hormones into the extracellular spaces, from which they diffuse into the circulatory system.

**endocytosis** The uptake of material into cells by inclusion within an invagination of the plasma membrane; the uptake of solid material is phagocytosis, and that of dissolved material is pinocytosis.

**endoderm** One of the three embryonic germ layers of early vertebrate embryos, destined to give rise to the epithelium that lines internal structures and most of the digestive and respiratory tracts.

**endodermis** In vascular plants, a layer of cells forming the innermost layer of the cortex in roots and some stems.

**endomembrane system** A system of connected membranous compartments found in eukaryotic cells.

**endometrium** The lining of the uterus in mammals; thickens in response to secretion of estrogens and progesterone and is sloughed off in menstruation.

**endomycorrhizae** Mycorrhizae that develop within cells.

**endonuclease** An enzyme capable of cleaving phosphodiester bonds between nucleotides located internally in a DNA strand.

**endoplasmic reticulum (ER)** Internal membrane system that forms a netlike array of channels and interconnections within the cytoplasm of eukaryotic cells. The ER is divided into rough (RER) and smooth (SER) compartments.

**endorphin** One of a group of small neuropeptides produced by the vertebrate brain; like morphine, endorphins modulate pain perception.

**endosperm** A storage tissue characteristic of the seeds of angiosperms, which develops from the union of a male nucleus and the polar nuclei of the embryo sac. The endosperm is digested by the growing sporophyte either before maturation of the seed or during its germination.

**endospore** A highly resistant, thick-walled bacterial spore that can survive harsh environmental stress, such as heat or desiccation, and then germinate when conditions become favorable.

**endosymbiosis** Theory that proposes that eukaryotic cells evolved from a symbiosis between different species of prokaryotes.

**endotherm** An animal capable of maintaining a constant body temperature. *See* homeotherm.

**energy level** A discrete level, or quantum, of energy that an electron in an atom possesses. To change energy levels, an electron must absorb or release energy.

**enhancer** A site of regulatory protein binding on the DNA molecule distant from the promoter and start site for a gene's transcription.

**enthalpy** In a chemical reaction, the energy contained in the chemical bonds of the molecule, symbolized as *H*; in a cellular reaction, the free energy is equal to the enthalpy of the reactant molecules in the reaction.

**entropy** A measure of the randomness or disorder of a system; a measure of how much energy in a system has become so dispersed (usually as evenly distributed heat) that it is no longer available to do work.

- enzyme** A protein that is capable of speeding up specific chemical reactions by lowering the required activation energy.
- enzyme–substrate complex** The complex formed when an enzyme binds with its substrate. This complex often has an altered configuration compared with the nonbound enzyme.
- epicotyl** The region just above where the cotyledons are attached.
- epidermal cell** In plants, a cell that collectively forms the outermost layer of the primary plant body; includes specialized cells such as trichomes and guard cells.
- epidermis** The outermost layers of cells; in plants, the exterior primary tissue of leaves, young stems, and roots; in vertebrates, the nonvascular external layer of skin, of ectodermal origin; in invertebrates, a single layer of ectodermal epithelium.
- epididymis** A sperm storage vessel; a coiled part of the sperm duct that lies near the testis.
- epistasis** Interaction between two nonallelic genes in which one of them modifies the phenotypic expression of the other.
- epithelium** In animals, a type of tissue that covers an exposed surface or lines a tube or cavity.
- equilibrium** A stable condition; the point at which a chemical reaction proceeds as rapidly in the reverse direction as it does in the forward direction, so that there is no further net change in the concentrations of products or reactants. In ecology, a stable condition that resists change and fairly quickly returns to its original state if disturbed by humans or natural events.
- erythrocyte** Red blood cell, the carrier of hemoglobin.
- erythropoiesis** The manufacture of blood cells in the bone marrow.
- E site** In a ribosome, the exit site that binds to the tRNA that carried the previous amino acid added to the polypeptide chain.
- estrus** The period of maximum female sexual receptivity, associated with ovulation of the egg.
- ethology** The study of patterns of animal behavior in nature.
- euchromatin** That portion of a eukaryotic chromosome that is transcribed into mRNA; contains active genes that are not tightly condensed during interphase.
- eukaryote** A cell characterized by membrane-bounded organelles, most notably the nucleus, and one that possesses chromosomes whose DNA is associated with proteins; an organism composed of such cells.
- eutherian** A placental mammal.
- eutrophic** Refers to a lake in which an abundant supply of minerals and organic matter exists.
- evolution** Genetic change in a population of organisms; in general, evolution leads to progressive change from simple to complex.
- excision repair** A nonspecific mechanism to repair damage to DNA during synthesis. The damaged or mismatched region is excised, and DNA polymerase replaces the region removed.
- exergonic** Describes a chemical reaction in which the products contain less free energy than the reactants, so that free energy is released in the reaction.
- exhalant siphon** In bivalve mollusks, the siphon through which outgoing water leaves the body.
- exocrine gland** A type of gland that releases its secretion through a duct, such as a digestive gland or a sweat gland.
- exocytosis** A type of bulk transport out of cells in which a vacuole fuses with the plasma membrane, discharging the vacuole's contents to the outside.
- exon** A segment of DNA that is both transcribed into RNA and translated into protein. *See* intron.
- exonuclease** An enzyme capable of cutting phosphodiester bonds between nucleotides located at an end of a DNA strand. This allows sequential removal of nucleotides from the end of DNA.
- exoskeleton** An external skeleton, as in arthropods.
- experiment** A test of one or more hypotheses. Hypotheses make contrasting predictions that can be tested experimentally in control and test experiments where a single variable is altered.
- expressed sequence tag (EST)** A short sequence of a cDNA that unambiguously identifies the cDNA.
- expression vector** A type of vector (plasmid or phage) that contains the sequences necessary to drive expression of inserted DNA in a specific cell type.
- exteroceptor** A receptor that is excited by stimuli from the external world.
- extremophile** An archaean organism that lives in extreme environments; different archaean species may live in hot springs (thermophiles), highly saline environments (halophiles), highly acidic or basic environments, or under high pressure at the bottom of oceans.
- F**
- 5' cap** In eukaryotes, a structure added to the 5' end of an mRNA consisting of methylated GTP attached by a 5' to 5' bond. The cap protects this end from degradation and is involved in the initiation of translation.
- facilitated diffusion** Carrier-assisted diffusion of molecules across a cellular membrane through specific channels from a region of higher concentration to one of lower concentration; the process is driven by the concentration gradient and does not require cellular energy from ATP.
- family** A taxonomic grouping of similar species above the level of genus.
- fat** A molecule composed of glycerol and three fatty acid molecules.
- feedback inhibition** Control mechanism whereby an increase in the concentration of some molecules inhibits the synthesis of that molecule.
- fermentation** The enzyme-catalyzed extraction of energy from organic compounds without the involvement of oxygen.
- fertilization** The fusion of two haploid gamete nuclei to form a diploid zygote nucleus.
- fibroblast** A flat, irregularly branching cell of connective tissue that secretes structurally strong proteins into the matrix between the cells.
- first filial (F<sub>1</sub>) generation** The offspring resulting from a cross between a parental generation (P); in experimental crosses, these parents usually have different phenotypes.
- First Law of Thermodynamics** Energy cannot be created or destroyed, but can only undergo conversion from one form to another; thus, the amount of energy in the universe is unchangeable.
- fitness** The genetic contribution of an individual to succeeding generations. relative fitness refers to the fitness of an individual relative to other individuals in a population.
- fixed action pattern** A stereotyped animal behavior response, thought by ethologists to be based on programmed neural circuits.
- flagellin** The protein composing bacterial flagella, which allow a cell to move through an aqueous environment.
- flagellum** A long, threadlike structure protruding from the surface of a cell and used in locomotion.
- flame cell** A specialized cell found in the network of tubules inside flatworms that assists in water regulation and some waste excretion.
- flavin adenine dinucleotide (FAD, FADH<sub>2</sub>)** A cofactor that acts as a soluble (not membrane-bound) electron carrier (can be reversibly oxidized and reduced).
- fluorescent in situ hybridization (FISH)** A cytological method used to find specific DNA sequences on chromosomes with a specific fluorescently labeled probe.
- food security** Having access to sufficient, safe food to avoid malnutrition and starvation; a global human issue.
- foraging behavior** A collective term for the many complex, evolved behaviors that influence what an animal eats and how the food is obtained.
- founder effect** The effect by which rare alleles and combinations of alleles may be enhanced in new populations.
- fovea** A small depression in the center of the retina with a high concentration of cones; the area of sharpest vision.
- frameshift mutation** A mutation in which a base is added or deleted from the DNA sequence. These changes alter the reading frame downstream of the mutation.
- free energy** Energy available to do work.
- free radical** An ionized atom with one or more unpaired electrons, resulting from electrons that have been energized by ionizing radiation being ejected from the atom; free radicals react violently with other molecules, such as DNA, causing damage by mutation.
- frequency-dependent selection** A type of selection that depends on how frequently or infrequently a phenotype occurs in a population.
- fruit** In angiosperms, a mature, ripened ovary (or group of ovaries), containing the seeds.
- functional genomics** The study of the function of genes and their products, beyond simply ascertaining gene sequences.
- functional group** A molecular group attached to a hydrocarbon that confers chemical properties or reactivities. Examples include hydroxyl (—OH), carboxylic acid (—COOH) and amino groups (—NH<sub>2</sub>).
- fundamental niche** Also referred to as the hypothetical niche, this is the entire niche an organism could fill if there were no other interacting factors (such as competition or predation).
- G**
- G<sub>0</sub> phase** The stage of the cell cycle occupied by cells that are not actively dividing.
- G<sub>1</sub> phase** The phase of the cell cycle after cytokinesis and before DNA replication called the first “gap” phase. This phase is the primary growth phase of a cell.

- G<sub>1</sub>/S checkpoint** The primary control point at which a cell “decides” whether or not to divide. Also called START and the restriction point.
- G<sub>2</sub> phase** The phase of the cell cycle between DNA replication and mitosis called the second “gap” phase. During this phase, the cell prepares for mitosis.
- G<sub>2</sub>/M checkpoint** The second cell-division control point, at which division can be delayed if DNA has not been properly replicated or is damaged.
- gametangium, pl. gametangia** A cell or organ in which gametes are formed.
- gamete** A haploid reproductive cell.
- gametocytes** Cells in the malarial sporozoite life cycle capable of giving rise to gametes when in the correct host.
- gametophyte** In plants, the haploid (*n*), gamete-producing generation, which alternates with the diploid (*2n*) sporophyte.
- ganglion, pl. ganglia** An aggregation of nerve cell bodies; in invertebrates, ganglia are the integrative centers; in vertebrates, the term is restricted to aggregations of nerve cell bodies located outside the central nervous system.
- gap gene** Any of certain genes in *Drosophila* development that divide the embryo into large blocks in the process of segmentation; *bunchback* is a gap gene.
- gap junction** A junction between adjacent animal cells that allows the passage of materials between the cells.
- gastrodermis** In eumetazoan animals, the layer of digestive tissue that develops from the endoderm.
- gastrula** In vertebrates, the embryonic stage in which the blastula with its single layer of cells turns into a three-layered embryo made up of ectoderm, mesoderm, and endoderm.
- gastrulation** Developmental process that converts blastula into embryo with three embryonic germ layers: endoderm, mesoderm, and ectoderm. Involves massive cell migration to convert the hollow structure into a three-layered structure.
- gene** The basic unit of heredity; a sequence of DNA nucleotides on a chromosome that encodes a protein, tRNA, or rRNA molecule, or regulates the transcription of such a sequence.
- gene conversion** Alteration of one homologous chromosome by the cell’s error-detection and repair system to make it resemble the sequence on the other homologue.
- gene expression** The conversion of the genotype into the phenotype; the process by which DNA is transcribed into RNA, which is then translated into a protein product.
- gene pool** All the alleles present in a species.
- gene-for-gene hypothesis** A plant defense mechanism in which a specific protein encoded by a viral, bacterial, or fungal pathogen binds to a protein encoded by a plant gene and triggers a defense response in the plant.
- general transcription factor** Any of a group of transcription factors that are required for formation of an initiation complex by RNA polymerase II at a promoter. This allows a basal level that can be increased by the action of specific factors.
- generalized transduction** A form of gene transfer in prokaryotes in which any gene can be transferred between cells. This uses a lytic bacteriophage as a carrier where the virion is accidentally packaged with host DNA.
- genetic counseling** The process of evaluating the risk of genetic defects occurring in offspring, testing for these defects in unborn children, and providing the parents with information about these risks and conditions.
- genetic drift** Random fluctuation in allele frequencies over time by chance.
- genetic map** An abstract map that places the relative location of genes on a chromosome based on recombination frequency.
- genome** The entire DNA sequence of an organism.
- genomic imprinting** Describes an exception to Mendelian genetics in some mammals in which the phenotype caused by an allele is exhibited when the allele comes from one parent, but not from the other.
- genomic library** A DNA library that contains a representation of the entire genome of an organism.
- genomics** The study of genomes as opposed to individual genes.
- genotype** The genetic constitution underlying a single trait or set of traits.
- genotype frequency** A measure of the occurrence of a genotype in a population, expressed as a proportion of the entire population, for example, an occurrence of 0.25 (25%) for a homozygous recessive genotype.
- genus, pl. genera** A taxonomic group that ranks below a family and above a species.
- germination** The resumption of growth and development by a spore or seed.
- germ layers** The three cell layers formed at gastrulation of the embryo that foreshadow the future organization of tissues; the layers, from the outside inward, are the ectoderm, the mesoderm, and the endoderm.
- germ-line cells** During zygote development, cells that are set aside from the somatic cells and that will eventually undergo meiosis to produce gametes.
- gill** (1) In aquatic animals, a respiratory organ, usually a thin-walled projection from some part of the external body surface, endowed with a rich capillary bed and having a large surface area. (2) In basidiomycete fungi, the plates on the underside of the cap.
- globular protein** Proteins with a compact tertiary structure with hydrophobic amino acids mainly in the interior.
- glomerular filtrate** The fluid that passes out of the capillaries of each glomerulus.
- glomerulus** A cluster of capillaries enclosed by Bowman’s capsule.
- glucagon** A vertebrate hormone produced in the pancreas that acts to initiate the breakdown of glycogen to glucose subunits.
- gluconeogenesis** The synthesis of glucose from noncarbohydrates (such as proteins or fats).
- glucose** A common six-carbon sugar (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>); the most common monosaccharide in most organisms.
- glucose repression** In *E. coli*, the preferential use of glucose even when other sugars are present; transcription of mRNA encoding the enzymes for utilizing the other sugars does not occur.
- glycocalyx** A “sugar coating” on the surface of a cell resulting from the presence of polysaccharides on glycolipids and glycoproteins embedded in the outer layer of the plasma membrane.
- glycogen** Animal starch; a complex branched polysaccharide that serves as a food reserve in animals, bacteria, and fungi.
- glycolipid** Lipid molecule modified within the Golgi complex by having a short sugar chain (polysaccharide) attached.
- glycolysis** The anaerobic breakdown of glucose; this enzyme-catalyzed process yields two molecules of pyruvate with a net of two molecules of ATP.
- glycoprotein** Protein molecule modified within the Golgi complex by having a short sugar chain (polysaccharide) attached.
- glyoxysome** A small cellular organelle or microbody containing enzymes necessary for conversion of fats into carbohydrates.
- glyphosate** A biodegradable herbicide that works by inhibiting EPSP synthetase, a plant enzyme that makes aromatic amino acids; genetic engineering has allowed crop species to be created that are resistant to glyphosate.
- Golgi apparatus (Golgi body)** A collection of flattened stacks of membranes in the cytoplasm of eukaryotic cells; functions in collection, packaging, and distribution of molecules synthesized in the cell.
- G protein** A protein that binds guanosine triphosphate (GTP) and assists in the function of cell-surface receptors. When the receptor binds its signal molecule, the G protein binds GTP and is activated to start a chain of events within the cell.
- G protein-coupled receptor (GPCR)** A receptor that acts through a heterotrimeric (three component) G protein to activate effector proteins. The effector proteins then function as enzymes to produce second messengers such as cAMP or IP<sub>3</sub>.
- gradualism** The view that species change very slowly in ways that may be imperceptible from one generation to the next but that accumulate and lead to major changes over thousands or millions of years.
- Gram stain** Staining technique that divides bacteria into gram-negative or gram-positive based on retention of a violet dye. Differences in staining are due to cell wall construction.
- granum (pl. grana)** A stacked column of flattened, interconnected disks (thylakoids) that are part of the thylakoid membrane system in chloroplasts.
- gravitropism** Growth response to gravity in plants; formerly called geotropism.
- ground meristem** The primary meristem, or meristematic tissue, that gives rise to the plant body (except for the epidermis and vascular tissues).
- ground tissue** In plants, a type of tissue that performs many functions, including support, storage, secretion, and photosynthesis; may consist of many cell types.
- growth factor** Any of a number of proteins that bind to membrane receptors and initiate intracellular signaling systems that result in cell growth and division.
- guard cell** In plants, one of a pair of sausage-shaped cells flanking a stoma; the guard cells open and close the stomata.
- guttation** The exudation of liquid water from leaves due to root pressure.

**gymnosperm** A seed plant with seeds not enclosed in an ovary; conifers are gymnosperms.  
**gynoecium** The aggregate of carpels in the flower of a seed plant.

## H

**habitat** The environment of an organism; the place where it is usually found.  
**habituation** A form of learning; a diminishing response to a repeated stimulus.  
**halophyte** A plant that is salt-tolerant.  
**haplodiploidy** A phenomenon occurring in certain organisms such as wasps, wherein both haploid (male) and diploid (female) individuals are encountered.  
**haploid** Having only one set of chromosomes ( $n$ ), in contrast to diploid ( $2n$ ).  
**haplotype** A region of a chromosome that is usually inherited intact, that is, it does not undergo recombination. These are identified based on analysis of SNPs.  
**Hardy-Weinberg equilibrium** A mathematical description of the fact that allele and genotype frequencies remain constant in a random-mating population in the absence of inbreeding, selection, or other evolutionary forces; usually stated: if the frequency of allele  $a$  is  $p$  and the frequency of allele  $b$  is  $q$ , then the genotype frequencies after one generation of random mating will always be  $p^2 + 2pq + q^2 = 1$ .  
**Haversian canal** Narrow channels that run parallel to the length of a bone and contain blood vessels and nerve cells.  
**heat** A measure of the random motion of molecules; the greater the heat, the greater the motion. Heat is one form of kinetic energy.  
**heat of vaporization** The amount of energy required to change 1 g of a substance from a liquid to a gas.  
**heavy metal** Any of the metallic elements with high atomic numbers, such as arsenic, cadmium, lead, etc. Many heavy metals are toxic to animals even in small amounts.  
**helicase** Any of a group of enzymes that unwind the two DNA strands in the double helix to facilitate DNA replication.  
**helix-turn-helix motif** A common DNA-binding motif found in regulatory proteins; it consists of two  $\alpha$ -helices linked by a nonhelical segment (the “turn”).  
**helper T cell** A class of white blood cells that initiates both the cell-mediated immune response and the humoral immune response; helper T cells are the targets of the AIDS virus (HIV).  
**hemoglobin** A globular protein in vertebrate red blood cells and in the plasma of many invertebrates that carries oxygen and carbon dioxide.  
**hemopoietic stem cell** The cells in bone marrow where blood cells are formed.  
**hermaphroditism** Condition in which an organism has both male and female functional reproductive organs.  
**heterochromatin** The portion of a eukaryotic chromosome that is not transcribed into RNA; remains condensed in interphase and stains intensely in histological preparations.  
**heterochrony** An alteration in the timing of developmental events due to a genetic change; for example, a mutation that delays flowering in plants.

**heterokaryotic** In fungi, having two or more genetically distinct types of nuclei within the same mycelium.  
**heterosporous** In vascular plants, having spores of two kinds, namely, microspores and megaspores.  
**heterotroph** An organism that cannot derive energy from photosynthesis or inorganic chemicals, and so must feed on other plants and animals, obtaining chemical energy by degrading their organic molecules.  
**heterozygote advantage** The situation in which individuals heterozygous for a trait have a selective advantage over those who are homozygous; an example is sickle cell anemia.  
**heterozygous** Having two different alleles of the same gene; the term is usually applied to one or more specific loci, as in “heterozygous with respect to the  $W$  locus” (that is, the genotype is  $W/w$ ).  
**Hfr cell** An *E. coli* cell that has a high frequency of recombination due to integration of an F plasmid into its genome.  
**histone** One of a group of relatively small, very basic polypeptides, rich in arginine and lysine, forming the core of nucleosomes around which DNA is wrapped in the first stage of chromosome condensation.  
**histone protein** Any of eight proteins with an overall positive charge that associate in a complex. The DNA duplex coils around a core of eight histone proteins, held by its negatively charged phosphate groups, forming a nucleosome.  
**holoblastic cleavage** Process in vertebrate embryos in which the cleavage divisions all occur at the same rate, yielding a uniform cell size in the blastula.  
**homeobox** A sequence of 180 nucleotides located in homeotic genes that produces a 60-amino-acid peptide sequence (the homeodomain) active in transcription factors.  
**homeodomain motif** A special class of helix-turn-helix motifs found in regulatory proteins that control development in eukaryotes.  
**homeosis** A change in the normal spatial pattern of gene expression that can result in homeotic mutants where a wild-type structure develops in the wrong place in or on the organism.  
**homeostasis** The maintenance of a relatively stable internal physiological environment in an organism; usually involves some form of feedback self-regulation.  
**homeotherm** An organism, such as a bird or mammal, capable of maintaining a stable body temperature independent of the environmental temperature. *See* endotherm.  
**homeotic gene** One of a series of “master switch” genes that determine the form of segments developing in the embryo.  
**hominid** Any primate in the human family, Hominidae. *Homo sapiens* is the only living representative.  
**hominoid** Collectively, hominids and apes; the monkeys and hominoids constitute the anthropoid primates.  
**homokaryotic** In fungi, having nuclei with the same genetic makeup within a mycelium.  
**homologue** One of a pair of chromosomes of the same kind located in a diploid cell; one copy of each pair of homologues comes from each gamete that formed the zygote.

**homologous** (1) Refers to similar structures that have the same evolutionary origin. (2) Refers to a pair of the same kind of chromosome in a diploid cell.  
**homoplasy** In cladistics, a shared character state that has not been inherited from a common ancestor exhibiting that state; may result from convergent evolution or evolutionary reversal. The wings of birds and of bats, which are convergent structures, are examples.  
**homosporous** In some plants, production of only one type of spore rather than differentiated types. *Compare with* heterosporous.  
**homozygous** Being a homozygote, having two identical alleles of the same gene; the term is usually applied to one or more specific loci, as in “homozygous with respect to the  $W$  locus” (i.e., the genotype is  $W/W$  or  $w/w$ ).  
**horizontal gene transfer (HGT)** The passing of genes laterally between species; more prevalent very early in the history of life.  
**hormone** A molecule, usually a peptide or steroid, that is produced in one part of an organism and triggers a specific cellular reaction in target tissues and organs some distance away.  
**host range** The range of organisms that can be infected by a particular virus.  
**Hox gene** A group of homeobox-containing genes that control developmental events, usually found organized into clusters of genes. These genes have been conserved in many different multicellular animals, both invertebrates and vertebrates, although the number of clusters changes in lineages, leading to four clusters in vertebrates.  
**humoral immunity** Arm of the adaptive immune system involving B cells that produce soluble antibodies specific for foreign antigens.  
**humus** Partly decayed organic material found in topsoil.  
**hybridization** The mating of unlike parents.  
**hydration shell** A “cloud” of water molecules surrounding a dissolved substance, such as sucrose or  $\text{Na}^+$  and  $\text{Cl}^-$  ions.  
**hydrogen bond** A weak association formed with hydrogen in polar covalent bonds. The partially positive hydrogen is attracted to partially negative atoms in polar covalent bonds. In water, oxygen and hydrogen in different water molecules form hydrogen bonds.  
**hydrolysis reaction** A reaction that breaks a bond by the addition of water. This is the reverse of dehydration, a reaction that joins molecules with the loss of water.  
**hydrophilic** Literally translates as “water-loving” and describes substances that are soluble in water. These must be either polar or charged (ions).  
**hydrophobic** Literally translates as “water-fearing” and describes nonpolar substances that are not soluble in water. Nonpolar molecules in water associate with each other and form droplets.  
**hydrophobic exclusion** The tendency of nonpolar molecules to aggregate together when placed in water. Exclusion refers to the action of water in forcing these molecules together.  
**hydrostatic skeleton** The skeleton of most soft-bodied invertebrates that have neither an internal nor an external skeleton. They use the relative incompressibility of the water within their bodies as a kind of skeleton.

**hyperosmotic** The condition in which a (hyperosmotic) solution has a higher osmotic concentration than that of a second solution. *Compare with* hypoosmotic.

**hyperpolarization** Above-normal negativity of a cell membrane during its resting potential.

**hypersensitive response** Plants respond to pathogens by selectively killing plant cells to block the spread of the pathogen.

**hypertonic** A solution with a higher concentration of solutes than the cell. A cell in a hypertonic solution tends to lose water by osmosis.

**hypha**, pl. **hyphae** A filament of a fungus or oomycete; collectively, the hyphae constitute the mycelium.

**hypocotyl** The region immediately below where the cotyledons are attached.

**hypoosmotic** The condition in which a (hypoosmotic) solution has a lower osmotic concentration than that of a second solution. *Compare with* hyperosmotic.

**hypothalamus** A region of the vertebrate brain just below the cerebral hemispheres, under the thalamus; a center of the autonomic nervous system, responsible for the integration and correlation of many neural and endocrine functions.

**hypotonic** A solution with a lower concentration of solutes than the cell. A cell in a hypotonic solution tends to take in water by osmosis.

**Icosahedron** A structure consisting of 20 equilateral triangular facets; this is commonly seen in viruses and forms one kind of viral capsid.

**imaginal disk** One of about a dozen groups of cells set aside in the abdomen of a larval insect and committed to forming key parts of the adult insect's body.

**immune response** In vertebrates, a defensive reaction of the body to invasion by a foreign substance or organism. *See* antibody and B cell.

**immunoglobulin** An antibody molecule.

**immunological tolerance** Process where immune system learns to not react to self-antigens.

**in vitro mutagenesis** The ability to create mutations at any site in a cloned gene to examine the mutations' effects on function.

**inbreeding** The breeding of genetically related plants or animals; inbreeding tends to increase homozygosity.

**inclusive fitness** Describes the sum of the number of genes directly passed on in an individual's offspring and those genes passed on indirectly by kin (other than offspring) whose existence results from the benefit of the individual's altruism.

**incomplete dominance** Describes a case in which two or more alleles of a gene do not display clear dominance. The phenotype of a heterozygote is intermediate between the homozygous forms. For example, crossing red-flowered with white-flowered four o'clocks yields pink heterozygotes.

**independent assortment** In a dihybrid cross, describes the random assortment of alleles for each of the genes. For genes on different chromosomes this results from the random orientations of different homologous pairs during metaphase I of meiosis. For genes on

the same chromosome, this occurs when the two loci are far enough apart for roughly equal numbers of odd- and even-numbered multiple crossover events.

**indeterminate development** A type of development in animals in which the first few embryonic cells are identical daughter cells, any one of which could develop separately into a complete organism; their fate is indeterminate.

**inducer exclusion** Part of the mechanism of glucose repression in *E. coli* in which the presence of glucose prevents the entry of lactose such that the *lac* operon cannot be induced.

**induction** (1) Production of enzymes in response to a substrate; a mechanism by which binding of an inducer to a repressor allows transcription of an operon. This is seen in catabolic operons and results in production of enzymes to degrade a compound only when it is available. (2) In embryonic development, the process by which the development of a cell is influenced by interaction with an adjacent cell.

**inductive reasoning** The logical application of specific observations to make a generalization. In science, inductive reasoning is used to formulate testable hypotheses.

**industrial melanism** Phrase used to describe the evolutionary process in which initially light-colored organisms become dark as a result of natural selection.

**inflammatory response** A generalized nonspecific response to infection that acts to clear an infected area of infecting microbes and dead tissue cells so that tissue repair can begin.

**inhalant siphon** In bivalve mollusks, the siphon through which incoming water enters the body.

**inheritance of acquired characteristics** Also known as Lamarckism; the theory, now discounted, that individuals genetically pass on to their offspring physical and behavioral changes developed during the individuals' own lifetime.

**inhibitor** A substance that binds to an enzyme and decreases its activity.

**initiation factor** One of several proteins involved in the formation of an initiation complex in prokaryote polypeptide synthesis.

**initiator tRNA** A tRNA molecule involved in the beginning of translation. In prokaryotes, the initiator tRNA is charged with *N*-formylmethionine (tRNA<sup>fMet</sup>); in eukaryotes, the tRNA is charged simply with methionine.

**inorganic phosphate** A phosphate molecule that is not a part of an organic molecule; inorganic phosphate groups are added and removed in the formation and breakdown of ATP and in many other cellular reactions.

**inositol-1,4,5-trisphosphate (IP<sub>3</sub>)** Second messenger produced by the cleavage of phosphatidylinositol-4,5-bisphosphate.

**insertional inactivation** Destruction of a gene's function by the insertion of a transposon.

**instar** A larval developmental stage in insects.

**integrin** Any of a group of cell-surface proteins involved in adhesion of cells to substrates. Critical to migrating cells moving through the cell matrix in tissues such as connective tissue.

**intercalary meristem** A type of meristem that arises in stem internodes in some plants, such as corn and horsetails; responsible for elongation of the internodes.

**interferon** In vertebrates, a protein produced in virus-infected cells that inhibits viral multiplication.

**intermembrane space** The outer compartment of a mitochondrion that lies between the two membranes.

**interneuron (association neuron)** A nerve cell found only in the middle of the spinal cord that acts as a functional link between sensory neurons and motor neurons.

**internode** In plants, the region of a stem between two successive nodes.

**interoceptor** A receptor that senses information related to the body itself, its internal condition, and its position.

**interphase** The period between two mitotic or meiotic divisions in which a cell grows and its DNA replicates; includes G<sub>1</sub>, S, and G<sub>2</sub> phases.

**intracellular receptor** A signal receptor that binds a ligand inside a cell, such as the receptors for NO, steroid hormones, vitamin D, and thyroid hormones.

**intron** Portion of mRNA as transcribed from eukaryotic DNA that is removed by enzymes before the mature mRNA is translated into protein. *See* exon.

**inversion** A reversal in order of a segment of a chromosome; also, to turn inside out, as in embryogenesis of sponges or discharge of a nematocyst.

**ionizing radiation** High-energy radiation that is highly mutagenic, producing free radicals that react with DNA; includes X-rays and  $\gamma$ -rays.

**isomer** One of a group of molecules identical in atomic composition but differing in structural arrangement; for example, glucose and fructose.

**isosmotic** The condition in which the osmotic concentrations of two solutions are equal, so that no net water movement occurs between them by osmosis.

**isotonic** A solution having the same concentration of solutes as the cell. A cell in an isotonic solution takes in and loses the same amount of water.

**isotope** Different forms of the same element with the same number of protons but different numbers of neutrons.

**J**  
**jasmonic acid** An organic molecule that is part of a plant's wound response; it signals the production of a proteinase inhibitor.

**K**  
**karyotype** The morphology of the chromosomes of an organism as viewed with a light microscope.

**keratin** A tough, fibrous protein formed in epidermal tissues and modified into skin, feathers, hair, and hard structures such as horns and nails.

**key innovation** A newly evolved trait in a species that allows members to use resources or other aspects of the environment that were previously inaccessible.

**kidney** In vertebrates, the organ that filters the blood to remove nitrogenous wastes and regulates the balance of water and solutes in blood plasma.

**kilocalorie** Unit describing the amount of heat required to raise the temperature of a kilogram of water by 1°C; sometimes called a Calorie, equivalent to 1000 calories.

**kinase cascade** A series of protein kinases that phosphorylate each other in succession; a kinase cascade can amplify signals during the signal transduction process.

**kinesis** Changes in activity level in an animal that are dependent on stimulus intensity. *See* kinetic energy.

**kinetic energy** The energy of motion.

**kinetochore** Disk-shaped protein structure within the centromere to which the spindle fibers attach during mitosis or meiosis. *See* centromere.

**kingdom** The second highest commonly used taxonomic category.

**kin selection** Selection favoring relatives; an increase in the frequency of related individuals (kin) in a population, leading to an increase in the relative frequency in the population of those alleles shared by members of the kin group.

**knockout mice** Mice in which a known gene is inactivated (“knocked out”) using recombinant DNA and ES cells.

**Krebs cycle** Another name for the citric acid cycle; also called the tricarboxylic acid (TCA) cycle.

## L

**labrum** The upper lip of insects and crustaceans situated above or in front of the mandibles.

**lac operon** In *E. coli*, the operon containing genes that encode the enzymes to metabolize lactose.

**lagging strand** The DNA strand that must be synthesized discontinuously because of the 5'-to-3' directionality of DNA polymerase during replication, and the antiparallel nature of DNA. Compare *leading strand*.

**larva** A developmental stage that is unlike the adult found in organisms that undergo metamorphosis. Embryos develop into larvae that produce the adult form by metamorphosis.

**larynx** The voice box; a cartilaginous organ that lies between the pharynx and trachea and is responsible for sound production in vertebrates.

**lateral line system** A sensory system encountered in fish, through which mechanoreceptors in a line down the side of the fish are sensitive to motion.

**lateral meristems** In vascular plants, the meristems that give rise to secondary tissue; the vascular cambium and cork cambium.

**Law of Independent Assortment** Mendel's second law of heredity, stating that genes located on nonhomologous chromosomes assort independently of one another.

**Law of Segregation** Mendel's first law of heredity, stating that alternative alleles for the same gene segregate from each other in production of gametes.

**leading strand** The DNA strand that can be synthesized continuously from the origin of replication. Compare *lagging strand*.

**leaf primordium, pl. primordia** A lateral outgrowth from the apical meristem that will eventually become a leaf.

**lenticels** Spongy areas in the cork surfaces of stem, roots, and other plant parts that allow interchange of gases between internal tissues and the atmosphere through the periderm.

**leucine zipper motif** A motif in regulatory proteins in which two different protein subunits associate to form a single DNA-binding site; the proteins are connected by an association between hydrophobic regions containing leucines (the “zipper”).

**leucoplast** In plant cells, a colorless plastid in which starch grains are stored; usually found in cells not exposed to light.

**leukocyte** A white blood cell; a diverse array of nonhemoglobin-containing blood cells, including phagocytic macrophages and antibody-producing lymphocytes.

**lichen** Symbiotic association between a fungus and a photosynthetic organism such as a green alga or cyanobacterium.

**ligand** A signaling molecule that binds to a specific receptor protein, initiating signal transduction in cells.

**light-dependent reactions** In photosynthesis, the reactions in which light energy is captured and used in production of ATP and NADPH. In plants this involves the action of two linked photosystems.

**light-independent reactions** In photosynthesis, the reactions of the Calvin cycle in which ATP and NADPH from the light-dependent reactions are used to reduce CO<sub>2</sub> and produce organic compounds such as glucose. This involves the process of carbon fixation, or the conversion of inorganic carbon (CO<sub>2</sub>) to organic carbon (ultimately carbohydrates).

**lignin** A highly branched polymer that makes plant cell walls more rigid; an important component of wood.

**limbic system** The hypothalamus, together with the network of neurons that link the hypothalamus to some areas of the cerebral cortex. Responsible for many of the most deep-seated drives and emotions of vertebrates, including pain, anger, sex, hunger, thirst, and pleasure.

**linked genes** Genes that are physically close together and therefore tend to segregate together; recombination occurring between linked genes can be used to produce a map of genetic distance for a chromosome.

**linkage disequilibrium** Association of alleles for 2 or more loci in a population that is higher than expected by chance.

**lipase** An enzyme that catalyzes the hydrolysis of fats.

**lipid** A nonpolar hydrophobic organic molecule that is insoluble in water (which is polar) but dissolves readily in nonpolar organic solvents; includes fats, oils, waxes, steroids, phospholipids, and carotenoids.

**lipid bilayer** The structure of a cellular membrane, in which two layers of phospholipids spontaneously align so that the hydrophilic head groups are exposed to water, while the hydrophobic fatty acid tails are pointed toward the center of the membrane.

**lipopolysaccharide** A lipid with a polysaccharide molecule attached; found in the outer membrane layer of gram-negative bacteria; the outer membrane layer protects the cell wall from antibiotic attack.

**locus** The position on a chromosome where a gene is located.

**long interspersed element (LINE)** Any of a type of large transposable element found in humans and other primates that contains all the biochemical machinery needed for transposition.

**long terminal repeat (LTR)** A particular type of retrotransposon that has repeated elements at its ends. These elements make up 8% of the human genome.

**loop of Henle** In the kidney of birds and mammals, a hairpin-shaped portion of the renal tubule in which water and salt are reabsorbed from the glomerular filtrate by diffusion.

**lophophore** A horseshoe-shaped crown of ciliated tentacles that surrounds the mouth of certain spiralian animals; seen in the phyla Brachiopoda and Bryozoa.

**lumen** A term for any bounded opening; for example, the cisternal space of the endoplasmic reticulum of eukaryotic cells, the passage through which blood flows inside a blood vessel, and the passage through which material moves inside the intestine during digestion.

**luteal phase** The second phase of the female reproductive cycle, during which the mature eggs are released into the fallopian tubes, a process called ovulation.

**lymph** In animals, a colorless fluid derived from blood by filtration through capillary walls in the tissues.

**lymphatic system** In animals, an open vascular system that reclaims water that has entered interstitial regions from the bloodstream (lymph); includes the lymph nodes, spleen, thymus, and tonsils.

**lymphocyte** A type of white blood cell. Lymphocytes are responsible for the immune response; there are two principal classes: B cells and T cells.

**lymphokine** A regulatory molecule that is secreted by lymphocytes. In the immune response, lymphokines secreted by helper T cells unleash the cell-mediated immune response.

**lysis** Disintegration of a cell by rupture of its plasma membrane.

**lysogenic cycle** A viral cycle in which the viral DNA becomes integrated into the host chromosome and is replicated during cell reproduction. Results in vertical rather than horizontal transmission.

**lysosome** A membrane-bounded vesicle containing digestive enzymes that is produced by the Golgi apparatus in eukaryotic cells.

**lytic cycle** A viral cycle in which the host cell is killed (lysed) by the virus after viral duplication to release viral particles.

## M

**macroevolution** The creation of new species and the extinction of old ones.

**macromolecule** An extremely large biological molecule; refers specifically to proteins, nucleic acids, polysaccharides, lipids, and complexes of these.

**macronutrients** Inorganic chemical elements required in large amounts for plant growth, such as nitrogen, potassium, calcium, phosphorus, magnesium, and sulfur.

**macrophage** A large phagocytic cell that is able to engulf and digest cellular debris and invading bacteria.

**madreporite** A sievelike plate on the surface of echinoderms through which water enters the water-vascular system.

**MADS box gene** Any of a family of genes identified by possessing shared motifs that are the predominant homeotic genes of plants; a small number of MADS box genes are also found in animals.

- major groove** The larger of the two grooves in a DNA helix, where the paired nucleotides' hydrogen bonds are accessible; regulatory proteins can recognize and bind to regions in the major groove.
- major histocompatibility complex (MHC)** A set of protein cell-surface markers anchored in the plasma membrane, which the immune system uses to identify "self." All the cells of a given individual have the same "self" marker, called an MHC protein.
- Malpighian tubules** Blind tubules opening into the hindgut of terrestrial arthropods; they function as excretory organs.
- mandibles** In crustaceans, insects, and myriapods, the appendages immediately posterior to the antennae; used to seize, hold, bite, or chew food.
- mantle** The soft, outermost layer of the body wall in mollusks; the mantle secretes the shell.
- map unit** Each 1% of recombination frequency between two genetic loci; the unit is termed a centimorgan (cM) or simply a map unit (m.u.).
- marsupial** A mammal in which the young are born early in their development, sometimes as soon as eight days after fertilization, and are retained in a pouch.
- mass extinction** A relatively sudden, sharp decline in the number of species; for example, the extinction at the end of the Cretaceous period in which the dinosaurs and a variety of other organisms disappeared.
- mass flow hypothesis** The overall process by which materials move in the phloem of plants.
- mast cells** Leukocytes with granules containing molecules that initiate inflammation.
- maternal inheritance** A mode of uniparental inheritance from the female parent; for example, in humans mitochondria and their genomes are inherited from the mother.
- matrix** In mitochondria, the solution in the interior space surrounded by the cristae that contains the enzymes and other molecules involved in oxidative respiration; more generally, that part of a tissue within which an organ or process is embedded.
- medusa** A free-floating, often umbrella-shaped body form found in cnidarian animals, such as jellyfish.
- megapascal (MPa)** A unit of measure used for pressure in water potential.
- megaphyll** In plants, a leaf that has several to many veins connecting it to the vascular cylinder of the stem; most plants have megaphylls.
- mesoglea** A layer of gelatinous material found between the epidermis and gastrodermis of eumetazoans; it contains the muscles in most of these animals.
- mesohyl** A gelatinous, protein-rich matrix found between the choanocyte layer and the epithelial layer of the body of a sponge; various types of amoeboid cells may occur in the mesohyl.
- metacercaria** An encysted form of a larval liver fluke, found in muscle tissue of an infected animal; if the muscle is eaten, cysts dissolve in the digestive tract, releasing the flukes into the body of the new host.
- methylation** The addition of a methyl group to bases (primarily cytosine) in DNA. Cytosine methylation is correlated with DNA that is not expressed.
- meiosis I** The first round of cell division in meiosis; it is referred to as a "reduction division" because homologous chromosomes separate, and the daughter cells have only the haploid number of chromosomes.
- meiosis II** The second round of division in meiosis, during which the two haploid cells from meiosis I undergo a mitosis-like division without DNA replication to produce four haploid daughter cells.
- membrane receptor** A signal receptor present as an integral protein in the cell membrane, such as GPCRs, chemically gated ion channels in neurons, and RTKs.
- Mendelian ratio** The characteristic dominant-to-recessive phenotypic ratios that Mendel observed in his genetics experiments. For example, the F<sub>2</sub> generation in a monohybrid cross shows a ratio of 3:1; the F<sub>2</sub> generation in a dihybrid cross shows a ratio of 9:3:3:1.
- menstruation** Periodic sloughing off of the blood-enriched lining of the uterus when pregnancy does not occur.
- meristem** Undifferentiated plant tissue from which new cells arise.
- meroblastic cleavage** A type of cleavage in the eggs of reptiles, birds, and some fish. Occurs only on the blastodisc.
- mesoderm** One of the three embryonic germ layers that form in the gastrula; gives rise to muscle, bone and other connective tissue, the peritoneum, the circulatory system, and most of the excretory and reproductive systems.
- mesophyll** The photosynthetic parenchyma of a leaf, located within the epidermis.
- messenger RNA (mRNA)** The RNA transcribed from structural genes; RNA molecules complementary to a portion of one strand of DNA, which are translated by the ribosomes to form protein.
- metabolism** The sum of all chemical processes occurring within a living cell or organism.
- metamorphosis** Process in which a marked change in form takes place during postembryonic development as, for example, from tadpole to frog.
- metaphase** The stage of mitosis or meiosis during which microtubules become organized into a spindle and the chromosomes come to lie in the spindle's equatorial plane.
- metastasis** The process by which cancer cells move from their point of origin to other locations in the body; also, a population of cancer cells in a secondary location, the result of movement from the primary tumor.
- methanogens** Obligate, anaerobic archaeobacteria that produce methane.
- microarray** DNA sequences are placed on a microscope slide or chip with a robot. The microarray can then be probed with RNA from specific tissues to identify expressed DNA.
- microbody** A cellular organelle bounded by a single membrane and containing a variety of enzymes; generally derived from endoplasmic reticulum; includes peroxisomes and glyoxysomes.
- microevolution** Refers to the evolutionary process itself. Evolution within a species. Also called adaptation.
- micronutrient** A mineral required in only minute amounts for plant growth, such as iron, chlorine, copper, manganese, zinc, molybdenum, and boron.
- microphyll** In plants, a leaf that has only one vein connecting it to the vascular cylinder of the stem; the club mosses in particular have microphylls.
- micropyle** In the ovules of seed plants, an opening in the integuments through which the pollen tube usually enters.
- micro-RNA (miRNA)** A class of RNAs that are very short and only recently could be detected. *See also* small interfering RNAs (siRNAs).
- microtubule** In eukaryotic cells, a long, hollow protein cylinder, composed of the protein tubulin; these influence cell shape, move the chromosomes in cell division, and provide the functional internal structure of cilia and flagella.
- microvillus** Cytoplasmic projection from epithelial cells; microvilli greatly increase the surface area of the small intestine.
- middle lamella** The layer of intercellular material, rich in pectic compounds, that cements together the primary walls of adjacent plant cells.
- mimicry** The resemblance in form, color, or behavior of certain organisms (mimics) to other more powerful or more protected ones (models).
- miracidium** The ciliated first-stage larva inside the egg of the liver fluke; eggs are passed in feces, and if they reach water they may be eaten by a host snail in which they continue their life cycle.
- missense mutation** A base substitution mutation that results in the alteration of a single amino acid.
- mitochondrion** The organelle called the powerhouse of the cell. Consists of an outer membrane, an elaborate inner membrane that supports electron transport and chemiosmotic synthesis of ATP, and a soluble matrix containing Krebs cycle enzymes.
- mitogen-activated protein (MAP) kinase** Any of a class of protein kinases that activate transcription factors to alter gene expression. A mitogen is any molecule that stimulates cell division. MAP kinases are activated by kinase cascades.
- mitosis** Somatic cell division; nuclear division in which the duplicated chromosomes separate to form two genetically identical daughter nuclei.
- molar concentration** Concentration expressed as moles of a substance in 1 L of pure water.
- mole** The weight of a substance in grams that corresponds to the atomic masses of all the component atoms in a molecule of that substance. One mole of a compound always contains  $6.023 \times 10^{23}$  molecules.
- molecular clock method** In evolutionary theory, the method in which the rate of evolution of a molecule is constant through time.
- molecular cloning** The isolation and amplification of a specific sequence of DNA.
- monocot** Short for monocotyledon; flowering plant in which the embryos have only one cotyledon, the floral parts are generally in threes, and the leaves typically are parallel-veined.
- monocyte** A type of leukocyte that becomes a phagocytic cell (macrophage) after moving into tissues.
- monoecious** A plant in which the staminate and pistillate flowers are separate, but borne on the same individual.
- monomer** The smallest chemical subunit of a polymer. The monosaccharide  $\alpha$ -glucose is the monomer found in plant starch, a polysaccharide.

**monophyletic** In phylogenetic classification, a group that includes the most recent common ancestor of the group and all its descendants. A clade is a monophyletic group.

**monosaccharide** A simple sugar that cannot be decomposed into smaller sugar molecules.

**monosomic** Describes the condition in which a chromosome has been lost due to nondisjunction during meiosis, producing a diploid embryo with only one of these autosomes.

**monotreme** An egg-laying mammal.

**morphogen** A signal molecule produced by an embryonic organizer region that informs surrounding cells of their distance from the organizer, thus determining relative positions of cells during development.

**morphogenesis** The development of an organism's body form, namely its organs and anatomical features; it may involve apoptosis as well as cell division, differentiation, and changes in cell shape.

**morphology** The form and structure of an organism.

**morula** Solid ball of cells in the early stage of embryonic development.

**mosaic development** A pattern of embryonic development in which initial cells produced by cleavage divisions contain different developmental signals (determinants) from the egg, setting the individual cells on different developmental paths.

**motif** A substructure in proteins that confers function and can be found in multiple proteins. One example is the helix-turn-helix motif found in a number of proteins that is used to bind to DNA.

**motor (efferent) neuron** Neuron that transmits nerve impulses from the central nervous system to an effector, which is typically a muscle or gland.

**M phase** The phase of cell division during which chromosomes are separated. The spindle assembles, binds to the chromosomes, and moves the sister chromatids apart.

**M phase-promoting factor (MPF)** A Cdk enzyme active at the G<sub>2</sub>/M checkpoint.

**Müllerian mimicry** A phenomenon in which two or more unrelated but protected species resemble one another, thus achieving a kind of group defense.

**multidrug-resistant (MDR) strain** Any bacterial strain that has become resistant to more than one antibiotic drug; MDR *Staphylococcus* strains, for example, are responsible for many infection deaths.

**multienzyme complex** An assembly consisting of several enzymes catalyzing different steps in a sequence of reactions. Close proximity of these related enzymes speeds the overall process, making it more efficient.

**multigene family** A collection of related genes on a single chromosome or on different chromosomes.

**muscle fiber** A long, cylindrical, multinucleated cell containing numerous myofibrils, which is capable of contraction when stimulated.

**mutagen** An agent that induces changes in DNA (mutations); includes physical agents that damage DNA and chemicals that alter DNA bases.

**mutation** A permanent change in a cell's DNA; includes changes in nucleotide sequence, alteration of gene position, gene loss or duplication, and insertion of foreign sequences.

**mutualism** A symbiotic association in which two (or more) organisms live together, and both members benefit.

**mycelium, pl. mycelia** In fungi, a mass of hyphae.

**mycorrhiza, pl. mycorrhizae** A symbiotic association between fungi and the roots of a plant.

**myelin sheath** A fatty layer surrounding the long axons of motor neurons in the peripheral nervous system of vertebrates.

**myofilament** A contractile microfilament, composed largely of actin and myosin, within muscle.

**myosin** One of the two protein components of microfilaments (the other is actin); a principal component of vertebrate muscle.

## N

**natural killer cell** A cell that does not kill invading microbes, but rather, the cells infected by them.

**natural selection** The differential reproduction of genotypes; caused by factors in the environment; leads to evolutionary change.

**nauplius** A larval form characteristic of crustaceans.

**negative control** A type of control at the level of DNA transcription initiation in which the frequency of initiation is decreased; repressor proteins mediate negative control.

**negative feedback** A homeostatic control mechanism whereby an increase in some substance or activity inhibits the process leading to the increase; also known as feedback inhibition.

**nematocyst** A harpoonlike structure found in the cnidocytes of animals in the phylum Cnidaria, which includes the jellyfish among other groups; the nematocyst, when released, stings and helps capture prey.

**nephridium, pl. nephridia** In invertebrates, a tubular excretory structure.

**nephrid organ** A filtration system of many freshwater invertebrates in which water and waste pass from the body across the membrane into a collecting organ, from which they are expelled to the outside through a pore.

**nephron** Functional unit of the vertebrate kidney; one of numerous tubules involved in filtration and selective reabsorption of blood; each nephron consists of a Bowman's capsule, an enclosed glomerulus, and a long attached tubule; in humans, called a renal tubule.

**nephrostome** The funnel-shaped opening that leads to the nephridium, which is the excretory organ of mollusks.

**nerve** A group or bundle of nerve fibers (axons) with accompanying neurological cells, held together by connective tissue; located in the peripheral nervous system.

**nerve cord** One of the distinguishing features of chordates, running lengthwise just beneath the embryo's dorsal surface; in vertebrates, differentiates into the brain and spinal cord.

**neural crest** A special strip of cells that develops just before the neural groove closes over to form the neural tube in embryonic development.

**neural groove** The long groove formed along the long axis of the embryo by a layer of ectodermal cells.

**neural tube** The dorsal tube, formed from the neural plate, that differentiates into the brain and spinal cord.

**neuroglia** Nonconducting nerve cells that are intimately associated with neurons and appear to provide nutritional support.

**neuromuscular junction** The structure formed when the tips of axons contact (innervate) a muscle fiber.

**neuron** A nerve cell specialized for signal transmission; includes cell body, dendrites, and axon.

**neurotransmitter** A chemical released at the axon terminal of a neuron that travels across the synaptic cleft, binds a specific receptor on the far side, and depending on the nature of the receptor, depolarizes or hyperpolarizes a second neuron or a muscle or gland cell.

**neurulation** A process in early embryonic development by which a dorsal band of ectoderm thickens and rolls into the neural tube.

**neutrophil** An abundant type of granulocyte capable of engulfing microorganisms and other foreign particles; neutrophils comprise about 50–70% of the total number of white blood cells.

**niche** The role played by a particular species in its environment.

**nicotinamide adenine dinucleotide (NAD)** A molecule that becomes reduced (to NADH) as it carries high-energy electrons from oxidized molecules and delivers them to ATP-producing pathways in the cell.

**NADH dehydrogenase** An enzyme located on the inner mitochondrial membrane that catalyzes the oxidation by NAD<sup>+</sup> of pyruvate to acetyl-CoA. This reaction links glycolysis and the Krebs cycle.

**nitrification** The oxidation of ammonia or nitrite to produce nitrate, the form of nitrogen taken up by plants; some bacteria are capable of nitrification.

**nociceptor** A naked dendrite that acts as a receptor in response to a pain stimulus.

**nocturnal** Active primarily at night.

**node** The part of a plant stem where one or more leaves are attached. *See* internode.

**node of Ranvier** A gap formed at the point where two Schwann cells meet and where the axon is in direct contact with the surrounding intercellular fluid.

**nodule** In plants, a specialized tissue that surrounds and houses beneficial bacteria, such as root nodules of legumes that contain nitrogen-fixing bacteria.

**nonassociative learning** A learned behavior that does not require an animal to form an association between two stimuli, or between a stimulus and a response.

**noncompetitive inhibitor** An inhibitor that binds to a location other than the active site of an enzyme, changing the enzyme's shape so that it cannot bind the substrate.

**noncyclic photophosphorylation** The set of light-dependent reactions of the two plant photosystems, in which excited electrons are shuttled between the two photosystems, producing a proton gradient that is used for the

chemiosmotic synthesis of ATP. The electrons are used to reduce NADP to NADPH. Lost electrons are replaced by the oxidation of water producing O<sub>2</sub>.

**nondisjunction** The failure of homologues or sister chromatids to separate during mitosis or meiosis, resulting in an aneuploid cell or gamete.

**nonextreme archaea** Archaeal groups that are not extremophiles, living in more moderate environments on Earth today.

**nonpolar** Said of a covalent bond that involves equal sharing of electrons. Can also refer to a compound held together by nonpolar covalent bonds.

**nonsense codon** One of three codons (UAA, UAG, and UGA) that are not recognized by tRNAs, thus serving as “stop” signals in the mRNA message and terminating translation.

**nonsense mutation** A base substitution in which a codon is changed into a stop codon. The protein is truncated because of premature termination.

**Northern blot** A blotting technique used to identify a specific mRNA sequence in a complex mixture. *See* Southern blot.

**notochord** In chordates, a dorsal rod of cartilage that runs the length of the body and forms the primitive axial skeleton in the embryos of all chordates.

**nuellus** Tissue composing the chief pair of young ovules, in which the embryo sac develops; equivalent to a megasporangium.

**nuclear envelope** The bounding structure of the eukaryotic nucleus. Composed of two phospholipid bilayers with the outer one connected to the endoplasmic reticulum.

**nuclear pore** One of a multitude of tiny but complex openings in the nuclear envelope that allow selective passage of proteins and nucleic acids into and out of the nucleus.

**nuclear receptor** Intracellular receptors are found in both the cytoplasm and the nucleus. The site of action of the hormone–receptor complex is in the nucleus where they modify gene expression.

**nucleic acid** A nucleotide polymer; chief types are deoxyribonucleic acid (DNA), which is double-stranded, and ribonucleic acid (RNA), which is typically single-stranded.

**nucleoid** The area of a prokaryotic cell, usually near the center, that contains the genome in the form of DNA compacted with protein.

**nucleolus** In eukaryotes, the site of rRNA synthesis; a spherical body composed chiefly of rRNA in the process of being transcribed from multiple copies of rRNA genes.

**nucleosome** A complex consisting of a DNA duplex wound around a core of eight histone proteins.

**nucleotide** A single unit of nucleic acid, composed of a phosphate, a five-carbon sugar (either ribose or deoxyribose), and a purine or a pyrimidine.

**nucleus** In atoms, the central core, containing positively charged protons and (in all but hydrogen) electrically neutral neutrons; in eukaryotic cells, the membranous organelle that houses the chromosomal DNA; in the central nervous system, a cluster of nerve cell bodies.

**nutritional mutation** A mutation affecting a synthetic pathway for a vital compound, such as an amino acid or vitamin; microorganisms with a nutritional mutation must be grown on medium that supplies the missing nutrient.

## O

**ocellus**, pl. **ocelli** A simple light receptor common among invertebrates.

**octet rule** Rule to describe patterns of chemical bonding in main group elements that require a total of eight electrons to complete their outer electron shell.

**Okazaki fragment** A short segment of DNA produced by discontinuous replication elongating in the 5'-to-3' direction away from the replication.

**olfaction** The function of smelling.

**ommatidium**, pl. **ommatidia** The visual unit in the compound eye of arthropods; contains light-sensitive cells and a lens able to form an image.

**oncogene** A mutant form of a growth-regulating gene that is inappropriately “on,” causing unrestrained cell growth and division.

**oocyst** The zygote in a sporozoan life cycle. It is surrounded by a tough cyst to prevent dehydration or other damage.

**open circulatory system** A circulatory system in which the blood flows into sinuses in which it mixes with body fluid and then reenters the vessels in another location.

**open reading frame (ORF)** A region of DNA that encodes a sequence of amino acids with no stop codons in the reading frame.

**operant conditioning** A learning mechanism in which the reward follows only after the correct behavioral response.

**operator** A regulatory site on DNA to which a repressor can bind to prevent or decrease initiation of transcription.

**operculum** A flat, bony, external protective covering over the gill chamber in fish.

**operon** A cluster of adjacent structural genes transcribed as a unit into a single mRNA molecule.

**opisthosoma** The posterior portion of the body of an arachnid.

**oral surface** The surface on which the mouth is found; used as a reference when describing the body structure of echinoderms because of their adult radial symmetry.

**orbital** A region around the nucleus of an atom with a high probability of containing an electron. The position of electrons can only be described by these probability distributions.

**order** A category of classification above the level of family and below that of class.

**organ** A body structure composed of several different tissues grouped in a structural and functional unit.

**organelle** Specialized part of a cell; literally, a small cytoplasmic organ.

**orthologues** Genes that reflect the conservation of a single gene found in an ancestor.

**oscillating selection** The situation in which selection alternately favors one phenotype at one time, and a different phenotype at another time, for example, during drought conditions versus during wet conditions.

**osculum** A specialized, larger pore in sponges through which filtered water is forced to the outside of the body.

**osmoconformer** An animal that maintains the osmotic concentration of its body fluids at about the same level as that of the medium in which it is living.

**osmosis** The diffusion of water across a selectively permeable membrane (a membrane that permits the free passage of water but prevents or retards the passage of a solute); in the absence of differences in pressure or volume, the net movement of water is from the side containing a lower concentration of solute to the side containing a higher concentration.

**osmotic concentration** The property of a solution that takes into account all dissolved solutes in the solution; if two solutions with different osmotic concentrations are separated by a water-permeable membrane, water will move from the solution with lower osmotic concentration to the solution with higher osmotic concentration.

**osmotic pressure** The potential pressure developed by a solution separated from pure water by a differentially permeable membrane. The higher the solute concentration, the greater the osmotic potential of the solution; also called *osmotic potential*.

**ossicle** Any of a number of movable or fixed calcium-rich plates that collectively make up the endoskeleton of echinoderms.

**osteoblast** A bone-forming cell.

**osteocyte** A mature osteoblast.

**outcrossing** Breeding with individuals other than oneself or one's close relatives.

**ovary** (1) In animals, the organ in which eggs are produced. (2) In flowering plants, the enlarged basal portion of a carpel that contains the ovule(s); the ovary matures to become the fruit.

**oviduct** In vertebrates, the passageway through which ova (eggs) travel from the ovary to the uterus.

**oviparity** Refers to a type of reproduction in which the eggs are developed after leaving the body of the mother, as in reptiles.

**ovoviviparity** Refers to a type of reproduction in which young hatch from eggs that are retained in the mother's uterus.

**ovulation** In animals, the release of an egg or eggs from the ovary.

**ovum**, pl. **ova** The egg cell; female gamete.

**oxidation** Loss of an electron by an atom or molecule; in metabolism, often associated with a gain of oxygen or a loss of hydrogen.

**oxidation–reduction reaction** A type of paired reaction in living systems in which electrons lost from one atom (oxidation) are gained by another atom (reduction). Termed a *redox reaction* for short.

**oxidative phosphorylation** Synthesis of ATP by ATP synthase using energy from a proton gradient. The proton gradient is generated by electron transport, which requires oxygen.

**oxygen debt** The amount of oxygen required to convert the lactic acid generated in the muscles during exercise back into glucose.

**oxytocin** A hormone of the posterior pituitary gland that affects uterine contractions during childbirth and stimulates lactation.

**ozone** O<sub>3</sub>, a stratospheric layer of the Earth's atmosphere responsible for filtering out ultraviolet radiation supplied by the Sun.

# P

**p53 gene** The gene that produces the p53 protein that monitors DNA integrity and halts cell division if DNA damage is detected. Many types of cancer are associated with a damaged or absent p53 gene.

**pacemaker** A patch of excitatory tissue in the vertebrate heart that initiates the heartbeat.

**pair-rule gene** Any of certain genes in *Drosophila* development controlled by the gap genes that are expressed in stripes that subdivide the embryo in the process of segmentation.

**paleopolyploid** An ancient polyploid organism used in analysis of polyploidy events in the study of a species' genome evolution.

**palisade parenchyma** In plant leaves, the columnar, chloroplast-containing parenchyma cells of the mesophyll. Also called *palisade cells*.

**panspermia** The hypothesis that meteors or cosmic dust may have brought significant amounts of complex organic molecules to Earth, kicking off the evolution of life.

**papilla** A small projection of tissue.

**paracrine** A type of chemical signaling between cells in which the effects are local and short-lived.

**paralogues** Two genes within an organism that arose from the duplication of one gene in an ancestor.

**paraphyletic** In phylogenetic classification, a group that includes the most recent common ancestor of the group, but not all its descendants.

**parapodia** One of the paired lateral processes on each side of most segments in polychaete annelids.

**parasexuality** In certain fungi, the fusion and segregation of heterokaryotic haploid nuclei to produce recombinant nuclei.

**parasitism** A living arrangement in which an organism lives on or in an organism of a different species and derives nutrients from it.

**parenchyma cell** The most common type of plant cell, characterized by large vacuoles, thin walls, and functional nuclei.

**parthenogenesis** The development of an egg without fertilization, as in aphids, bees, ants, and some lizards.

**partial diploid (merodiploid)** Describes an *E. coli* cell that carries an F' plasmid with host genes. This makes the cell diploid for the genes carried by the F' plasmid.

**partial pressure** The components of each individual gas—such as nitrogen, oxygen, and carbon dioxide—that together constitute the total air pressure.

**passive transport** The movement of substances across a cell's membrane without the expenditure of energy.

**pedigree** A consistent graphic representation of matings and offspring over multiple generations for a particular genetic trait, such as albinism or hemophilia.

**pedipalps** A pair of specialized appendages found in arachnids; in male spiders, these are specialized as copulatory organs, whereas in scorpions they are large pincers.

**pelagic** Free-swimming, usually in open water.

**pellicle** A tough, flexible covering in ciliates and euglenoids.

**pentaradial symmetry** The five-part radial symmetry characteristic of adult echinoderms.

**peptide bond** The type of bond that links amino acids together in proteins through a dehydration reaction.

**peptidoglycan** A component of the cell wall of bacteria, consisting of carbohydrate polymers linked by protein cross-bridges.

**peptidyl transferase** In translation, the enzyme responsible for catalyzing the formation of a peptide bond between each new amino acid and the previous amino acid in a growing polypeptide chain.

**perianth** In flowering plants, the petals and sepals taken together.

**pericycle** In vascular plants, one or more cell layers surrounding the vascular tissues of the root, bounded externally by the endodermis and internally by the phloem.

**periderm** Outer protective tissue in vascular plants that is produced by the cork cambium and functionally replaces epidermis when it is destroyed during secondary growth; the periderm includes the cork, cork cambium, and phelloderm.

**peristalsis** In animals, a series of alternating contracting and relaxing muscle movements along the length of a tube such as the oviduct or alimentary canal that tend to force material such as an egg cell or food through the tube.

**peroxisome** A microbody that plays an important role in the breakdown of highly oxidative hydrogen peroxide by catalase.

**petal** A flower part, usually conspicuously colored; one of the units of the corolla.

**petiole** The stalk of a leaf.

**phage conversion** The phenomenon by which DNA from a virus, incorporated into a host cell's genome, alters the host cell's function in a significant way; for example, the conversion of *Vibrio cholerae* bacteria into a pathogenic form that releases cholera toxin.

**phage lambda ( $\lambda$ )** A well-known bacteriophage that has been widely used in genetic studies and is often a vector for DNA libraries.

**phagocyte** Any cell that engulfs and devours microorganisms or other particles.

**phagocytosis** Endocytosis of a solid particle; the plasma membrane folds inward around the particle (which may be another cell) and engulfs it to form a vacuole.

**pharyngeal pouches** In chordates, embryonic regions that become pharyngeal slits in aquatic and marine chordates and vertebrates, but do not develop openings to the outside in terrestrial vertebrates.

**pharyngeal slits** One of the distinguishing features of chordates; a group of openings on each side of the anterior region that form a passageway from the pharynx and esophagus to the external environment.

**pharynx** A muscular structure lying posterior to the mouth in many animals; aids in propelling food into the digestive tract.

**phenotype** The realized expression of the genotype; the physical appearance or functional expression of a trait.

**pheromone** Chemical substance released by one organism that influences the behavior or physiological processes of another organism of the same species. Pheromones serve as sex attractants, as trail markers, and as alarm signals.

**phloem** In vascular plants, a food-conducting tissue basically composed of sieve elements, various kinds of parenchyma cells, fibers, and sclereids.

**phoronid** Any of a group of lophophorate invertebrates, now classified in the phylum Brachiopoda, that burrows into soft underwater substrates and secretes a chitinous tube in which it lives out its life; it extends its lophophore tentacles to feed on drifting food particles.

**phosphatase** Any of a number of enzymes that removes a phosphate group from a protein, reversing the action of a kinase.

**phosphodiester bond** The linkage between two sugars in the backbone of a nucleic acid molecule; the phosphate group connects the pentose sugars through a pair of ester bonds.

**phospholipid** Similar in structure to a fat, but having only two fatty acids attached to the glycerol backbone, with the third space linked to a phosphorylated molecule; contains a polar hydrophilic "head" end (phosphate group) and a nonpolar hydrophobic "tail" end (fatty acids).

**phospholipid bilayer** The main component of cell membranes; phospholipids naturally associate in a bilayer with hydrophobic fatty acids oriented to the inside and hydrophilic phosphate groups facing outward on both sides.

**phosphorylation** Chemical reaction resulting in the addition of a phosphate group to an organic molecule. Phosphorylation of ADP yields ATP. Many proteins are also activated or inactivated by phosphorylation.

**photoelectric effect** The ability of a beam of light to excite electrons, creating an electrical current.

**photon** A particle of light having a discrete amount of energy. The wave concept of light explains the different colors of the spectrum, whereas the particle concept of light explains the energy transfers during photosynthesis.

**photoperiodism** The tendency of biological reactions to respond to the duration and timing of day and night; a mechanism for measuring seasonal time.

**photoreceptor** A light-sensitive sensory cell.

**photorespiration** Action of the enzyme rubisco, which catalyzes the oxidation of RuBP, releasing CO<sub>2</sub>; this reverses carbon fixation and can reduce the yield of photosynthesis.

**photosystem** An organized complex of chlorophyll, other pigments, and proteins that traps light energy as excited electrons. Plants have two linked photosystems in the thylakoid membrane of chloroplasts. Photosystem II passes an excited electron through an electron transport chain to photosystem I to replace an excited electron passed to NADPH. The electron lost from photosystem II is replaced by the oxidation of water.

**phototropism** In plants, a growth response to a light stimulus.

**pH scale** A scale used to measure acidity and basicity. Defined as the negative log of H<sup>+</sup> concentration. Ranges from 0 to 14. A value of 7 is neutral; below 7 is acidic and above 7 is basic.

**phycobiloprotein** A type of accessory pigment found in cyanobacteria and some algae. Complexes of phycobiloprotein are able to absorb light energy in the green range.

- phycologist** A scientist who studies algae.
- phyllotaxy** In plants, a spiral pattern of leaf arrangement on a stem in which sequential leaves are at a 137.5° angle to one another, an angle related to the golden mean.
- phylogenetic species concept (PSC)** The concept that defines species on the basis of their phylogenetic relationships.
- phylogenetic tree** A pattern of descent generated by analysis of similarities and differences among organisms. Modern gene-sequencing techniques have produced phylogenetic trees showing the evolutionary history of individual genes.
- phylogeny** The evolutionary history of an organism, including which species are closely related and in what order related species evolved; often represented in the form of an evolutionary tree.
- phylum, pl. phyla** A major category, between kingdom and class, of taxonomic classifications.
- physical map** A map of the DNA sequence of a chromosome or genome based on actual landmarks within the DNA.
- phytochrome** A plant pigment that is associated with the absorption of light; photoreceptor for red to far-red light.
- phytoestrogen** One of a number of secondary metabolites in some plants that are structurally and functionally similar to the animal hormone estrogen.
- phytoremediation** The process that uses plants to remove contamination from soil or water.
- pigment** A molecule that absorbs light.
- pilus, pl. pili** Extensions of a bacterial cell enabling it to transfer genetic materials from one individual to another or to adhere to substrates.
- pinocytosis** The process of fluid uptake by endocytosis in a cell.
- pistil** Central organ of flowers, typically consisting of ovary, style, and stigma; a pistil may consist of one or more fused carpels and is more technically and better known as the gynoecium.
- pith** The ground tissue occupying the center of the stem or root within the vascular cylinder.
- pituitary gland** Endocrine gland at the base of the hypothalamus composed of anterior and posterior lobes. Pituitary hormones affect a wide variety of processes in vertebrates.
- placenta, pl. placentae** (1) In flowering plants, the part of the ovary wall to which the ovules or seeds are attached. (2) In mammals, a tissue formed in part from the inner lining of the uterus and in part from other membranes, through which the embryo (later the fetus) is nourished while in the uterus and through which wastes are carried away.
- plankton** Free-floating, mostly microscopic, aquatic organisms.
- plant receptor kinase** Any of a group of plant membrane receptors that, when activated by binding ligand, have kinase enzymatic activity. These receptors phosphorylate serine or threonine, unlike RTKs in animals that phosphorylate tyrosine.
- planula** A ciliated, free-swimming larva produced by the medusae of cnidarian animals.
- plasma** The fluid of vertebrate blood; contains dissolved salts, metabolic wastes, hormones, and a variety of proteins, including antibodies and albumin; blood minus the blood cells.
- plasma cell** An antibody-producing cell resulting from the multiplication and differentiation of a B lymphocyte that has interacted with an antigen.
- plasma membrane** The membrane surrounding the cytoplasm of a cell; consists of a single phospholipid bilayer with embedded proteins.
- plasmid** A small fragment of extrachromosomal DNA, usually circular, that replicates independently of the main chromosome, although it may have been derived from it.
- plasmodesmata** In plants, cytoplasmic connections between adjacent cells.
- plasmodium** Stage in the life cycle of myxomycetes (plasmodial slime molds); a multinucleate mass of protoplasm surrounded by a membrane.
- plasmolysis** The shrinking of a plant cell in a hypertonic solution such that it pulls away from the cell wall.
- plastid** An organelle in the cells of photosynthetic eukaryotes that is the site of photosynthesis and, in plants and green algae, of starch storage.
- platelet** In mammals, a fragment of a white blood cell that circulates in the blood and functions in the formation of blood clots at sites of injury.
- pleiotropy** Condition in which an individual allele has more than one effect on production of the phenotype.
- plesiomorphy** In cladistics, another term for an ancestral character state.
- plumule** The epicotyl of a plant with its two young leaves.
- point mutation** An alteration of one nucleotide in a chromosomal DNA molecule.
- polar body** Minute, nonfunctioning cell produced during the meiotic divisions leading to gamete formation in vertebrates.
- polar covalent bond** A covalent bond in which electrons are shared unequally due to differences in electronegativity of the atoms involved. One atom has a partial negative charge and the other a partial positive charge, even though the molecule is electrically neutral overall.
- polarity** (1) Refers to unequal charge distribution in a molecule such as water, which has a positive region and a negative region although it is neutral overall. (2) Refers to axial differences in a developing embryo that result in anterior–posterior and dorsal–ventral axes in a bilaterally symmetrical animal.
- polarize** In cladistics, to determine whether character states are ancestral or derived.
- pollen tube** A tube formed after germination of the pollen grain; carries the male gametes into the ovule.
- pollination** The transfer of pollen from an anther to a stigma.
- polyandry** The condition in which a female mates with more than one male.
- polyclonal antibody** An antibody response in which an antigen elicits many different antibodies, each fitting a different portion of the antigen surface.
- polygenic inheritance** Describes a mode of inheritance in which more than one gene affects a trait, such as height in human beings; polygenic inheritance may produce a continuous range of phenotypic values, rather than discrete either–or values.
- polygyny** A mating choice in which a male mates with more than one female.
- polymer** A molecule composed of many similar or identical molecular subunits; starch is a polymer of glucose.
- polymerase chain reaction (PCR)** A process by which DNA polymerase is used to copy a sequence of interest repeatedly, making millions of copies of the same DNA.
- polymorphism** The presence in a population of more than one allele of a gene at a frequency greater than that of newly arising mutations.
- polyp** A typically sessile, cylindrical body form found in cnidarian animals, such as hydras.
- polypeptide** A molecule consisting of many joined amino acids; not usually as complex as a protein.
- polyphyletic** In phylogenetic classification, a group that does not include the most recent common ancestor of all members of the group.
- polyploidy** Condition in which one or more entire sets of chromosomes is added to the diploid genome.
- polysaccharide** A carbohydrate composed of many monosaccharide sugar subunits linked together in a long chain; examples are glycogen, starch, and cellulose.
- polyunsaturated fat** A fat molecule having at least two double bonds between adjacent carbons in one or more of the fatty acid chains.
- population** Any group of individuals, usually of a single species, occupying a given area at the same time.
- population genetics** The study of the properties of genes in populations.
- positive control** A type of control at the level of DNA transcription initiation in which the frequency of initiation is increased; activator proteins mediate positive control.
- posttranscriptional control** A mechanism of control over gene expression that operates after the transcription of mRNA is complete.
- postzygotic isolating mechanism** A type of reproductive isolation in which zygotes are produced but are unable to develop into reproducing adults; these mechanisms may range from inviability of zygotes or embryos to adults that are sterile.
- potential energy** Energy that is not being used, but could be; energy in a potentially usable form; often called “energy of position.”
- precapillary sphincter** A ring of muscle that guards each capillary loop and that, when closed, blocks flow through the capillary.
- pre-mRNA splicing** In eukaryotes, the process by which introns are removed from the primary transcript to produce mature mRNA; pre-mRNA splicing occurs in the nucleus.
- pressure potential** In plants, the turgor pressure resulting from pressure against the cell wall.
- prezygotic isolating mechanism** A type of reproductive isolation in which the formation of a zygote is prevented; these mechanisms may range from physical separation in different habitats to gametic in which gametes are incapable of fusing.
- primary endosperm nucleus** In flowering plants, the result of the fusion of a sperm nucleus and the (usually) two polar nuclei.

**primary growth** In vascular plants, growth originating in the apical meristems of shoots and roots; results in an increase in length.

**primary immune response** The first response of an immune system to a foreign antigen. If the system is challenged again with the same antigen, the memory cells created during the primary response will respond more quickly.

**primary induction** Inductions between the three primary tissue types: mesoderm and endoderm.

**primary meristem** Any of the three meristems produced by the apical meristem; primary meristems give rise to the dermal, vascular, and ground tissues.

**primary nondisjunction** Failure of chromosomes to separate properly at meiosis I.

**primary phloem** The cells involved in food conduction in plants.

**primary plant body** The part of a plant consisting of young, soft shoots and roots derived from apical meristem tissues.

**primary productivity** The amount of energy produced by photosynthetic organisms in a community.

**primary structure** The specific amino acid sequence of a protein.

**primary tissues** Tissues that make up the primary plant body.

**primary transcript** The initial mRNA molecule copied from a gene by RNA polymerase, containing a faithful copy of the entire gene, including introns as well as exons.

**primary wall** In plants, the wall layer deposited during the period of cell expansion.

**primase** The enzyme that synthesizes the RNA primers required by DNA polymerases.

**primate** Monkeys and apes (including humans).

**primitive streak** In the early embryos of birds, reptiles, and mammals, a dorsal, longitudinal strip of ectoderm and mesoderm that is equivalent to the blastopore in other forms.

**primordium** In plants, a bulge on the young shoot produced by the apical meristem; primordia can differentiate into leaves, other shoots, or flowers.

**principle of parsimony** Principle stating that scientists should favor the hypothesis that requires the fewest assumptions.

**prions** Infectious proteinaceous particles.

**procambium** In vascular plants, a primary meristematic tissue that gives rise to primary vascular tissues.

**product rule** See rule of multiplication.

**proglottid** A repeated body segment in tapeworms that contains both male and female reproductive organs; proglottids eventually form eggs and embryos, which leave the host's body in feces.

**prokaryote** A bacterium; a cell lacking a membrane-bounded nucleus or membrane-bounded organelles.

**prometaphase** The transitional phase between prophase and metaphase during which the spindle attaches to the kinetochores of sister chromatids.

**promoter** A DNA sequence that provides a recognition and attachment site for RNA polymerase to begin the process of gene transcription; it is located upstream from the transcription start site.

**prophase** The phase of cell division that begins when the condensed chromosomes become visible and ends when the nuclear envelope breaks down. The assembly of the spindle takes place during prophase.

**proprioceptor** In vertebrates, a sensory receptor that senses the body's position and movements.

**prosimian** Any member of the mammalian group that is a sister group to the anthropoids; prosimian means "before monkeys." Members include the lemurs, lorises, and tarsiers.

**prosome** The anterior portion of the body of an arachnid, which bears all the appendages.

**prostaglandins** A group of modified fatty acids that function as chemical messengers.

**prostate gland** In male mammals, a mass of glandular tissue at the base of the urethra that secretes an alkaline fluid that has a stimulating effect on the sperm as they are released.

**protease** An enzyme that degrades proteins by breaking peptide bonds; in cells, proteases are often compartmentalized into vesicles such as lysosomes.

**proteasome** A large, cylindrical cellular organelle that degrades proteins marked with ubiquitin.

**protein** A chain of amino acids joined by peptide bonds.

**protein kinase** An enzyme that adds phosphate groups to proteins, changing their activity.

**protein microarray** An array of proteins on a microscope slide or silicon chip. The array may be used with a variety of probes, including antibodies, to analyze the presence or absence of specific proteins in a complex mixture.

**proteome** All the proteins coded for by a particular genome.

**proteomics** The study of the proteomes of organisms. This is related to functional genomics as the proteome is responsible for much of the function encoded by a genome.

**protoderm** The primary meristem that gives rise to the dermal tissue.

**proton pump** A protein channel in a membrane of the cell that expends energy to transport protons against a concentration gradient; involved in the chemiosmotic generation of ATP.

**proto-oncogene** A normal cellular gene that can act as an oncogene when mutated.

**protostome** Any member of a grouping of bilaterally symmetrical animals in which the mouth develops first and the anus second; flatworms, nematodes, mollusks, annelids, and arthropods are protostomes.

**pseudocoel** A body cavity located between the endoderm and mesoderm.

**pseudogene** A copy of a gene that is not transcribed.

**pseudomurien** A component of the cell wall of archaea; it is similar to peptidoglycan in structure and function but contains different components.

**pseudopod** A nonpermanent cytoplasmic extension of the cell body.

**P site** In a ribosome, the peptidyl site that binds to the tRNA attached to the growing polypeptide chain.

**punctuated equilibrium** A hypothesis about the mechanism of evolutionary change proposing that long periods of little or no change are punctuated by periods of rapid evolution.

**Punnett square** A diagrammatic way of showing the possible genotypes and phenotypes of genetic crosses.

**pupa** A developmental stage of some insects in which the organism is nonfeeding, immotile, and sometimes encapsulated or in a cocoon; the pupal stage occurs between the larval and adult phases.

**purine** The larger of the two general kinds of nucleotide base found in DNA and RNA; a nitrogenous base with a double-ring structure, such as adenine or guanine.

**pyrimidine** The smaller of two general kinds of nucleotide base found in DNA and RNA; a nitrogenous base with a single-ring structure, such as cytosine, thymine, or uracil.

**pyruvate** A three-carbon molecule that is the end product of glycolysis; each glucose molecule yields two pyruvate molecules.

## Q

**quantitative trait** A trait that is determined by the effects of more than one gene; such a trait usually exhibits continuous variation rather than discrete either-or values.

**quaternary structure** The structural level of a protein composed of more than one polypeptide chain, each of which has its own tertiary structure; the individual chains are called subunits.

## R

**radial canal** Any of five canals that connect to the ring canal of an echinoderm's water-vascular system.

**radial cleavage** The embryonic cleavage pattern of deuterostome animals in which cells divide parallel to and at right angles to the polar axis of the embryo.

**radial symmetry** A type of structural symmetry with a circular plan, such that dividing the body or structure through the midpoint in any direction yields two identical sections.

**radicle** The part of the plant embryo that develops into the root.

**radioactive isotope** An isotope that is unstable and undergoes radioactive decay, releasing energy.

**radioactivity** The emission of nuclear particles and rays by unstable atoms as they decay into more stable forms.

**radula** Rasping tongue found in most mollusks.

**reaction center** A transmembrane protein complex in a photosystem that receives energy from the antenna complex exciting an electron that is passed to an acceptor molecule.

**reading frame** The correct succession of nucleotides in triplet codons that specify amino acids on translation. The reading frame is established by the first codon in the sequence as there are no spaces in the genetic code.

**realized niche** The actual niche occupied by an organism when all biotic and abiotic interactions are taken into account.

**receptor-mediated endocytosis** Process by which specific macromolecules are transported into eukaryotic cells at clathrin-coated pits, after binding to specific cell-surface receptors.

- receptor protein** A highly specific cell-surface receptor embedded in a cell membrane that responds only to a specific messenger molecule.
- receptor tyrosine kinase (RTK)** A diverse group of membrane receptors that when activated have kinase enzymatic activity. Specifically, they phosphorylate proteins on tyrosine. Their activation can lead to diverse cellular responses.
- recessive** An allele that is only expressed when present in the homozygous condition, but being “hidden” by the expression of a dominant allele in the heterozygous condition.
- redia** A secondary, nonciliated larva produced in the sporocysts of liver flukes.
- regulatory protein** Any of a group of proteins that modulates the ability of RNA polymerase to bind to a promoter and begin DNA transcription.
- replicon** An origin of DNA replication and the DNA whose replication is controlled by this origin. In prokaryotic replication, the chromosome plus the origin consist of a single replicon; eukaryotic chromosomes consist of multiple replicons.
- repisome** The macromolecular assembly of enzymes involved in DNA replication; analogous to the ribosome in protein synthesis.
- reciprocal altruism** Performance of an altruistic act with the expectation that the favor will be returned. A key and very controversial assumption of many theories dealing with the evolution of social behavior. *See* altruism.
- reciprocal cross** A genetic cross involving a single trait in which the sex of the parents is reversed; for example, if pollen from a white-flowered plant is used to fertilize a purple-flowered plant, the reciprocal cross would be pollen from a purple-flowered plant used to fertilize a white-flowered plant.
- reciprocal recombination** A mechanism of genetic recombination that occurs only in eukaryotic organisms, in which two chromosomes trade segments; can occur between nonhomologous chromosomes as well as the more usual exchange between homologous chromosomes in meiosis.
- recombinant DNA** Fragments of DNA from two different species, such as a bacterium and a mammal, spliced together in the laboratory into a single molecule.
- recombination frequency** The value obtained by dividing the number of recombinant progeny by the total progeny in a genetic cross. This value is converted into a percentage, and each 1% is termed a map unit.
- reduction** The gain of an electron by an atom, often with an associated proton.
- reflex** In the nervous system, a motor response subject to little associative modification; a reflex is among the simplest neural pathways, involving only a sensory neuron, sometimes (but not always) an interneuron, and one or more motor neurons.
- reflex arc** The nerve path in the body that leads from stimulus to reflex action.
- refractory period** The recovery period after membrane depolarization during which the membrane is unable to respond to additional stimulation.
- reinforcement** In speciation, the process by which partial reproductive isolation between populations is increased by selection against mating between members of the two populations, eventually resulting in complete reproductive isolation.
- replica plating** A method of transferring bacterial colonies from one plate to another to make a copy of the original plate; an impression of colonies growing on a Petri plate is made on a velvet surface, which is then used to transfer the colonies to plates containing different media, such that auxotrophs can be identified.
- replication fork** The Y-shaped end of a growing replication bubble in a DNA molecule undergoing replication.
- repolarization** Return of the ions in a nerve to their resting potential distribution following depolarization.
- repression** In general, control of gene expression by preventing transcription. Specifically, in bacteria such as *E. coli* this is mediated by repressor proteins. In anabolic operons, repressors bind DNA in the absence of corepressors to repress an operon.
- repressor** A protein that regulates DNA transcription by preventing RNA polymerase from attaching to the promoter and transcribing the structural gene. *See* operator.
- reproductive isolating mechanism** Any barrier that prevents genetic exchange between species.
- residual volume** The amount of air remaining in the lungs after the maximum amount of air has been exhaled.
- resting membrane potential** The charge difference (difference in electric potential) that exists across a neuron at rest (about 70 mV).
- restriction endonuclease** An enzyme that cleaves a DNA duplex molecule at a particular base sequence, usually within or near a palindromic sequence; also called a restriction enzyme.
- restriction fragment length polymorphism (RFLP)** Restriction enzymes recognize very specific DNA sequences. Alleles of the same gene or surrounding sequences may have base-pair differences, so that DNA near one allele is cut into a different-length fragment than DNA near the other allele. These different fragments separate based on size on electrophoresis gels.
- retina** The photosensitive layer of the vertebrate eye; contains several layers of neurons and light receptors (rods and cones); receives the image formed by the lens and transmits it to the brain via the optic nerve.
- retinoblastoma susceptibility gene (Rb)** A gene that, when mutated, predisposes individuals to a rare form of cancer of the retina; one of the first tumor-suppressor genes discovered.
- retrovirus** An RNA virus. When a retrovirus enters a cell, a viral enzyme (reverse transcriptase) transcribes viral RNA into duplex DNA, which the cell’s machinery then replicates and transcribes as if it were its own.
- reverse genetics** An approach by which a researcher uses a cloned gene of unknown function, creates a mutation, and introduces the mutant gene back into the organism to assess the effect of the mutation.
- reverse transcriptase** A viral enzyme found in retroviruses that is capable of converting their RNA genome into a DNA copy.
- Rh blood group** A set of cell-surface markers (antigens) on the surface of red blood cells in humans and rhesus monkeys (for which it is named); although there are several alleles, they are grouped into two main types: Rh-positive and Rh-negative.
- rhizome** In vascular plants, a more or less horizontal underground stem; may be enlarged for storage or may function in vegetative reproduction.
- rhynchoel** A true coelomic cavity in ribbonworms that serves as a hydraulic power source for extending the proboscis.
- ribonucleic acid (RNA)** A class of nucleic acids characterized by the presence of the sugar ribose and the pyrimidine uracil; includes mRNA, tRNA, and rRNA.
- ribosomal RNA (rRNA)** A class of RNA molecules found, together with characteristic proteins, in ribosomes; transcribed from the DNA of the nucleolus.
- ribosome** The molecular machine that carries out protein synthesis; the most complicated aggregation of proteins in a cell, also containing three different rRNA molecules.
- ribosome-binding sequence (RBS)** In prokaryotes, a conserved sequence at the 5’ end of mRNA that is complementary to the 3’ end of a small subunit rRNA and helps to position the ribosome during initiation.
- ribozyme** An RNA molecule that can behave as an enzyme, sometimes catalyzing its own assembly; rRNA also acts as a ribozyme in the polymerization of amino acids to form protein.
- ribulose 1,5-bisphosphate (RuBP)** In the Calvin cycle, the five-carbon sugar to which CO<sub>2</sub> is attached, accomplishing carbon fixation. This reaction is catalyzed by the enzyme rubisco.
- ribulose bisphosphate carboxylase/oxygenase (rubisco)** The four-subunit enzyme in the chloroplast that catalyzes the carbon fixation reaction joining CO<sub>2</sub> to RuBP.
- RNA interference** A type of gene silencing in which the mRNA transcript is prevented from being translated; small interfering RNAs (siRNAs) have been found to bind to mRNA and target its degradation prior to its translation.
- RNA polymerase** An enzyme that catalyzes the assembly of an mRNA molecule, the sequence of which is complementary to a DNA molecule used as a template. *See* transcription.
- RNA primer** In DNA replication, a sequence of about 10 RNA nucleotides complementary to unwound DNA that attaches at a replication fork; the DNA polymerase uses the RNA primer as a starting point for addition of DNA nucleotides to form the new DNA strand; the RNA primer is later removed and replaced by DNA nucleotides.
- RNA splicing** A nuclear process by which intron sequences of a primary mRNA transcript are cut out and the exon sequences spliced together to give the correct linkages of genetic information that will be used in protein construction.
- rod** Light-sensitive nerve cell found in the vertebrate retina; sensitive to very dim light; responsible for “night vision.”
- root** The usually descending axis of a plant, normally below ground, which anchors the plant and serves as the major point of entry for water and minerals.

**root cap** In plants, a tissue structure at the growing tips of roots that protects the root apical meristem as the root pushes through the soil; cells of the root cap are continually lost and replaced.

**root hair** In plants, a tubular extension from an epidermal cell located just behind the root tip; root hairs greatly increase the surface area for absorption.

**root pressure** In plants, pressure exerted by water in the roots in response to a solute potential in the absence of transpiration; often occurs at night. Root pressure can result in guttation, excretion of water from cells of leaves as dew.

**root system** In plants, the portion of the plant body that anchors the plant and absorbs ions and water.

**R plasmid** A resistance plasmid; a conjugative plasmid that picks up antibiotic resistance genes and can therefore transfer resistance from one bacterium to another.

**rule of addition** The rule stating that for two independent events, the probability of either event occurring is the sum of the individual probabilities.

**rule of multiplication** The rule stating that for two independent events, the probability of both events occurring is the product of the individual probabilities.

**rumen** An “extra stomach” in cows and related mammals wherein digestion of cellulose occurs and from which partially digested material can be ejected back into the mouth.

## S

**salicylic acid** In plants, an organic molecule that is a long-distance signal in systemic acquired resistance.

**saltatory conduction** A very fast form of nerve impulse conduction in which the impulses leap from node to node over insulated portions.

**saprobies** Heterotrophic organisms that digest their food externally (e.g., most fungi).

**sarcolemma** The specialized cell membrane in a muscle cell.

**sarcomere** Fundamental unit of contraction in skeletal muscle; repeating bands of actin and myosin that appear between two Z lines.

**sarcoplasmic reticulum** The endoplasmic reticulum of a muscle cell. A sleeve of membrane that wraps around each myofibril.

**satellite DNA** A nontranscribed region of the chromosome with a distinctive base composition; a short nucleotide sequence repeated tandemly many thousands of times.

**saturated fat** A fat composed of fatty acids in which all the internal carbon atoms contain the maximum possible number of hydrogen atoms.

**Schwann cells** The supporting cells associated with projecting axons, along with all the other nerve cells that make up the peripheral nervous system.

**sclereid** In vascular plants, a sclerenchyma cell with a thick, lignified, secondary wall having many pits; not elongate like a fiber.

**sclerenchyma cell** Tough, thick-walled cells that strengthen plant tissues.

**scolex** The attachment organ at the anterior end of a tapeworm.

**scrotum** The pouch that contains the testes in most mammals.

**scutellum** The modified cotyledon in cereal grains.

**second filial (F<sub>2</sub>) generation** The offspring resulting from a cross between members of the first filial (F<sub>1</sub>) generation.

**secondary cell wall** In plants, the innermost layer of the cell wall. Secondary walls have a highly organized microfibrillar structure and are often impregnated with lignin.

**secondary growth** In vascular plants, an increase in stem and root diameter made possible by cell division of the lateral meristems.

**secondary immune response** The swifter response of the body the second time it is invaded by the same pathogen because of the presence of memory cells, which quickly become antibody-producing plasma cells.

**secondary induction** An induction between tissues that have already differentiated.

**secondary metabolite** A molecule not directly involved in growth, development, or reproduction of an organism; in plants these molecules, which include nicotine, caffeine, tannins, and menthols, can discourage herbivores.

**secondary plant body** The part of a plant consisting of secondary tissues from lateral meristem tissues; the older trunk, branches, and roots of woody plants.

**secondary structure** In a protein, hydrogen-bonding interactions between —CO and —NH groups of the primary structure.

**secondary tissue** Any tissue formed from lateral meristems in trees and shrubs.

**Second Law of Thermodynamics** A statement concerning the transformation of potential energy into heat; it says that disorder (entropy) is continually increasing in the universe as energy changes occur, so disorder is more likely than order.

**second messenger** A small molecule or ion that carries the message from a receptor on the target cell surface into the cytoplasm.

**seed bank** Ungerminated seeds in the soil of an area. Regeneration of plants after events such as fire often depends on the presence of a seed bank.

**seed coat** In plants, the outer layers of the ovule, which become a relatively impermeable barrier to protect the dormant embryo and stored food.

**segment polarity gene** Any of certain genes in *Drosophila* development that are expressed in stripes that subdivide the stripes created by the pair-rule genes in the process of segmentation.

**segmentation** The division of the developing animal body into repeated units; segmentation allows for redundant systems and more efficient locomotion.

**segmentation gene** Any of the three classes of genes that control development of the segmented body plan of insects; includes the gap genes, pair-rule genes, and segment polarity genes.

**segregation** The process by which alternative forms of traits are expressed in offspring rather than blending each trait of the parents in the offspring.

**selection** The process by which some organisms leave more offspring than competing ones, and their genetic traits tend to appear in greater proportions among members of succeeding generations than the traits of those individuals that leave fewer offspring.

**selectively permeable** Condition in which a membrane is permeable to some substances but not to others.

**self-fertilization** The union of egg and sperm produced by a single hermaphroditic organism.

**semen** In reptiles and mammals, sperm-bearing fluid expelled from the penis during male orgasm.

**semicircular canal** Any of three fluid-filled canals in the inner ear that help to maintain balance.

**semiconservative replication** DNA replication in which each strand of the original duplex serves as the template for construction of a totally new complementary strand, so the original duplex is partially conserved in each of the two new DNA molecules.

**senescent** Aged, or in the process of aging.

**sensory (afferent) neuron** A neuron that transmits nerve impulses from a sensory receptor to the central nervous system or central ganglion.

**sensory setae** In insect, bristles attached to the nervous system that are sensitive mechanical and chemical stimulation; most abundant on antennae and legs.

**sepal** A member of the outermost floral whorl of a flowering plant.

**septation** In prokaryotic cell division, the formation of a septum where new cell membrane and cell wall is formed to separate the two daughter cells.

**septum, pl. septa** A wall between two cavities.

**sequence-tagged site (STS)** A small stretch of DNA that is unique in a genome, that is, it occurs only once; useful as a physical marker on genomic maps.

**seta, pl. setae (L., bristle)** In an annelid, bristles of chitin that help anchor the worm during locomotion or when it is in its burrow.

**severe acute respiratory syndrome (SARS)** A respiratory infection with an 8% mortality rate that is caused by a coronavirus.

**sex chromosome** A chromosome that is related to sex; in humans, the sex chromosomes are the X and Y chromosomes.

**sex-linked** A trait determined by a gene carried on the X chromosome and absent on the Y chromosome.

**Sexual dimorphism** Morphological differences between the sexes of a species.

**sexual reproduction** The process of producing offspring through an alternation of fertilization (producing diploid cells) and meiotic reduction in chromosome number (producing haploid cells).

**sexual selection** A type of differential reproduction that results from variable success in obtaining mates.

**shared derived character** In cladistics, character states that are shared by species and that are different from the ancestral character state.

**shoot** In vascular plants, the aboveground portions, such as the stem and leaves.

**short interspersed element (SINE)** Any of a type of retrotransposon found in humans and other primates that does not contain the biochemical machinery needed for transposition; half a million copies of a SINE element called Alu is nested in the LINEs of the human genome.

**shotgun sequencing** The method of DNA sequencing in which the DNA is randomly cut into small fragments, and the fragments cloned and sequenced. A computer is then used to assemble a final sequence.

- sieve cell** In the phloem of vascular plants, a long, slender element with relatively unspecialized sieve areas and with tapering end walls that lack sieve plates.
- signal recognition particle (SRP)** In eukaryotes, a cytoplasmic complex of proteins that recognizes and binds to the signal sequence of a polypeptide, and then docks with a receptor that forms a channel in the ER membrane. In this way the polypeptide is released into the lumen of the ER.
- signal transduction** The events that occur within a cell on receipt of a signal, ligand binding to a receptor protein. Signal transduction pathways produce the cellular response to a signaling molecule.
- simple sequence repeat (SSR)** A one- to three-nucleotide sequence such as CA or CCG that is repeated thousands of times.
- single-nucleotide polymorphism (SNP)** A site present in at least 1% of the population at which individuals differ by a single nucleotide. These can be used as genetic markers to map unknown genes or traits.
- sinus** A cavity or space in tissues or in bone.
- sister chromatid** One of two identical copies of each chromosome, still linked at the centromere, produced as the chromosomes duplicate for mitotic division; similarly, one of two identical copies of each homologous chromosome present in a tetrad at meiosis.
- small interfering RNAs (siRNAs)** A class of micro-RNAs that appear to be involved in control of gene transcription and that play a role in protecting cells from viral attack.
- small nuclear ribonucleoprotein particles (snRNP)** In eukaryotes, a complex composed of snRNA and protein that clusters together with other snRNPs to form the spliceosome, which removes introns from the primary transcript.
- small nuclear RNA (snRNA)** In eukaryotes, a small RNA sequence that, as part of a small nuclear ribonucleoprotein complex, facilitates recognition and excision of introns by base-pairing with the 5' end of an intron or at a branch site of the same intron.
- sodium-potassium pump** Transmembrane channels engaged in the active (ATP-driven) transport of Na<sup>+</sup>, exchanging them for K<sup>+</sup>, where both ions are being moved against their respective concentration gradients; maintains the resting membrane potential of neurons and other cells.
- solute** A molecule dissolved in some solution; as a general rule, solutes dissolve only in solutions of similar polarity; for example, glucose (polar) dissolves in (forms hydrogen bonds with) water (also polar), but not in vegetable oil (nonpolar).
- solute potential** The amount of osmotic pressure arising from the presence of a solute or solutes in water; measure by counterbalancing the pressure until osmosis stops.
- solvent** The medium in which one or more solutes is dissolved.
- somatic cell** Any of the cells of a multicellular organism except those that are destined to form gametes (germ-line cells).
- somatic cell nuclear transfer (SCNT)** The transfer of the nucleus of a somatic cell into an enucleated egg cell that then undergoes development. Can be used to make ES cells and to create cloned animals.
- somatic mutation** A change in genetic information (mutation) occurring in one of the somatic cells of a multicellular organism, not passed from one generation to the next.
- somatic nervous system** In vertebrates, the neurons of the peripheral nervous system that control skeletal muscle.
- somite** One of the blocks, or segments, of tissue into which the mesoderm is divided during differentiation of the vertebrate embryo.
- Southern blot** A technique in which DNA fragments are separated by gel electrophoresis, denatured into single-stranded DNA, and then "blotted" onto a sheet of filter paper; the filter is then incubated with a labeled probe to locate DNA sequences of interest.
- S phase** The phase of the cell cycle during which DNA replication occurs.
- specialized transduction** The transfer of only a few specific genes into a bacterium, using a lysogenic bacteriophage as a carrier.
- speciation** The process by which new species arise, either by transformation of one species into another, or by the splitting of one ancestral species into two descendant species.
- species, pl. species** A kind of organism; species are designated by binomial names written in italics.
- specific heat** The amount of heat that must be absorbed or lost by 1 g of a substance to raise or lower its temperature 1°C.
- specific transcription factor** Any of a great number of transcription factors that act in a time- or tissue-dependent manner to increase DNA transcription above the basal level.
- spectrin** A scaffold of proteins that links plasma membrane proteins to actin filaments in the cytoplasm of red blood cells, producing their characteristic biconcave shape.
- spermatid** In animals, each of four haploid (*n*) cells that result from the meiotic divisions of a spermatocyte; each spermatid differentiates into a sperm cell.
- spermatozoa** The male gamete, usually smaller than the female gamete, and usually motile.
- sphincter** In vertebrate animals, a ring-shaped muscle capable of closing a tubular opening by constriction (e.g., between stomach and small intestine or between anus and exterior).
- spicule** Any of a number of minute needles of silica or calcium carbonate made in the mesohyl by some kinds of sponges as a structural component.
- spindle** The structure composed of microtubules radiating from the poles of the dividing cell that will ultimately guide the sister chromatids to the two poles.
- spindle apparatus** The assembly that carries out the separation of chromosomes during cell division; composed of microtubules (spindle fibers) and assembled during prophase at the equator of the dividing cell.
- spindle checkpoint** The third cell-division checkpoint, at which all chromosomes must be attached to the spindle. Passage through this checkpoint commits the cell to anaphase.
- spinnerets** Organs at the posterior end of a spider's abdomen that secrete a fluid protein that becomes silk.
- spiracle** External opening of a trachea in arthropods.
- spiral cleavage** The embryonic cleavage pattern of some protostome animals in which cells divide at an angle oblique to the polar axis of the embryo; a line drawn through the sequence of dividing cells forms a spiral.
- spiralian** A member of a group of invertebrate animals; many groups exhibit spiral cleavage. Mollusks, annelids, and flatworms are examples of spiralian.
- spliceosome** In eukaryotes, a complex composed of multiple snRNPs and other associated proteins that is responsible for excision of introns and joining of exons to convert the primary transcript into the mature mRNA.
- spongin** A tough protein made by many kinds of sponges as a structural component within the mesohyl.
- spongy parenchyma** A leaf tissue composed of loosely arranged, chloroplast-bearing cells. *See* palisade parenchyma.
- sporangium, pl. sporangia** A structure in which spores are produced.
- spore** A haploid reproductive cell, usually unicellular, capable of developing into an adult without fusion with another cell.
- sporophyte** The spore-producing, diploid (*2n*) phase in the life cycle of a plant having alternation of generations.
- stabilizing selection** A form of selection in which selection acts to eliminate both extremes from a range of phenotypes.
- stamen** The organ of a flower that produces the pollen; usually consists of anther and filament; collectively, the stamens make up the androecium.
- starch** An insoluble polymer of glucose; the chief food storage substance of plants.
- start codon** The AUG triplet, which indicates the site of the beginning of mRNA translation; this codon also codes for the amino acid methionine.
- stasis** A period of time during which little evolutionary change occurs.
- statocyst** Sensory receptor sensitive to gravity and motion.
- stele** The central vascular cylinder of stems and roots.
- stem cell** A relatively undifferentiated cell in animal tissue that can divide to produce more differentiated tissue cells.
- stereoscopic vision** Ability to perceive a single, three-dimensional image from the simultaneous but slightly divergent two-dimensional images delivered to the brain by each eye.
- stigma** (1) In angiosperm flowers, the region of a carpel that serves as a receptive surface for pollen grains. (2) Light-sensitive eyespot of some algae.
- stipules** Leaflike appendages that occur at the base of some flowering plant leaves or stems.
- stolon** A stem that grows horizontally along the ground surface and may form adventitious roots, such as runners of the strawberry plant.
- stoma, pl. stomata** In plants, a minute opening bordered by guard cells in the epidermis of leaves and stems; water passes out of a plant mainly through the stomata.
- stop codon** Any of the three codons UAA, UAG, and UGA, that indicate the point at which mRNA translation is to be terminated.

**stratify** To hold plant seeds at a cold temperature for a certain period of time; seeds of many plants will not germinate without exposure to cold and subsequent warming.

**stratum corneum** The outer layer of the epidermis of the skin of the vertebrate body.

**striated muscle** Skeletal voluntary muscle and cardiac muscle.

**stroma** In chloroplasts, the semiliquid substance that surrounds the thylakoid system and that contains the enzymes needed to assemble organic molecules from CO<sub>2</sub>.

**stromatolite** A fossilized mat of ancient bacteria formed as long as 2 BYA, in which the bacterial remains individually resemble some modern-day bacteria.

**style** In flowers, the slender column of tissue that arises from the top of the ovary and through which the pollen tube grows.

**stylet** A piercing organ, usually a mouthpart, in some species of invertebrates.

**suberin** In plants, a fatty acid chain that forms the impermeable barrier in the Casparian strip of root endoderm.

**subspecies** A geographically defined population or group of populations within a single species that has distinctive characteristics.

**substrate** (1) The foundation to which an organism is attached. (2) A molecule on which an enzyme acts.

**subunit vaccine** A type of vaccine created by using a subunit of a viral protein coat to elicit an immune response; may be useful in preventing viral diseases such as hepatitis B.

**succession** In ecology, the slow, orderly progression of changes in community composition that takes place through time.

**summation** Repetitive activation of the motor neuron resulting in maximum sustained contraction of a muscle.

**supercoiling** The coiling in space of double-stranded DNA molecules due to torsional strain, such as occurs when the helix is unwound.

**surface tension** A tautness of the surface of a liquid, caused by the cohesion of the molecules of liquid. Water has an extremely high surface tension.

**surface area-to-volume ratio** Relationship of the surface area of a structure, such as a cell, to the volume it contains.

**suspensor** In gymnosperms and angiosperms, the suspensor develops from one of the first two cells of a dividing zygote; the suspensor of an angiosperm is a nutrient conduit from maternal tissue to the embryo. In gymnosperms the suspensor positions the embryo closer to stored food reserves.

**swim bladder** An organ encountered only in the bony fish that helps the fish regulate its buoyancy by increasing or decreasing the amount of gas in the bladder via the esophagus or a specialized network of capillaries.

**swimmerets** In lobsters and crayfish, appendages that occur in lines along the ventral surface of the abdomen and are used in swimming and reproduction.

**symbiosis** The condition in which two or more dissimilar organisms live together in close association; includes parasitism (harmful to one

of the organisms), commensalism (beneficial to one, of no significance to the other), and mutualism (advantageous to both).

**sympatric speciation** The differentiation of populations within a common geographic area into species.

**sympplast route** In plant roots, the pathway for movement of water and minerals within the cell cytoplasm that leads through plasmodesmata that connect cells.

**symplesiomorphy** In cladistics, another term for a shared ancestral character state.

**symporter** A carrier protein in a cell's membrane that transports two molecules or ions in the same direction across the membrane.

**synapomorphy** In systematics, a derived character that is shared by clade members.

**synapse** A junction between a neuron and another neuron or muscle cell; the two cells do not touch, the gap being bridged by neurotransmitter molecules.

**synapsid** Any of an early group of reptiles that had a pair of temporal openings in the skull behind the eye sockets; jaw muscles attached to these openings. Early ancestors of mammals belonged to this group.

**synapsis** The point-by-point alignment (pairing) of homologous chromosomes that occurs before the first meiotic division; crossing over takes place during synapsis.

**synaptic cleft** The space between two adjacent neurons.

**synaptic vesicle** A vesicle of a neurotransmitter produced by the axon terminal of a nerve. The filled vesicle migrates to the presynaptic membrane, fuses with it, and releases the neurotransmitter into the synaptic cleft.

**synaptonemal complex** A protein lattice that forms between two homologous chromosomes in prophase I of meiosis, holding the replicated chromosomes in precise register with each other so that base-pairs can form between nonsister chromatids for crossing over that is usually exact within a gene sequence.

**syncytial blastoderm** A structure composed of a single large cytoplasm containing about 4000 nuclei in embryonic development of insects such as *Drosophila*.

**syngamy** The process by which two haploid cells (gametes) fuse to form a diploid zygote; fertilization.

**synthetic polyploidy** A polyploidy organism created by crossing organisms most closely related to an ancestral species and then manipulating the offspring.

**systematics** The reconstruction and study of evolutionary relationships.

**systemic acquired resistance (SAR)** In plants, a longer-term response to a pathogen or pest attack that can last days to weeks and allow the plant to respond quickly to later attacks by a range of pathogens.

**systemin** In plants, an 18-amino-acid peptide that is produced by damaged or injured leaves that leads to the wound response.

**systolic pressure** A measurement of how hard the heart is contracting. When measured during a blood pressure reading, ventricular systole (contraction) is what is being monitored.

**T**

**3' poly-A tail** In eukaryotes, a series of 1–200 adenine residues added to the 3' end of an mRNA; the tail appears to enhance the stability of the mRNA by protecting it from degradation.

**T box** A transcription factor protein domain that has been conserved, although with differing developmental effects, in invertebrates and chordates.

**tagma**, pl. **tagmata** A compound body section of an arthropod resulting from embryonic fusion of two or more segments; for example, head, thorax, abdomen.

**Taq polymerase** A DNA polymerase isolated from the thermophilic bacterium *Thermus aquaticus* (Taq); this polymerase is functional at higher temperatures, and is used in PCR amplification of DNA.

**TATA box** In eukaryotes, a sequence located upstream of the transcription start site. The TATA box is one element of eukaryotic core promoters for RNA polymerase II.

**taxis**, pl. **taxes** An orientation movement by a (usually) simple organism in response to an environmental stimulus.

**taxonomy** The science of classifying living things. By agreement among taxonomists, no two organisms can have the same name, and all names are expressed in Latin.

**T cell** A type of lymphocyte involved in cell-mediated immunity and interactions with B cells; the "T" refers to the fact that T cells are produced in the thymus.

**telencephalon** The most anterior portion of the brain, including the cerebrum and associated structures.

**telomerase** An enzyme that synthesizes telomeres on eukaryotic chromosomes using an internal RNA template.

**telomere** A specialized nontranscribed structure that caps each end of a chromosome.

**telophase** The phase of cell division during which the spindle breaks down, the nuclear envelope of each daughter cell forms, and the chromosomes uncoil and become diffuse.

**telson** The tail spine of lobsters and crayfish.

**temperate (lysogenic) phage** A virus that is capable of incorporating its DNA into the host cell's DNA, where it remains for an indeterminate length of time and is replicated as the cell's DNA replicates.

**template strand** The DNA strand that is used as a template in transcription. This strand is copied to produce a complementary mRNA transcript.

**tendon** (Gr. *tendon*, stretch) A strap of cartilage that attaches muscle to bone.

**tensile strength** A measure of the cohesiveness of a substance; its resistance to being broken apart. Water in narrow plant vessels has tensile strength that helps keep the water column continuous.

**tertiary structure** The folded shape of a protein, produced by hydrophobic interactions with water, ionic and covalent bonding between side chains of different amino acids, and van der Waal's forces; may be changed by denaturation so that the protein becomes inactive.

- testcross** A mating between a phenotypically dominant individual of unknown genotype and a homozygous “tester,” done to determine whether the phenotypically dominant individual is homozygous or heterozygous for the relevant gene.
- testis, pl. testes** In mammals, the sperm-producing organ.
- tetanus** Sustained forceful muscle contraction with no relaxation.
- thalamus** That part of the vertebrate forebrain just posterior to the cerebrum; governs the flow of information from all other parts of the nervous system to the cerebrum.
- therapeutic cloning** The use of somatic cell nuclear transfer to create stem cells from a single individual that may be reimplanted in that individual to replace damaged cells, such as in a skin graft.
- thermodynamics** The study of transformations of energy, using heat as the most convenient form of measurement of energy.
- thermogenesis** Generation of internal heat by endothermic animals to modulate temperature.
- thigmotropism** In plants, unequal growth in some structure that comes about as a result of physical contact with an object.
- threshold** The minimum amount of stimulus required for a nerve to fire (depolarize).
- thylakoid** In chloroplasts, a complex, organized internal membrane composed of flattened disks, which contain the photosystems involved in the light-dependent reactions of photosynthesis.
- Ti (tumor-inducing) plasmid** A plasmid found in the plant bacterium *Agrobacterium tumefaciens* that has been extensively used to introduce recombinant DNA into broadleaf plants. Recent modifications have allowed its use with cereal grains as well.
- tight junction** Region of actual fusion of plasma membranes between two adjacent animal cells that prevents materials from leaking through the tissue.
- tissue** A group of similar cells organized into a structural and functional unit.
- tissue plasminogen activator (TPA)** A human protein that causes blood clots to dissolve; if used within 3 hours of an ischemic stroke, TPA may prevent disability.
- tissue-specific stem cell** A stem cell that is capable of developing into the cells of a certain tissue, such as muscle or epithelium; these cells persist even in adults.
- tissue system** In plants, any of the three types of tissue; called a system because the tissue extends throughout the roots and shoots.
- tissue tropism** The affinity of a virus for certain cells within a multicellular host; for example, hepatitis B virus targets liver cells.
- tonoplast** The membrane surrounding the central vacuole in plant cells that contains water channels; helps maintain the cell's osmotic balance.
- topoisomerase** Any of a class of enzymes that can change the topological state of DNA to relieve torsion caused by unwinding.
- torsion** The process in embryonic development of gastropods by which the mantle cavity and anus move from a posterior location to the front of the body, closer to the location of the mouth.
- totipotent** A cell that possesses the full genetic potential of the organism.
- trachea, pl. tracheae** A tube for breathing; in terrestrial vertebrates, the windpipe that carries air between the larynx and bronchi (which leads to the lungs); in insects and some other terrestrial arthropods, a system of chitin-lined air ducts.
- tracheids** In plant xylem, dead cells that taper at the ends and overlap one another.
- tracheole** The smallest branches of the respiratory system of terrestrial arthropods; tracheoles convey air from the tracheae, which connect to the outside of the body at spiracles.
- trait** In genetics, a characteristic that has alternative forms, such as purple or white flower color in pea plants or different blood type in humans.
- transcription** The enzyme-catalyzed assembly of an RNA molecule complementary to a strand of DNA.
- transcription complex** The complex of RNA polymerase II plus necessary activators, coactivators, transcription factors, and other factors that are engaged in actively transcribing DNA.
- transcription factor** One of a set of proteins required for RNA polymerase to bind to a eukaryotic promoter region, become stabilized, and begin the transcription process.
- transcription bubble** The region containing the RNA polymerase, the DNA template, and the RNA transcript, so called because of the locally unwound “bubble” of DNA.
- transcription unit** The region of DNA between a promoter and a terminator.
- transcriptome** All the RNA present in a cell or tissue at a given time.
- transfection** The transformation of eukaryotic cells in culture.
- transfer RNA (tRNA)** A class of small RNAs (about 80 nucleotides) with two functional sites; at one site, an “activating enzyme” adds a specific amino acid, while the other site carries the nucleotide triplet (anticodon) specific for that amino acid.
- transformation** The uptake of DNA directly from the environment; a natural process in some bacterial species.
- transgenic organism** An organism into which a gene has been introduced without conventional breeding, that is, through genetic engineering techniques.
- translation** The assembly of a protein on the ribosomes, using mRNA to specify the order of amino acids.
- translation repressor protein** One of a number of proteins that prevent translation of mRNA by binding to the beginning of the transcript and preventing its attachment to a ribosome.
- translocation** (1) In plants, the long-distance transport of soluble food molecules (mostly sucrose), which occurs primarily in the sieve tubes of phloem tissue. (2) In genetics, the interchange of chromosome segments between nonhomologous chromosomes.
- transmembrane domain** Hydrophobic region of a transmembrane protein that anchors it in the membrane. Often composed of  $\alpha$ -helices, but sometimes utilizing  $\beta$ -pleated sheets to form a barrel-shaped pore.
- transmembrane route** In plant roots, the pathway for movement of water and minerals that crosses the cell membrane and also the membrane of vacuoles inside the cell.
- transpiration** The loss of water vapor by plant parts; most transpiration occurs through the stomata.
- transposable elements** Segments of DNA that are able to move from one location on a chromosome to another. Also termed *transposons* or *mobile genetic elements*.
- transposition** Type of genetic recombination in which transposable elements (transposons) move from one site in the DNA sequence to another, apparently randomly.
- transposon** DNA sequence capable of transposition.
- trichome** In plants, a hairlike outgrowth from an epidermal cell; glandular trichomes secrete oils or other substances that deter insects.
- triglyceride (triacylglycerol)** An individual fat molecule, composed of a glycerol and three fatty acids.
- triploid** Possessing three sets of chromosomes.
- trisomic** Describes the condition in which an additional chromosome has been gained due to nondisjunction during meiosis, and the diploid embryo therefore has three of these autosomes. In humans, trisomic individuals may survive if the autosome is small; Down syndrome individuals are trisomic for chromosome 21.
- trochophore** A specialized type of free-living larva found in lophotrochozoans.
- trophic level** A step in the movement of energy through an ecosystem.
- trophoblast** In vertebrate embryos, the outer ectodermal layer of the blastodermic vesicle; in mammals, it is part of the chorion and attaches to the uterine wall.
- tropism** Response to an external stimulus.
- tropomyosin** Low-molecular-weight protein surrounding the actin filaments of striated muscle.
- troponin** Complex of globular proteins positioned at intervals along the actin filament of skeletal muscle; thought to serve as a calcium-dependent “switch” in muscle contraction.
- trp operon** In *E. coli*, the operon containing genes that code for enzymes that synthesize tryptophan.
- true-breeding** Said of a breed or variety of organism in which offspring are uniform and consistent from one generation to the next; for example. This is due to the genotypes that determine relevant traits being homozygous.
- tube foot** In echinoderms, a flexible, external extension of the water-vascular system that is capable of attaching to a surface through suction.
- tubulin** Globular protein subunit forming the hollow cylinder of microtubules.
- tumor-suppressor gene** A gene that normally functions to inhibit cell division; mutated forms can lead to the unrestrained cell division of cancer, but only when both copies of the gene are mutant.
- turgor pressure** The internal pressure inside a plant cell, resulting from osmotic intake of water, that presses its cell membrane tightly against the cell wall, making the cell rigid. Also known as *hydrostatic pressure*.

**tympa-num** In some groups of insects, a thin membrane associated with the tracheal air sacs that functions as a sound receptor; paired on each side of the abdomen.

## U

**ubiquitin** A 76-amino-acid protein that virtually all eukaryotic cells attach as a marker to proteins that are to be degraded.

**unequal crossing over** A process by which a crossover in a small region of misalignment at synapsis causes two homologous chromosomes to exchange segments of unequal length.

**uniporter** A carrier protein in a cell's membrane that transports only a single type of molecule or ion.

**uniramous** Single-branched; describes the appendages of insects.

**unsaturated fat** A fat molecule in which one or more of the fatty acids contain fewer than the maximum number of hydrogens attached to their carbons.

**urea** An organic molecule formed in the vertebrate liver; the principal form of disposal of nitrogenous wastes by mammals.

**urethra** The tube carrying urine from the bladder to the exterior of mammals.

**uric acid** Insoluble nitrogenous waste products produced largely by reptiles, birds, and insects.

**urine** The liquid waste filtered from the blood by the kidney and stored in the bladder pending elimination through the urethra.

**uropod** One of a group of flattened appendages at the end of the abdomen of lobsters and crayfish that collectively act as a tail for a rapid burst of speed.

**uterus** In mammals, a chamber in which the developing embryo is contained and nurtured during pregnancy.

## V

**vacuole** A membrane-bounded sac in the cytoplasm of some cells, used for storage or digestion purposes in different kinds of cells; plant cells often contain a large central vacuole that stores water, proteins, and waste materials.

**valence electron** An electron in the outermost energy level of an atom.

**variable** A factor that influences a process, outcome, or observation. In experiments, scientists attempt to isolate variables to test hypotheses.

**vascular cambium** In vascular plants, a cylindrical sheath of meristematic cells, the division of which produces secondary phloem outwardly and secondary xylem inwardly; the activity of the vascular cambium increases stem or root diameter.

**vascular tissue** Containing or concerning vessels that conduct fluid.

**vas deferens** In mammals, the tube carrying sperm from the testes to the urethra.

**vasopressin** A posterior pituitary hormone that regulates the kidney's retention of water.

**vector** In molecular biology, a plasmid, phage or artificial chromosome that allows propagation of recombinant DNA in a host cell into which it is introduced.

**vegetal pole** The hemisphere of the zygote comprising cells rich in yolk.

**vein** (1) In plants, a vascular bundle forming a part of the framework of the conducting and supporting tissue of a stem or leaf. (2) In animals, a blood vessel carrying blood from the tissues to the heart.

**veliger** The second larval stage of mollusks following the trochophore stage, during which the beginning of a foot, shell, and mantle can be seen.

**ventricle** A muscular chamber of the heart that receives blood from an atrium and pumps blood out to either the lungs or the body tissues.

**vertebrate** A chordate with a spinal column; in vertebrates, the notochord develops into the vertebral column composed of a series of vertebrae that enclose and protect the dorsal nerve cord.

**vertical gene transfer (VGT)** The passing of genes from one generation to the next within a species.

**vesicle** A small intracellular, membrane-bounded sac in which various substances are transported or stored.

**vessel element** In vascular plants, a typically elongated cell, dead at maturity, which conducts water and solutes in the xylem.

**vestibular apparatus** The complicated sensory apparatus of the inner ear that provides for balance and orientation of the head in vertebrates.

**vestigial structure** A morphological feature that has no apparent current function and is thought to be an evolutionary relic; for example, the vestigial hip bones of boa constrictors.

**villus**, pl. **villi** In vertebrates, one of the minute, fingerlike projections lining the small intestine that serve to increase the absorptive surface area of the intestine.

**virion** A single virus particle.

**viroid** Any of a group of small, naked RNA molecules that are capable of causing plant diseases, presumably by disrupting chromosome integrity.

**virus** Any of a group of complex biochemical entities consisting of genetic material wrapped in protein; viruses can reproduce only within living host cells and are thus not considered organisms.

**visceral mass** Internal organs in the body cavity of an animal.

**vitamin** An organic substance that cannot be synthesized by a particular organism but is required in small amounts for normal metabolic function.

**viviparity** Refers to reproduction in which eggs develop within the mother's body and young are born free-living.

**voltage-gated ion channel** A transmembrane pathway for an ion that is opened or closed by a change in the voltage, or charge difference, across the plasma membrane.

## W

**water potential** The potential energy of water molecules. Regardless of the reason (e.g., gravity, pressure, concentration of solute particles) for the water potential, water moves from a region where water potential is greater to a region where water potential is lower.

**water-vascular system** A fluid-filled hydraulic system found only in echinoderms that provides body support and a unique type of locomotion via extensions called tube feet.

**Western blot** A blotting technique used to identify specific protein sequences in a complex mixture. *See* Southern blot.

**wild type** In genetics, the phenotype or genotype that is characteristic of the majority of individuals of a species in a natural environment.

**wobble pairing** Refers to flexibility in the pairing between the base at the 5' end of a tRNA anticodon and the base at the 3' end of an mRNA codon. This flexibility allows a single tRNA to read more than one mRNA codon.

**wound response** In plants, a signaling pathway initiated by leaf damage, such as being chewed by a herbivore, and lead to the production of proteinase inhibitors that give herbivores indigestion.

## X

**X chromosome** One of two sex chromosomes; in mammals and in *Drosophila*, female individuals have two X chromosomes.

**xylem** In vascular plants, a specialized tissue, composed primarily of elongate, thick-walled conducting cells, which transports water and solutes through the plant body.

## Y

**Y chromosome** One of two sex chromosomes; in mammals and in *Drosophila*, male individuals have a Y chromosome and an X chromosome; the Y determines maleness.

**yolk plug** A plug occurring in the blastopore of amphibians during formation of the archenteron in embryological development.

**yolk sac** The membrane that surrounds the yolk of an egg and connects the yolk, a rich food supply, to the embryo via blood vessels.

## Z

**zinc finger motif** A type of DNA-binding motif in regulatory proteins that incorporates zinc atoms in its structure.

**zona pellucida** An outer membrane that encases a mammalian egg.

**zone of cell division** In plants, the part of the young root that includes the root apical meristem and the cells just posterior to it; cells in this zone divide every 12–36 hr.

**zone of elongation** In plants, the part of the young root that lies just posterior to the zone of cell division; cells in this zone elongate, causing the root to lengthen.

**zone of maturation** In plants, the part of the root that lies posterior to the zone of elongation; cells in this zone differentiate into specific cell types.

**zoospore** A motile spore.

**zooxanthellae** Symbiotic photosynthetic protists in the tissues of corals.

**zygomycetes** A type of fungus whose chief characteristic is the production of sexual structures called zygospangia, which result from the fusion of two of its simple reproductive organs.

**zygote** The diploid ( $2n$ ) cell resulting from the fusion of male and female gametes (fertilization).

Boldface page numbers correspond with **boldface terms** in the text. Page numbers followed by an “f” indicate figures; page numbers followed by a “t” indicate tabular material.

## A

- A band, 969  
 Aardvark, 525, 525f  
 ABC model, of floral organ specification, 846, 846f, 847f, 848, 848f  
 ABO blood group, 90t, 230t, 234-235, 235f, 1077  
 Abscisic acid, 779, 779f, 826t, 836, 836f  
 Abscission, **823-824**, 823f  
 Abscission zone, 823, 823f  
 Absolute dating, 424  
 Absorption  
   in digestive tract, 982, 989-990, 989f  
   water and minerals in plants, 771f, 773-775, 774f-775f  
 Absorption spectrum, of photosynthetic pigments, **152-154**, 152f, 153f  
 Abstinence, 1100  
 Acacia, mutualism with ants, 809, 809f, 1198, 1198f  
 Acari (order), 682  
 Acceptor stem, **291-292**, 291f  
 Accessory digestive organs, 983f, 988-989, 988f-989f, 994-995, 995f  
 Accessory pigment, **152**, 153f  
 Accessory sex organs  
   female, 1097-1098, 1098f  
   male, 1092-1093, 1093f  
 Acetaldehyde, 35f  
 Acetic acid, 35f  
 Acetyl-CoA  
   in Krebs cycle, 131, 132, 133f, 138, 138f  
   from protein catabolism, 141f  
   from pyruvate, 130, 130f  
   uses of, 142  
 Acetylcholine, 897-898, 897f-898f, 909t, 910, 912, 912f, 973, 1034  
 Acetylcholine (ACh) receptor, 172, 893f, 912, 912f  
 Acetylcholinesterase (AChE), 898  
 Achiasmata segregation, **214**  
 Acid, **29-30**  
 Acid growth hypothesis, **830**, 831f  
 Acid precipitation, 1246, 1246f-1247f  
 Acid rain, 1247, 1247f  
 Acid soil, 789  
 Acini, **989**  
 Acoela, 644f, 660, 660f  
 Acoelomate, 637, 637f, 643, 644f, 656-660, 657f, 659f-661f  
 Acoelomorpha, 644f  
 Acromegaly, **950**  
 Acrosomal process, 1106  
 Acrosome, **1106**  
 ACTH, 947-948  
 Actin, 970f  
 Actin filament, **76**, 76f, **84**, 84f  
 Actinobacteria, 550f  
*Actinomyces*, 550f, 561  
 Actinopoda (phylum), 583  
 Action potential, 893-895  
   all-or-none law of, 894  
   falling phase of, 893, 894f  
   generation of, 893-895, 894f-895f  
   propagation of, 894-895, 895f  
   rising phase of, 893, 894f, 895, 895f  
   undershoot phase of, 893, 894f  
 Action spectrum, **153**  
   of chlorophyll, 153, 153f  
 Activation energy, **111**, 111f, 113-114  
 Activator, 117, 308, 313, 314-315, 314f-315f, 316-317  
   allosteric, **117**  
 Active immunity, 1063  
 Active site, **114**, 114f  
 Active transport, across plasma membrane, **99-102**, 104t  
 Acute-phase protein, 1059  
 ADA-SCID, 345  
 Adaptation, speciation and, 443, 443f  
 Adapter protein, **176**, 178  
 Adaptive radiation, **446-447**, 446f-447f, 450, 450f  
 Adaptive significance, of behavior, 1148  
 Adaptive value, of egg coloration, 1147-1148, 1147f  
 Addiction, drug, 900-901, 900f  
 Adenine, 42, 42f, 259f, 260, 262  
 Adenohypophysis, **946**  
 Adenosine diphosphate. *See* ADP  
 Adenosine monophosphate. *See* AMP  
 Adenosine triphosphate. *See* ATP  
 Adenovirus, 531f  
 Adenyl cyclase, **179-180**, 180f, 946  
 ADH. *See* Antidiuretic hormone  
 Adherens junction, **84**  
 Adhesion, 27, 27f  
 Adipose cells, **868**  
 Adipose tissue, **868**, 868f  
 ADP, 113, 113f  
 Adrenal cortex, 954, 954f  
 Adrenal gland, **953-954**, 954f  
 Adrenal medulla, 953-954, 954f  
 Adrenocorticotrophic hormone (ACTH), 947-948  
 Adsorption, of virus to host, 533  
 Adventitious plantlet, 858  
 Adventitious root, **742**, 746f, 765f  
 Aerenchyma, **780**, 781f  
 Aerial root, 742, 743f  
 Aerobic capacity, 974  
 Aerobic metabolism, 129  
 Aerobic respiration, **124**, 126, 126f, 129, 136f  
   ATP yield from, 137-138, 137f  
   evolution of, 143  
   regulation of, 138, 138f  
 Aesthetic value, of biodiversity, 1263  
 Afferent arteriole, 1046  
 Afferent neuron. *See* Sensory neuron  
 Aflatoxin, 630, 630f  
 African savanna, 1186f  
 African sleeping sickness, 574  
 African violet, 748f  
*Afrovenator*, 709f  
 Age, at first reproduction, 1173  
 Age structure, of population, **1169**  
 Agent Orange, 831  
 Aging, telomerase and, 273  
 Agriculture  
   applications of genetic engineering to, 346-349, 346f-348f  
   applications of genomics to, 368-369, 368f-369f  
   effect of global warming on, 1252-1253  
   pollution due to, 1251  
*Agrobacterium tumefaciens*, 346, 346f, 832, 833f  
 AIDS, 470-471, 531, 532t, 535-538, **1079**  
   deaths in United States, 535  
   gene therapy for, 345, 345t  
 Air pollution, monitoring with lichens, 627  
 Akiapolaau, 1270f  
 Alanine, 35f, 46, 47f  
 Alaskan near-shore habitat, 1271-1272, 1272f  
 Albinism, 227t, 228, 228f  
 Albumin, **1019**  
 Aldosterone, 954, **1035**, 1050, 1051, 1052f  
 Aleurone, 764f, **765**  
 Alfalfa plant bug, 803, 803f  
 Alkaptonuria, 227t, 229  
 Allantoin, **1044**  
 Allantois, **706**, 708f, 1089, 1116  
 Allee effect, **1176**  
 Allee, Warder, 1176  
 Allele, **225**  
   multiple, 233t, 233-235, 235f  
   temperature-sensitive, 235, 235f  
 Allele frequency, 397, **399-400**  
   changes in populations, 398-400, 399f  
 Allelopathy, **807**, 807f  
 Allen's rule, 1164  
 Allergy, 1075, 1076f  
 Alligator, 707t, 711, 711f  
 Allometric growth, **1128**  
*Allomyces*, 615t, 620, 621f  
 Allopatric speciation, **442**, 442f, 444-445, 444f  
 Allopolyploidy, **445**, 445f, 477, 477f, 479f  
 Allosteric activator, **117**  
 Allosteric enzymes, 117  
 Allosteric inhibitor, **117**, 117f  
 Allosteric site, **117**  
 Alpha helix, **48**  
 Alpha wave, 905  
 Alternate leaf, 744, 744f  
 Alternation of generations, 850  
 Alternative splicing, **290**, 320, 321f, 322f, 361, 361f  
 Altricial young, **1153**  
 Altruism, **1154-1157**, 1155f-1157f  
   reciprocal, 1154-1155, 1155f  
 Alveolata, 515f, 570f, 576-579, 569f-579f  
 Alveoli, **1007-1008**, 1008f  
 Alveoli, of protists, 576, 576f  
 Alzheimer disease, 906-907  
*Amborella*, 607, 607f  
*Amborella trichopoda*, 521-522, 522f, 607, 607f  
 American basswood, 836f  
 American woodcock (*Scolopax minor*), 933  
 Amino acid, **44**  
   abbreviations for, 47f  
   catabolism of, 141, 141f  
   chemical classes of, 46, 47f  
   as neurotransmitters, 898-899  
   in proteins, 36f, 44  
   structure of, 44-46, 47f  
   twenty common, 47f  
 Amino acid derivative, 939  
 Amino group, 35, 35f  
 Aminoacyl-tRNA synthetase, **291-291**, 291f-292f  
 Ammonia, 1044, 1045f  
 Amniocentesis, **252**, 252f  
 Amnion, 1089, 1116  
 Amniotic egg, **706**, 708f, 1089  
 Amniotic fluid, 1116  
 Amniotic membrane, 1116
