The PSC is controversial, however, for several reasons. First, some critics contend that it will lead to the recognition of every slightly differentiated population as a distinct species. In Missouri, for example, open, desert-like habitat patches called glades are distributed throughout much of the state. These glades contain a variety of warmth-loving species of plants and animals that do not occur in the forests that separate the glades. Glades have been isolated from one another for a few thousand years, allowing enough time for populations on each glade to evolve differences in some rapidly evolving parts of the genome. Does that mean that each of the hundreds, if not thousands, of Missouri glades contains its own species of lizards, grasshoppers, and scorpions? Some scientists argue that if one takes the PSC to its logical extreme, that is exactly what would result.

**Figure 23.6 Phylogenetic information transforms plant classification.** The traditional classification included two groups that we now realize are not monophyletic: the green algae and bryophytes. For this reason, plant systematists have developed a new classification of plants that does not include these groups (discussed in chapter 30).

**Figure 23.7 Paraphyly and the phylogenetic species concept.** The five populations initially were all members of the same species, with their historical relationships indicated by the cladogram. Then, population C evolved in some ways to become greatly differentiated ecologically and reproductively from the other populations. By all species concepts, this population would qualify as a different species. However, the remaining four species do not form a clade; they are paraphyletic because population C has been removed and placed in a different species. This scenario may occur commonly in nature, but most versions of the phylogenetic species concept do not recognize paraphyletic species.

A second problem is that species may not always be monophyletic, contrary to the definition of some versions of the phylogenetic species concept. Consider, for example, a species composed of five populations, with evolutionary relationships like those indicated in figure 23.7. Suppose that population C becomes isolated and evolves differences that make it qualify as a species by any concept (for example, reproductively isolated, ecologically differentiated). But this distinction would mean that the remaining populations, which might still be perfectly capable of exchanging genes, would be paraphyletic, rather than monophyletic. Such situations probably occur often in the natural world.

Phylogenetic species concepts, of which there are many different permutations, are increasingly used, but are also contentious for the reasons just discussed. Evolutionary biologists are trying to find ways to reconcile the historical perspective of the PSC with the process-oriented perspective of the BSC and other species concepts.

### Learning Outcomes Review 23.3

By definition, a clade is monophyletic. A paraphyletic group contains the most recent common ancestor, but not all its descendants; a polyphyletic group does not contain the most recent common ancestor of all members. The phylogenetic species concept focuses on the possession of shared derived characters, in contrast to the biological species concept, which emphasizes reproductive isolation. The PSC solves some problems of the BSC but has difficulties of its own.

- Under the biological species concept, is it possible for a species to be polyphyletic?

## 23.4 Phylogenetics and Comparative Biology

### Learning Outcomes

1. Explain the concept of homoplasy.
2. Describe how phylogenetic trees can reveal the existence of homoplasy.
3. Discuss how a phylogenetic tree can indicate the timing of species diversification.

Phylogenies not only provide information about evolutionary relationships among species, but they are also indispensable for understanding how evolution has occurred. By examining the distribution of traits among species in the context of their phylogenetic relationships, much can be learned about how and why evolution may have proceeded. In this way, phylogenetics is the basis of all comparative biology.

### Homologous features are derived from the same ancestral source; homoplastic features are not

In chapter 21, we pointed out that homologous structures are those that are derived from the same body part in a common ancestor. Thus, the forelegs of a dolphin (flipper) and of a horse (leg) are homologous because they are derived from the same bones in an ancestral vertebrate. By contrast, the wings of birds and those of dragonflies are homoplastic structures because they are derived from different ancestral structures. Phylogenetic analysis can help determine whether structures are homologous or homoplastic.

### Homologous parental care in dinosaurs, crocodiles, and birds

Recent fossil discoveries have revealed that many species of dinosaurs exhibited parental care. They incubated eggs laid in nests and took care of growing baby dinosaurs, many of which could not have fended for themselves. Some recent fossils show dinosaurs sitting on a nest in exactly the same posture used by birds today (figure 23.8*a*)! Initially, these discoveries were treated as remarkable and unexpected—dinosaurs apparently had independently evolved behaviors similar to those of modern-day organisms. But examination of the phylogenetic position of dinosaurs (see figure 23.5) indicates that they are most closely related to two living groups of animals—crocodiles and birds—both of which exhibit parental care (figure 23.8*b*).

It appears likely, therefore, that the parental care exhibited by crocodiles, dinosaurs, and birds did not evolve convergently from different ancestors that did not exhibit parental care; rather, the behaviors are homologous, inherited by each of these groups from their common ancestor that cared for its young.

### Homoplastic convergence: Saber teeth and plant conducting tubes

In other cases, by contrast, phylogenetic analysis can indicate that similar traits have evolved independently in different

a.

b.

**Figure 23.8 Parental care in dinosaurs and crocodiles** *a.* Fossil dinosaur incubating its eggs. This remarkable fossil of *Oviraptor* shows the dinosaur sitting on its nest of eggs just as chickens do today. Not only is the dinosaur squatting on the nest, but its forelimbs are outstretched, perhaps to shade the eggs. *b.* Crocodile exhibiting parental care. Female crocodilians build nests and then remain nearby, guarding them, while the eggs incubate. When they are ready to hatch, the baby crocodiles vocalize; females respond by digging up the eggs and carrying the babies to the water.

clades. This convergent evolution from different ancestral sources indicates that such traits represent homoplasies. As one example, the fossil record reveals that extremely elongated canine teeth (saber teeth) occurred in a number of different groups of extinct carnivorous mammals. Although how these teeth were actually used is still debated, all saber-

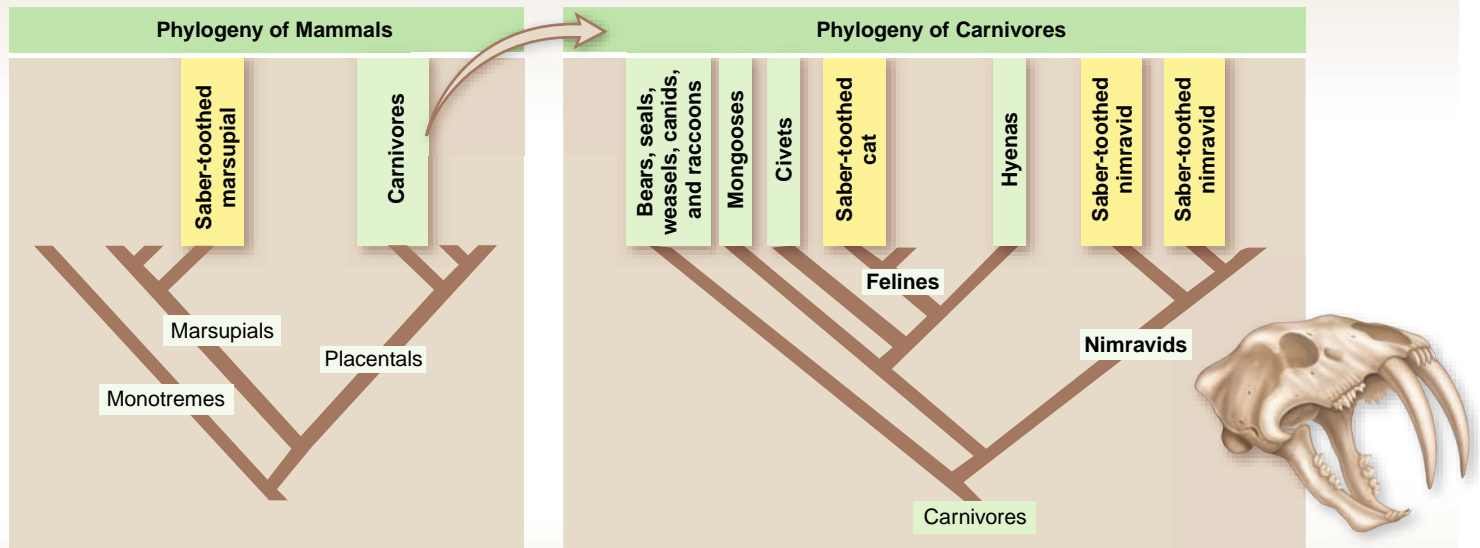

toothed carnivores had body proportions similar to those of cats, which suggests that these different types of carnivores all evolved into a similar predatory lifestyle. Examination of the saber-toothed character state in a phylogenetic context reveals that it most likely evolved independently at least three times (figure 23.9).

### SCIENTIFIC THINKING

**Question:** How many times have saber teeth evolved in carnivores?

**Hypothesis:** Saber teeth are homologous and have only evolved once in carnivores (or, conversely, saber teeth are convergent and have evolved multiple times in carnivores).

**Phylogenetic Analysis:** Examine the distribution of saber teeth on a phylogeny of carnivores, and use parsimony to infer the history of saber tooth evolution (note that not all branches within marsupials and placentals are shown on the phylogeny).

**Result:** Saber teeth have evolved at least three times in mammals: once within marsupials, once in felines, and at least once in nimravids.

**Interpretation:** Note that it is possible that saber teeth evolved twice in nimravids, but another possibility that requires the same number of evolutionary changes (and thus is equally parsimonious) is that saber teeth evolved only once in the ancestor of nimravids and then were subsequently lost in one group of nimravids.

**Figure 23.9 Distribution of saber-toothed mammals.** Saber teeth have evolved at least three times in mammals: once within marsupials, once in felines, and at least once in a now-extinct group of catlike carnivores called nimravids. It is possible that the condition evolved twice in nimravids, but another possibility that requires the same number of evolutionary changes (and thus is equally parsimonious) is that saber teeth evolved only once in the ancestor of nimravids and then were subsequently lost in one group of nimravids (not all of the branches within marsupials and placentals are shown).

**Figure 23.10 Convergent evolution of conducting tubes.** Sieve tubes, which transport hormones and other substances throughout the plant, have evolved in two distantly related plant groups (brown algae are stramenopiles and angiosperms are tracheophytes).

© Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited

Conducting tubes in plants provide a similar example. The tracheophytes, a large group of land plants discussed in chapter 30, transport photosynthetic products, hormones, and other molecules over long distances through elongated, tubular cells that have perforated walls at the end. These structures are stacked upon each other to create a conduit called a sieve tube. Sieve tubes facilitate long-distance transport that is essential for the survival of tall plants on land.

Most members of the brown algae, which includes kelp, also have sieve elements (see figure 23.10 for a comparison of the sieve plates in brown algae and angiosperms) that aid in the rapid transport of materials. The land plants and brown algae are distantly related (see figure 23.10), and their last common ancestor was a single-celled organism that could not have had a multicellular transport system. This indicates that the strong structural and functional similarity of sieve elements in these plant groups is an example of convergent evolution.

### Complex characters evolve through a sequence of evolutionary changes

Most complex characters do not evolve, fully formed, in one step. Rather, they are often built up, step-by-step, in a series of evolutionary transitions. Phylogenetic analysis can help discover these evolutionary sequences.

Modern-day birds—with their wings, feathers, light bones, and breastbone—are exquisitely adapted flying machines. Fossil discoveries in recent years now allow us to reconstruct the evolution of these features. When the fossils are arranged phylogenetically, it becomes clear that the features characterizing living birds did not evolve simultaneously. Figure 23.11 shows how the features important to flight evolved sequentially, probably over a long period of time, in the ancestors of modern birds.

One important finding often revealed by studies of the evolution of complex characters is that the initial stages of a character evolved as an adaptation to some environmental selective pressure different from that for which the character is currently adapted. Examination of figure 23.11 reveals that the

first feathery structures evolved deep in the theropod phylogeny, in animals with forearms clearly not modified for flight. Therefore, the initial feather-like structures must have evolved for some other reason, perhaps serving as insulation or decoration. Through time, these structures have become modified to the extent that modern feathers produce excellent aerodynamic performance.

### Phylogenetic methods can be used to distinguish between competing hypotheses

Understanding the causes of patterns of biological diversity observed today can be difficult because a single pattern often could have resulted from several different processes. In many cases, scientists can use phylogenies to distinguish between competing hypotheses.

#### Larval dispersal in marine snails

An example of this use of phylogenetic analysis concerns the evolution of larval forms in marine snails. Most species of snails produce microscopic larvae that drift in the ocean currents, sometimes traveling hundreds or thousands of miles before becoming established and transforming into adults. Some species, however, have evolved larvae that settle to the ocean bottom very quickly and thus don't disperse far from their place of origin. Studies of fossil snails indicate that the proportion of species that produce nondispersing larvae has increased through geological time (figure 23.12).

Two processes could produce an increase in nondispersing larvae through time. First, if evolutionary change from dispersing to nondispersing occurs more often than change in the opposite direction, then the proportion of species that are nondispersing would increase through time.

Alternatively, if species that are nondispersing speciate more frequently, or become extinct less frequently, than dispersing species, then through time the proportion of nondispersers would also increase (assuming that the descendants of nondispersing species also were nondispersing). This latter case is a reasonable hypothesis because nondispersing species

**Figure 23.11 The evolution of birds.** The traits we think of as characteristic of modern birds have evolved in stages over many millions of years.

From Richard O. Prum and Alan H. Brush, “The Evolutionary Origin and Diversification of Feathers,” *Quarterly Review of Biology*, September 2002. Reprinted with permission of the University of Chicago Press.

probably have lower amounts of gene flow than dispersing species, and thus might more easily become geographically isolated, increasing the likelihood of allopatric speciation (see chapter 22).

These two processes would result in different phylogenetic patterns. If evolution from a dispersing ancestor to a nondispersing descendant occurred more often than the reverse, then an excess of such changes should be evident in the phylog-

**Figure 23.12 Larvae dispersal.** Increase through time in the proportion of species whose larvae do not disperse far from their place of birth.

eny, as shown by more dispersing  $\rightarrow$  nondispersing branch-points in figure 23.13a. In contrast, if nondispersing species underwent greater speciation, then clades of nondispersing species would contain more species than clades of dispersing species, as shown in figure 23.13b.

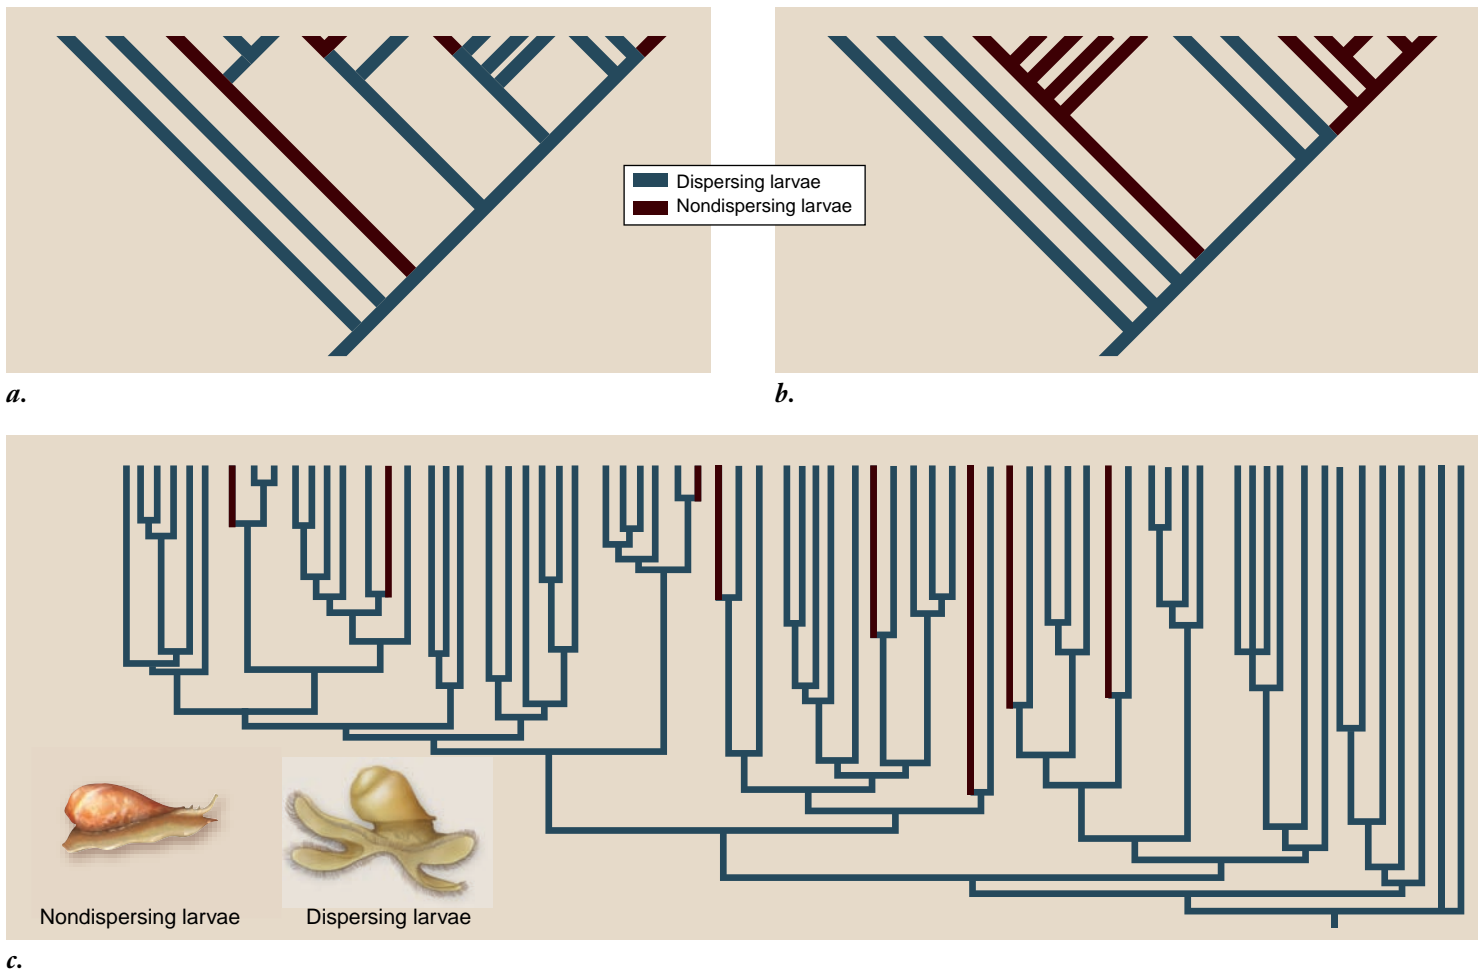

Evidence for both processes was revealed in an examination of the phylogeny of marine snails in the genus *Comus*, in which 30% of species are nondispersing (figure 23.13c). The phylogeny indicates that possession of dispersing larvae was the ancestral state; nondispersing larvae are inferred to have evolved eight times, with no evidence for evolutionary reversal from nondispersing to dispersing larvae.

At the same time, clades of nondispersing larvae tend to have on average 3.5 times as many species as dispersing larvae, which suggests that in nondispersing species, rates of speciation are higher, rates of extinction are lower, or both.

This analysis therefore indicates that the evolutionary increase in nondispersing larvae through time may be a result both of a bias in the direction in which evolution proceeds plus an increase in rate of diversification (that is, speciation rate minus extinction rate) in nondispersing clades.

The lack of evolutionary reversal is not surprising because when larvae evolve to become nondispersing, they often lose a variety of structures used for feeding while drifting in the ocean current. In most cases, once a structure is lost, it rarely re-evolves, and thus the standard view is that the

**Figure 23.13** Phylogenetic investigation of the evolution of nondispersing larvae. *a.* In this hypothetical example, the evolutionary transition from dispersing to nondispersing larvae occurs more frequently (four times) than the converse (once). By contrast, in *(b)* clades that have nondispersing larvae diversify to a greater extent due to higher rates of speciation or lower rates of extinction (assuming that extinct forms are not shown). *c.* Phylogeny for *Conus*, a genus of marine snails. Nondispersing larvae have evolved eight separate times from dispersing larvae, with no instances of evolution in the reverse direction. This phylogeny does not show all species, however; nondispersing clades contain on average 3.5 times as many species as dispersing clades.

evolution of nondispersing larvae is a one-way street, with few examples of re-evolution of dispersing larvae.

### Loss of the larval stage in marine invertebrates

A related phenomenon in many marine invertebrates is the loss of the larval stage entirely. Most marine invertebrates—in groups as diverse as snails, sea stars, and anemones—pass through a larval stage as they develop. But in a number of different types of organisms, the larval stage is omitted, and the eggs develop directly into adults.

The evolutionary loss of the larval stage has been suggested as another example of a nonreversible evolutionary change because once the larval stages are lost, it is difficult for them to re-evolve—or so the argument goes. A recent study on one group of marine limpets, shelled marine organisms related to snails, shows that this is not necessarily the case. Among these limpets, direct development has evolved many times; however, in three cases, the phylogeny strongly suggests that evolution reversed and a larval stage re-evolved (figure 23.14*a*).

It is important to remember that patterns of evolution suggested by phylogenetic analysis are not always correct—evolution does not necessarily occur parsimoniously. In the limpet study, for example, it is possible that within the clade in the light blue box, presence of a larva was retained as the ancestral state, and direct development evolved independently six times (figure 23.14*b*). Phylogenetic analysis cannot rule out this possibility, even if it is less phylogenetically parsimonious.

If the re-evolution of lost traits seems unlikely, then the alternative hypothesis that direct development evolved six—rather than only once at the base of the clade, with two instances of evolutionary reversal—should be considered. For example, studies of the morphology or embryology of direct-developing species might shed light on whether such structures are homologous or convergent. In some cases, artificial selection experiments in the laboratory or genetic manipulations can test the hypothesis that it is difficult for lost structures to re-evolve. Conclusions from phylogenetic analyses are always stronger when supported by results of other types of studies.

**Figure 23.14** Evolution of direct development in a family of limpets. *a.* Direct development evolved many times (indicated by beige lines stemming from a red ancestor), and three instances of reversed evolution from direct development to larval development are indicated (red lines from a beige ancestor). *b.* A less parsimonious interpretation of evolution in the clade in the light blue box is that, rather than two evolutionary reversals, six instances of the evolution of development occurred without any evolutionary reversal.

## Phylogenetics helps explain species diversification

One of the central goals of evolutionary biology is to explain patterns of species diversity: Why do some types of plants and animals exhibit more **species richness**—a greater number of species per clade—than others? Phylogenetic analysis can be used both to suggest and to test hypotheses about such differences.

### Species richness in beetles

Beetles (order Coleoptera) are the most diverse group of animals. Approximately 60% of all animal species are insects, and approximately 80% of all insect species are beetles. Among beetles, families that are herbivorous are particularly species-rich.

Examination of the phylogeny provides insight into beetle evolutionary diversification (figure 23.15). Among the Phytophaga, the clade which contains most herbivorous beetle species, the deepest branches belong to beetle families that specialize on conifers. This finding agrees with the fossil record because conifers were among the earliest seed plant groups to evolve. By contrast, the flowering plants (angiosperms) evolved more recently, in the Cretaceous, and beetle families specializing on them have shorter evolutionary branches, indicating their more recent evolutionary appearance.

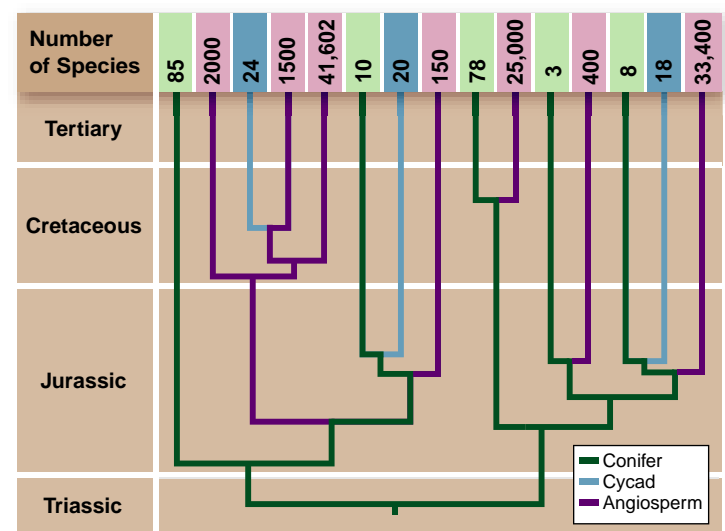

This correspondence between phylogenetic position and timing of plant origins suggests that beetles have been remarkably conservative in their diet. The family Nemonychidae, for example, appears to have remained specialized on conifers since the beginning of the Jurassic, approximately 210 MYA.

### Phylogenetic explanations for beetle diversification

The phylogenetic perspective suggests factors that may be responsible for the incredible diversity of beetles. The phylogeny for the Phytophaga indicates that it is not the evolution of herbivory itself that is linked to great species richness. Rather, specialization on angiosperms seems to have been a prerequisite for great species diversification. Specialization on angiosperms

appears to have arisen five times independently within herbivorous beetles; in each case, the angiosperm-specializing clade is substantially more species-rich than the clade to which it is most closely related (termed a *sister clade*) and which specializes on some other type of plant.

Why specialization on angiosperms has led to great species diversity is not yet clear and is the focus of much current research. One possibility is that this diversity is linked to the great species-richness of angiosperms themselves. With more than 250,000 species of angiosperms, beetle clades specializing on them may have had a multitude

**Figure 23.15** Evolutionary diversification of the Phytophaga, the largest clade of herbivorous beetles.

Clades that originated deep in the phylogenetic tree feed on conifers; clades that feed on angiosperms, which evolved more recently, originated more recently. Age of clades is established by examination of fossil beetles.

of opportunities to adapt to feed on individual species, thus promoting divergence and speciation.

### Learning Outcomes Review 23.4

Homologous traits are derived from the same ancestral character states, whereas homoplastic traits are not, even though they may have similar function. Phylogenetic analysis can help determine whether homology or homoplasy has occurred. By correlating phylogenetic branching with known evolutionary events, the timing and cause of diversification can be inferred.

- Does the possession of the same character state by all members of a clade mean that the ancestor of that clade necessarily possessed that character state?

## 23.5 Phylogenetics and Disease Evolution

### Learning Outcome

1. Discuss how phylogenetic analysis can help identify patterns of disease transmission.

The examples so far have illustrated the use of phylogenetic analysis to examine relationships among species. Such analyses can also be conducted on virtually any group of biological entities, as long as evolutionary divergence in these groups occurs by a branching process, with little or no genetic exchange between different groups. No example illustrates this better than recent attempts to understand the evolution of the virus that causes autoimmune deficiency syndrome (AIDS).

### HIV has evolved from a simian viral counterpart

AIDS was first recognized in the early 1980s, and it rapidly became epidemic in the human population. Current estimates are that more than 33 million people are infected with the human immunodeficiency virus (HIV), of whom more than 2 million die each year.

At first, scientists were perplexed about where HIV had originated and how it had infected humans. In the mid-1980s, however, scientists discovered a related virus in laboratory monkeys, termed simian immunodeficiency virus (SIV). In biochemical terms, the viruses are very similar, although genetic differences exist. At last count, SIV has been detected in 36 species of primates, but only in species found in sub-Saharan Africa. Interestingly, SIV—which appears to be transmitted sexually—does not appear to cause any illness in these primates.

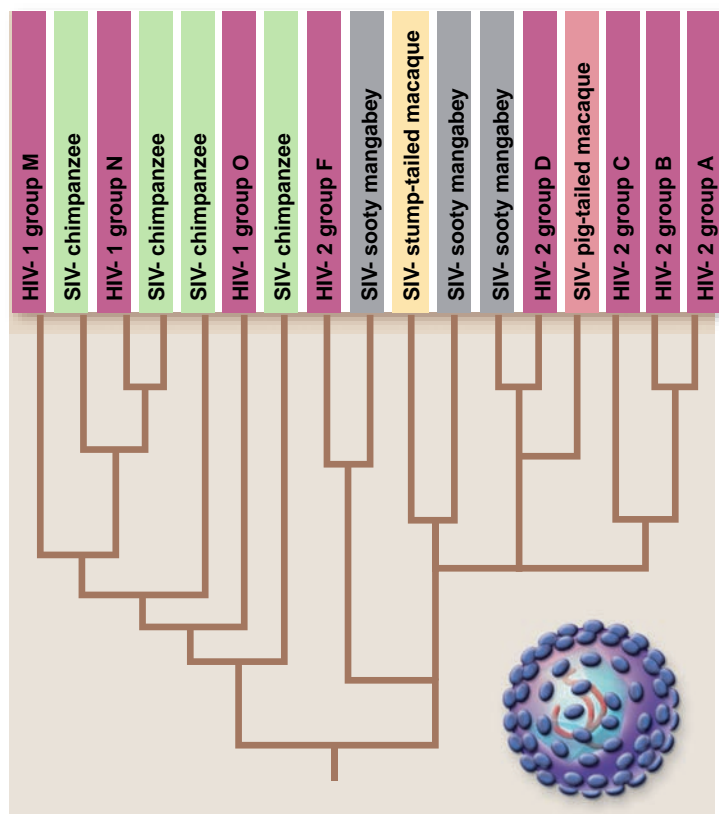

Based on the degree of genetic differentiation among strains of SIV, scientists estimate that SIV may have been around for more than a million years in these primates, perhaps providing enough time for these species to adapt to the virus and thus prevent it from having adverse effects.

### Phylogenetic analysis identifies the path of transmission

Phylogenetic analysis of strains of HIV and SIV reveals three clear findings. First, HIV obviously descended from SIV. All strains of HIV are phylogenetically nested within clades of SIV strains, indicating that HIV is derived from SIV (figure 23.16).

Second, a number of different strains of HIV exist, and they appear to represent independent transfers from different primate species. Each of the human strains is more closely related to a strain of SIV than it is to other HIV strains, indicating separate origins of the HIV strains.

Finally, humans have acquired HIV from different host species. HIV-1, which is the virus responsible for the global epidemic, has three subtypes. Each of these subtypes is most closely related to a different strain of chimpanzee SIV, indicating that the transfer occurred from chimps to humans. By contrast, subtypes of HIV-2, which is much less widespread (in some cases known from only one individual), are related to SIV found in West African monkeys, primarily the sooty mangabey (*Cercocebus atys*). Moreover, the subtypes of HIV-2 also appear to represent several independent cross-species transmissions to humans.

**Figure 23.16 Evolution of HIV and SIV.** HIV has evolved multiple times and from strains of SIV in different primate species (each primate species indicated by a different color). The three-way branching event on the right side of the phylogeny results because the data do not clearly indicate the relationships among the three clades.

### Transmission from other primates to humans

Several hypotheses have been proposed to explain how SIV jumped from chimps and monkeys to humans. The most likely idea is that transmission occurred as the result of blood-to-blood contact that may occur when humans kill and butcher monkeys and apes. Recent years have seen a huge increase in the rate at which primates are hunted for the “bushmeat” market, particularly in central and western Africa. This increase has resulted from a combination of increased human populations desiring ever greater amounts of protein, combined with increased access to the habitats in which these primates live as the result of road building and economic development. The unfortunate result is that population sizes of many primate species, including our closest relatives, are plummeting toward extinction. A second consequence of this hunting is that humans are increasingly brought into contact with bodily fluids of these animals, and it is easy to imagine how during the butchering process, blood from a recently killed animal might enter the human bloodstream through cuts in the skin, perhaps obtained during the hunting process.

### Establishing the crossover time line and location

Where and when did this cross-species transmission occur? HIV strains are most diverse in Africa, and the incidence of HIV is higher there than elsewhere in the world. Combined with the evidence that HIV is related to SIV in African primates, it seems certain that AIDS appeared first in Africa.

As for when the jump from other primates to humans occurred, the fact that AIDS was not recognized until the 1980s suggests that HIV probably arose recently. Descendants of slaves brought to North America from West Africa in the 19th century lacked the disease, indicating that it probably did not occur at the time of the slave trade.

Once the disease was recognized in the 1980s, scientists scoured repositories of blood samples to see whether HIV could be detected in blood samples from the past. The earliest HIV-positive result was found in a sample from 1959, pushing the date of origin back at least two decades. Based on the amount of genetic difference between strains of HIV-1, including the 1959 sample, and assuming the operation of a molecular clock, scientists estimate that the deadly strain of AIDS probably crossed into humans some time before 1940.

### Phylogenies can be used to track the evolution of AIDS among individuals

The AIDS virus evolves extremely rapidly, so much so that different strains can exist within different individuals in a single population. As a result, phylogenetic analysis can be applied to answer very specific questions; just as phylogeny proved useful in determining the source of HIV, it can also pinpoint the source of infection for particular individuals.

This ability became apparent in a court case in Louisiana in 1998, in which a dentist was accused of injecting his former girlfriend with blood drawn from an HIV-infected patient. The dentist’s records revealed that he had drawn blood from the patient and had done so in a suspicious manner. Scientists sequenced the viral strains from the victim, the

patient, and from a large number of HIV-infected people in the local community. The phylogenetic analysis clearly demonstrated that the victim’s viral strain was most closely related to the patient’s (figure 23.17). This analysis, which for the first time established phylogenetics as a legally admissible form of evidence in courts in the United States, helped convict the dentist, who is now serving a 50-year sentence for attempted murder.

### Learning Outcome Review 23.5

Modern phylogenetic techniques and analysis can track the evolution of disease strains, uncovering sources and progression. The HIV virus provides a prime example: Analysis of viral strains has shown that the progression from simian immunodeficiency virus (SIV) into human hosts has occurred several times. Phylogenetic analysis is also used to track the transmission of human disease.

- **Could HIV have arisen in humans and then have been transmitted to other primate species?**

**Figure 23.17 Evolution of HIV strains reveals the source of infection.** HIV mutates so rapidly that a single HIV-infected individual often contains multiple genotypes in his or her body. As a result, it is possible to create a phylogeny of HIV strains and to identify the source of infection of a particular individual. In this case, the HIV strains of the victim clearly are derived from strains in the body of another individual, the patient. Other HIV strains are from HIV-infected individuals in the local community.

### Inquiry question

- ? **What would the phylogeny look like if the victim had not gotten HIV from the patient?**

### 23.1 Systematics

***Branching diagrams depict evolutionary relationships.***

Systematics is the study of evolutionary relationships, which are depicted on branching evolutionary trees, called phylogenies.

***Similarity may not accurately predict evolutionary relationships.***

The rate of evolution can vary among species and can even reverse direction. Closely related species can therefore be dissimilar in phenotypic characteristics.

Conversely, convergent evolution results in distantly related species being phenotypically similar.

### 23.2 Cladistics

***The cladistic method requires that character variation be identified as ancestral or derived.***

Derived character states are those that differ from the ancestral condition.

Character polarity is established using an outgroup comparison in which the outgroup consists of closely related species or a group of species, relative to the group under study.

Character states exhibited by the outgroup are assumed to be ancestral, and other character states are considered derived.

A cladogram is a graphically represented hypothesis of evolutionary relationships.

***Homoplasy complicates cladistic analysis.***

Homoplasy refers to a shared character state, such as wings of birds and wings of insects, that has not been inherited from a common ancestor.

Cladograms are constructed based on the principle of parsimony, which indicates that the phylogeny requiring the fewest evolutionary changes is accepted as the best working hypothesis.

***Other phylogenetic methods work better than cladistics in some situations.***

When evolutionary change is rapid, other methods, such as statistical approaches and the use of the molecular clock, are sometimes more useful.

### 23.3 Systematics and Classification

***Current classification sometimes does not reflect evolutionary relationships.***

A monophyletic group consists of the most recent common ancestor and all of its descendants.

A paraphyletic group consists of the most recent common ancestor and some of its descendants.

A polyphyletic group does not contain the most recent ancestor of the group. Some currently recognized taxa are not monophyletic, such as reptiles, which are paraphyletic with respect to birds.

***The phylogenetic species concept focuses on shared derived characters.***

The phylogenetic species concept emphasizes the possession of shared derived characters, whereas the biological species concept focuses on reproductive isolation. Many versions of this concept only recognize species that are monophyletic.

***The PSC (phylogenetic species concept) also has drawbacks.***

Among criticisms of the PSC (phylogenetic species concept) are that it subdivides groups too far via impractical distinctions, and that the PSC definition of a group may not always apply as selection proceeds.

### 23.4 Phylogenetics and Comparative Biology

***Homologous features are derived from the same ancestral source; homoplastic features are not.***

Homologous structures can be identified by phylogenetic analysis, establishing whether or not different structures have been built from the same ancestral structure.

***Complex characters evolve through a sequence of evolutionary changes.***

Most complex features do not evolve in a single step but include stages of transition. They may have begun as an adaptation to a selective pressure different from the one for which the feature is currently adapted.

***Phylogenetic methods can be used to distinguish between competing hypotheses.***

Different evolutionary scenarios can be distinguished by phylogenetic analysis. The minimum number of times a trait may have evolved can be established, as well as the direction of trait evolution, the timing, and the cause of diversification.

***Phylogenetics helps explain species diversification.***

Questions regarding the causes of species richness may be addressed with phylogenetic analysis.

### 23.5 Phylogenetics and Disease Evolution

***HIV has evolved from a simian viral counterpart.***

Phylogenetic methods have indicated that HIV is related to SIV.

***Phylogenetic analysis identifies the path of transmission.***

It is clear that HIV has descended from SIV, and that independent transfers from simians to humans have occurred several times. Application of findings has allowed identification of the first occurrence in humans, in 1959.

***Phylogenies can be used to track the evolution of AIDS among individuals.***

Even though HIV evolves rapidly, phylogenetic analysis can trace the origin of a current strain to a specific source of infection.

## Review Questions

### UNDERSTAND

- Overall similarity of phenotypes may not always reflect evolutionary relationships
  - due to convergent evolution.
  - because of variation in rates of evolutionary change of different kinds of characters.
  - due to homoplasy.
  - due to all of the above.
- Cladistics
  - is based on overall similarity of phenotypes.
  - requires distinguishing similarity due to inheritance from a common ancestor from other reasons for similarity.
  - is not affected by homoplasy.
  - is none of the above.
- The principle of parsimony
  - helps evolutionary biologists distinguish among competing phylogenetic hypotheses.
  - does not require that the polarity of traits be determined.
  - is a way to avoid having to use outgroups in a phylogenetic analysis.
  - cannot be applied to molecular traits.
- Parsimony suggests that parental care in birds, crocodiles, and some dinosaurs
  - evolved independently multiple times by convergent evolution.
  - evolved once in an ancestor common to all three groups.
  - is a homoplastic trait.
  - is not a homologous trait.
- The forelimb of a bird and the forelimb of a rhinoceros
  - are homologous and symplesiomorphic.
  - are not homologous but are symplesiomorphic.
  - are homologous and synapomorphic.
  - are not homologous but are synapomorphic.
- In order to determine polarity for different states of a character
  - there must be a fossil record of the groups in question.
  - genetic sequence data must be available.
  - an appropriate name for the taxonomic group must be selected.
  - an outgroup must be identified.
- A paraphyletic group includes
  - an ancestor and all of its descendants.
  - an ancestor and some of its descendants.
  - descendants of more than one common ancestor.
  - all of the above.
- Sieve tubes and sieve elements are
  - homoplastic because they have different function.
  - homologous because they have similar function.
  - homoplastic because their common ancestor was single-celled.
  - structures involved in transport within animals.

### APPLY

- A taxonomic group that contains species that have similar phenotypes due to convergent evolution is
  - paraphyletic.
  - monophyletic.
  - polyphyletic.
  - a good cladistic group.
- Rapid rates of character change relative to the rate of speciation pose a problem for cladistics because
  - the frequency with which distantly related species evolve the same derived character state may be high.
  - evolutionary reversals may occur frequently.
  - homoplasy will be common.
  - all of the above.
- In a paraphyletic group
  - all species are more closely related to each other than they are to a species outside the group.
  - evolutionary reversal is common.
  - polyphyly also usually occurs.
  - some species are more closely related to species outside the group than they are to some species within the group.
- Species recognized by the phylogenetic species concept
  - sometimes also would be recognized as species by the biological species concept.
  - are sometimes paraphyletic.
  - are characterized by symplesiomorphies.
  - are more frequent in plants than in animals.

### SYNTHESIZE

- List the synapomorphy and the taxa defined by that synapomorphy for the groups pictured in figure 23.2. Name each group defined by a set of synapomorphies in a way that might be construed as informative about what kind of characters define the group.
- Identifying “outgroups” is a central component of cladistic analysis. As described on page 458, a group is chosen that is closely related to, but not a part of the group under study. If one does not know the relationships of members of the group under study, how can one be certain that an appropriate outgroup is chosen? Can you think of any approaches that would minimize the effect of a poor choice of outgroup?
- As noted in your reading, cladistics is a widely utilized method of systematics, and our classification system (taxonomy) is increasingly becoming reflective of our knowledge of evolutionary relationships. Using birds as an example, discuss the advantages and disadvantages of recognizing them as reptiles versus as a group separate and equal to reptiles.
- Across many species of limpets, loss of larval development and reversal from direct development appears to have occurred multiple times. Under the simple principle of parsimony are changes in either direction merely counted equally in evaluating the most parsimonious hypothesis? If it is much more likely to lose a larval mode than to re-evolve it from direct development, should that be taken into account? If so, how?
- Birds, pterosaurs (a type of flying reptile that lived in the Cretaceous period), and bats all have modified their forelimbs to serve as wings, but they have done so in different ways. Are these structures homologous? If so, how can they be both homologous and convergent? Do any organisms possess wings that are convergent, but not homologous?
- In what sense does the biological species concept focus on evolutionary mechanisms and the phylogenetic species concept on evolutionary patterns? Which, if either, is correct?

## Chapter 24

# Genome Evolution

## Chapter Outline

- 24.1 Comparative Genomics
- 24.2 Whole-Genome Duplications
- 24.3 Evolution Within Genomes
- 24.4 Gene Function and Expression Patterns
- 24.5 Nonprotein-Coding DNA and Regulatory Function
- 24.6 Genome Size and Gene Number
- 24.7 Genome Analysis and Disease Prevention and Treatment
- 24.8 Crop Improvement Through Genome Analysis

## Introduction

*Genomes contain the raw material for evolution, and many clues to evolution are hidden in the ever-changing nature of genomes. As more genomes have been sequenced, the new and exciting field of comparative genomics has emerged and has yielded some surprising results as well as many, many questions. Comparing whole genomes, not just individual genes, enhances our ability to understand the workings of evolution, to improve crops, and to identify the genetic basis of disease so that we might develop more effective treatments with minimal side effects. The focus of this chapter is the role of comparative genomics in enhancing our understanding of genome evolution and how this new knowledge can be applied to improve our lives.*

## 24.1 Comparative Genomics

### Learning Outcomes

1. Describe the kinds of differences that can be found between genomes.
2. Relate timescale to genome evolution.
3. Explain why genomes may evolve at different rates.

A key challenge of modern evolutionary biology is finding a way to link changes in DNA sequences, which we are now able to study in great detail, with the evolution of the complex morphological characters used to construct a traditional phylogeny. Many different genes contribute to complex characters. Making the connection between a specific change in a gene and a modification in a morphological character is particularly difficult.

Comparing genomes (entire DNA sequences) provides a powerful tool for exploring evolutionary divergence among organisms to connect DNA level changes with

morphological differences. Genomes are more than instruction books for building and maintaining an organism; they also record the history of life. The growing number of fully sequenced genomes in all kingdoms is leading to a revolu-

tion in comparative evolutionary biology (figure 24.1). Genetic differences between species can be explored in a very direct way, examining the footprints on the evolutionary path between different species.

**Figure 24.1** Milestones of comparative eukaryotic genomics.

## Evolutionary differences accumulate over long periods

Genomes of viruses and bacteria can evolve in a matter of days, whereas complex eukaryotic species evolve over millions of years. To illustrate this point, we compare four vertebrate genomes: human, tiger pufferfish (*Fugu rubripes*), mouse (*Mus musculus*), and chimpanzee (*Pan troglodytes*).

### Comparison between human and pufferfish genomes

The draft (preliminary) sequence of the tiger pufferfish was completed in 2002; it was only the second vertebrate genome to be sequenced. For the first time, we were able to compare the genomes of two vertebrates: humans and pufferfish. These two animals last shared a common ancestor 450 MYA.

Some human and pufferfish genes have been conserved during evolution, but others are unique to each species. About 25% of human genes have no counterparts in *Fugu*. Also, extensive genome rearrangements have occurred during the 450 million years since the mammal lineage and the teleost fish diverged, indicating a considerable scrambling of gene order. Finally, the human genome is 97% repetitive DNA (chapter 18), but repetitive DNA accounts for less than one-sixth of the *Fugu* sequence.

### Comparison between human and mouse genomes

Later in 2002, a draft sequence of the mouse genome was completed by an international consortium of investigators, allowing for the first time a comparison of two mammalian genomes. In contrast to the human–pufferfish genome comparison, the differences between these two mammalian genomes are miniscule.

The human genome has about 400 million more nucleotides than that of the mouse. A comparison of the genomes reveals that both have about 25,000 genes, and that they share the bulk of them; in fact, the human genome shares 99% of its genes with mice. Humans and mice diverged about 75 MYA, approximately one-sixth of the amount of time that separates humans from pufferfish. There are only 300 genes unique to either human or mouse, constituting about 1% of the genome. Even 450 million years after last sharing a common ancestor, 75% of the genes found in humans have counterparts in pufferfish.

### Comparison between human and chimpanzee genomes

Humans and chimpanzees, *Pan troglodytes*, diverged only about 4.1 MYA, leaving even less time for their genomes to accumulate mutational differences. The chimp genome was sequenced in 2005, providing a comparative window between us and our closest living relative. A 1.5% difference in insertions and deletions (indels) is found between chimps and humans. Comparing chimp and human indels to outgroups can allow a determination of whether the indel was ancestrally present, and thus can identify which species has the derived condition. Fifty-three of the potentially human-specific indels lead to loss-of-function changes that might correlate with some of the traits that distinguish us from chimps, including a larger cranium and lack of body hair. As will be discussed later in this chapter, mutations leading to differences in the patterns of gene expression are particularly important in understanding why chimps are chimps and humans are humans.

Comparisons of single-nucleotide substitutions reveal that only 2.7% of the two genomes have consistent differences in single nucleotides. Mutations in coding DNA are classified into two groups: those that alter the amino acids coded for in the sequence (nonsynonymous changes) and those that do not (synonymous changes). For example, a synonymous mutation that changed UUU to UUC would still code for phenylalanine (use the genetic code in table 15.1 to see if you can identify examples of possible synonymous and nonsynonymous changes).

## Genomes evolve at different rates

A comparison of the mouse and rat genomes reveals a smaller ratio of nonsynonymous to synonymous changes than that seen between humans and chimps. The higher ratio in the primates indicates that fewer nonsynonymous mutations have been removed by natural selection than has occurred in mice and rats. The removal of nonsynonymous codons during evolution is called stabilizing selection. Stabilizing selection prevents change and maintains the same protein structure across species. For 387 human and chimp genes, the rate of nonsynonymous changes was higher than expected. Selection has not been preventing change in protein structure between these genes in human and chimp. Rather, divergent selection has been at work. Comparing these sequences with an outgroup, the macaque, we see that chimps have experienced a higher rate of divergent selection than humans since they last shared a common ancestor.

## Plant, fungal, and animal genomes have unique and shared genes

We now step back farther and consider genomic differences among the eukaryotic kingdoms that diverged long before the examples just discussed. You have already seen that many genes are highly conserved in animals. Are plant genes also highly conserved, and if so, are they similar to animal and fungal genes?

### Comparison between two plant genomes

The first plant genome to be sequenced was *Arabidopsis thaliana*, the wall cress, a tiny member of the mustard family often used as a model organism for studying flowering plant molecular genetics and development. Its genome sequence, largely completed in 2000, revealed 25,948 genes, about as many as humans have, in a genome with a size of only 125 million base-pairs, a 30-fold smaller genome than that of humans.

Rice, *Oryza sativa*, belongs to the grass family, which includes maize (corn), wheat, barley, sorghum, and sugarcane. Unlike most grasses, rice has a relatively small genome of 430 million base-pairs. Its close relative maize, *Zea mays*, has a 60-fold larger genome. Although rice and *Arabidopsis* are distant relatives, they share many genes. More than 80% of the genes found in rice, including duplicates, are also found in *Arabidopsis*. Among the other 20% are genes that may be responsible for some of the physiological and morphological differences between rice and *Arabidopsis*. It is probable that many of the other differences between the two species reflect differences in gene expression, as discussed later in this chapter. (The

morphological and physiological distinctions are described in chapter 30.)

### Comparison of plants with animals and fungi

About one-third of the genes in *Arabidopsis* and rice appear to be in some sense “plant” genes—that is, genes not found in any animal or fungal genome sequenced so far. These include the many thousands of genes involved in photosynthesis and photosynthetic anatomy. Few plant genomes have been sequenced to date, however.

Among the remaining genes found in plants are many that are very similar to those found in animal and fungal genomes, particularly the genes involved in basic intermediary metabolism, in genome replication and repair, and in transcription and protein synthesis. Prior to the availability of whole-genome sequences, assessment of the extent of genetic similarity and difference among diverse organisms had been difficult at best.

### Learning Outcomes Review 24.1

Genomes vary in number of similar genes, arrangement of genes, total number of base pairs, and base-pair differences. Closely related organisms such as humans and chimps exhibit highly similar genomes.

- Would you expect a high degree of similarity between genomes of a bony fish, such as a swordfish, and a cartilaginous fish, such as a shark? What genes might be different?

## 24.2 Whole-Genome Duplications

### Learning Outcomes

1. Differentiate between autopolyploidy and allopolyploidy.
2. Explain why most crosses between two species do not result in a new polyploid species.
3. Explain why the genome of a polyploid is not identical to the sum of the two parental genomes.

Polyploidy (three or more chromosome sets) can give rise to new species, as you learned in chapter 22. Polyploidy can result from either genome duplication in one species or from hybridization of two different species. In autopolyploids, the genome of one species is duplicated through a meiotic error, resulting in four copies of each chromosome. Allopolyploids result from the hybridization and subsequent duplication of the genomes of two different species (figure 24.2). The origins of wheat, illustrated in figure 24.3, involve two successive allopolyploid events.

### Ancient and newly created polyploids guide studies of genome evolution

Two avenues of research have led to intriguing insights into genome alterations following polyploidization. The first method studies ancient polyploids, called **paleopolyploids**.

**Figure 24.2** Allopolyploidy occurred in tobacco 5 MYA, but can be approximated by crossing the progenitor species and initiating a doubling of chromosomes, often through tissue culture followed by plant regeneration, which can lead to chromosome doubling. Tobacco species have many chromosomes, not all of which are visible in a single plane of a cell.

**Figure 24.3 Evolutionary history of wheat.**

Domestic wheat arose in southwestern Asia in the hilly country of what is now Iraq. This region contains a rich assembly of grasses of the genus *Triticum*. Domestic wheat (*T. aestivum*) is a polyploid species of *Triticum* that arose through two so-called allopolyploid events. (1) Two different diploid genomes, symbolized here as *AA* and *BB*, hybridized to form an *AB* species hybrid; the species were so different that A and B chromosomes could not pair in meiosis, so the *AB* hybrid was sterile. However, in some plants the chromosome number spontaneously doubled due to a failure of chromosomes to separate in meiosis, producing a fertile tetraploid species, *AABB*. This wheat (durum semolina) is used in the production of pasta. (2) In a similar fashion, the tetraploid species *AABB* hybridized much more recently, within the last 10,000 years, with a different diploid species, with genome *CC*. The second hybridization produced, after another doubling event, the hexaploid *T. aestivum*, *AABBCC*. This bread wheat is one of the most important food plants in the world. Not all chromosomes appear in a single plane of any cell.

Sequence comparisons and phylogenetic tools establish the time and patterns of polyploidy events (figure 24.4). Sequence divergence between homologues, as well as the presence or absence of duplicated gene pairs from the hybridization, can be used for historical reconstructions of genome evolution. All copies of duplicate gene pairs arising through polyploidy are not necessarily found thousands or millions of years after polyploidization. The loss of duplicate genes is considered later in this section.

The second approach is to create **synthetic polyploids** by crossing plants most closely related to the ancestral species and then chemically inducing chromosome doubling. Unless the hybrid genome becomes doubled, the plant will be sterile because it will lack homologous chromosomes that need to pair during metaphase I of meiosis.

Because meiosis requires an even number of chromosome sets, species with ploidy levels that are multiples of two can reproduce sexually. However, meiosis would be a disaster in a  $3n$  organism such as asexually propagated commercial bananas since three sets of chromosomes can't be evenly divided between two cells. Triploid bananas are seedless. The aborted ovules appear as the little brown dots in the center of any cross section of a banana.

**Inquiry question**

? Sketch out what would happen in meiosis in a  $3n$  banana cell, referring back to chapter 11 if necessary.

**Figure 24.4** Sequence comparisons of numerous genes in a polyploid genome tell us how long ago allopolyploidy or autopolyploidy events occurred. Complex analyses of sequence divergence among duplicate gene pairs and presence or absence of duplicate gene pairs provide information about when both genome duplication and gene loss occurred. The graph reveals multiple polyploidy events over evolutionary time.

### Inquiry question

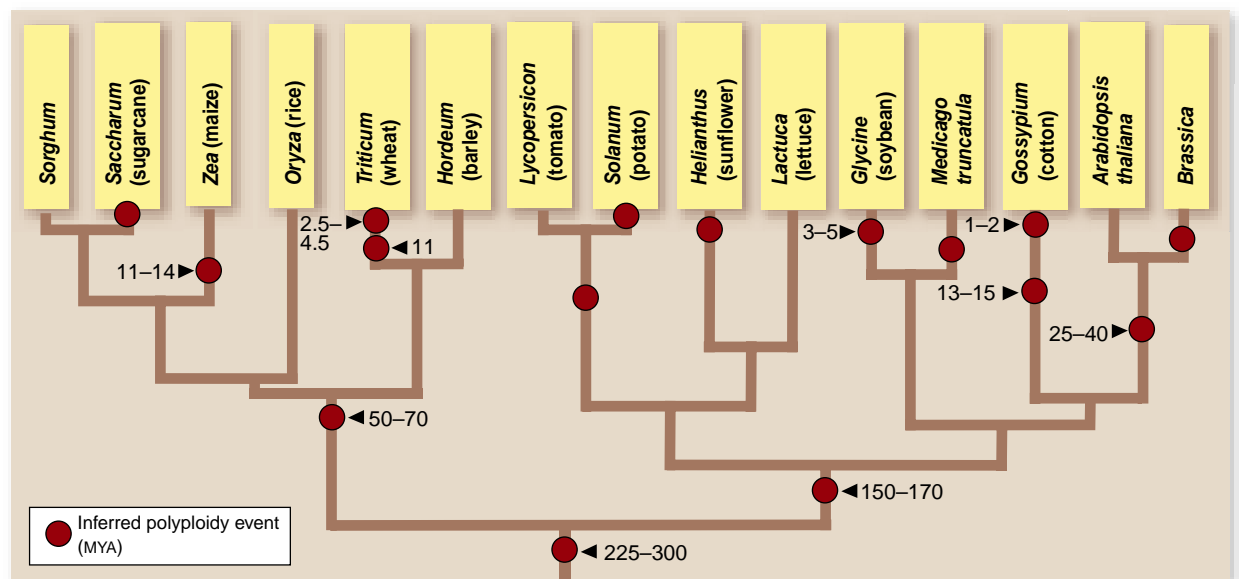

**?** Why is there a decrease in the number of duplicate genes after multiple rounds of polyploidization?

In the following sections we examine further the effect of polyploidization on genomes. Plant examples have been selected to illustrate key points in this section because polyploidization occurs more frequently in plants. The somewhat surprising findings, however, are not limited to the plant kingdom.

## Evidence of ancient polyploidy is found in plant genomes

Polyploidy has occurred numerous times in the evolution of the flowering plants (figure 24.5). The legume clade that includes the soybean (*Glycine max*), the plant *Medicago truncatula*

**Figure 24.5** Polyploidy has occurred numerous times in the evolution of the flowering plants.

**Figure 24.6** Genome downsizing. Genome downsizing must have occurred in *M. truncatula*.

*tula* (a forage legume often used in research), and the garden pea (*Pisum sativum*) underwent a major polyploidization event 44 to 58 MYA and again 15 MYA (figure 24.6).

A quick comparison of the genomes of soybean and *M. truncatula* reveal a huge difference in genome size. In addition to increasing genome size through polyploidization, genomes like *M. truncatula* definitely downsized over evolutionary time as well. The total size of a genome cannot be explained solely on the basis of polyploidization.

A number of independent whole-genome duplications in plants cluster around 65 MYA, coinciding with a mass extinction event caused by a catastrophic change due to an asteroid impact or increased volcanic activity. Polyploids may have had a better chance of surviving the extinction event with increased genes and alleles available for selection.

## Polyploidy induces elimination of duplicated genes

Formation of an allopolyploid from two different species is often followed by a rapid loss of genes (figure 24.7) or even whole chromosomes. In some polyploids, however, loss of one copy of many duplicated genes arises over a much longer period. In some species a great deal of gene loss occurs in the first few generations after polyploidization.

Modern tobacco, *Nicotiana tabacum* arose from the hybridization and genome duplication of a cross between *Nicotiana sylvestris* (female parent) and *N. tomentosiformis* (male parent) (see figure 24.2). To complement the analysis based on a cross that occurred over 5 MYA, researchers constructed synthetic *N. tabacum* and observed the chromosome loss that followed. Curiously, the loss of chromosomes is not even. More *N. tomentosiformis* chromosomes were jettisoned than those of *N. sylvestris*. Similar unequal chromosome loss has been observed in synthetic wheat hybrids, in which 13% of the genome of one parent is lost in contrast to 0.5% of the other parental genome. It is possible that different rates of genome replication could explain the differential loss, as is true for synthetic human–mouse hybrid cultured cells.

## Polyploidy can alter gene expression

A striking discovery is the change in gene expression that occurs in the early generations after polyploidization. Some of this may be connected to an increase in the methylation of cytosines in the DNA. Methylated genes cannot be transcribed, as described in chapter 16. Simply put, polyploidization can lead to a short-term silencing of some genes. In subsequent generations, there is a decrease in methylation.

## Transposons jump around following polyploidization

Barbara McClintock, in her Nobel Prize-winning work on transposable (mobile) genetic elements, referred to these jumping DNA regions as *controlling elements*. She hypothesized that transposons could respond to genome shock and jump into a new position in the genome. Depending on where the transposon moved, new phenotypes could emerge.

Recent work on transposon activity following hybridization supports McClintock's hypothesis. Again, during the early generations following a polyploidization event, new transposon insertions occur because of unusually active transposition.

### SCIENTIFIC THINKING

**Hypothesis:** Some duplicated genes may be eliminated after polyploidy.

**Prediction:** More duplicate genes will be present when an allopolyploid forms than a few generations later.

**Test:** Make a synthetic polyploid from two *Nicotiana* species and look at the chromosomes under a microscope then and after 3 generations of self-fertilizing offspring.

**Result:** Over time, *N. tomentosiformis* chromosomes are lost or shortened.

**Conclusion:** Chromosomes and genes are preferentially eliminated following polyploidy.

**Further Experiments:** Why might the chromosomes and genes of one species be preferentially eliminated? How could you test your explanation?

**Figure 24.7** Polyploidy may be followed by the unequal loss of duplicate genes from the combined genomes.

These new insertions may cause gene mutations, changes in gene expression, and chromosomal rearrangements, all of which provide additional genetic variation on which evolution might act.

### Learning Outcomes Review 24.2

Autopolyploids arise from duplication of a species' genome; allopolyploids occur from hybridization between two species. Unless the number of chromosomes doubles, an allopolyploid will likely be sterile because of lack of homologous pairs at meiosis. Polyploidization can lead to major changes in genome structure, including loss of genes, alteration of gene expression, increased transposon hopping, and chromosomal rearrangements. Polyploidy is considered important in generation of biodiversity and adaptation, especially in plants.

- What would be the result if a synthetic autopolyploid eliminated one of four duplicate chromosomes?

## 24.3 Evolution Within Genomes

### Learning Outcomes

1. Define the terms *segmental duplication*, *genome rearrangement*, and *pseudogene*.
2. Explain why *horizontal gene transfer* can complicate *evolutionary hypotheses*.

From individual genes to whole chromosomes, duplications of portions of genomes contribute to evolution. Duplications provide opportunities for genes with the same function to diverge because a “backup pair” of genes is in place. After duplication, one gene can lose function, because the duplicate compensates for it. The mutated gene is not selected against because another functioning gene, not just an allele, exists. The duplicated gene can also diverge and acquire new functions because a backup copy exists.

### Individual chromosomes may be duplicated

**Aneuploidy** refers to the duplication or loss of an individual chromosome rather than of an entire genome. Failure of a pair of homologous chromosomes or sister chromatids

to separate during meiosis is the most common way that aneuploids occur.

In general, plants are better able to tolerate aneuploidy than animals, but the explanation for this difference is elusive.

### DNA segments may be duplicated

One of the greatest sources of novel traits in genomes is duplication of segments of DNA. Two genes within an organism that have arisen from the duplication of a single gene in an ancestor are called *paralogues*. In contrast, *orthologues* reflect the conservation of a single gene from a common ancestor.

When a gene duplicates, the most likely fates of the duplicate gene are (1) losing function through subsequent mutation, (2) gaining a novel function through subsequent mutation, and (3) having the total function of the ancestral gene partitioned into the two duplicates. Gene families grow through gene duplication. In reality, however, most duplicate genes lose function.

How then can researchers claim that gene duplication is a major evolutionary force for gene innovation, that is, genes gaining new function? One piece of the answer can be found by noting where gene duplication is most likely to occur in the genome. In humans, the highest rates of duplication have occurred in the three most gene-rich chromosomes of the genome. The seven chromosomes with the fewest genes also show the least amount of duplication. (Remember, having fewer genes does not mean that there is less total DNA.)

Even more compelling, certain types of human genes appear to be more likely to be duplicated: growth and development genes, immune system genes, and cell-surface receptors. About 5% of the human genome consists of segmental duplications (figure 24.8). Finally, and important, gene duplication is thought to be a major evolutionary force for gene innovation because the duplicated genes are found to have different patterns of gene expression (see chapter 25 for examples). For example, the two duplicated copies may be expressed in different or overlapping sets of tissues or organs during development.

Segmental duplications may account for differences between human and chimp. Species-specific segmental duplications tend to contain genes that are differentially expressed between the species. This is true for genes expressed in liver, kidney, or heart. A simple explanation is that there are more copies of the gene being expressed, but experimental evidence shows that it is more likely that the regulatory DNA near the duplicate is different.

**Figure 24.8 Segmental duplication on the human Y chromosome.** Each orange region has 98% sequence similarity with a sequence on a different human chromosome. Each dark blue region has 98% sequence similarity with a sequence elsewhere on the Y chromosome.

## Genomes may become rearranged

Humans have one fewer chromosome than chimpanzees, gorillas, and orangutans (figure 24.9). It's not that we have lost a chromosome. Rather, at some point in time, two mid-sized ape chromosomes fused to make what is now human chromosome 2, the second largest chromosome in our genome.

The fusion leading to human chromosome 2 is an example of the sort of genome reorganization that has occurred in many species. Rearrangements like this can provide evolutionary clues, but they are not always definitive proof of how closely related two species are.

Consider the organization of known orthologues shared by humans, chickens, and mice. One study estimated that 72 chromosome rearrangements had occurred since the chicken and human last shared a common ancestor. This number is substantially less than the estimated 128 rearrangements between chicken and mouse, or 171 between mouse and human.

This does not mean that chickens and humans are more closely related than mice and humans or mice and chickens. What these data actually show is that chromosome rearrangements have occurred at a much lower frequency in the lineages that led to humans and to chickens than in the lineages leading to mice. Chromosomal rearrangements in mouse ancestors seem to have occurred at twice the rate seen in the human line. These different rates of change help counter the notion that humans existed hundreds of millions of years ago.

Genomes that have undergone relatively slow chromosome change are the most helpful in reconstructing the hypothetical genomes of ancestral vertebrates. If regions of chromosomes have changed little in distantly related vertebrates over the last 300 million years, then we can reasonably infer that the common ancestor of these vertebrates had genomic similarities.

Variation in the organization of genomes is as intriguing as gene sequence differences. Chromosome rearrangements are common, yet over long segments of chromosomes, the linear order of mouse and human genes is the same—the common ancestral se-

quence has been preserved in both species. This **conservation of synteny** (see chapter 18) was anticipated from earlier gene-mapping studies, and it provides strong evidence that evolution actively shapes the organization of the eukaryotic genome. As seen in figure 24.10, the conservation of synteny allows researchers to more readily locate a gene in a different species using information about synteny, thus underscoring the power of a comparative genomic approach.

## Gene inactivation results in pseudogenes

The loss of gene function is another important way genomes evolve. Consider the olfactory receptor (OR) genes that are responsible for our sense of smell. These genes code for receptors that bind odorants, initiating a cascade of signaling events that eventually lead to our perception of scents.

Gene inactivation seems to be the best explanation for our reduced sense of smell relative to that of the great apes and other mammals. Mice have about 1500 OR genes, the largest mammalian gene family. Mice have about 50% more OR genes than humans. Only 20% of the mouse OR genes are pseudogenes, in contrast to about 60% in humans, which are inactive **pseudogenes** (sequences of DNA that are very similar to functional genes but that do not produce a functional product because they have premature stop codons, missense mutations, or deletions that prevent the production of an active protein). In contrast, half the chimpanzee and gorilla OR genes function effectively, and over 95% of New World monkey OR genes and probably all mouse OR genes are working quite well. The most likely explanation for these differences is that humans came to rely on other senses, reducing the selection pressure against loss of OR gene function by random mutation.

An older question about the possibility of positive selection for OR genes in chimps was resolved with the completion of the chimp genome. A careful analysis indicated that both humans and chimps are gradually losing OR genes to pseudogenes and that there is no evidence to support positive selection for any of the OR genes in the chimp.

**Figure 24.9 Living great apes.** All living great apes, with the exception of humans, have a haploid chromosome number of 24. Humans have not lost a chromosome; rather, two smaller chromosomes fused to make a single chromosome.

**Figure 24.10 Synteny and gene identification.** Genes sequenced in the model legume, *Medicago truncatula*, can be used to identify homologous genes in soybean, *Glycine max*, because large regions of the genomes are syntenic as illustrated for some of the linkage groups (chromosomes) of the two species. Regions of the same color represent homologous genes.

### Rearranged DNA can acquire new functions

Errors in meiosis that rearrange parts of genes most often create pseudogenes, but occasionally a broken piece of a gene can end up in a new spot in the genome where it acquires a new function. One of the most intriguing examples occurred within a family of fish in the suborder Notothenioidae found in the Antarctic ocean. These fish are called icefish because they survive the frigid temperatures in the Antarctic, in part because of a protein in their blood that works like antifreeze. Reconstructing evolutionary history using comparative genomics reveals that 9 bp of a gene coding for a digestive enzyme evolved to encode part of an antifreeze protein. The series of errors that gave rise to the new protein persisted only because the change coincided with a massive cooling of the Antarctic waters. Natural selection acted on this mutation over millions of years.

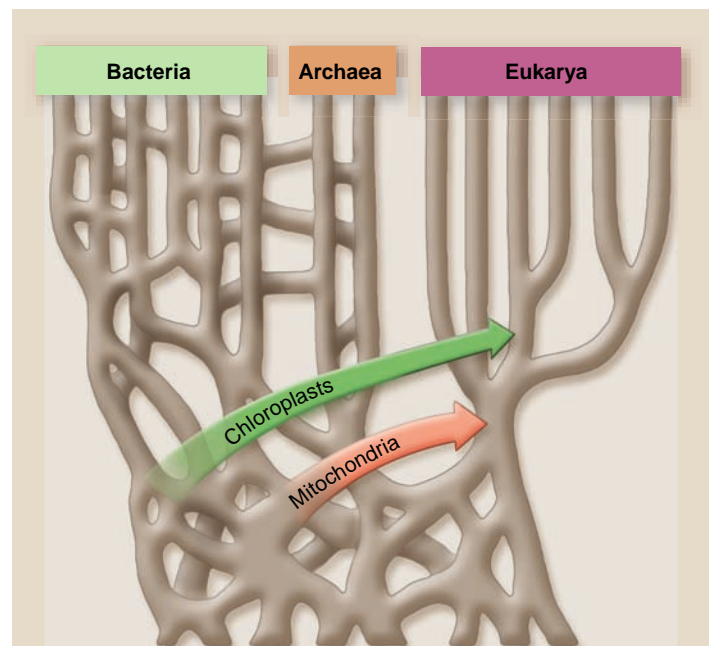

### Horizontal gene transfer complicates matters

Evolutionary biologists build phylogenies on the assumption that genes are passed from generation to generation, a process called **vertical gene transfer (VGT)**. Hitchhiking genes from other species, a process referred to as **horizontal gene transfer (HGT)** and sometimes called *lateral gene transfer*, can lead to phylogenetic complexity. HGT was likely most prevalent very early in the history of life, when the boundaries between individual cells and species seem to have been less firm than they are now and DNA more readily moved among different organisms. Although earlier in the history of life, gene swapping between species was rampant, HGT continues today in prokaryotes and eukaryotes. An intriguing example of more recent HGT between moss and a flowering plant is described in chapter 26.

#### Gene swapping in early lineages

The extensive gene swapping among early organisms has caused many researchers to reexamine the base of the tree of life. Early phylogenies based on ribosomal RNA (rRNA) sequences indicate that an early prokaryote gave rise to two major domains: the Bacteria and the Archaea. From one of these lineages, the domain Eukarya emerged; its organelles originated as unicellular organisms engulfed specialized prokaryotes.

This rRNA phylogeny is being revised as more microbial genomes are sequenced. By 2009, the Microbial Genome Program of the U.S. Department of Energy had sequenced 485 microbial genomes and 30 microbial communities. With new sequencing technology, microbial genomes can be sequenced in less than a day. Phylogenies built with rRNA sequences suggest that the domain Archaea is more closely related to the Eukarya than to the Bacteria. But as more microbial genomes are sequenced, investigators find bacterial and archaeal genes showing up in the same organism! The most likely conclusion is that organisms swapped genes, even absorbing DNA obtained from a food source. Perhaps the base of the tree of life is better viewed as a web than a branch (figure 24.11).

**Figure 24.11 Horizontal gene transfer.** Early in the history of life, organisms may have freely exchanged genes beyond multiple endosymbiotic events. To a lesser extent, this transfer continues today. The tree of life may be more like a web or a net.

## Gene swapping evidence in the human genome

Let's move closer to home and look at the human genome, which is riddled with foreign DNA, often in the form of transposons. The many transposons of the human genome provide a paleontological record over several hundred million years.

Comparisons of versions of a transposon that has duplicated many times allow researchers to construct a “family tree” to identify the ancestral form of the transposon. The percent of sequence divergence found in duplicates allows an estimate of the time at which that particular transposon originally invaded the human genome. In humans, most of the DNA hitchhiking seems to have occurred millions of years ago in very distant ancestor genomes.

Our genome carries many more ancient transposons than genomes of *Drosophila*, *C. elegans*, and *Arabidopsis*. One explanation for the observed low level of transposons in *Drosophila* is that fruit flies somehow eliminate unnecessary DNA from their genome 75 times faster than humans do. Our genome has simply hung on to hitchhiking DNA more often.

The human genome has had minimal transposon activity in the past 50 million years; mice, by contrast, are continuing to acquire new transposable elements. This difference may explain in part the more rapid change in chromosome organization in mice than in humans.

### Learning Outcomes Review 24.3

In segmental duplication, part of a chromosome and the genes it contains are duplicated. In genome rearrangement, segments of chromosomes may change places or chromosomes may fuse with one another. Pseudogenes have become inactivated in the course of evolution but still persist in the genome. All these changes have evolutionary consequences. Horizontal gene transfer has led to an unexpected mixing of genes among organisms, creating many phylogenetic questions.

- How would you determine whether a gene was a pseudogene or an example of horizontal gene transfer?

## 24.4 Gene Function and Expression Patterns

### Learning Outcomes

1. Explain how species with nearly identical genes can look very different.
2. Describe the action of the *FOXP2* gene across species.

Gene function can be inferred by comparing genes in different species. You saw earlier that the function of 1000 human genes was understood once the mouse genome was sequenced. One of the major puzzles arising from comparative genomics is that organisms with very different forms can share so many conserved genes in their genomic toolkit.

The best explanation for why a mouse develops into a mouse and not a human is that the same or similar genes are expressed at different times, in different tissues, and in different amounts and combinations. For example, the cystic fibrosis gene (cystic fibrosis transmembrane conductance regulator, *CFTR*), which has been identified in both species and affects a chloride ion channel, illustrates this point. Defects in the human *CFTR* gene cause especially devastating effects in the lungs, but mice with the mutant *CFTR* gene do not have lung symptoms. Possibly variations in expression of *CFTR* between mouse and human explain the difference in lung symptoms when *CFTR* is defective.

## Chimp and human gene transcription patterns differ

Humans and chimps diverged from a common ancestor only about 4.1 MYA—too little time for much genetic differentiation to evolve, but enough for significant morphological and behavioral differences to have developed. Sequence comparisons indicate that chimp DNA is 98.7% identical to human DNA. If just the gene sequences encoding proteins are considered, the similarity increases to 99.2%. How could two species differ so much in body and behavior, and yet have almost equivalent sets of genes?

One potential answer to this question is based on the observation that chimp and human genomes show very different patterns of gene transcription activity, at least in brain cells. Investigators used microarrays containing up to 18,000 human genes to analyze RNA isolated from cells in the fluid extracted from several regions of living brains of chimps and humans. (See figure 18.10 for a summary of this technique.) The RNA was linked with a fluorescent tag and then incubated with the microarray under conditions that allow the formation of DNA–RNA hybrids if the sequences are complementary. If the transcript of a particular gene is present in the cells, then the microarray spot corresponding to that gene lights up under UV light. The more copies of the RNA, the more intense the signal.

Because the chimp genome is so similar to that of humans, the microarray detects the activity of chimp genes reasonably well. Although the same genes were transcribed in chimp and human brain cells, the patterns and levels of transcription varied. Much of the difference between human and chimp brains lies in which genes are transcribed, and when and where that transcription occurs.

### Inquiry question

- ? You are given a microarray of ape genes and RNA from both human and ape brain cells. Using the experimental technique described for comparison of humans and chimps, what would you expect to find in terms of genes being transcribed? What about levels of transcription?

Posttranscriptional differences may also play a role in building distinct organisms from similar genomes. As research continues to push the frontiers of proteomics and functional genomics, a more detailed picture of the subtle differences in the developmental and physiological processes of closely related species will be revealed. The integration of

development and genome evolution is explored in depth in the following chapter.

## Speech is uniquely human: An example of complex expression

Development of human culture is closely tied to the capacity to control the larynx and mouth to produce speech. Humans with a single point mutation in the transcription factor gene *FOXP2* have impaired speech and grammar but not impaired language comprehension.

The *FOXP2* gene is also found in chimpanzees, gorillas, orangutans, rhesus macaques, and even the mouse, yet none of these mammals speak (figure 24.12). The gene is expressed in areas of the brain that affect motor function, including the complex coordination needed to create words.

*FOXP2* protein in mice and humans differs by only three amino acids. There is only a single amino acid difference between mouse and chimp, gorilla, and rhesus macaque, which all have identical amino acid sequences for *FOXP2*. Two more amino acid differences exist between humans and the sequence shared by chimp, gorilla, and macaques. The difference of only two amino acids between human and other primate *FOXP2* appears to have made it possible for language to arise. Evidence points to strong selective pressure for the two *FOXP2* mutations that allow brain, larynx, and mouth to coordinate to produce speech.

Is it possible that two amino acid changes lead to speech, language, and ultimately human culture? This box of mysteries will take a long time to unpack, but hints indicate that the changes are linked to signaling and gene expression. The two

altered amino acids may change the ability of *FOXP2* transcription factor to be phosphorylated. One way signaling pathways operate is through activation or inactivation of an existing transcription factor by phosphorylation.

Comparative genomics efforts are now extending beyond primates. A role for *FOXP2* in songbird singing and vocal learning has been proposed. Mice communicate via squeaks, with lost young mice emitting high-pitched squeaks. *FOXP2* mutations leave mice squeakless. For both mice and songbirds, it is a stretch to claim that *FOXP2* is a language gene—but it likely is needed in the neuromuscular pathway to make sounds.

### Learning Outcomes Review 24.4

To understand functional differences between genes shared by species, one must look beyond sequence similarity. Alterations in the time and place of gene expression can lead to marked differences in phenotype. As an example, the *FOXP2* factor appears to be involved in sound production in mice, chimps, gorillas, macaques, and humans, and only very small differences may have led to human speech.

- How can a single-nucleotide difference in a gene lead to a noticeably different phenotype? Give examples.

## 24.5 Nonprotein-Coding DNA and Regulatory Function

### Learning Outcome

1. Describe the role of nonprotein-coding DNA.

So far, we have primarily compared genes that code for proteins. As more genomes are sequenced, we learn that much of the genome is composed of nonprotein-coding DNA (ncDNA). The repetitive DNA is often retrotransposon DNA, contributing to as much as 30% of animal genomes and 40 to 80% of plant genomes. (Refer to chapter 18 for more information on repetitive DNA in genomes.)

Perhaps the most unexpected finding in comparing the mouse and human genomes lies in the similarities between the repetitive DNA, mostly retrotransposons, in the two species. This DNA does not code for proteins. Retrotransposon DNA in both species shows that it has independently ended up in comparable regions of the genome.

At first glance it appeared that all this extra DNA was “junk” DNA, DNA just along for the ride. But it is beginning to look like this ncDNA may have more of a function than was previously assumed. If the DNA had no function, differences should begin to accumulate in mouse and human as mutations occur and occasionally become fixed due to genetic drift. The fact that the “junk” regions are so conserved in mouse and human indicates that, in fact, mutations are being selected out to maintain some function, thus keeping them similar. Hence, these regions of DNA must

**Figure 24.12 Evolution of *FOXP2*.** Comparisons of synonymous and nonsynonymous changes in mouse and primate *FOXP2* genes indicate that changing two amino acids in the gene corresponds to the emergence of human language. Black bars represent synonymous changes and gray bars represent nonsynonymous changes.

have some function. The point is that the differences in the “junk” DNA between mouse and human are too small to have resulted from genetic drift.

The possibility that this DNA is rich in regulatory RNA sequences is being actively investigated. RNAs that are not translated can play several roles, including silencing other genes. Small RNAs can form double-stranded RNA with complementary mRNA sequences, blocking translation. They can also participate in the targeted degradation of RNAs. For details on other possible functions of ncDNA, refer to chapter 16.

In one study, researchers collected almost all of the RNA transcripts made by mouse cells taken from every tissue. Although most of the transcripts coded for mouse proteins, as many as 4280 could not be matched to any known mouse protein. This finding suggests that a large part of the transcribed genome consists of genes that do not code for proteins—that is, transcripts that function as RNA. Perhaps this function can explain why a single retrotransposon can cause heritable differences in coat color in mice.

### Learning Outcome Review 24.5

DNA that does not code for protein may regulate gene expression, often through its RNA transcript. Nonprotein-coding sequences can be found in retrotransposon-rich regions of the genome.

- How would you determine whether RNA produced by a nonprotein-coding gene has a regulatory function?

## 24.6 Genome Size and Gene Number

### Learning Outcome

1. Explain why genome size and gene number do not correlate.

Genome size was a major factor in selecting which genomes would be sequenced first. Practical considerations led to the choice of organisms with relatively small genomes. Considering genome size, the original gene count for the human genome was estimated at 100,000 genes.

As sequence data were analyzed, the predicted number of genes started to decrease. A very different picture emerged. Our genome has only 25% of the 100,000 anticipated genes, approximately the same number of genes as the tiny *Arabidopsis* plant. Humans have nine times the amount of DNA found in the  $3.65 \times 10^8$  bp-pufferfish genome, but about the same number of genes. Keep in mind that the number of genes may not correspond to the number of proteins. For example, alternative splicing (see chapter 16) can produce multiple, distinct transcripts from a single gene.

## Noncoding DNA inflates genome size

Why do humans have so much extra DNA? Much of it appears to be in the form of introns, noncoding segments within a gene's sequence, that are substantially bigger than those in pufferfish. The *Fugu* genome has only a handful of “giant” genes containing long introns; studying them should provide insight into the evolutionary forces that have driven the change in genome size during vertebrate evolution.

As described earlier, large expanses of retrotransposon DNA contribute to the differences in genome size from one species to another. Although part of the genome, ncDNA does not contain genes in the usual sense. As another example, *Drosophila* exhibits less ncDNA than *Anopheles*, although the evolutionary force driving this reduction in noncoding regions is unclear. The number of genes are not correlated with genome size.

## Plants have widely varying genome size

Plants have an even greater range of genome sizes. As much as a 200-fold difference has been found, yet all these plants weigh in with about 30,000 to 59,000 genes. Tulips for example, have 170 times more DNA than *Arabidopsis*.

Both rice and *Arabidopsis* have higher *copy numbers* for gene families (multiple slightly divergent copies of a gene) than are seen in animals or fungi, suggesting that these plants have undergone numerous episodes of polyploidy, segmental duplication, or both during the 150 to 200 million years since rice and *Arabidopsis* diverged from a common ancestor.

Whole-genome duplication is insufficient to explain the size of some genomes. Wheat and rice are very closely related and have similar gene content, and yet the wheat genome is 40 times larger than the rice genome. This difference cannot be explained solely by the fact that bread wheat is a hexaploid ( $6n$ ) and rice is a diploid ( $2n$ ).

Now that the rice genome is fully sequenced, attention has shifted to sequencing the other cereal grains, especially maize and wheat, both of which apparently contain lots of repetitive DNA, which has increased their DNA content, but not necessarily their gene content. Comparisons between the rice, maize, and wheat genomes should provide clues about the genome of their common ancestor and the dynamic evolutionary balance between opposing forces that increase genome size (polyploidy, transposable element proliferation, and gene duplication) and those that decrease genome size (mutational loss).

### Learning Outcome Review 24.6

Increases or decreases in genome size do not correlate with the number of genes. Evidently DNA content is not the same as gene content. Polyploidy in plants does not by itself explain differences in genome size. Often a greater amount of DNA is explained by the presence of introns and nonprotein-coding sequences than by gene duplicates.

- How might a genome with a small number of genes and a small number of total base pairs evolve into a genome with the same small number of genes and a thousand-fold larger genome?

## 24.7 Genome Analysis and Disease Prevention and Treatment

### Learning Outcomes

1. Describe how comparative genomics can reveal the genetic basis for disease.
2. Explain how genome comparisons between a pathogen and its host can aid drug development.

Comparisons among individual human genomes continue to provide information on genetic disease detection and the best course of treatment. An even broader array of possibilities arises when comparisons are made among species. There are advantages to comparing both closely and distantly related pairs of species, as well as comparing the genomes of a pathogen and its host. Examples of the benefits of each type of genome comparison follow.

### Distantly related genomes offer clues for causes of disease

Sequences that are conserved between humans and pufferfish provide valuable clues for understanding the genetic basis of many human diseases. Amino acids critical to protein function tend to be preserved over the course of evolution, and changes at such sites within genes are more likely to cause disease.

It is difficult to distinguish functionally conserved sites when comparing human proteins with those of other mammals because not enough time has elapsed for sufficient changes to accumulate at nonconserved sites. A promising exception is the duck-billed platypus (*Ornithorhynchus anatinus*), which diverged from other mammals about 166 MYA and whose genome provides clues to the evolution of the immune system. Because the pufferfish genome is only distantly related to humans, conserved sequences are far more easily distinguished than even in the platypus.

### Closely related organisms enhance medical research

It is much easier to design experiments to identify gene function in an experimental system like the mouse than it is in humans. Comparing mouse and human genomes quickly revealed the function of 1000 previously unidentified human genes. The effects of these genes can be studied in mice, and the results can be used in potential treatments for human diseases.

A draft of the rat genome has been completed, and even more exciting news about the evolution of mammalian genomes may emerge from comparisons of these species. One of the most exciting aspects of comparing rat and mice

genomes is the potential to capitalize on the extensive research on rat physiology, especially heart disease, and the long history of genetics in mice. Linking genes to disease has become much easier.

Humans have been found to contain segmental duplications that are absent in the chimp. Some of these duplications correspond to human disease. These differences can aid medical researchers in developing treatments for genetic disease. For example, some of the regions duplicated only in humans correspond with regions of the human genome that have been implicated in Prader-Willi syndrome and spinal muscular atrophy. Children with Prader-Willi lack muscle tone and struggle with life-threatening obesity because of an insatiable appetite. Spinal muscular atrophy affects all muscles in the body, but especially those nearest the trunk. Affected individuals can have difficulty swallowing and breathing, as well as experiencing weakness in the legs, but ethical issues surrounding chimpanzee research and protection should be of paramount importance.

### Pathogen–host genome differences reveal drug targets

With genome sequences in hand, pharmaceutical researchers are more likely to find suitable drug targets to eliminate pathogens without harming the host. Diseases in many developing countries—including malaria and Chagas disease—have both human and insect hosts. Both these infections are caused by protists (see chapter 29). The value of comparative genomics in drug discovery is illustrated for both malaria and Chagas disease in the following sections.

#### Malaria

*Anopheles gambiae*, the malaria-carrying mosquito, along with *Plasmodium falciparum*, the protistan parasite it transmits, together have an enormous effect on human health, resulting in 1.7 to 2.5 million deaths each year from malaria. The genomes of both *Anopheles* and *Plasmodium* were sequenced in 2002.

*Plasmodium falciparum*, which causes malaria, has a relatively small genome of  $2.46 \times 10^7$  bp that proved very difficult to sequence. It has an unusually high proportion of adenine and thymine, making it hard to distinguish one portion of the genome from the next. The project took five years to complete. *P. falciparum* appears to have about 5300 genes, with those of related function clustered together, suggesting that they might share the same regulatory DNA.

*P. falciparum* is a particularly crafty organism that hides from our immune system inside red blood cells, regularly changing the proteins it presents on the surface of the red blood cell. This “cloaking” has made developing a vaccine or other treatment for malaria particularly difficult.

Recently, a link to chloroplast-like structures in *P. falciparum* has raised other possibilities for treatment. An odd subcellular component called the *apicoplast*, found only in *Plasmodium* and its relatives, appears to be derived from a

**Figure 24.13** *Plasmodium* apicoplast. Drugs targeting enzymes used for fatty acid biosynthesis within *Plasmodium* apicoplasts (colored dark green) offer hope for treating malaria.

chloroplast appropriated from algae engulfed by the parasite's ancestor (figure 24.13).

Analysis of the *Plasmodium* genome reveals that about 12% of all the parasite's proteins, encoded by the nuclear genome, head for the apicoplast. These proteins act there to produce fatty acids. The apicoplast is the only location in which the parasite makes the fatty acids, suggesting that drugs targeted at this biochemical pathway might be very effective against malaria.

Another disease-prevention possibility is to look at chloroplast-specific herbicides, which might kill *Plasmodium* by targeting the chloroplast-derived apicoplast.

### Chagas disease

*Trypanosoma cruzi*, an insect-borne protozoan, kills about 21,000 people in Central and South America each year. As many as 18 million suffer from this infection, called Chagas disease, the symptoms of which include damage to the heart and other internal organs. Genome sequencing of *T. cruzi* was completed in 2005.

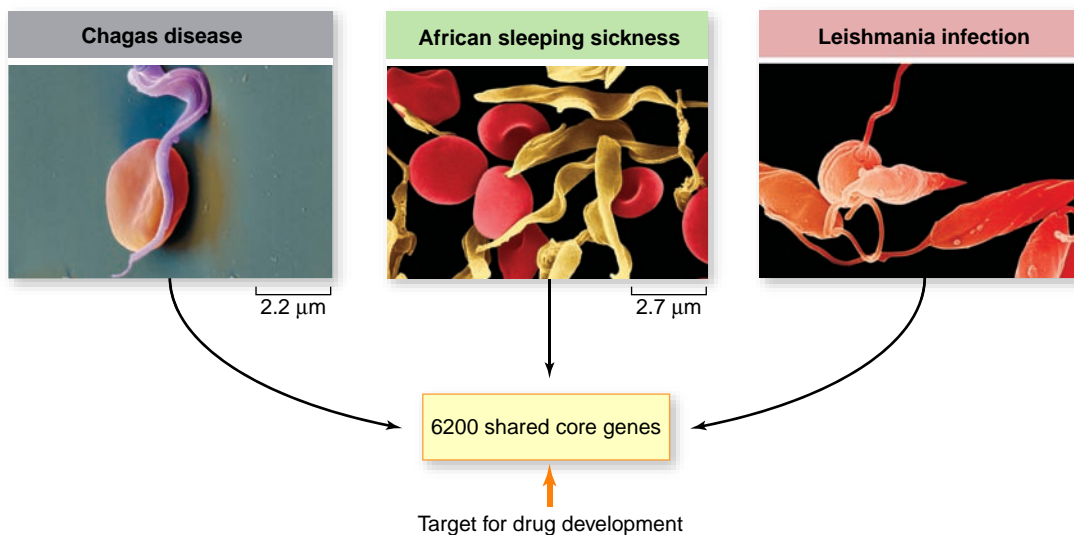

A surprising and hopeful finding is that a common core of 6200 genes is shared among *T. cruzi* and two other insect-borne pathogens: *T. brucei* and *Leishmania major*. *T. brucei* causes African sleeping sickness, and *L. major* infections result in lesions of the skin of the limbs and face. These core genes are being considered as possible targets for drug treatments.

Currently, no effective vaccines and only a few drugs with limited effectiveness are available to treat any of these diseases. The genomic similarities may aid not only in targeting drug development, but perhaps also result in a treatment or vaccine that is effective against all three devastating illnesses (figure 24.14).

### Learning Outcomes Review 24.7

DNA sequences conserved over evolutionary time tend to be those critical for protein function and survival. Variations in these conserved sequences may provide clues to diseases with a hereditary component. Knowledge of a pathogenic organism's genome and its differences from a host's genome may allow targeting of drugs and vaccines that affect the invader but leave the host unharmed.

- A pathogen makes a critical protein that differs from the human version by only seven amino acids. What approaches might lead to an effective drug against the pathogen? What drawbacks might be encountered?

**Figure 24.14** Comparative genomics may aid in drug development. The organisms that cause Chagas disease, African sleeping sickness, and leishmaniasis, which claim millions of lives in developing nations each year, share 6200 core genes. Drug development targeted at proteins encoded by the shared core genes could yield a single treatment for all three diseases.

## 24.8 Crop Improvement Through Genome Analysis

### Learning Outcome

1. Describe how the genome sequence of one plant can be used to improve a number of crop species.

Farmers and researchers have long relied on genetics for crop improvement. Whole-genome sequences offer even more information for research on artificial selection for crop improvement. Highly conserved genes can be characterized in a model system and then used to identify orthologues in crop species.

### Model plant genomes provide links to genetics of crop plants

*Arabidopsis* is a flowering plant mainly used for experimental purposes, but with no commercial significance. The second plant genome for which a draft sequence has been prepared—rice—is, however, of enormous economic significance. Rice, as mentioned earlier, belongs to the grass family, which includes a number of other important cereal crop plants. Together, these crops provide most of the world's food and animal feed.

Unlike most grasses, rice has a relatively small genome of  $4.3 \times 10^8$  bp, in contrast to the maize (corn) genome ( $2.5 \times 10^9$  bp) and that of barley (an enormous  $4.9 \times 10^9$  bp). Two different subspecies of rice have been sequenced, yielding similar results. The proportion of the rice nuclear genome devoted to repetitive DNA, for example, was 42% in one variety, and 45% in the other.

Genome sequencing is underway for maize and for another model plant, *Medicago truncatula*. *M. truncatula* has a much smaller genome than its close relative, soybean, making it much easier to sequence. Large regions of *M. truncatula* DNA are syntenous with soybean DNA, increasing the odds of finding agriculturally important soybean genes using the *M. truncatula* genome (see figure 24.10).

### Beneficial bacterial genes can be located and utilized

Genome sequences of beneficial microbes may also improve crop yield. *Pseudomonas fluorescens* naturally protects plant roots from disease by excreting protective compounds. In 2005, *P. fluorescens* became the first biological control agent to have its genome sequenced. Work on identifying chemical pathways that produce protective compounds should proceed rapidly, given the bacterium's small genome size. Understanding these pathways can lead to more effective methods of protecting crops from disease—for example, isolation of a protective gene (or genes) could lead to being able to insert this beneficial gene into a crop plant's genome, so that the plant could protect itself directly. Bt (*Bacillus thuringiensis*) crops, as described in chapter 17, are one example.

### Learning Outcome Review 24.8

Comparative genomics extends the benefits of sequenced genomes in model plant species to other species important as crops, allowing potential improvement. A growing understanding of microbial genomes may also be used to improve crop yield by allowing targeted protection.

- One ounce of soybeans contains half as much protein as one ounce of beefsteak. How would you go about increasing the protein content in soybeans?

## Chapter Review

### 24.1 Comparative Genomics

**Evolutionary differences accumulate over long periods.**

Even distantly related species may often have many genes in common. Changes in DNA codons that do not alter the amino acid specified are termed synonymous changes.

**Genomes evolve at different rates.**

Mouse DNA has apparently mutated twice as fast as human DNA, and insect evolution is even more rapid. Short generation time may be responsible for these rate differences.

**Plant, fungal, and animal genomes have unique and shared genes.**

Plants, animals, and fungi have approximately 70% of their genes in common.

### 24.2 Whole-Genome Duplications

**Ancient and newly created polyploids guide studies of genome evolution.**

Autopolyploidy results from an error in meiosis that leads to a duplicated genome; allopolyploidy is the result of hybridization between species (see figure 24.2).

**Evidence of ancient polyploidy is found in plant genomes.**

Polyploidy has occurred numerous times in the evolution of flowering plants, and downsizing of genomes is common.

**Polyploidy induces elimination of duplicated genes.**

Downsizing of a polyploid genome can be caused by unequal loss of duplicated genes (see figure 24.7).

***Polyploidy can alter gene expression.***

Polyploidization can lead to short-term silencing of genes via methylation of cytosines in the DNA.

***Transposons jump around following polyploidization.***

Transposons become highly active after polyploidization; their insertions into new positions may lead to new phenotypes.

### **24.3 Evolution Within Genomes**

***Individual chromosomes may be duplicated.***

Aneuploidy creates problems in gamete formation. It is tolerated better in plants than in animals.

***DNA segments may be duplicated (see figure 24.8).***

Duplicated DNA is common for genes associated with growth and development, immunity, and cell-surface receptors. Paralogues are duplicated ancestral genes; orthologues are conserved ancestral genes.

***Genomes may become rearranged.***

Genomes may be rearranged by moving gene locations within a chromosome or by the fusion of two chromosomes.

Conservation of synteny refers to preservation of long segments of ancestral chromosome sequences identifiable in related species (see figure 24.10).

***Gene inactivation results in pseudogenes.***

Some ancestral genes become inactivated as they acquire mutations and are termed pseudogenes.

***Rearranged DNA can acquire new functions.***

Occasionally part of a gene can end up in a new spot in the genome where its function changes.

***Horizontal gene transfer complicates matters.***

Horizontal gene transfer creates many phylogenetic questions, such as the origins of the three major domains (see figure 24.11).

### **24.4 Gene Function and Expression Patterns**

***Chimp and human gene transcription patterns differ.***

Even when species have highly similar genes, expression of these genes may vary greatly. Posttranscriptional differences may also contribute to species differences.

***Speech is uniquely human: An example of complex expression.***

Small evolutionary changes in the FOXP2 protein and its expression may have led to human speech (see figure 24.12).

### **24.5 Nonprotein-Coding DNA and Regulatory Function**

Nonprotein-coding sequences are found in retrotransposon-rich regions of the genome. Noncoding DNA may contain regulatory RNA sequences for silencing other genes.

### **24.6 Genome Size and Gene Number**

***Noncoding DNA inflates genome size.***

Genome size is most often inflated due to the presence of introns and nonprotein-coding sequences. Genome size does not correlate with the number of genes.

***Plants have widely varying genome size.***

As much as a 200-fold difference in genome size has been found in plants; the number of genes has a narrower range.

### **24.7 Genome Analysis and Disease Prevention and Treatment**

***Distantly related genomes offer clues for causes of disease.***

Changes in amino acid sequences of critical proteins are a likely cause of diseases, and these differences can be identified by genome comparison.

***Closely related organisms enhance medical research.***

By comparing related organisms, researchers can focus on genes that cause diseases and devise possible treatments.

***Pathogen–host genome differences reveal drug targets.***

Analysis of the genomes of pathogenic organisms may provide new avenues of treatment and prevention.

### **24.8 Crop Improvement Through Genome Analysis**

***Model plant genomes provide links to genetics of crop plants.***

Research on *Arabidopsis* and *Medicago* species may provide insight into improvements in crop production and value.

***Beneficial bacterial genes can be located and utilized.***

Bacterial genes that produce protective compounds may be identified and used to engineer crop plants.

## Review Questions

### UNDERSTAND

- Humans and pufferfish diverged from a common ancestor about 450 MYA, and these two genomes have
  - very few of the same genes in common.
  - all the same genes.
  - a large proportion of the genes in in common.
  - no nucleotide divergence.
- Genome comparisons have suggested that mouse DNA has mutated about twice as fast as human DNA. What is a possible explanation for this discrepancy?
  - Mice are much smaller than humans.
  - Mice live in much less sanitary conditions than humans and are therefore exposed to a wider range of mutation-causing substances.
  - Mice have a smaller genome size.
  - Mice have a much shorter generation time.
- Polyploidy in plants
  - has only arisen once and therefore is very rare.
  - only occurs naturally when there is a hybridization event between two species.
  - is common, but never occurs in animals.
  - is common, and does occur in some animals.
- Homologous genes in distantly related organisms can often be easily located on chromosomes due to
  - horizontal gene transfer.
  - conservation of synteny.
  - gene inactivation.
  - pseudogenes.
- All of the following are believed to contribute to genomic diversity among various species, *except*
  - gene duplication.
  - gene transcription.
  - lateral gene transfer.
  - chromosomal rearrangements.
- What is the fate of *most* duplicated genes?
  - Gene inactivation
  - Gain of a novel function through subsequent mutation
  - They are transferred to a new organism using lateral gene transfer.
  - They become orthologues.

### APPLY

- Chimp and human DNA whole genome sequences differ by about 2.7%. Determine which of the following explanations is most consistent with the substantial differences in morphology and behavior between the two species.
  - It must be due largely to gene expression.
  - It must be due exclusively to environmental differences.
  - It cannot be explained with current genetic theory.
  - The differences are caused by random effects during development.

- You are offered a summer research opportunity to investigate a region of ncDNA in maize. A friend politely smiles and says that only graduate students get to work on the coding regions of DNA. How would you critique your friend's statement?
  - The friend has a point; ncDNA is “junk” DNA and therefore not very important.
  - The ncDNA produces protein through mechanisms other than transcription.
  - Most ncDNA is usually translated.
  - Often ncDNA produces RNA transcripts that themselves have regulatory function.
- Analyze the conclusion that the *Medicago truncatula* genome has been downsized relative to its ancestral legume, and circle the evidence that is consistent with this conclusion.
  - Medicago* has a proportional decrease in the number of genes.
  - Medicago* has a proportional increase in the number of genes.
  - Medicago* has an increase in the amount of DNA.
  - Medicago* has a decrease in the amount of DNA.
- Analyze why a herbicide that targets the chloroplast is effective against malaria.
  - Because *Plasmodium* needs a functional apicoplast
  - Because the main vector for malaria is a plant
  - Because mosquitoes require plant leaves for food
  - Because *Plasmodium* mitochondria are very similar to chloroplasts

### SYNTHESIZE

- The *FOXP2* gene is associated with speech in humans. It is also found in chimpanzees, gorillas, orangutans, rhesus macaques, and even the mouse, yet none of these mammals speak. Develop a hypothesis that explains why *FOXP2* supports speech in humans but not other mammals.
- One of the common misconceptions about sequencing projects (especially the high-profile Human Genome Project) is that creating a complete road map of the DNA will lead directly to cures for genetically based diseases. Given the percentage similarity in DNA between humans and chimps, is this simplistic view justified? Explain.
- How does horizontal gene transfer (HGT) complicate phylogenetic analysis?

# Chapter 25

## Evolution of Development

### Chapter Outline

- 25.1** Overview of Evolutionary Developmental Biology
- 25.2** One or Two Gene Mutations, New Form
- 25.3** Same Gene, New Function
- 25.4** Different Genes, Convergent Function
- 25.5** Gene Duplication and Divergence
- 25.6** Functional Analysis of Genes Across Species
- 25.7** Diversity of Eyes in the Natural World: A Case Study

### Introduction

*How is it that closely related species of frogs can have completely different patterns of development? One frog goes from fertilized egg to adult frog with no intermediate tadpole stage. The sister species has an extra developmental stage neatly slipped in between early development and the formation of limbs—the tadpole stage. The answer to this and other such evolutionary differences in development that yield novel phenotypes are now being investigated with modern genetic and genomic tools. Research findings are accentuating the biological puzzle that many developmental genes are highly conserved, and a tremendous diversity of life shares this basic toolkit of developmental genes. In this chapter, we explore the emerging field of developmental evolution, a field that brings together previously distinct fields of biology.*

### 25.1 Overview of Evolutionary Developmental Biology

#### Learning Outcomes

1. Explain how the same gene can produce different morphologies in different species.
2. Identify types of genes most likely to affect morphology.

Ultimately, to explain the differences among species, we need to look at changes in developmental processes. These changes result in a different phenotype and trace back to changes in genes.

Phenotypic diversity could either result from many different genes or be explained by how a smaller set of genes are deployed and regulated. In some cases, changes in the protein-coding region have been implicated in novel phenotypes. In other cases, a conserved set of genes appear to be responsible for the basic body plan of organisms with changes in regulation of gene expression accounting for phenotypic differences. The latter is true for two sea urchin species.

Closely related sea urchins have been discovered that have very distinctive developmental patterns (figure 25.1). The direct-developing urchin never makes a pluteus (free-swimming) larva—it just jumps ahead to its adult form. We could speculate that the two forms have different developmental genes, but it turns out that this is not the case. Instead, the two forms have undergone dramatic changes in patterns of developmental gene expression, even though their adult form is nearly the same. In this case, patterns of expression have changed.

## Highly conserved genes produce diverse morphologies

Transcription factors and genes involved in signaling pathways are responsible for coordination of development. As you saw in chapter 9, key elements of kinase and G protein-signaling pathways are also highly conserved among organisms. Even subtle changes in a signaling pathway can alter the enzyme that is activated or repressed, the transcription factor that is activated or repressed, or the activation or repression of gene expression. Any of these changes can have dramatic effects on the development of an organism.

A relatively small number of gene families, about two dozen, regulate animal and plant development. The developmental roles of several of these families, including *Hox* gene transcription factors, are described in chapter 19.

*Hox* (homeobox) genes appeared before the divergence of plants and animals; in plants, they have a role in shoot growth and leaf development, and in animals they establish body plans. These genes code for proteins with a highly conserved homeodomain that binds to the regulatory region of other genes to activate or repress these genes' expression. *Hox* genes specify when and where genes are expressed.

Another family of transcription factors, *MADS* box genes, are found throughout the eukaryotes. The *MADS* box also codes for a DNA-binding motif. Large numbers of *MADS* box genes establish the body plan of plants, especially the flowers. Although the *MADS* box region is highly conserved, variation exists in other regions of the coding sequence. Later in this chapter, we consider how there came to be so many *MADS* box genes in plants and how such similar genes can have very different functions.

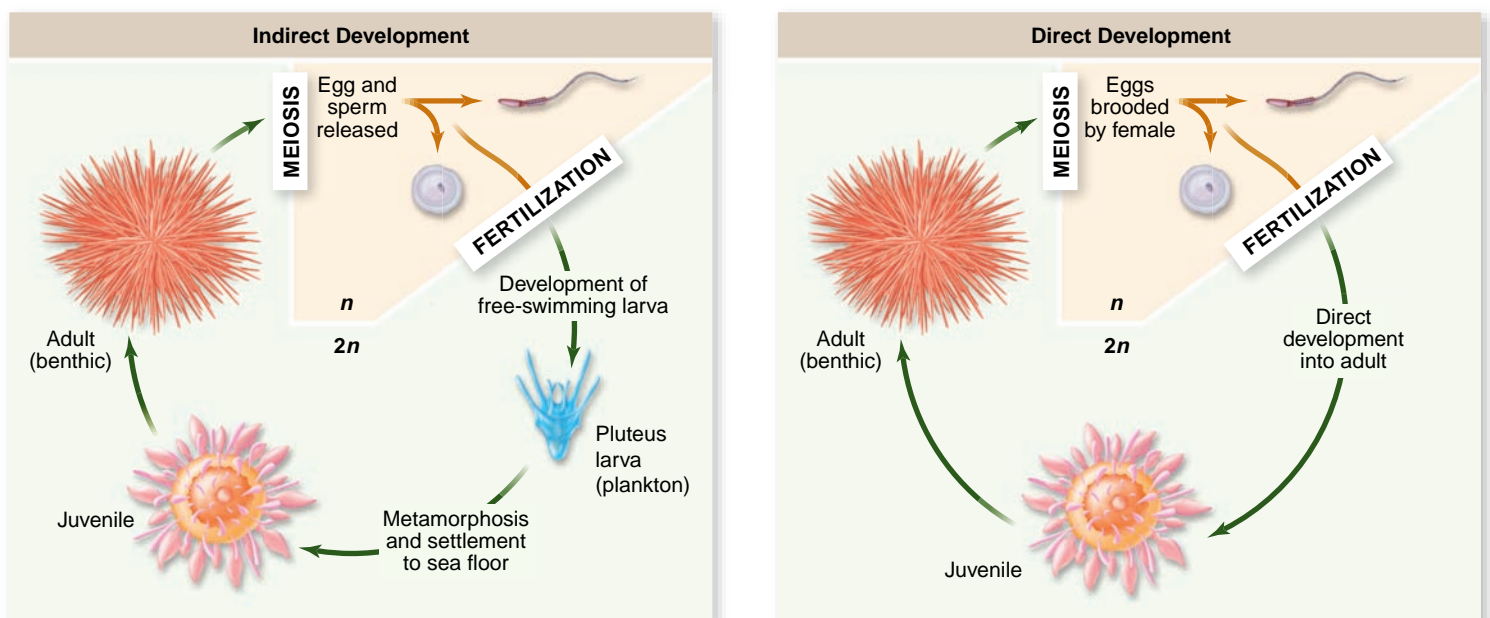

## Developmental mechanisms exhibit evolutionary change

Understanding how development evolves requires integration of knowledge about genes, gene expression, development, and evolution. Either transcription factors or signaling molecules can be modified during evolution, changing the timing or position of gene expression and, as a result, gene function.

### Heterochrony

Alterations in timing of developmental events due to a genetic change are called **heterochrony**. A heterochronic mutation could affect a gene that controls when a plant transitions from the juvenile to the adult stage, at which point it can produce reproductive organs. A mutation in a gene that delays flowering in plants can result in a small plant that flowers quickly rather than requiring months or years of growth.

Most mutations that affect developmental regulatory genes are lethal, but every so often a novel phenotype emerges that persists because of increased fitness. If a mutation leading to early flowering increased the fitness of a plant, the new phenotype will persist. For example, a tundra plant that flowers earlier, enabling it to be fertilized and set seed, could have increased fitness over an individual of the same species that flowers later, just as the short summer comes to a close.

**Figure 25.1** Direct and indirect sea urchin development. Phylogenetic analysis shows that indirect development (pluteus larva) was the ancestral state. Direct-developing sea urchins have lost an intermediate stage of development.

## Homeosis

Alterations in the spatial pattern of gene expression can result in **homeosis**. A four-winged *Drosophila* fly is an example of a homeotic mutation in which gene expression patterns shift. Mutations in three genes in the *Bithorax* complex are required to produce this phenotype, which resembles more ancestral insects with four rather than two wings.

The *Drosophila Antennapedia* mutant, which has a leg where an antenna should be, is another example of a homeotic mutation. Mutations in genes such as *Antennapedia* can arise spontaneously in the natural world or by mutagenesis in the laboratory, but their bizarre phenotypes would have little survival value in nature.

## Changes in translated regions of transcription factors

The coding sequence of a gene can contain multiple regions with different functions (figure 25.2). The DNA-binding motifs, exemplified by *MADS* box and *Hox* genes, could be altered so that they no longer bind to their target genes; as a result, that developmental pathway would cease to function. Alternatively, the modified transcription factor might bind to a different target and initiate a new sequence of developmental events.

The regulatory region sequence of a transcription factor must also be considered in the evolution of developmental mechanisms. A sequence change could alter the transcription complex that forms at a regulatory region, resulting in novel expression patterns. Either the time or place of gene expression could be affected, giving rise to heterochrony or homeosis. In this case, the downstream targets might be the same, but the cells that express the target genes or the time at which these target genes are expressed could change.

## Changes in signaling pathways

Coordinating information about neighboring cells and the external environment is essential for successful development. Signaling pathways are essential for cell-to-cell communication. If the structure of a ligand changes, it may no longer bind to its target receptor, or it could bind to a different receptor or no receptor at all. If, as a result of a genetic change, a receptor is produced in a different cell type, a homeotic phenotype may appear. And, as mentioned earlier, small changes in signaling molecules can alter their targets.

The sections that follow use specific examples of the evolution of diverse morphologies. For each example, consider how the mechanism of development has been altered and what the outcome is. Keep in mind that these are the successful examples; most morphological novelties that arise quickly, but do not improve fitness, go extinct.

### Learning Outcomes Review 25.1

Highly conserved genes can undergo small changes in their coding or regulatory regions that alter the place or time of gene expression and function, resulting in new body plans. Changes in transcription factors and signaling pathways are the most common source of new morphologies.

- Two closely related species of *Drosophila* in Hawaii can be distinguished by the presence of one pair of wings versus two pairs. How would you explain the evolution of this difference?

## SCIENTIFIC THINKING

**Hypothesis:** A transcription factor can affect the expression of more than one gene.

**Prediction:** The protein encoded by a transcription factor gene will have multiple DNA- or protein-binding sites.

**Test:** Experimentally identify molecules that bind to the transcription factor.

**Result:** This transcription factor has a site that binds to the regulatory region of a gene and a site that binds to a transcription factor that regulates expression of a second gene.

**Conclusion:** A single transcription factor can regulate the expression of more than one gene.

**Further Experiments:** Determine the specific developmental role of each binding domain by creating mutations in regions of the gene that code for specific binding sites in the protein.

**Figure 25.2** Transcription factors have a key role in the evolution of development.

## 25.2 One or Two Gene Mutations, New Form

### Learning Outcome

1. Explain how a small number of mutations can give rise to a new species.

Here we consider three examples of single gene mutations with altered morphology: (1) wild cabbage, (2) jaw shape in cichlid fish, and (3) bony armor in threespine sticklebacks. In all cases, the change increased fitness in a particular environment at a specific time, leading to selection of the new phenotypes.

### Cauliflower and broccoli began with a stop codon

The species *Brassica oleracea* is particularly fascinating because individual members can have extraordinarily diverse phenotypes. The diversity in form is so great that *B. oleracea* members are divided into subspecies (figure 25.3).

Wild cabbage, kale, tree kale, red cabbage, green cabbage, brussels sprouts, broccoli, and cauliflower are all members of the same species. Some flower early, some late. Some have long stems, others have short ones. Some form a few flowers, and others, like broccoli and cauliflower, initiate many flowers but development of the flowers is arrested. Curiously, these plants with such different appearances are very closely related.

One piece of the puzzle lies with the gene *CAL* (*Cauliflower*), which was first cloned in a close *Brassica* relative, *Arabidopsis*. In combination with another mutation, *Apetala1*, *Arabidopsis* plants can be turned from plants with a limited number of simple flowers into miniature broccoli or cauliflower plants with masses of arrested flower meristems or flower buds. These two genes are needed for the transition to making flowers and arose through duplication of a single ancestral gene within the brassica group. When they are absent, meristems continue to make branches, but are delayed in producing flowers.

The *CAL* gene was cloned from large numbers of *B. oleracea* subspecies, and a stop codon, TAG, was found in the middle of the *CAL* coding sequences of broccoli and cauliflower. A phylogenetic analysis of *B. oleracea* coupled with the *CAL* sequence analysis leads to the conclusion that this stop codon appeared after the ancestors of broccoli and cauliflower diverged from other subspecies members, but before broccoli and cauliflower diverged from each other (see figure 25.3).

### Inquiry question

Knowing that cauliflower and broccoli have a stop codon in the middle of the *CAL* gene-coding sequence, predict the wild-type function of *CAL*. What additional evolutionary events may have occurred since broccoli and cauliflower diverged?

**Figure 25.3** Evolution of cauliflower and broccoli.

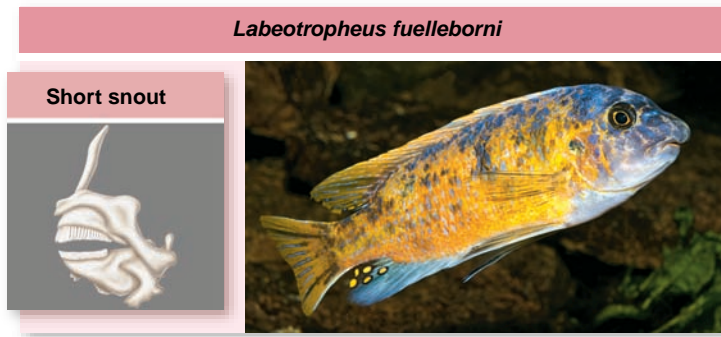

A point mutation that converted an amino acid-coding region into a stop codon resulted in the extensive reproductive branching pattern that was artificially selected for in two crop plants that are subspecies of *Brassica oleracea*.

This study points out the importance of having well-documented phylogenies in place to enable the analysis of developmental pattern evolution. A second, somewhat unusual, feature of this example is that the driving selective force for these subspecies was artificial. Wild relatives are still found scattered along the rocky coasts of Spain and the Mediterranean region. The most likely scenario is that humans found a *cal* mutant and selected for that phenotype through cultivation. The large heads of broccoli and cauliflower offer a larger amount of a vegetable material than the wild kale plants and a tasty alternative to *Brassica* leaves.

### Cichlid fish jaws demonstrate morphological diversity

Our second example of how a single gene can change form and function comes from natural selection of cichlid fish in Lake Malawi in East Africa. In less than a few million years, hundreds of species have evolved in the lake from a common ancestor. The rapid speciation of cichlids is discussed in chapter 22.

One explanation for the successful speciation is that different species have acquired different niches based on feeding habits. There are bottom eaters, biters, and rammers. The rammers have particularly long snouts with which to ram their prey; biters have an intermediate snout; and the bottom feeders

**Figure 25.4 Diversity of cichlid fish jaws.** A difference in one gene is responsible for a short snout in *Labeotropheus fuelleborni* and a long snout in *Metriaclicma zebra*. Genes that affect jaw length can affect body shape as well because of the constraints the size of the jaw places on muscle development.

have short snouts adapted to scrounging for food at the base of the lake (figure 25.4).

How did these fish acquire such different snout forms? An extensive genetic analysis revealed that two genes, of yet unknown function, are likely responsible for the shape and size of the jaw. The results of crossing long- and short-snouted cichlids indicate the importance of a single gene in determining jaw length and height.

Regulating the length versus the height of the jaw may well be an early and important developmental event. The overall size of the fish and the extent of muscle development both hinge on the form of the jaw. The range of jaw forms appears to have persisted because the cichlids establish unique niches for feeding within the lake.

Our third example underscores the critical link between persistence of a new mutation and increased fitness. The freshwater, threespine stickleback fish, *Gasterosteus aculeatus*, originated after the last ice from marine populations with bony plates that protect the fish from predators. Freshwater populations, subject to less predation, have lost their bony armor. The *Ectodysplasin* (*Eda*) gene is one of a few associated with reduced armor in freshwater threespine sticklebacks. The *Eda* allele that causes reduced armor originated about 2 MYA in marine sticklebacks and persists with a frequency of about 1% in marine environments. The frequency is much higher in freshwater populations. To test the fitness of the *Eda* allele in freshwater, marine sticklebacks that were heterozygous for the *Eda* allele were moved to four freshwater environments and allowed to breed. Positive selection for the reduced armor allele was observed and correlated with longer length in juvenile fish, likely because fewer resources were allocated to armor development. Although the reduced armor allele has persisted in marine populations for 2 million years as a rare genetic variant, increased frequency of the allele and phenotype are only seen under adaptive conditions.

### Learning Outcome Review 25.2

Although most mutations are lethal, some confer a fitness advantage. These may consist of very small mutations, such as a change to a single codon, that have large effects on development and morphology.

- A cichlid hatches with a much longer jaw than ever observed before. You determine that a mutation is responsible for the extra-long jaw. Is this fish a new species? How would you determine this?

## 25.3 Same Gene, New Function

### Learning Outcome

1. Explain how a gene could acquire a new function.

In the preceding chapter, we discussed the similarity between human and mouse genomes. If all but 300 of the 20,000 to 25,000 human genes are shared with mice, why are mice and humans so different? Part of the answer is that genes with similar sequences in two different species may work in slightly or even dramatically different ways.

### Ancestral genes may be co-opted for new functions

The evolution of chordates can partially be explained by the co-option of an existing gene for a new function. Ascidians are basal chordates that have a notochord but no vertebrae (chapter 35). The *Brachyury* gene of ascidians encodes a transcription factor, and it is expressed in the developing notochord (figure 25.5).

*Brachyury* is not a novel gene that appeared as vertebrates evolved. It is also found in invertebrates. For example, a mollusk homologue of *Brachyury* is associated with anterior–posterior axis specification. Most likely, an ancestral *Brachyury* gene was co-opted for a new role in notochord development.

*Brachyury* is a member of a gene family with a specific domain, that is, a conserved sequence of base-pairs within the gene. A region of *Brachyury* encodes a protein domain called the **T box**, which is a transcription factor. So, *Brachyury*-encoded protein turns on a gene or genes. The details of which genes are regulated by *Brachyury* are only now being discovered.

In mice and dogs, a mutation in *Brachyury* that prevents the encoded protein from binding to DNA causes a short tail to develop. In some dog breeds it is customary to “bob” (surgically shorten) a puppy’s tail. Nonlethal, short-tail mutations are being used to breed dogs like Welsh corgis to avoid bobbing. Humans lack tails, but have wild-type copies of *Brachyury*. Genes in addition to *Brachyury* must be needed to make a tail.

**Figure 25.5 Co-opting a gene for a new function.**

*Brachyury* is a gene found in invertebrates that has been used for notochord development in this ascidian, a basal chordate. By attaching the *Brachyury* promoter to a gene with a protein product that stains blue, it is possible to see that *Brachyury* gene expression in ascidians is associated with the development of the notochord, a novel function compared with its function in organisms lacking a notochord. The orthologue in the nematode *Caenorhabditis elegans* is important for hind gut and male tail development, but there is no evidence of a notochord precursor.

How a single genetic toolkit can be used to build an insect, a bird, a bat, a whale, or a human is an intriguing puzzle for evolutionary developmental biologists, exemplified with the *Brachyury* gene. One explanation is that *Brachyury* turns on different genes or combinations of genes in different animals. Although there are not yet enough data to sort out the details

of *Brachyury*, we can look at limb formation for an explanation of how such a change could have evolved.

## Limbs have developed through modification of transcriptional regulation

Most tetrapods have four limbs—two hindlimbs and two forelimbs, although two or more limbs have been lost in snakes and many lizards. The forelimb in a bird is actually the wing. Our forelimb is the arm. Clearly, these are two very different structures, but they have a common evolutionary origin. As you learned in chapter 23, these are termed *homologous structures*.

At the genetic level, humans and birds both express the *Tbx5* gene in developing forelimb buds. Like *Brachyury*, *Tbx5* is a member of a transcription factor gene family with T box domain, that is, a conserved sequence of base-pairs within the gene. So, *Tbx5*-encoded protein turns on a gene or genes that are needed to make a limb. Mutations in the human *Tbx5* gene cause Holt–Oram syndrome, resulting in forelimb and heart abnormalities.

What seems to have changed as birds and humans evolved are the genes that are transcribed because of the *Tbx5* protein (figure 25.6). In the ancestral tetrapod, perhaps *Tbx5* protein bound to only one gene and triggered transcription. In humans and birds, different genes are expressed in response to *Tbx5*.

*Tbx5* evolution corresponds to changes in the coding sequence for the *Tbx5* protein in different species. But, it is also possible for changes in noncoding regions of a gene to alter gene expression during evolution. The *paired-like homeodomain transcription factor 1* (*pitx1*) is expressed in the hindlimbs of developing mouse embryos and its homologue

**Figure 25.6 *Tbx5* regulates wing and arm development.** Wings and arms are very different, but the development of each depends on *Tbx5*. Why the difference? *Tbx5* turns on different genes in birds and humans.

is expressed in the pelvic region of the ninespine stickleback fish (*Pungitius pungitius*). Much like *Brachyury* gene evolution, *pitx1* was co-opted for a new function in tetrapods. Within the sticklebacks, *pitx1* gene expression is different in marine and freshwater populations of the same species, yet the *pitx1* proteins in both populations have identical amino acid sequences. The explanation for the difference can be found in the regulatory regions of the gene that are not translated into protein.

Marine sticklebacks have skeletal armor, including spines, in the pelvic region that protects them from predatory fish. Isolated populations in freshwater have lost the pelvic skeletal armor and do not express *pitx1* in the pelvic region. Loss of gene expression, rather than a change in the protein structure of this transcription factor accounts for the morphological differences between the marine and freshwater sticklebacks.

### Learning Outcome Review 25.3

During the long course of evolution, genes have been co-opted for new functions. A change in the protein-coding region of a transcription factor can change the genes it can bind to and regulate. A change in the regulatory region of a gene can change where or when that gene is expressed, which can lead to altered morphology.

- A marine threespine stickleback fish is mated with a freshwater threespine with reduced armor, and all the offspring have reduced armor. Both populations have identical *pitx1* coding regions. Could *pitx1* be the cause of the difference in armor? How could you test this?

## 25.4 Different Genes, Convergent Function

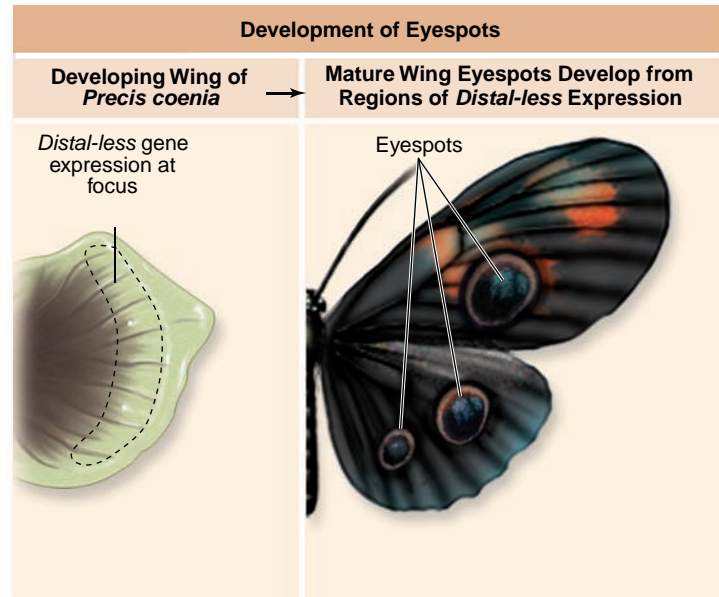

### Learning Outcomes

1. Differentiate between homologous structures and homoplastic structures.
2. Explain how two very similar morphologies can arise from different developmental pathways.

*Homoplastic structures*, also known as analogous structures, have the same or similar functions, but arose independently—unlike homologous structures that arose once from a common ancestor. Phylogenies reveal convergent events, but the origin of the convergence may not be easily understood. In many cases different developmental pathways have been modified, as is the case with the spots on butterfly wings. In other cases, such as flower shape, it is not always as clear whether the same or different genes are responsible for convergent evolution.

### Insect wing patterns demonstrate homoplastic convergence

Insect wings, especially those of moths and butterflies, have beautiful patterns that can protect them from predation and al-

**Figure 25.7 Butterfly eyespot evolution.** The *Distal-less* gene, usually used for limb development, was recruited for eyespot development on butterfly wings. *Distal-less* initiates the development of different colored spots in different butterfly species by regulating different pigment genes in different species. Eyespots can protect butterflies by startling predators.

low them to thermoregulate (figure 25.7). The origins of these patterns are best explained by co-option, the recruitment of existing regulatory programs for new functions.

*Distal-less* is one of the genes co-opted for butterfly spot development. Limb development in insects and arthropods requires *Distal-less*, but the expression of this gene also predicts where spots will form on butterfly wings (figure 27.7). *Distal-less* determines the center of the spot, but several other genes have been co-opted to determine the overall size and pattern of different spots.

Not all insects have co-opted the same sets of genes for these new functions, but all the evolutionary pathways have converged around production of these novel, highly patterned wings.

## Flower shapes also demonstrate convergence

Flowers exhibit two types of symmetry. Looking down on a **radially symmetrical** flower, you see a circle. No matter how you cut that flower, as long as you have a straight line that intersects with the center, you end up with two identical parts. Examples of radially symmetrical flowers are daisies, roses, tulips, and many other flowers.

**Bilaterally symmetrical** flowers have mirror-image halves on each side of a single central axis. If they are cut in any other direction, two nonsimilar shapes result. Plants with bilaterally symmetrical flowers include snapdragons, mints, and peas. Bilaterally symmetrical flowers are attractive to their pollinators, and the shape may have been an important factor in their evolutionary success.

At the crossroads of evolution and development, two questions arise: first, What genes are involved in bilateral symmetry? And second, Are the same genes involved in the numerous, independent origins of asymmetrical flowers?

*Cycloidea* (*CYC*) is a snapdragon gene responsible for the bilateral symmetry of the flower. Snapdragons with mutations in *CYC* have radially symmetrical flowers (see figure 42.17b). Beginning with robust phylogenies, researchers have selected flowers that evolved bilateral symmetry independently from snapdragons and cloned the *CYC* gene. The *CYC* gene in closely related symmetrical flowers has also been sequenced.

Comparisons of the *CYC* gene sequence among phylogenetically diverse flowers indicate that both radial symmetry and bilateral symmetry evolved in multiple ways in flowers. Although radial symmetry is the ancestral condition, some radially symmetrical flowers have a bilaterally symmetrical ancestor. Loss of *CYC* function accounts for the loss of bilateral symmetry in some of these plants.

Gain of bilateral symmetry arose independently among some species because of the *CYC* gene. This change is an example of convergent evolution through mutations of the same gene. In other cases, *CYC* is not clearly responsible for the bilateral symmetry. Other genes also played a role in the convergent evolution of bilaterally symmetrical flowers.

### Learning Outcomes Review 25.4

Homoplastic features have a similar function but different evolutionary origins and are examples of convergent evolution. Homologous features have the same evolutionary origins, but may have a different function. Knowledge of the underlying genes often reveals that a feature thought to be homoplastic has a more common origin than expected.

- Both sharks and whales have pectoral fins. Are these features homologous or homoplastic?

## 25.5 Gene Duplication and Divergence

### Learning Outcome

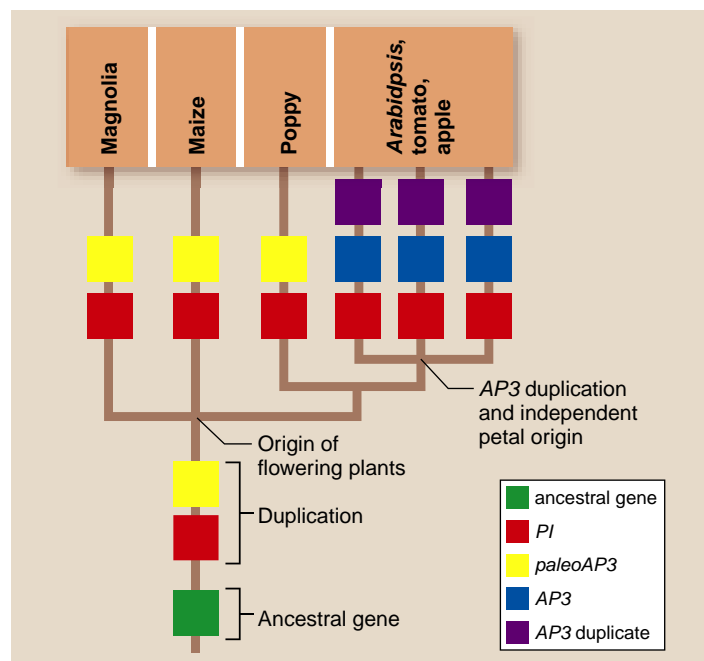

- Describe how duplicated genes could give rise to new functions in an organism.

You encountered the role of gene duplication in genome evolution in chapter 24. In this section, we explore a specific example of the evolution of development through gene duplication and divergence in flower form.

### Gene duplications of *paleoAP3* led to flowering-plant morphology

Before the flowering plants originated, a *MADS* box gene duplicated, giving rise to genes called *PI* and *paleoAP3*. In ancestral flowering plants, these genes affected stamen development, and this function has been retained. (Stamens are the male reproductive structures of flowering plants.)

The *paleoAP3* gene duplicated to produce *AP3* and an *AP3* duplicate some time after members of the poppy family last shared a common ancestor with the clade of plants called the eudicots (plants like apple, tomato, and *Arabidopsis*). This clade of eudicots is distinguished on the genome level by both the duplication of *paleoAP3* and the origins of a precise pattern of petal development in their last common ancestor (figure 25.8). The phylogenetic inference is that *AP3* gained a role in petal development.

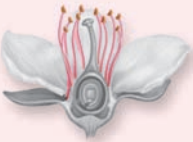

**Figure 25.8** Petal evolution through gene duplication.

Two gene duplications resulted in the *AP3* gene in the eudicots that has acquired a role in petal development.

**Figure 25.9 AP3 has acquired a domain necessary for petal development.** The *AP3* gene includes MADS box encoding a DNA-binding domain and a highly specific sequence near the C terminus. Without the 3' region of the *AP3* gene, the *Arabidopsis* plant will not make petals.

AP3 Gene Construct Added to AP3 Mutant Arabidopsis		Petals Present	Stamen Present
			
Complete AP3 Gene		YES	YES
No AP3 C terminus		NO	NO
PI C terminus replaces AP3 C terminus		NO	SOME

### Gene divergence of AP3 altered function to control petal development

Although the occurrence of *AP3* through duplication corresponds with a uniform developmental process for specifying petal development, the correlation could simply be coincidental. Experiments that mix and match parts of the *AP3* and *PI* genes, and then introduce them into *ap3* mutant plants, confirm that the phylogenetic correspondence is not a coincidence. The *ap3* plants do not produce either petals or stamens. A summary of the experiments is shown in figure 25.9.

Earlier in this chapter, the *MADS* box transcription factor gene family was introduced. One region of a *MADS* gene codes for a DNA-binding motif; other regions code for different functions, including protein–protein binding. The *PI* and *AP3* proteins can bind to each other, and, as a result, can regulate the transcription of genes needed for stamen and petal formation.

#### The C terminus of AP3

Both *AP3* and *PI* have distinct sequences at the C (carboxy) protein terminus (coded for by the 3' end of the genes). The C-terminus sequence of the *AP3* protein is essential for specifying petal function, and it contains a conserved sequence shared among the eudicots. The *AP3* C-terminus DNA sequence was deleted from the wild-type gene, and the new construct was inserted into *ap3* plants to create a transgenic plant. Other transgenic plants were created by inserting the complete *AP3* sequence into *ap3* plants. The complete *AP3* sequence rescued the mutant, and petals were produced. No petals formed when the C-terminus motif was absent.

*AP3* is also needed for stamen development, an ancestral trait found in *paleoAP3*. Plants lacking *AP3* fail to produce either stamens or petals. Transgenic plants with the C-terminus deletion construct also failed to produce stamens.

#### The C terminus of PI

The *pi* mutant phenotype also lacks stamens and petals. To test whether the *PI* C terminus could substitute for the *AP3* C terminus in specifying petal formation, the *PI* C terminus

was added to the truncated *AP3* gene. No petals formed, but stamen development was partially rescued. These experiments demonstrate that *AP3* has acquired an essential role in petal development, encoded in a sequence at the 3' end of the gene.

### Learning Outcome Review 25.5

Gene duplication allows divergence that can lead to novel function. In eudicot flowering plants, the *AP3* gene, which arose by duplication from the *paleoAP3* gene, gained a role in petal development in addition to its function in stamen development.

- Suppose duplication of a particular gene proved to be lethal. What changes, if any, would allow this duplication to persist and possibly evolve into a new function?

## 25.6 Functional Analysis of Genes Across Species

### Learning Outcome

1. Evaluate the limitations of comparative genomics in exploring the evolution of development.

Comparative genomics is amazingly useful for understanding morphological diversity. Limitations exist, however, in the inferences about evolution of development that we can draw from sequence comparison alone. *Functional genomics* includes a range of experiments designed to test the actual function of a gene in different species as explained in chapter 18.

Sequence comparisons among organisms are essential for both phylogenetic and comparative developmental studies. Careful analysis is needed to distinguish paralogues from orthologues. Rapidly evolving research using bioinformatics, which utilizes computer programming to

analyze DNA and protein data, leads to hypotheses that can be tested experimentally.

You have already seen how this can work with highly conserved genes such as *Tbx5*. However, a single base mutation can change an active gene into an inactive pseudogene and experiments are necessary to demonstrate the actual function of the gene.

### Inquiry question

? Explain how functional analysis was used to support the claim that petal development evolved through the acquisition of petal function in the *AP3* gene of *Arabidopsis*.

Tools for functional analysis exist in model systems but need to be developed in other organisms on the tree of life if we are going to piece together evolutionary history. Model systems such as yeast, the flowering plant *Arabidopsis*, the nematode *Caenorhabditis elegans*, *Drosophila*, and the mouse have been selected because they are easy to manipulate in the laboratory, have short life cycles, and have well-delineated genomes. Also, it is possible to visualize gene expression within parts of the organism using labeled markers and to create transgenic organisms that contain and express foreign genes.

### Learning Outcome Review 25.6

Genomic similarities alone are not enough to determine the function of genes in different species; functional genomics studies whether conserved genes operate in the same way across species utilizing model organisms and genetic engineering.

- What tests and techniques were used to demonstrate the *AP3* gene's role in petal development?

## 25.7 Diversity of Eyes in the Natural World: A Case Study

### Learning Outcome

1. Explain how the compound eye of a fly, the human eye, and the eyespot of a ribbon worm could have a common evolutionary origin.

The eye is one of the most complex organs. Biologists have studied it for centuries. Indeed, explaining how such a complicated structure could evolve was one of the great challenges facing Darwin. If all parts of a structure such as an eye are required for proper functioning, how could natural selection build such a structure?

Darwin's response was that even intermediate structures—which provide, for example, the ability to distinguish light from dark—would be advantageous compared with the ancestral state of no visual capability whatsoever, and thus these structures would be favored by natural selection. In this way, by incremental improvements in function, natural selection could build a complicated structure.

### Morphological evidence indicates eyes evolved at least twenty times

Comparative anatomists long have noted that the structures of the eyes of different types of animals are quite different. Consider, for example, the difference in the eyes of a vertebrate, an insect, a mollusk (octopus), and a planarian (figure 25.10). The eyes of these organisms are extremely different in many ways, ranging from compound eyes, to simple eyes, to mere eyespots.

**Figure 25.10** A diversity of eyes. Morphological and anatomical comparisons of eyes are consistent with the hypothesis of independent, convergent evolution of eyes in diverse species such as flies and humans.

**Figure 25.11** Mouse *Pax6* makes an eye on the leg of a fly. *Pax6* and *eyeless* are functional homologues. The *Pax6* master regulator gene can initiate compound eye development in a fruit fly or simple eye development in a mouse.

Consequently, these eyes are examples of convergent evolution and are homoplastic. For this reason, evolutionary biologists traditionally viewed the eyes of different organisms as having independently evolved, perhaps as many as 20 times. Moreover, this view holds that the most recent common ancestor of all these forms was a primitive animal with no ability to detect light.

### The same gene, *Pax6*, initiates fly and mouse eye development

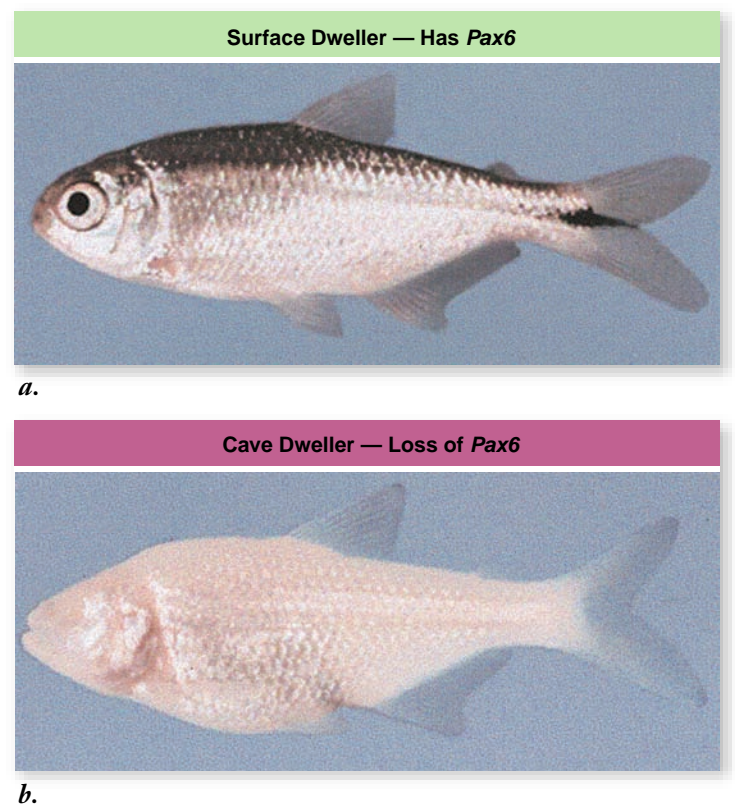

In the early 1990s, biologists studied the development of the eye in both vertebrates and insects. In each case, a gene was discovered that codes for a transcription factor important in lens formation; the mouse gene was given the name *Pax6*, whereas the fly gene was called *eyeless*. A mutation in the *eyeless* gene led to a lack of production of the transcription factor, and thus the complete absence of eye development, giving the gene its name.

When these genes were sequenced, it became apparent that they were highly similar; in essence, the homologous *Pax6* gene was responsible for triggering lens formation in both insects and vertebrates. A stunning demonstration of this homology was conducted by the Swiss biologist Walter Gehring, who inserted the mouse version of the *Pax6* into the genome of a fruit fly, creating a transgenic fly. In this fly, the *Pax6* gene was turned on by regulatory factors in the fly's leg and an eye formed on the leg of the fly (figure 25.11)!

These results were truly shocking to the evolutionary biology community. Insects and vertebrates diverged from a common ancestor more than 500 MYA. Moreover, given the large differences in structure of the vertebrate eye and insect eye, the standard assumption was that the eyes evolved independently, and thus that their development would be controlled by completely different genes. That eye development was affected by the same homologous gene, and that these genes

were so similar that the vertebrate gene seemed to function normally in the insect genome, was completely unexpected.

The *Pax6* story extends to eyeless fish found in caves (figure 25.12). Fish that live in dark caves need to rely on senses other than sight. In cavefish, *Pax6* gene expression is greatly reduced. Eyes start to develop, but then degenerate.

**Figure 25.12** Cavefish have lost their sight. Mexican tetras (*Astyanax mexicanus*) have (a) surface-dwelling members and (b) cave-dwelling members of the same species. The cavefish have very tiny eyes, partly because of reduced expression of *Pax6*.

## Ribbon worms, but not planaria, use *Pax6* for eye development

Recent discoveries have yielded further surprises about the *Pax6* gene. Even the very simple ribbon worm, *Lineus sanguineus*, relies on *Pax6* for development of its eyespots. A *Pax6* homologue has been cloned and has been shown to express at the sites where eyespots develop. In contrast, planarian worms do not rely on *Pax6* for eyespot development.

### Ribbon worm eyespot regeneration

The simple marine ribbon worm evolved later than the flatworm planaria. Just like planaria, ribbon worms can regenerate their head region if it is removed. In an elegant experiment, the head of a ribbon worm was removed, and biologists followed the regeneration of eyespots. At the same time, the expression of the *Pax6* homologue was observed using in situ hybridization.

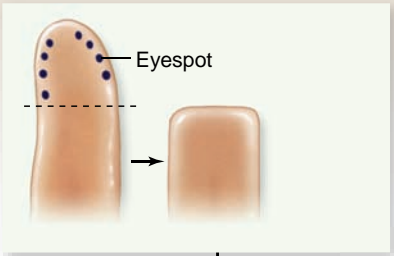

**SCIENTIFIC THINKING**

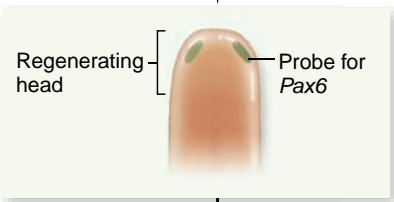

**Hypothesis:** *Pax6* is necessary for eyespot regeneration in ribbon worms.

**Prediction:** Eyespots will regenerate where *Pax6* is expressed.

**Test:**

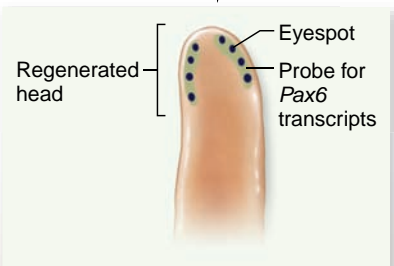

1. Cut and remove head.

2. Visualize *Pax6* transcripts (RNA) in the regenerating head region using in situ hybridization with a colored antisense DNA probe that is complementary to the *Pax6* RNA.

**Result:** *Pax6* transcripts are found only where eyespots regenerate.

**Conclusion:** *Pax6* is expressed where eyespots regenerate and is likely necessary for eyespot regeneration.

**Further Experiments:** What additional evidence would convince you that *Pax6* expression was necessary for eyespot regeneration? Consider the approach in Scientific Thinking figure 25.14.

**Figure 25.13** *Pax6* expression correlates with ribbon worm eyespot regeneration.

To observe *Pax6* gene expression, an antisense RNA sequence of the *Pax6* was made and labeled with a color marker. When the regenerating ribbon worms were exposed to the antisense *Pax6* probe, the antisense RNA paired with expressed *Pax6* RNA transcripts and could be seen as colored spots under the microscope (figure 25.13).

### Planarian eyespot regeneration

Similar experiments were tried with planaria species that are phylogenetically related to ribbon worms, but the conclusion was quite different from that in ribbon worms. If a planaria is cut in half lengthwise, it can regenerate its missing half, including the second eyespot, but no *Pax6* gene expression is associated with regenerating the eyespots.

Planaria do have *Pax6*-related genes, but inactivating those genes does not stop eye regeneration (figure 25.14). These *Pax6*-related genes are, however, expressed in the central nervous system. A *Pax6*-responsive element, P3-enhancer, has also been identified and shown to be active in planaria. Perhaps some clues as to the origin of *Pax6*'s role in eye development will be uncovered as comparisons between ribbon worm and planarian eyespot regeneration continue.

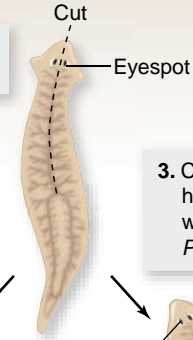

**SCIENTIFIC THINKING**

**Hypothesis:** *Pax6* is necessary for planaria eyespot regeneration which occurs when planaria are cut in half longitudinally.

**Prediction:** Eyespot regeneration will not occur without *Pax6* protein.

**Test:**

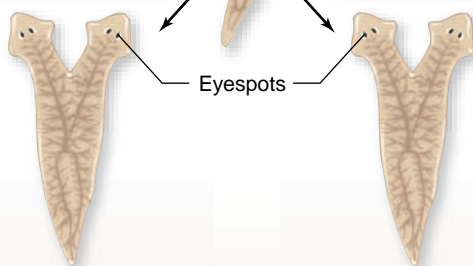

1. Cut a planaria in half longitudinally.

Cut  
Eyespot

2. Block expression of both *Pax6*-related genes and allow heads to regenerate.

3. Control—Allow heads to regenerate without blocking *Pax6* expression.

Eyespots

**Result:** Eyespots regenerate.

**Conclusion:** *Pax6* is not required for eyespot regeneration in planaria.

**Further Experiments:** Can you design an experiment to test if the planaria *Pax6* gene can initiate eyespot development in a ribbon worm or eye development in a fly?

**Figure 25.14** *Pax6* is not required for planaria eyespot regeneration.

## The initiation of eye development may have evolved just once

Several explanations are possible for these findings. One is that eyes in different types of animals evolved truly independently, as originally believed. But if this is the case, why is *Pax6* so structurally similar and able to play a similar role in so many different groups? Opponents of single evolution of the eye point out that *Pax6* is involved not only in development of the eye, but also in development of the entire forehead region of many organisms. Consequently, it is possible that if *Pax6* had a regulatory role in the forehead of early animals, perhaps it has been independently co-opted time and time again to serve a role in eye development. This role would be consistent with the data on planarians (see figure 25.14).

Many other biologists find this interpretation unlikely. The consistent use of *Pax6* in eye development in so many organisms, the fact that it functions in the same role in each case, and the great similarity in DNA sequence and even functional replaceability suggest to many that *Pax6* acquired its evolutionary role in eye development only a single time, in the common ancestor of all extant organisms that use *Pax6* in eye development.

Given the great dissimilarity among eyes of different groups, how can this be? One hypothesis is that the common ancestor of these groups was not completely blind, as traditionally assumed. Rather, that organism may have had some sort of

rudimentary visual system—maybe no more than a pigmented photoreceptor cell, maybe a slightly more elaborate organ that could distinguish light from dark.

Whatever the exact phenotype, the important point is that some sort of basic visual system existed that used *Pax6* in its development. Subsequently, the descendants of this ancestor diversified independently, evolving the sophisticated and complex image-forming eyes exhibited by different animal groups today.

Most evolutionary and developmental biologists today support some form of this hypothesis. Nonetheless, no independent evidence exists that the common ancestor of most of today's animal groups, a primitive form that lived probably more than 500 MYA, had any ability to detect light. The reason for this belief comes not from the fossil record, but from a synthesis of phylogenetic and molecular developmental data.

### Learning Outcome Review 25.7

Multidisciplinary approaches can clarify the evolutionary history of the world's biological diversity. The *Pax6* gene and its many homologues indicate that eye development, although highly diverse in outcome, may have a single evolutionary origin.

- *Why would mutations leading to defective Pax6 persist in cavefish? If these fish were introduced into a habitat with light, what would you expect to occur?*

## Chapter Review

### 25.1 Overview of Evolutionary Developmental Biology

#### *Highly conserved genes produce diverse morphologies.*

The *Hox* genes establish body form in animals; *MADS* box genes have a similar function in plants. Changes in these transcription factors and in genes involved in signaling pathways are responsible for new morphologies.

#### *Developmental mechanisms exhibit evolutionary change.*

Heterochrony refers to alteration of timing of developmental events due to genetic changes; homeosis refers to alterations in the spatial pattern of gene expression.

Modifications of different parts of the coding and regulatory sequences of a transcription factor can alter development and phenotypic expression (see figure 25.2).

### 25.2 One or Two Gene Mutations, New Form

#### *Cauliflower and broccoli began with a stop codon.*

The wide diversity of cabbage subspecies is due to a simple mutation of one gene (see figure 25.3).

#### *Cichlid fish jaws demonstrate morphological diversity.*

Jaw and body armor morphology in fish have also been modified by mutations in one or a few genes.

### 25.3 Same Gene, New Function (see figure 25.6)

#### *Ancestral genes may be co-opted for new functions.*

A single gene may act on different genes or combinations of genes in different species.

#### *Limbs have developed through modification of transcriptional regulation.*

Species differences in limbs have resulted from evolutionary changes in gene expression and timing of expression.

### 25.4 Different Genes, Convergent Function

#### *Insect wing patterns demonstrate homoplastic convergence.*

Wing patterns in butterflies have evolved as wing scales developed from ancestral sensory bristles.

#### *Flower shapes also demonstrate convergence*

Both radial and bilateral symmetry have arisen in multiple ways in flowers, even though radial symmetry is considered ancestral.

## 25.5 Gene Duplication and Divergence

**Gene duplications of paleoAP3 led to flowering-plant morphology.**

Duplication of the *AP3* gene and subsequent divergence produced flower petals, whereas the ancestral form affected only stamen development.

**Gene divergence of AP3 altered function to control petal development.**

Studies have narrowed the active region in *AP3* to the C terminus, which acts differently from the C terminus of the related *PI* gene; only *AP3* can produce petals (see figure 25.9).

## 25.6 Functional Analysis of Genes Across Species

Sequence comparisons are essential for both phylogenetic and comparative development studies, but we can only infer function from this information.

## 25.7 Diversity of Eyes in the Natural World: A Case Study

**Morphological evidence indicates eyes evolved at least twenty times.**

Homoplasy and convergent evolution are supported as explaining the diversity of eyes found in the animal kingdom.

**The same gene, Pax6, initiates fly and mouse eye development.**

Transgenic experiments showed that the *Pax6* gene from a mouse, inserted into the genome of *Drosophila*, could cause development of an eye.

**Ribbon worms, but not planaria, use Pax6 for eye development.**

In planaria, *Pax6* gene expression does not occur even when an eyespot successfully regenerates.

**The initiation of eye development may have evolved just once.**

It appears that at some distant point in evolutionary time, *Pax6* was part of a visual system that later diverged many times.

## Review Questions

### UNDERSTAND

- Heterochrony is
  - the alteration of the spatial pattern of gene expression.
  - a change in the relative position of a body part.
  - a change in the relative timing of developmental events.
  - a change in a signaling pathway.
- Vast differences in the phenotypes of organisms as different as fruit flies and humans
  - must result from differences among many thousands of genes controlling development.
  - have apparently arisen largely through manipulation of the timing and regulation of expression of probably less than 100 highly conserved genes.
  - can be entirely explained by heterochrony.
  - can be entirely explained by homeotic factors.
- Homoplastic structures
  - can involve convergence of completely unrelated developmental pathways.
  - always are morphologically distinct.
  - are produced by divergent evolution of homologous structures.
  - are derived from the same structure in a shared common ancestor.
- Hox* genes are
  - found in both plants and animals.
  - found only in animals.
  - found only in plants.
  - only associated with genes in the *MADS* complex.
- The *Brachyury* and *pictx1* genes in vertebrates and the *Ap3* gene in flowering plants
  - are examples of *Hox* genes.
  - are examples of co-opting a gene for a new function.
  - are homologues for determining the body plan of eukaryotes.
  - help regulate the formation of appendages.
- Which of the following statements about *Pax6* is false?
  - Pax6* has a similar function in mice and flies.
  - Pax6* is involved in eyespot formation in ribbon worms.
  - Pax6* is required for eye formation in *Drosophila*.
  - Pax6* is required for eyespot formation in planaria.
- Which of the following statements about *Tbx5* is true?
  - Tbx5* is found only in tetrapods.
  - Tbx5* is involved in limb development in vertebrates.
  - Tbx5* is only found in the ancestors of tetrapods.
  - Tbx5* interacts with the same set of genes across different tetrapod species.
- Homeosis
  - refers to a maintained and unchanging genetic environment.
  - is a temporal change in gene expression.
  - is a spatial change in gene expression.
  - is not an important genetic mechanism in development.
- Transcription factors are
  - genes.
  - sequences of RNA.
  - proteins that affect the expression of genes.
  - none of the above

10. Independently derived mutations of the *CYC* gene in plants
  - a. suggests bilateral floral symmetry among all plants is homologous.
  - b. establishes that radial floral symmetry is preferred by pollinators.
  - c. establishes that radial floral symmetry is derived for all plants.
  - d. none of the above

## APPLY

1. Choose the statement that best explains how the *Tbx5* protein can be responsible for the development of arms in humans and wings in birds.
  - a. *Tbx5* is a key component of bone.
  - b. *Tbx5* is a transcription factor that binds to the promoters of different genes in humans and birds to initiate arm and wing development.
  - c. *Tbx5* was co-opted from its role in tail development for the role in limb development.
  - d. *Tbx5* is a signaling molecule involved in the signaling pathway for limb development in both species.
2. Analyze why it was important to create transgenic plants to determine the role of *AP3* in petal formation and choose the most compelling reason.
  - a. It provided a functional test of the role of *AP3* in petal development.
  - b. Duplication of *AP3* could not be resolved on the phylogeny.
  - c. To check if the phylogenetic position of *AP3* is really derived.
  - d. Because tests already established the role of *paleoAP3* in stamen development.
3. The *Eda* allele that causes reduced armor originated about 2 MYA in marine stickleback fish and persists with a frequency of about 1% in marine environments. The frequency is much higher in freshwater populations. Apply your understanding of evolution to determine the most likely reason for the difference in *Eda* allele frequency.
  - a. There is positive selection for armor in marine environments because fish are more buoyant in salt water.
  - b. Fish have many predators in the marine environment and fish with reduced armor have reduced fitness.
  - c. There is negative selection for armor in freshwater because building armor is energetically expensive.
  - d. Both b and c are valid.
4. In *Drosophila* species, the yellow (*y*) gene is responsible for the patterning of black pigment on the body and the wings. A comparison of two species reveals that one has a black spot on each wing, and the other species lacks black pigmentation on the wing. The sequence of the coding region for *y* is identical in both species. Critique the following explanations and choose the most plausible one.
  - a. The protein coded for by the *y* gene has a different structure in species with the black spots than the species without.
    - b. The species without black pigmentation on the wing has a mutation in a regulatory region of the *y* gene.
    - c. There is a deletion mutation in one of the exons of the *y* gene in the species without black pigment in the wings.
    - d. Convergent evolution explains why both species develop black wing spots.

## SYNTHESIZE

1. If the tetrapod ancestor of humans and birds had a single gene that was regulated by *Tbx5* transcription factor, propose an evolutionary hypothesis for how several genes are regulated by *Tbx5* in humans and birds.
2. From the chapter on evolution of development it would seem that the generation of new developmental patterns would be fairly easy and fast, leading to the ability of organisms to adapt quickly to environmental changes. Construct an explanation for why it can take millions of years, typically, for many of the traits examined to evolve. (Hint: Consider the differences in *Eda* allele frequency in marine and freshwater threespine stickleback fish.)
3. There are several ways in which phenotypic diversity among major groups of organisms can be explained. On one end of the spectrum, such differences could arise out of differences in many genes that control development. On the other end, small sets of genes might differ in how they regulate the expression of various parts of the genome. Evaluate which view represents our current understanding.
4. Critique the argument that eyes have multiple evolutionary origins.
5. Based on the information in figure 25.8, construct an explanation for the evolutionary differences in genes related to *AP3* in maize and tomato. Be sure to consider what happened before and after the two species diverged from a common ancestor.
6. Having read all of this chapter, return to the claim that the difference between direct and indirect development in sea urchins is caused by a change in gene expression, not differences in genes. Starting at the level of DNA sequence, formulate an argument in support of the claim.

# Chapter 26

## The Tree of Life

### Chapter Outline

- 26.1 Origins of Life
- 26.2 Classification of Organisms
- 26.3 Grouping Organisms
- 26.4 Making Sense of the Protists
- 26.5 Origin of Plants
- 26.6 Sorting out the Animals

### Introduction

*Different life forms descended from the same origin event and have many things in common: they are composed of one or more cells, they carry out metabolism and transfer energy with ATP, and they encode hereditary information in DNA. But living things are also highly diverse, ranging from bacteria and amoebas to blue whales and sequoia trees. Coral reefs, such as the one pictured here, are microcosms of diversity, comprising many life forms and sheltering an enormous array of life. For generations, biologists have tried to group organisms based on shared characteristics. The most meaningful groupings are based on the study of evolutionary relationships among organisms. These phylogenetic approaches and a sea of molecular sequence data are leading to new evolutionary hypotheses to explain life's variety. In this chapter and those that follow in this unit, we explore the diversity of the living world.*

## 26.1 Origins of Life

### Learning Outcomes

1. Explain what qualifies something as “living.”
2. Describe different proposals for the origin of life on Earth.

The cell is the basic unit of life, and today all cells come from preexisting cells. But, how can we explain the origins of the tremendous diversity of life on Earth today? The Earth formed as a hot mass of molten rock about 4.5 BYA. As it cooled, much of the water vapor present in Earth’s atmosphere condensed into liquid water that accumulated on the surface in chemically rich oceans. One scenario for the origin of life is that it originated in this dilute, hot, smelly soup of ammonia, formaldehyde, formic acid, cyanide, methane, hydrogen sulfide, and organic hydrocarbons. Whether at the oceans’ edges, in hydrothermal deep-sea vents, or elsewhere, the consensus among researchers is that life arose spontaneously from these early waters. Although the way in which this happened remains a puzzle, we cannot escape a certain curiosity about the earliest steps that eventually led to the origin of all living things on Earth, including ourselves. How did organisms evolve from the complex molecules that swirled in the early oceans?

### All organisms share fundamental properties of life

Before we can address the origins of life, we must consider what qualifies something as “living.” Biologists have found that the following set of properties are common to all organisms on Earth, with heredity playing a particularly key role.

**Cellular organization.** All organisms consist of one or more *cells*—complex, organized assemblages of molecules enclosed within membranes (figure 26.1).

**Sensitivity.** All organisms respond to stimuli—though not always to the same stimuli in the same ways.

**Growth.** All living things assimilate energy and use it to maintain internal order and grow, a process called **metabolism**. Plants, algae, and some bacteria use sunlight to create covalent carbon–carbon bonds from  $\text{CO}_2$  and  $\text{H}_2\text{O}$  through photosynthesis. This transfer of the energy in covalent bonds is essential to all life on Earth.

**Development.** Both unicellular and multicellular organisms undergo systematic, gene-directed changes as they grow and mature.

**Reproduction.** Organisms reproduce, passing on genes from one generation to the next.

**Regulation.** All organisms have regulatory mechanisms that coordinate internal processes.

**Homeostasis.** All living things maintain relatively constant internal conditions, different from their environment.

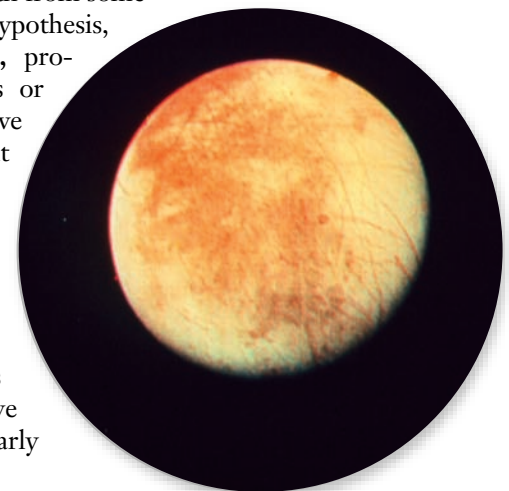

**Figure 26.1 Cellular compartmentalization.** These complex, single-celled organisms called Paramecia are classified as protists. The yeasts, stained red in this photograph, have been consumed and are enclosed within membrane-bounded sacs called digestive vacuoles.

**Heredity.** All organisms on Earth possess a *genetic system* that is based on the replication of a long, complex molecule called DNA. This mechanism allows for adaptation and evolution over time and is a distinguishing characteristic of living organisms.

Long before there were cells with the properties of life, organic (carbon-based) molecules formed from inorganic molecules. The formation of proteins, nucleic acids, carbohydrates, and lipids were essential, but not sufficient for life. The evolution of cells required early organic molecules to assemble into a functional, interdependent unit.

### Life may have had extraterrestrial origins

Life may not have originated on Earth at all; instead, life may have “infected” Earth from some other planet. This hypothesis, called **panspermia**, proposes that meteors or cosmic dust may have carried significant amounts of complex organic molecules to Earth, kicking off the evolution of life. Hundreds of thousands of meteorites and comets are known to have slammed into the early

**Figure 26.2** The Phoenix lander sent gigabytes of information and tens of thousands of images of Mars' surface back to Earth, providing clues about the possibility of ancient life on Mars.

Earth, and recent findings suggest that at least some may have carried organic materials. Nor is life on other planets ruled out. For example, the discovery of liquid water under the surfaces of Jupiter's ice-shrouded moon Europa and Saturn's moon, Enceladus, as well as suggestions of fossils in rocks from Mars lend some credence to this idea. Enceladus may harbor an ocean of liquid water, raising intriguing questions about whether it is habitable. Plumes of ice and vapor escape its gravitational field and contribute to the outermost ring around Saturn. In 2009, sodium salt was discovered in Saturn's ring that appears to originate from Enceladus. The Mars lander Phoenix confirmed the presence of frozen water on the planet in 2008 (figure 26.2). Analysis of soil samples from the same mission revealed an alkaline soil composed of sodium, magnesium, chloride, potassium, and other chemicals, but many questions remain about the watery environment that might have harbored life.

## Life may have originated on early Earth

### Conditions on early Earth

The more we learn about the Earth's early history, the more likely it seems that Earth's first organisms emerged and lived at very high temperatures. Rubble from the forming solar system slammed into the early Earth beginning about 4.6 BYA, keeping the surface molten hot. As the bombardment slowed down, temperatures dropped. By about 3.8 BYA, ocean temperatures are thought to have dropped to a hot 49° to 88°C (120° to 190°F). Between 3.8 and 3.5 BYA, life first appeared, promptly after the Earth was habitable. Thus, as intolerable as early Earth's infernal temperatures seem to us today, they gave birth to life.

Very few geochemists agree on the exact composition of the early atmosphere. One popular view is that it contained principally carbon dioxide (CO<sub>2</sub>) and nitrogen gas (N<sub>2</sub>), along with significant amounts of water vapor (H<sub>2</sub>O). It is possible that the early atmosphere also contained hydrogen gas (H<sub>2</sub>) and compounds in which hydrogen atoms were bonded to the other light elements (sulfur, nitrogen,

and carbon), producing hydrogen sulfide (H<sub>2</sub>S), ammonia (NH<sub>3</sub>), and methane (CH<sub>4</sub>).

We refer to such an atmosphere as a *reducing atmosphere* because of the ample availability of hydrogen atoms and their electrons. Because a reducing atmosphere would not require as much energy as it would today, it would have made it easier to form the carbon-rich molecules from which life evolved.

Exactly where on Earth life originated is also an open question. Possible locations include the ocean's edge, under frozen oceans, deep in the Earth's crust, within clay, or at deep-sea vents.

### Organic molecules on early Earth

An early attempt to determine what kinds of organic molecules might have been produced on the early Earth was carried out in 1953 by Stanley L. Miller and Harold C. Urey. In what has become a classic experiment, they attempted to reproduce the conditions in the Earth's primitive oceans under a reducing atmosphere. Even if this hypothesis proves incorrect—the jury is still out on this—their experiment is critically important because it ushered in the whole new field of prebiotic chemistry.

To carry out their experiment, Miller and Urey (1) assembled a reducing atmosphere rich in hydrogen and excluding gaseous oxygen; (2) placed this atmosphere over liquid water; (3) maintained this mixture at a temperature somewhat below 100°C; and (4) simulated lightning by bombarding it with energy in the form of sparks (figure 26.3).

They found that within a week, 15% of the carbon originally present as methane gas (CH<sub>4</sub>) had converted into other simple carbon compounds. Among these compounds were formaldehyde (CH<sub>2</sub>O) and hydrogen cyanide (HCN). These compounds then combined to form simple molecules, such as formic acid (HCOOH) and urea (NH<sub>2</sub>CONH<sub>2</sub>), and more complex molecules containing carbon-carbon bonds, including the amino acids glycine and alanine.

In similar experiments performed later by other scientists, more than 30 different carbon compounds were identified,

**Figure 26.3 The Miller–Urey experiment.** The apparatus consisted of a closed tube connecting two chambers. The upper chamber contained a mixture of gases thought to resemble the primitive Earth’s atmosphere. Electrodes discharged sparks through this mixture, simulating lightning. Condensers then cooled the gases, causing water droplets to form, which passed into the second heated chamber, the “ocean.” Any complex molecules formed in the atmosphere chamber would be dissolved in these droplets and carried to the ocean chamber, from which samples were withdrawn for analysis.

including the amino acids glycine, alanine, glutamic acid, valine, proline, and aspartic acid. As we saw in chapter 3, amino acids are the basic building blocks of proteins, and proteins are one of the major kinds of molecules of which organisms are composed. Other biologically important molecules were also formed in these experiments. For example, hydrogen cyanide contributed to the production of a complex ring-shaped molecule called adenine—one of the bases found in DNA and RNA. Thus, the key molecules of life could have formed in the reducing atmosphere of the early Earth.

## Cells evolved from the functional assembly of organic molecules

Organic molecules can convey information or provide energy to maintain life through metabolism. Although DNA is the hereditary information molecule, RNA can both act as an enzyme used in self-replication (a ribozyme) and may have been the first genetic material.

Many hypotheses for the emergence of metabolic pathways exist. One scenario assumes that primitive organisms were autotrophic, building all the complex organic molecules they require from simple inorganic compounds. For example, glucose may have been synthesized from formaldehyde,  $\text{CH}_2\text{O}$ , in the alkaline conditions that could have existed on early Earth. Glycolysis and a version of the Krebs cycle (see chapter 7) that functioned without enzymes are proposed to be the core from which other metabolic pathways emerged. Early autotrophs could have made, stored, and later used glucose as an energy source.

In addition to information and metabolism, cells require membranes. Constraining organic molecules to a physical space within a lipid or protein bubble could lead to an increased concentration of specific molecules. This in turn could increase the probability of metabolic reactions occurring. At some point, these bubbles became living cells with cell membranes and all the properties of life described earlier. As detailed in chapter 28, 3.5-billion-year-old prokaryotic fossils have been identified. For most of the history of life on Earth, these single-celled organisms were the only life forms. Several major evolutionary innovations—eukaryotic cells, sexual reproduction, and multicellularity—contributed to the diverse forms of life on Earth today (figure 26.4). We will continue with an overview of the amazing diversity of life on Earth and the evolutionary relationships among organisms.

### Learning Outcomes Review 26.1

Living organisms consist of one or more cells and are capable of sensing their environment, reproducing, developing, and maintaining their internal processes. Whether the organic molecules necessary for life formed on Earth or formed elsewhere and came to Earth within meteors remains an open question. Although conditions on early Earth cannot be completely reconstructed, it is likely that the temperatures were extreme and that the atmosphere had a very different gaseous composition than it does today.

- If you read a news headline claiming that life has been found on Mars, what type of evidence would you require to accept the claim?

**Figure 26.4** Geological timescale and the evolution of life on earth.

## 26.2 Classification of Organisms

### Learning Outcomes

1. Explain how taxonomists name and group organisms.
2. Evaluate the usefulness of taxonomic hierarchies in answering evolutionary questions.

People have known from the earliest times that differences exist between organisms. Early humans learned that some plants could be eaten, but others were poisonous. Some animals could be hunted or domesticated; others were dangerous hunters themselves. In this section, we review formal scientific classification.

### Taxonomy is a quest for identity and relationships

More than 2000 years ago, the Greek philosopher Aristotle formally categorized living things as either plants or animals. The Greeks and Romans expanded this simple system and grouped animals and plants into basic units such as cats, horses, and oaks. Eventually, these units began to be called genera (singular, *genus*), the Latin word for “groups.” Starting in the Middle Ages, these names began to be systematically written down in Latin, the language used by scholars at that time. Thus, cats were assigned to the genus *Felis*, horses to *Equus*, and oaks to *Quercus*.

### Linnaeus instituted the use of binomial names

Until the mid-1700s, whenever biologists wanted to refer to a particular kind of organism, which they called a species, they added a series of descriptive terms to the name of the genus; this was a polynomial, or “many names” system.

A much simpler system of naming organisms stemmed from the work of the Swedish biologist Carolus Linnaeus (1707–1778). In the 1750s, Linnaeus used the polynomial names *Apis pubescens, thorace subgriseo, abdomine fusco, pedibus posticis glabris utrinque margine ciliatis* to denote the European honeybee. But as a kind of shorthand, he also included a two-part name for the honeybee; he designated it *Apis mellifera*. These two-part names, or **binomials**, have become our standard way of designating species. You have already encountered many binomial names in earlier chapters.

**Taxonomy** is the science of classifying living things. A group of organisms at a particular level in a classification system is called a *taxon* (plural, *taxa*). By agreement among taxonomists throughout the world, no two organisms can have the same scientific name. The scientific name of an organism is the same anywhere in the world and avoids the confusion caused by common names (figure 26.5).

Also by agreement, the first word of the binomial name is the genus to which the organism belongs. This word is always capitalized. The second word refers to the particular species and is not capitalized. The two words together are called the species

**Figure 26.5** Common names make poor labels. In North America, the common names “bear” and “corn” bring clear images to our minds, but the images are very different for someone living in Europe or Australia.

name (or scientific name) and are written in italics—for example, *Homo sapiens*. Once a genus has been used in the body of a text, it is often abbreviated in later uses. For example, the dinosaur *Tyrannosaurus rex* becomes *T. rex*.

### Taxonomic hierarchies have limitations

Named species are organized into larger groups based on shared characteristics. As discussed in chapter 23, sound evolutionary hypotheses can be constructed when organisms are grouped based on derived characters, not ancestral characters. Early taxonomists were not aware that the distinction between derived and ancestral characters could make a difference; as a result, many hierarchies are now being re-examined. As the phylogenetic and systematic revolution continues, other limitations of the original levels of taxonomic organization, called the *Linnaean taxonomy*, are being revealed.

#### The Linnaean hierarchy

In the decades following Linnaeus, taxonomists began to group organisms into larger, more inclusive categories. Genera with similar characters were grouped into a cluster called a **family**, and similar families were placed into the same **order** (figure 26.6). Orders with common properties were placed into the same **class**, and classes with similar characteristics into the same **phylum** (plural, *phyla*). Finally, the phyla were assigned to one of several great groups, the **kingdoms**. These kingdoms include two kinds of prokaryotes (Archaea and Bacteria), a largely unicellular group of eukaryotes (Protista), and three multicellular groups (Fungi, Plantae, and Animalia). As you will see later in this chapter, the protists are not

**Figure 26.6** The hierarchical system used in classifying an organism. The organism, in this case the eastern gray squirrel, is first recognized as a eukaryote (domain Eukarya). Within this domain, it is an animal (kingdom Animalia). Among the different phyla of animals, it is a vertebrate (phylum Chordata, subphylum Vertebrata). The organism's fur characterizes it as a mammal (class Mammalia). Within this class, it is distinguished by its gnawing teeth (order Rodentia). Next, because it has four front toes and five back toes, it is a squirrel (family Sciuridae). Within this family, it is a tree squirrel (genus *Sciurus*), with gray fur and white-tipped hairs on the tail (species *Sciurus carolinensis*, the eastern gray squirrel).

a monophyletic group, and the term kingdom is a bit of a misnomer for protists.

In addition, an eighth level of classification, called a **domain**, is frequently used. Biologists recognize three domains, which will be discussed in section 26.3. The names of the taxonomic units from the genus level and higher are capitalized.

The categories at the different levels may include many, a few, or only one taxon. For example, there is only one living genus of the family Hominidae (namely *Homo*), but several living genera of Fagaceae (the birch family). To someone familiar with classification or having access to the appropriate reference books, each taxon implies both a set of characteristics and a group of organisms belonging to the taxon.

To return to the example of the European honeybee, we can analyze the bee's taxonomic classification as follows:

1. **Species level:** *Apis mellifera*, meaning honey-bearing bee.
2. **Genus level:** *Apis*, a genus of bees.
3. **Family level:** Apidae, a bee family. All members of this

family are bees—some solitary, some living in colonies as *A. mellifera* does.

4. **Order level:** Hymenoptera, a grouping that includes bees, wasps, ants, and sawflies—all of which have wings with membranes.
5. **Class level:** Insecta, a very large class that comprises animals with three major body segments, three pairs of legs attached to the middle segment, and wings.
6. **Phylum level:** Arthropoda. Animals in this phylum have a hard exoskeleton made of chitin and jointed appendages.
7. **Kingdom level:** Animalia. The animals are multicellular heterotrophs with cells that lack cell walls.

### Limitations of the hierarchy

In chapter 23, we discussed the modern phylogenetic approach, which distinguishes relationships between different species based on evolutionary history. Emerging phylogenies, frequently based on molecular data, reveal that the Linnaean hierarchy is inadequate for recognizing the hierarchical relationships among taxa that result naturally from a history of common ancestry and descent. New evolutionary hypotheses are developing.

One problem with the Linnaean system is that many higher taxonomic ranks are not monophyletic (for example, Reptilia) and therefore do not represent natural groups. A common ancestor and all of its descendants is a natural group that results from descent from a common ancestor, but any other type of group (paraphyletic or polyphyletic) is an artificial group created by taxonomists.

In addition, Linnaean ranks, as currently recognized, are not equivalent in any meaningful way. For example, two families may not represent clades that originated at the same time. One family may have diverged 70 million years before another family, and therefore these families have had vastly different amounts of time to diverge and develop evolutionary adaptations. Two groups that diverged from a common ancestor at the same time may be given different ranks. Thus, comparisons using Linnaean categories may be misleading. It is much better to use hypotheses of phylogenetic relationships in such instances.

One result of all these differences is that families demonstrate different degrees of biological diversity. Here's one example. It is difficult to say that the legume family with 16,000 species represents the same level of taxonomic organization as the cat family with only 36 species. The differences across a single rank, whether it is class, order, or family, limit the usefulness of taxonomic hierarchies in making evolutionary predictions.

### Learning Outcomes Review 26.2

By convention, a species is given a binomial name. The first part of the name identifies the genus, and the second part the individual species. The Linnaean taxonomic hierarchy groups species into genera, then families, orders, classes, phyla, and kingdoms. Traditional classification systems are based on similar traits, but because they include a mix of derived and ancestral traits, they do not necessarily take into account evolutionary relationships.

- **What can you infer about evolutionary relationships by comparing a taxonomic hierarchy for a squirrel and a fox (refer to figure 26.6)? What questions remain unanswered?**

## 26.3 Grouping Organisms

### Learning Outcomes

1. List examples showing that the three domains of life are monophyletic, but the six kingdoms are not.
2. Distinguish among the characteristics of Eukarya, Archaea, and Bacteria.
3. Explain why biologists do not include viruses in the tree of life.

In this section, we examine the largest groupings of organisms: kingdoms and domains. The earliest classification systems recognized only two kingdoms of living things: animals and plants. But as biologists discovered microorganisms and learned more about other multicellular organisms, they added kingdoms in recognition of certain fundamental differences. The six-kingdom system was first proposed by Carl Woese of the University of Illinois (figure 26.7b).

### The six kingdoms are not necessarily monophyletic

In the six-kingdom system, four of the kingdoms consist of eukaryotic organisms. The two most familiar kingdoms, *Animalia* and *Plantae*, contain only organisms that are multicellular during most of their life cycle. The kingdom *Fungi* contains multicellular forms and single-celled yeasts.

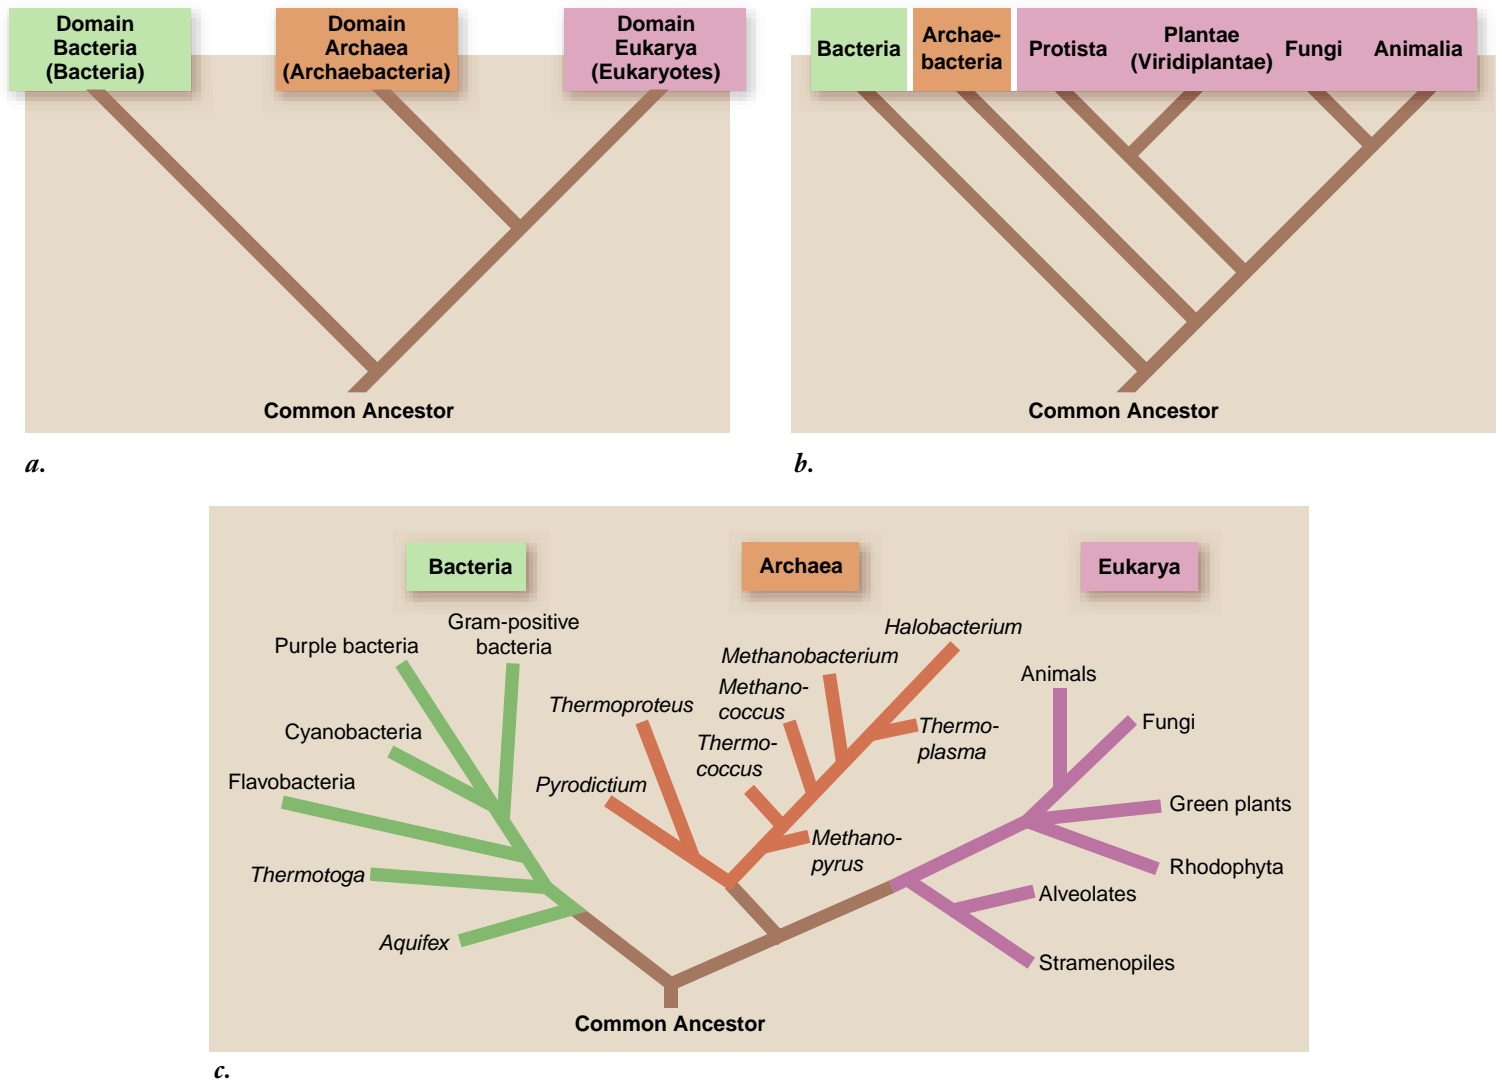

Fundamental differences divide these three kingdoms. Plants are mainly stationary, but some have motile sperm; most fungi lack motile cells; animals are mainly motile or mobile. Animals ingest their food, plants manufacture it, and fungi digest and absorb it by means of secreted extracellular enzymes.

The large number of eukaryotes that do not fit in any of the three eukaryotic kingdoms are arbitrarily grouped into a single kingdom called **Protista** (see chapter 29). Most protists are unicellular or, in the case of some algae, have a unicellular phase in their life cycle. This kingdom reflects the current controversy between taxonomic and phylogenetic approaches. The protists are a paraphyletic group, containing several nonmonophyletic adaptive lineages with distinct evolutionary origins.

The remaining two kingdoms, **Archaea** and **Bacteria**, consist of prokaryotic organisms, which are vastly different from all other living things (see chapter 28). Archaea are a diverse group that includes the methanogens and extreme thermophiles, and its members differ from the other prokaryotes—Bacteria.

### The three domains probably are monophyletic

As biologists have learned more about the Archaea, it has become increasingly clear that this group is very different from all other organisms. When the full genomic DNA sequences of an archaean and a bacterium were first compared in 1996,

**Figure 26.7** Different approaches to classifying living organisms. *a.* Bacteria and Archaea are so distinct that they have been assigned to separate domains distinct from the Eukarya. Members of the domain Bacteria are thought to have diverged early from the evolutionary line that gave rise to the archaea and eukaryotes. *b.* Eukarya are grouped into four kingdoms, but these, especially the protists, are not necessarily monophyletic groups. *c.* This phylogeny is prepared from rRNA analyses. The base of the tree was determined by examining genes that are duplicated in all three domains, the duplication presumably having occurred in the common ancestor. Archaea and eukaryotes diverged later than bacteria and are more closely related to each other than either is to bacteria. Bases of trees constructed with other traits are often less clear because of horizontal gene transfer (see chapter 24).

the differences proved striking. Archaea are as different from bacteria as bacteria are from eukaryotes.

Recognizing this, biologists are increasingly adopting a classification of living organisms that recognizes three **domains**, a taxonomic level higher than kingdom (figure 26.7*a*). Archaea are in one domain (**Domain Archaea**), bacteria in a second (**Domain Bacteria**), and eukaryotes in the third (**Domain Eukarya**). Phylogenetically each of these domains form a clade.

### Inquiry question

? Why would the Archaea be considered a clade?

In the remainder of this section, we preview the major characteristics of the three domains and viruses. Our current understanding of the “tree of life” is presented in figure 26.7*c*. The

oldest divergences represent the deepest rooted branches in the tree. The archaea and eukaryotes are more closely related to each other than to bacteria and are on a separate evolutionary branch of the tree.

### Bacteria are more numerous than any other organism

The bacteria are the most abundant organisms on Earth. There are more living bacteria in your mouth than there are mammals living on Earth.

Although too tiny to see with the unaided eye, bacteria play critical roles throughout the biosphere. Some extract from the air all the nitrogen used by organisms, and they play key roles in cycling carbon and sulfur. Much of the world’s

photosynthesis is carried out by bacteria. In contrast, certain bacteria are also responsible for many forms of disease. Understanding bacterial metabolism and genetics is a critical part of modern medicine.

Bacteria are highly diverse, and the evolutionary links among species are not well understood. Although taxonomists disagree about the details of bacterial classification, most recognize 12 to 15 major groups of bacteria. Comparisons of the nucleotide sequences of ribosomal RNA (rRNA) molecules are beginning to reveal how these groups are related to one another and to the other two domains.

## Archaea may live in extreme environments

The archaea seem to have diverged very early from the bacteria and are more closely related to eukaryotes than to bacteria (figure 26.7c). This conclusion comes largely from comparisons of genes that encode ribosomal RNAs.

### Horizontal gene transfer in microorganisms

Comparing whole-genome sequences from microorganisms has led evolutionary biologists to a variety of phylogenetic trees, some of which contradict each other. It appears that during their early evolution, microorganisms swapped genetic information via horizontal gene transfer (HGT), as you learned in chapter 24. The potential for gene transfer makes constructing phylogenetic trees for microorganisms very difficult.

Consider the archaean *Thermotoga*, a thermophile found on Vulcano Island off the coast of Italy. The sequence of one of its RNAs places it squarely within the bacteria near an ancient microbe called *Aquifex*. Recent DNA sequencing, however, fails to support any consistent relationship between the two microbes.

Over the next few years, we can expect to see considerable change in accepted viewpoints as more and more data are brought to bear.

### Archaeal characteristics

Although they are a diverse group, all archae share certain key characteristics (table 26.1). Their cell walls lack peptidoglycan (an important component of the cell walls of bacteria); the lipids in the cell membranes of archae have a different structure from those in all other organisms; and archae have distinctive ribosomal RNA sequences. Some of their genes possess introns, unlike those of bacteria. Both archae and eukaryotes lack the peptidoglycan cell wall found in bacteria.

The archae are grouped into three general categories—methanogens, extremophiles, and nonextreme archae—based primarily on the environments in which they live or on their specialized metabolic pathways. The word *extreme* refers to our current environment. When archae first appeared on the scene their now extreme habitats may have been typical.

**Methanogens** obtain their energy by using hydrogen gas ( $H_2$ ) to reduce carbon dioxide ( $CO_2$ ) to methane gas ( $CH_4$ ). They are strict anaerobes, poisoned by even traces of oxygen. They live in swamps, marshes, and the intestines of mammals. Methanogens release about 2 billion tons of methane gas into the atmosphere each year.

TABLE 26.1	Features of the Domains of Life		
	D O M A I N		
Feature	Archaea	Bacteria	Eukarya
Amino acid that initiates protein synthesis	Methionine	Formyl-methionine	Methionine
Introns	Present in some genes	Absent	Present
Membrane-bounded organelles	Absent	Absent	Present
Membrane lipid structure	Branched	Unbranched	Unbranched
Nuclear envelope	Absent	Absent	Present
Number of different RNA polymerases	Several	One	Several
Peptidoglycan in cell wall	Absent	Present	Absent
Response to the antibiotics streptomycin and chloramphenicol	Growth not inhibited	Growth inhibited	Growth not inhibited

**Extremophiles** are able to grow under conditions that seem extreme to us. There are several types of extremophiles:

- Thermophiles, which live in temperatures ranging from 60° to 80°C. Many of these are autotrophs with a sulfur-based metabolism.
- Cold-adapted, which live in glacier ice and alpine lakes.
- Halophiles, which live in very salty environments including the Great Salt Lake and the Dead Sea. These organisms require water with a salinity of 15 to 20%.
- pH-tolerant archaea, growing in highly acidic (pH = 0.7) or highly basic (pH = 11) environments.
- Pressure-tolerant archaea found in the ocean depths. These archaeans require at least 300 atmospheres (atm) of pressure to survive and tolerate up to 800 atm. To experience a pressure of 300 atm (300 times the pressure of our atmosphere) you would need to dive 3000 m below the surface of the ocean (not a good idea unless you were in a deep-sea submersible). The deepest recorded skin dive is 127 m and a 145-m record is reported for SCUBA diving.

**Nonextreme archaea** grow in the same environments bacteria do. As the genomes of archaea have become better known, microbiologists have been able to identify signature sequences of DNA present only in archaea. The newly discovered microbe *Nanoarchaeum equitens* was identified as an archaean based on a signature sequence. This odd Icelandic microbe may have the smallest known genome, only 500 bp.

## Eukaryotes have compartmentalized cells

For at least 1 billion years, prokaryotes ruled the Earth. No other types of organisms existed to eat them or compete with them, and their tiny cells formed the world's oldest fossils. Members of the third great domain of life, the eukaryotes, appear in the fossil record much later, only about 2.5 BYA. But despite the metabolic similarity of eukaryotic cells to prokaryotic cells, their structure and function enabled these cells to be larger, and eventually, allowed multicellular life to evolve.

### Endosymbiosis and the origin of eukaryotes

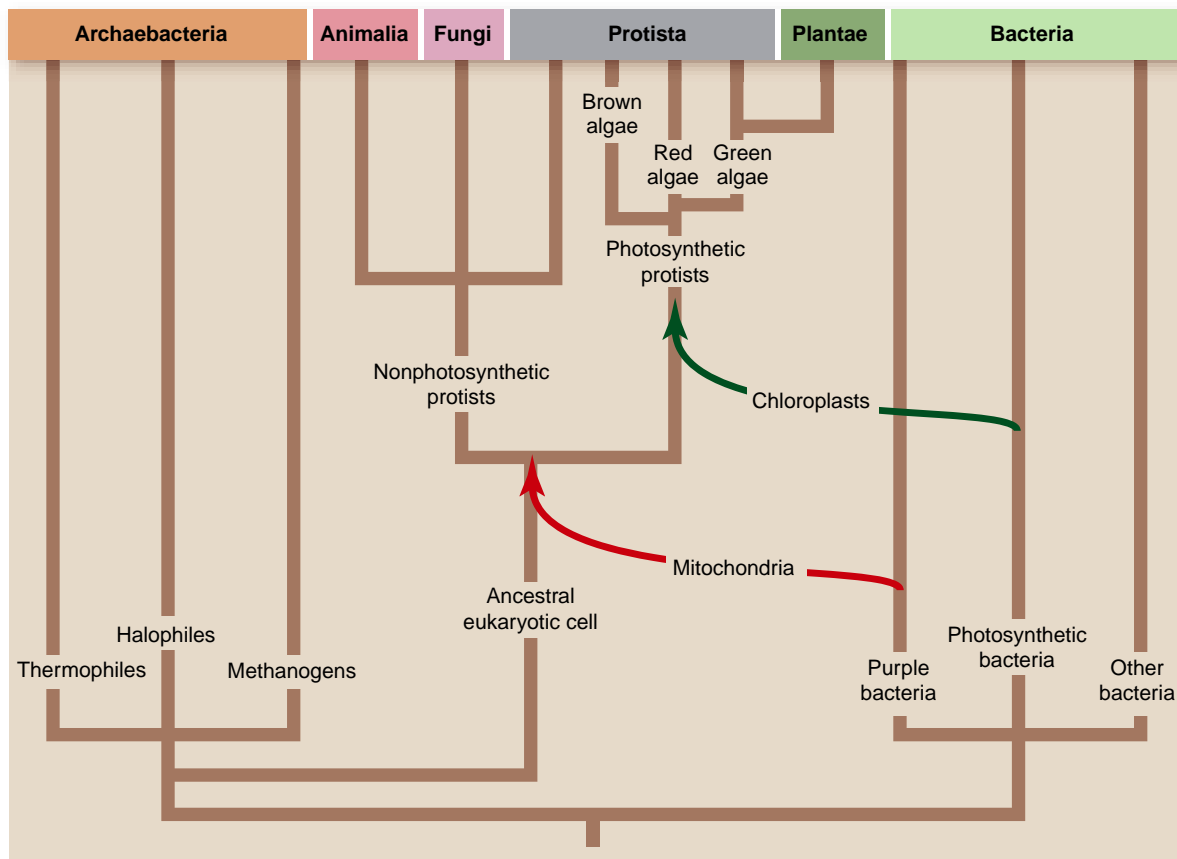

The hallmark of eukaryotes is complex cellular organization, highlighted by an extensive endomembrane system that subdivides the eukaryotic cell into functional compartments (chapter 4). Not all cellular compartments, however, are derived from the endomembrane system.

With few exceptions, modern eukaryotic cells possess the energy-producing organelles termed *mitochondria*, and photosynthetic eukaryotic cells possess *chloroplasts*, the energy-harvesting organelles. Mitochondria and chloroplasts are both believed to have entered early eukaryotic cells by a process called **endosymbiosis**, which is discussed in more detail in chapter 29 (figure 26.8).

Mitochondria are the descendants of relatives of purple sulfur bacteria and the parasitic *Rickettsia* that were incorporated into eukaryotic cells early in the history of the group. Chloroplasts are derived from cyanobacteria (figure 26.9). As shown in figures 26.8 and 26.9, the red and green algae

**Figure 26.8 All chloroplasts are monophyletic.** The same cyanobacteria were engulfed by multiple hosts that were ancestral to the red and green algae. Brown algae share the same ancestral chloroplast DNA, but most likely gained it by engulfing red algae.

**Figure 26.9 Hypothesis for evolutionary relationships among the six kingdoms of organisms.** The colored lines indicate symbiotic events.

acquired their chloroplasts by directly engulfing a cyanobacterium. The brown algae most likely engulfed red algae to obtain chloroplasts.

### The four kingdoms of eukaryotes

The first eukaryotes were unicellular organisms. A wide variety of unicellular eukaryotes exist today, grouped together in the kingdom Protista (along with some multicellular descendants) on the basis that they do not fit into any of the other three kingdoms of eukaryotes. Fungi, plants, and animals are largely multicellular kingdoms, each a distinct evolutionary line from a single-celled ancestor that would be classified in the kingdom Protista.

Because of the size and ecological dominance of plants, animals, and fungi, and because they are predominantly multicellular,

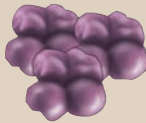

we recognize them as kingdoms distinct from Protista, even though the amount of diversity among the protists is much greater than that within or between the fungi, plants, and animals.

### Key characteristics of the eukaryotes

The characteristics of the six kingdoms are outlined in table 26.2; note that the archaea and bacteria are grouped in the same column. Although eukaryotic organisms are extraordinarily diverse, they share three characteristics that distinguish them from prokaryotes: compartmentalization; multicellularity in many, but not all, eukaryotes; and sexual reproduction.

**Compartmentalization.** Discrete compartments provide evolutionary opportunities for increased specialization

**TABLE 26.2** Characteristics of the Six Kingdoms and Three Domains

	 <b>Archaea and Bacteria</b>	 <b>Protista</b>	 <b>Plantae</b>	 <b>Fungi</b>	 <b>Animalia</b>
<b>Cell Type</b>	Prokaryotic	Eukaryotic	Eukaryotic	Eukaryotic	Eukaryotic
<b>Nuclear Envelope</b>	Absent	Present	Present	Present	Present
<b>Transcription and Translation</b>	Occur in same compartment	Occur in different compartments	Occur in different compartments	Occur in different compartments	Occur in different compartments
<b>Histone Proteins Associated with DNA</b>	Absent	Present	Present	Present	Present
<b>Cytoskeleton</b>	Absent	Present	Present	Present	Present
<b>Mitochondria</b>	Absent	Present (or absent)	Present	Present	Present
<b>Chloroplasts</b>	None (photosynthetic membranes in some types)	Present (some forms)	Present	Absent	Absent
<b>Cell Wall</b>	Noncellulose (polysaccharide plus amino acids)	Present in some forms, various types	Cellulose and other polysaccharides	Chitin and other noncellulose polysaccharides	Absent
<b>Means of Genetic Recombination, if Present</b>	Conjugation, transduction, transformation	Fertilization and meiosis	Fertilization and meiosis	Fertilization and meiosis	Fertilization and meiosis
<b>Mode of Nutrition</b>	Autotrophic (chemosynthetic, photosynthetic) or heterotrophic	Photosynthetic or heterotrophic, or combination of both	Photosynthetic, chlorophylls <i>a</i> and <i>b</i>	Absorption	Ingestion
<b>Motility</b>	Bacterial flagella, gliding or nonmotile	9 + 2 cilia and flagella; amoeboid, contractile fibrils	None in most forms; 9 + 2 cilia and flagella in gametes of some forms	Both motile and nonmotile	9 + 2 cilia and flagella, contractile fibrils
<b>Multicellularity</b>	Absent	Absent in most forms	Present in all forms	Present in most forms	Present in all forms
<b>Nervous System</b>	None	Primitive mechanisms for conducting stimuli in some forms	A few have primitive mechanisms for conducting stimuli	None	Present (except sponges), often complex

within the cell, as we see with chloroplasts and mitochondria. The evolution of a nuclear membrane, not found in prokaryotes, also accounts for increased complexity in eukaryotes. In eukaryotes, RNA transcripts from nuclear DNA are processed and transported across the nuclear membrane into the cytosol, where translation occurs. The physical separation of transcription and translation in eukaryotes adds additional levels of control to the process of gene expression.

**Multicellularity.** The unicellular body plan has been tremendously successful, with unicellular prokaryotes and eukaryotes constituting about half of the biomass on Earth. But a single cell has limits. The evolution of multicellularity allowed organisms to deal with their environments in novel ways through differentiation of cell types into tissues and organs.

True multicellularity, in which the activities of individual cells are coordinated and the cells themselves are in contact, occurs only in eukaryotes and is one of their major characteristics. Bacteria and many protists form colonial aggregates of many cells, but the cells in the aggregates have little differentiation or integration of function.

Other protists—the red, brown, and green algae, for example—have independently attained multicellularity. One lineage of multicellular green algae was the ancestor of the plants (see chapters 29 and 30), and most taxonomists now place its members in the green plant kingdom, the *Viridiplantae*.

The multiple origins of multicellularity are also seen in the fungi and the animals, which arose from unicellular protist ancestors with different characteristics. As you will see in subsequent chapters, the groups that seem to have given rise to each of these kingdoms are still in existence.

**Sexual Reproduction.** Another major characteristic of eukaryotic species as a group is sexual reproduction. Although some interchange of genetic material occurs in bacteria, it is certainly not a regular, predictable mechanism in the same sense that sex is in eukaryotes. Sexual reproduction allows greater genetic diversity through the processes of meiosis and crossing over, as you learned in chapter 13.

In many of the unicellular phyla of protists, sexual reproduction occurs only occasionally. The first eukaryotes were probably haploid; diploids seem to have arisen on a number of separate occasions by the fusion of haploid cells, which then eventually divided by mitosis.

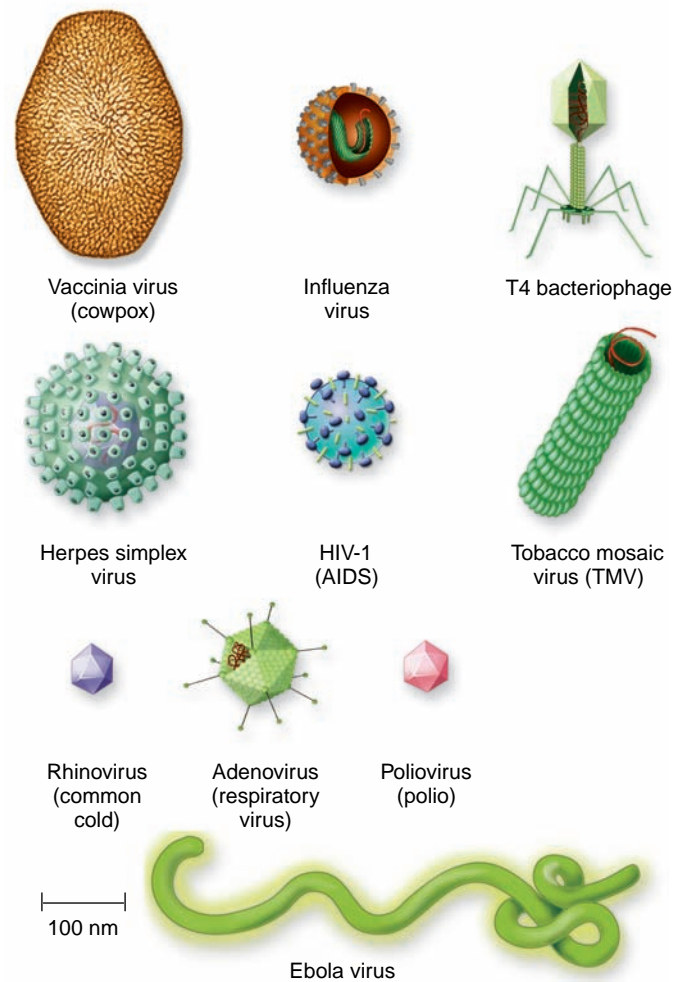

## Viruses are a special case

Viruses possess only a portion of the properties of organisms. Viruses are literally “parasitic” macromolecules, segments of DNA or RNA wrapped in a protein coat. They cannot reproduce on their own, and for this reason they are not considered alive by biologists. They can, however, reproduce within cells, often with disastrous results to the host.

Viruses are currently viewed as detached fragments of the genomes of organisms because of the high degree of similarity found in some viral and eukaryotic genes. Viruses thus present a special classification problem. Because they are not organisms, we cannot logically place them in any of the kingdoms.

Viruses vary greatly in appearance and size. The smallest are only about 17 nanometers (nm) in diameter, and the largest are up to 1000 nm (1 micrometer;  $\mu\text{m}$ ) in their greatest dimension, barely visible with a light microscope (figure 26.10). Viral morphology is best revealed using the electron microscope.

Biologists first began to suspect the existence of viruses near the end of the 19th century. European scientists were attempting to isolate the infectious agent responsible for hoof-and-mouth disease in cattle, and they concluded that it was smaller than a bacterium. The true nature of viruses was discovered in 1933, when biologist Wendell Stanley prepared an extract of the tobacco mosaic virus (TMV) and attempted to purify it. To his great surprise, the purified TMV preparation precipitated in the form of crystals—the virus was acting like a chemical off the shelf rather than like an organism. Stanley

**Figure 26.10 Viral diversity.** Viruses exhibit extensive diversity in shape and size. At the scale these sample viruses are shown, a human hair would be nearly 8 m thick.

concluded that TMV is best regarded as just that—chemical matter rather than a living organism.

Within a few years, scientists disassembled the TMV virus and found that Stanley was right. TMV was not cellular but chemical. Each particle of TMV virus is in fact a mixture of two chemicals: RNA and protein. The TMV virus consists of a tube made of protein with an RNA core. If these two components are separated and then reassembled, the re-constructed TMV particles are fully able to infect healthy tobacco plants.

Because eukaryote diversity is so vast, we next take a brief look at the three kingdoms of the eukaryote domain.

### Learning Outcomes Review 26.3

The six kingdoms are not necessarily based on common lineage; Kingdom Protista, for example, is not a monophyletic group. The three domains, however, do appear to be monophyletic. Bacteria and archaea are tiny but numerous unicellular organisms that lack internal compartmentalization. Eukaryotic cells are highly compartmentalized, and they have acquired mitochondria and chloroplasts by endosymbiosis. Viruses are not organisms classified in the kingdoms of life, but instead are chemical assemblies that can infect cells and replicate within them.

- **What would be the outcome if a virus infected a cell and became a permanent resident in the cell's genome?**

## 26.4 Making Sense of the Protists

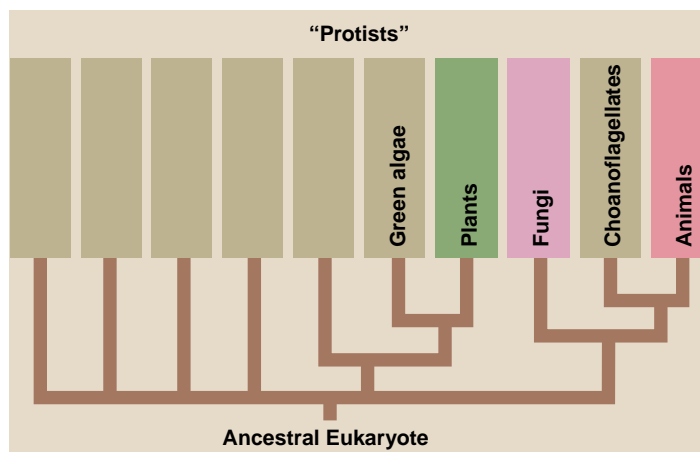

### Learning Outcome

1. Describe the relationships among groups of protists.

In reading this chapter and chapter 23, you may have sensed some tension between traditional classification systems and systems based on evolutionary relationships, such as cladistics and phylogenetic analysis. The kingdom Protista illustrates well the source of this tension. This kingdom is the weakest area of the six-kingdom classification system shown in figure 26.7.

Eukaryotes diverged rapidly in a world that was shifting from anaerobic to aerobic conditions. We may never be able to completely sort out the relationships among different lineages during this major evolutionary transition. Molecular systematics, however, clearly shows that the protists are a paraphyletic group (figure 26.11). Although biologists continue to use the term *protist* as a catchall for any eukaryote that is not a plant, fungus, or animal, this grouping is not based on evolutionary relationships.

The six main branchings of protists, shown at the base of figure 26.11, represent a current working hypothesis, although at least 60 lineages do not seem to fit in any of the six groups. Choanoflagellates are most closely related to sponges, and indeed, to all animals. The green algae can be split into two

**Figure 26.11 The fall of kingdom Protista.** Systematists have shown that protists as a group are not monophyletic. Note how some lineages are actually more closely related to plants or animals than they are to other protists.

monophyletic groups, one of which gave rise to land plants. Many systematists are calling for a new kingdom called Viridiplantae, or the green plant kingdom, which would include all the green algae (not red or brown algae) and the land plants. Thus, the definition of a plant has been expanded beyond those species that made it onto land. Although the kingdom Protista is in ruins, our understanding of the evolutionary relationships among these early eukaryotes is growing exponentially.

### Learning Outcome Review 26.4

Relationships among organisms in Kingdom Protista, a paraphyletic group, are being clarified by modern methods. Choanoflagellates are most closely related to animals, and green algae may belong in a new kingdom that would include plants. Systematics and cladistics continue to add to our knowledge of these relationships.

- **How might life have evolved if photosynthesis had not produced atmospheric oxygen?**

## 26.5 Origin of Plants

### Learning Outcomes

1. Describe the evolutionary relationship between algae and plants.
2. Explain how moss genes have come to be found in the genome of a flowering plant.

The origin of land plants from a green algal ancestor has long been recognized as a major evolutionary event. Molecular phylogenetics reveals that land plants arose from an ancestral green alga, and that the evolution of land plants occurred only once, an indication of the incredible challenges involved in the move onto land.

## Molecular phylogenetics has identified the closest living relatives of land plants

The phylogenetic relationships among the algae and the first land plants have been fuzzy and subject to long debate. Cell biology, biochemistry, and molecular systematics have provided surprising new evolutionary hypotheses.

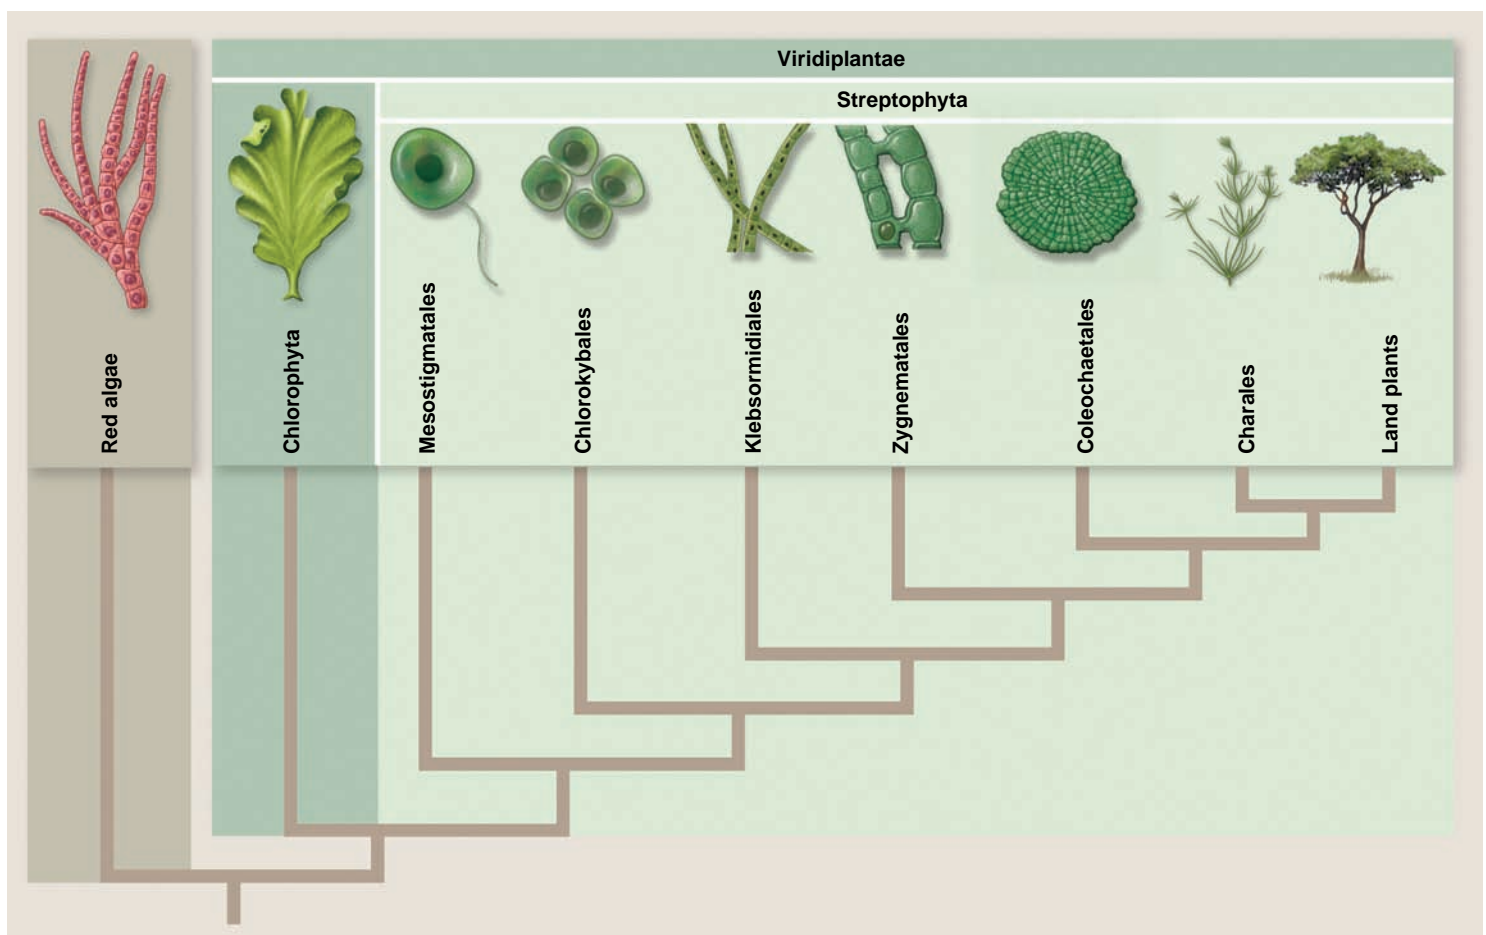

The green algae consist of two monophyletic groups, the *Chlorophyta* and the *Streptophyta* (chapter 30). Land plants are actually members of the Streptophyta, not a separate kingdom. This new phylogenetic information demoted the land plants from constituting a kingdom to being a branch within the algal group Streptophyta. The Streptophyta along with the sister green algal clade, Chlorophyta, are now considered by most to make up the kingdom Viridiplantae. The current phylogeny is shown in figure 26.12.

What was the earliest streptophyte? Conflicting answers have been obtained with different phylogenetic analyses, but growing evidence supports the hypothesis that the scaly, unicellular flagellate *Mesostigma* (order Mesostigmatales) represents the earliest streptophyte branch.

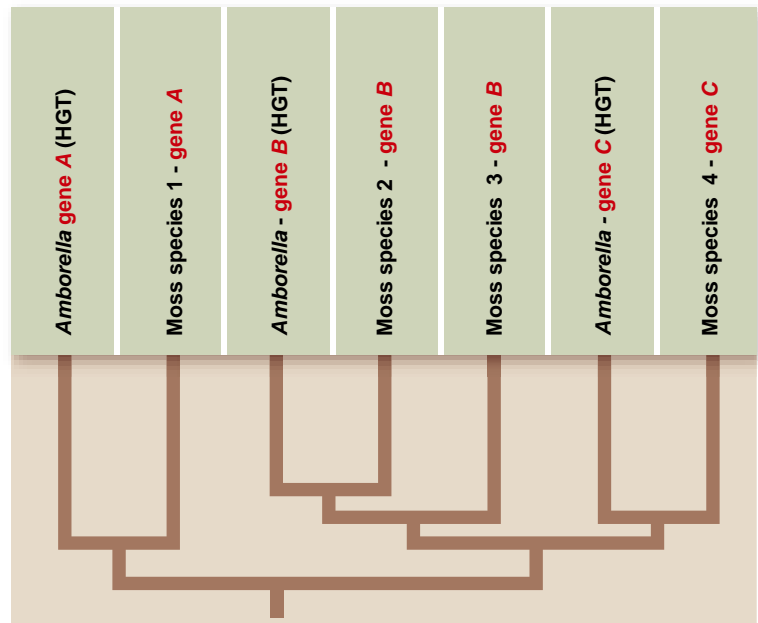

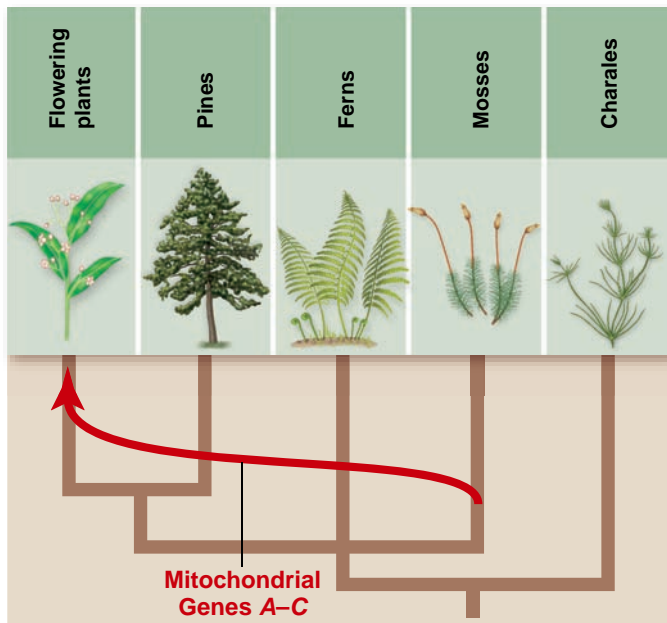

Which of the Streptophyta clades contains the closest living relative of land plants? The two contenders have been the Charales, with about 300 species, and the Coleochaetales, with about 30 species. Both lineages are freshwater algae, but the Charales are huge compared with the microscopic Coleochaetales. At the moment, the Charales appear to be the sister clade to land plants, with the Coleochaetales the next closest relatives. Charales fossils dating back 420 MYA indicate that the common ancestor of land plants was a relatively complex freshwater alga.

## Horizontal gene transfer occurred in land plants

The shrub *Amborella trichopoda* is the closest living relative to the earliest flowering plants (angiosperms). Its clade is a sister clade to all other flowering plants, yet at least one copy of 20 out of 31 of its known mitochondrial protein genes hopped into the mitochondrial genome from other land plants through horizontal gene transfer (HGT). In addition, three different moss species contributed to the mix (figure 26.13).

**Figure 26.12 A new hypothesis for land plant evolution.** Kingdom Plantae (land plants) has been reduced to a clade within the green algal branch Streptophyta, and a new kingdom, Viridiplantae, which includes the green algal branches Chlorophyta and Streptophyta, has been proposed. Within the Streptophyta, the relatively complex Charales are believed to be the sister clade to the land plants. Contrast this phylogeny with the one predicted by the six-kingdom system in figure 26.7b.

**Figure 26.13** The flowering plant *Amborella* acquired three moss genes through horizontal gene transfer. *a.* Phylogenetic relationship of *Amborella* to other land plants. As shown by the arrow connecting moss and the flowering plants, HGT is the only plausible explanation for the presence of moss mitochondrial genes in *Amborella*. *b.* Phylogenetic relationships among the horizontally transferred gene.

### Inquiry question

? Explain why a phylogenetic tree based on comparisons of a single gene could result in an inaccurate evolutionary hypothesis.

*Amborella* is not typical of most extant flowering plants. It is the only existing member of its genus and is native only to the tropical rain forests of New Caledonia, an island group east of Australia that has been isolated for some 70 million years and contains many ancient endemic species. Here parasitic plants called *epiphytes* (plants that derive nutrients from other plants) are common. Close contact with parasitic plants could increase the probability of HGT (figure 26.14).

An open question is whether the moss genes in *Amborella* have functions. About half the genes are intact and could be transcribed and translated into a protein. The protein would be similar to an existing protein in the plant, but its function, if any, remains to be determined.

**Figure 26.14** Close contact between species can lead to HGT. Here moss are growing on the base of an *Amborella* leaf with lichens scattered on the rest of the leaf.

### Inquiry question

? How would you determine if a moss gene in *Amborella* had a function? (Hint: Refer to chapter 25.)

### Learning Outcomes Review 26.5

Land plants are now thought to be most closely related to the Streptophyta group of green algae. The Charales appear to be the sister clade to land plants. Not all plant evolution is vertical, however; horizontal gene transfer has apparently mixed genes from distantly related species.

- How could genes from moss be transported into a flowering plant, other than via parasitic plants?

## 26.6 Sorting Out the Animals

### Learning Outcomes

1. Describe current ideas regarding the origin of segmentation in animals.
2. Explain why insects are termed “flying crustaceans.”
3. State the evidence for a common ancestor between whales and hippos.

Molecular systematics is leading to a revision of our understanding of evolutionary history in all kingdoms, including the

animals. Some phylogenies are changing, and others, including mammalian phylogenies, are actually being written for the first time. In this section, we explore three examples: the relationship between annelids and arthropods, relationships within the arthropods, and the discovery of phylogenetic relationships among mammals.

## The origins of segmentation are puzzling

The arthropod phylum is a group of over one million described invertebrates that includes the insects and crustaceans; the annelid phylum, another invertebrate group, contains the segmented worms such as the earthworm. Morphological traits such as segmentation have been used in the past to group arthropods and annelids close together, but comparisons of

rRNA sequences are raising questions about their relationship. As rRNA sequences are obtained, it is becoming increasingly clear that annelids and arthropods are more distantly related than taxonomists previously believed.

### Evolutionary occurrences of segmentation

Distinctions can be made among eukaryote animals on the basis of timing of embryonic development of the mouth and anus. Annelids and arthropods belong to the **protostome** group, in which the mouth develops before the anus. Chordates, including humans, fall into the **deuterostome** group, in which the anus forms first. (You will learn more about these divisions in chapter 33.)

With the addition of newly available molecular traits, annelids and arthropods fell into two distinct protostome branches (figure 26.15): **lophotrochozoans** and **ecdysozoans**.

## SCIENTIFIC THINKING

**Hypothesis:** Origins of segmentation can be explained by the duplication of a Hox gene that regulates segmentation.

**Prediction:** Duplication of Hox genes will correlate with changes in segmentation patterns.

**Test:**

1. Using primers for the Hox gene of interest and polymerase chain reaction (PCR), amplify the Hox gene of interest. Duplicated genes have nearly identical sequences and will be amplified with the same primer sets.

2. Sequence the PCR products and group them based on sequence similarity.

3. Map the gene duplication findings on a phylogeny based on ribosomal RNA.

**Result:** Four independent Hox gene duplication events were identified.

**Conclusion:** Three independent Hox gene duplication events correspond with the origins of segmentation.

**Further Research:** Explore where the duplicated Hox genes are expressed using *in situ* hybridization (refer to figure 19.13).

**Figure 26.15** Multiple origins of segmentation.

These two branches have been evolving independently since ancient times. Lophotrochozoans include flatworms, mollusks, and annelids. Two ecdysozoan phyla have been particularly successful: roundworms (nematodes) and arthropods.

In the new protostome phylogeny, annelids and arthropods do not constitute a monophyletic group, as they had in the past. The implication is that segmentation arose twice, not once, in the protostomes, as had been believed originally. Segmentation then arose independently once again in the deuterostomes, specifically in the chordates.

### Molecular details of segmentation

The most likely explanation for the independent appearance of segmentation is that members of the same family of genes were co-opted at least three times. Segmentation is regulated by the *Hox* gene family that contains a homeodomain region (see chapter 19). The *Hox* ancestral genes predate the ecdysozoans and lophotrochozoans. The ancient ancestor of the lophotrochozoans, ecdysozoans, and deuterostomes most likely already had seven *Hox* genes. Some of these genes appear to have evolved a role in segmentation (see figure 26.15).

### Insects and crustaceans are sister groups

Arthropods are the most diverse of all the animal phyla, composed of 80% of all described animal species. Within the arthropods, insects have traditionally been set apart from the crustaceans (such as shrimp, crabs, and lobsters), and grouped instead with the myriapods (centipedes and millipedes).

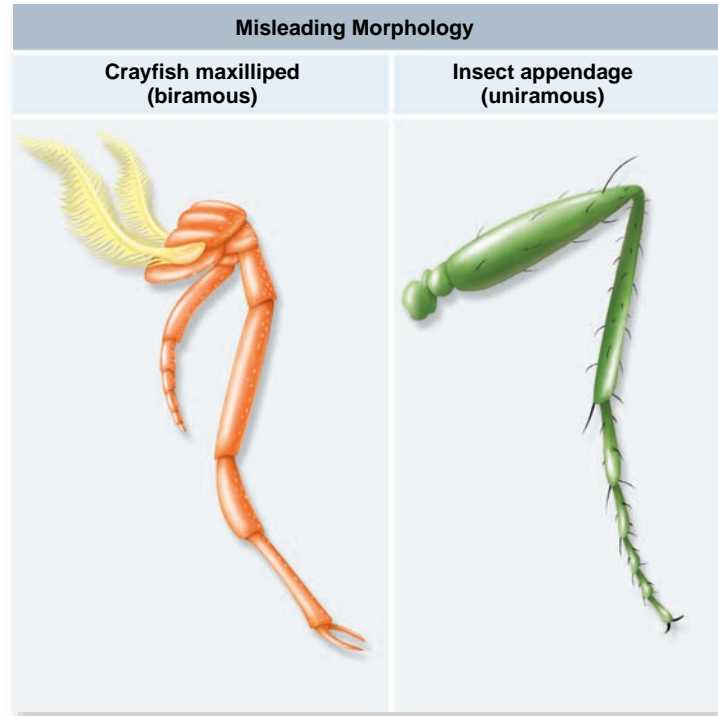

This phylogeny, still widely employed, dates back to benchmark work by Robert Snodgrass in the 1930s. He pointed out that insects, centipedes, and millipedes are united by several seemingly powerful attributes, including **uniramous** (single-branched) appendages. All crustacean appendages, by contrast, are basically **biramous**, or “two-branched” (figure 26.16), although some of these appendages have become single-branched by reduction in the course of their evolution.

Taxonomists have traditionally assumed a character such as two-branched appendages to be a fundamental one, conserved over the course of evolution, and thus suitable for making taxonomic distinctions. As molecular methods have been developed, however, this assumption has become questionable.

### Hox genes and appendages

The patterning of appendages among arthropods is orchestrated by *Hox* genes. A single one of these *Hox* genes, called *Distal-less*, has been shown to initiate development of unbranched limbs in insects and branched limbs in crustaceans. The same *Distal-less* gene is found in many animal phyla, including the vertebrates.

*Distal-less* appears to be necessary to initiate limb development, and it turns on genes that are more directly involved in the development of the limb itself. Evolutionary changes in the genes that *Distal-less* acts on most likely account for differences in limb morphology.

**Figure 26.16** Branched and single appendages.

Development of a biramous leg in a crustacean (crayfish) and a uniramous leg in an insect are both initiated by the *Distal-less* gene even though their adult morphologies are distinct.

### A change in taxonomic relationship?

In recent years, a mass of accumulating morphological and molecular data has led many taxonomists to suggest new arthropod phylogenies. Hexapods (insects) with their six legs and terrestrial habitat are the closest relatives of crustaceans, not the myriapods. Hexapods and crustaceans form a clade called pancrustacea. But, hexapods likely are not monophyletic, indicating that crustacean ancestors moved onto land multiple times. The relationships among the pancrustacea suggest that hexapods are “flying crustaceans.”

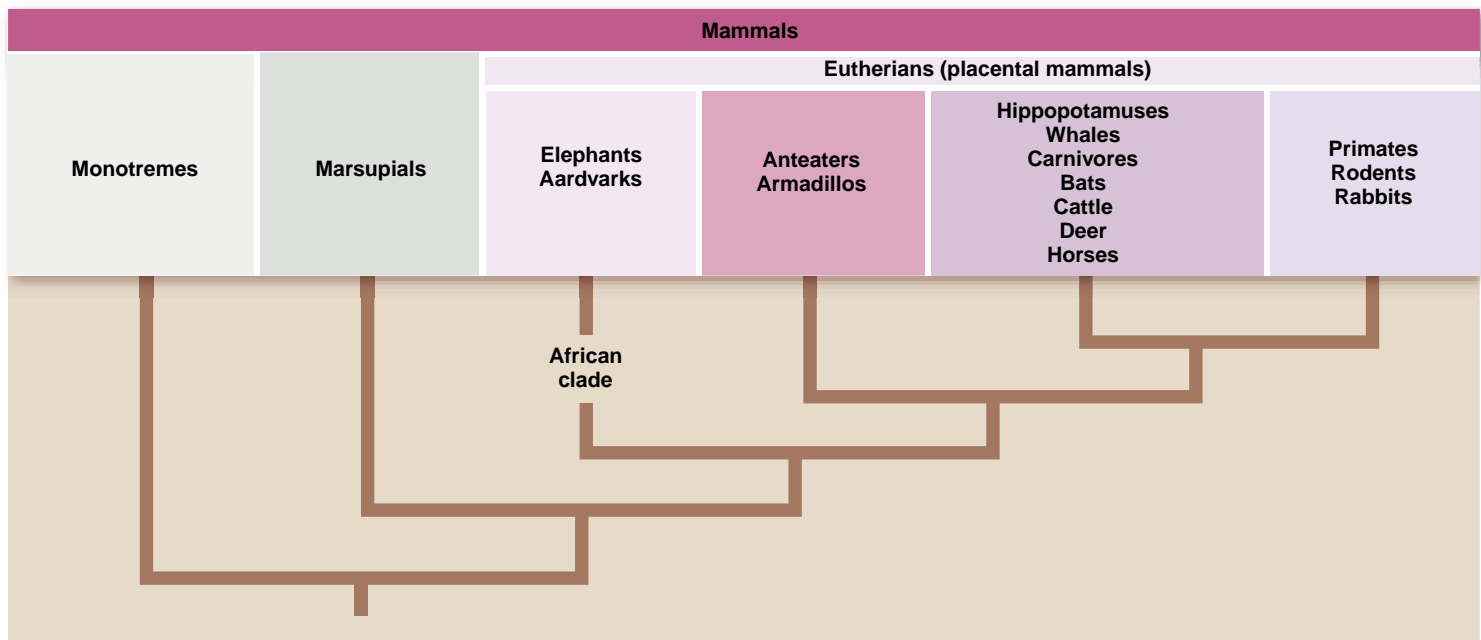

These conclusions engender lively discussion since they are in conflict with 150 years of morphology-based phylogenetic inference.

### The mammalian family tree is emerging

In the preceding arthropod examples, our interpretation of evolutionary history has been rewritten. In mammals, however, parts of the phylogeny are just emerging, based on molecular data.

### The four groups of placental mammals

Among the vertebrate classes, mammals are unique because they have mammary glands to feed their young. The majority of mammals—over 90%—are **eutherians**, or **placental mammals** (see chapter 36). There are at least 18 extant orders of eutherians, which are now divided into four major groups (figure 26.17).

**Figure 26.17** Major groups of mammals.

The first major split occurred between the African clade and the other placental mammals when South America and Africa separated about 100 MYA. Aardvarks and elephants are part of this African lineage, called the Afrotheria, a clade we did not even recognize a decade ago. In South America, anteaters and armadillos soon appeared. Then two other branches arose—one includes ungulates with an even number of toes (camels, llamas, and other artiodactyls), odd-toed ungulates (perissodactyls such as horses and rhinoceros), and carnivores, and the other, primates and rodents. Sorting out the relationships within these branches is an ongoing challenge.

### Whales and hippos

The origin and relationships of whales has been debated for over 200 years. Whales were initially thought to be relatives of pigs based on morphological information from fossils and extant animals, primarily the bones of the skull and shape of the teeth.

DNA sequence data, however, revealed a particularly close relationship between whales and hippopotamuses, suggesting that whales were derived from within the group Artiodactyla. Whales and hippopotamuses appear to be much more closely related than, for example, hippopotamuses and cows. With this new phylogenetic information, the possibility arises that some adaptations to aquatic environments in both species had a common origin. Recent finds of fossil whales with hind limbs have confirmed the artiodactyl origin of whales. Prior to these recent discoveries, no fossil whales with hind limbs had been found, so the key character

uniting whales and artiodactyls, the shape of a bone in the ankle, was not known. A careful analysis of 80 traits in fossil whales and hippos indicated a common, water-loving ancestor existed 50 to 60 MYA belonging to the anthracotheres. The anthracotheres split into two groups. One moved back to an aquatic environment. The other gave rise to at least 37 genera that left a single descendent, the hippopotamus. In this case, molecular data provided insight into whale origins that was later confirmed by fossil evidence.

Understanding evolutionary relationships among organisms does more than provide biologists with a sense of order and a logical way to name organisms. A phylogenetically based taxonomy allows researchers to ask important questions about physiology, behavior, and development using information already known about a related species. This information not only enriches our understanding of how biological complexity evolved, but also provides novel insights that lead to progress in our understanding of the history and origins of important features and functions.

### Learning Outcomes Review 26.6

Molecular systematics has provided new insight into evolutionary relationships of animals. Segmentation likely arose more than once; hexapods are more closely related to crustaceans than to myriapods; and relationships among mammalian groups are still being revised based on molecular data and new fossil finds.

- Why might the most closely related living organisms have very different appearances?

## Chapter Review

### 26.1 Origins of Life

#### *All organisms share fundamental properties of life.*

Common properties of living things include cellular organization, sensitivity, growth and development, reproduction, regulation and homeostasis, and heredity.

#### *Life may have had extraterrestrial origins.*

The panspermia hypothesis proposes that the organic molecules of life came to Earth inside meteorites.

#### *Life may have originated on early Earth.*

Conditions on the early Earth were very different, with a reducing atmosphere that may have led to formation of carbon-rich, organic molecules.

#### *Cells evolved from the functional assembly of organic molecules.*

Complex molecules may have coalesced inside a space surrounded by a lipid or protein “bubble,” a precursor of a cell membrane. Here, reactions could proceed more rapidly.

### 26.2 Classification of Organisms

#### *Taxonomy is a quest for identity and relationships.*

Taxonomy is the science of assigning organisms to a particular level of classification called a taxon. Taxonomic hierarchies are organized by domain, kingdom, phylum, class, order, family, genus, and species (see figure 26.6).

#### *Linnaeus instituted the use of binomial names.*

Carolus Linnaeus devised a system of giving individual species unique names, beginning with the capitalized genus, followed by a species name. These are italicized.

#### *Taxonomic hierarchies have limitations.*

Traditional classifications are limited because they are based on similar traits and do not take into account evolutionary relationships.

### 26.3 Grouping Organisms

#### *The six kingdoms are not necessarily monophyletic.*

The six kingdoms proposed by Woese are not necessarily monophyletic. In particular, Protista is paraphyletic (see figures 26.7 and 26.9).

#### *The three domains probably are monophyletic.*

Domain Eukarya contains the kingdoms Protista, Plantae, Fungi, and Animalia; the other two domains, Bacteria and Archaea, each contain only prokaryotes.

#### *Bacteria are more numerous than any other organism.*

Bacteria are the most abundant and diverse organisms on Earth; they consist of 12 to 15 major groups but their evolutionary links are unclear.

#### *Archaea may live in extreme environments.*

Archaea are prokaryotes that are more closely related to eukaryotes than to bacteria. They are grouped into methanogens, extremophiles, and nonextreme archaea.

#### *Eukaryotes have compartmentalized cells.*

Eukaryote cells have compartmentalized organelles and other structures. Eukaryotes acquired mitochondria and chloroplasts by endosymbiosis (see figure 26.8). Many eukaryotes are multicellular, and most undergo sexual reproduction.

#### *Viruses are a special case.*

Viruses are diverse chemical assemblies that cannot reproduce on their own (see figure 26.10).

### 26.4 Making Sense of the Protists

Protists are divided into six groups, but at least 60 known protists do not fit into any of these groups (see figure 26.11).

A new kingdom, Viridiplantae, has been suggested to include green algae and all aquatic and land plants.

### 26.5 Origin of Plants

#### *Molecular phylogenetics has identified the closest living relatives of land plants (see figure 26.12).*

Green algae consist of two monophyletic groups: Chlorophyta and Streptophyta. The latter group gave rise to land plants.

#### *Horizontal gene transfer occurred in land plants.*

Some land plants show evidence of horizontal gene transfer, such as between the flowering plant *Amborella* and mosses (see figure 26.13).

### 26.6 Sorting Out the Animals

#### *The origins of segmentation are puzzling.*

Phylogeny based on rRNA shows that segmentation in arthropods, annelids, and chordates arose independently at least three times. Evidence points to duplications in *Hox* genes that regulate segmentation as the cause (see figure 26.15).

#### *Insects and crustaceans are sister groups.*

Although previously based on appendages, classification of arthropods has now placed hexapods (insects) as close relatives of crustaceans based on molecular and genetic data.

#### *The mammalian family tree is emerging.*

Mammalian phylogeny continues to be refined as molecular data becomes available. Whales, for example, are most closely related to hippopotamuses, sharing a water-loving common ancestor.

## Review Questions

### UNDERSTAND

- The Miller–Urey experiment demonstrated that
  - life originated on Earth.
  - organic molecules could have originated in the early atmosphere.
  - the early genetic material on the planet was DNA.
  - the early atmosphere contained large amounts of oxygen.
- Which of the following properties of life would have to be significantly different for an organism that evolved on a planet located far from its sun?
  - Homeostasis
  - Reproduction
  - Growth
  - Sensitivity
- Analyze a key limitation of the Linnaean system of classification.
- Identify which of the following would not belong to the domain Eukarya.
  - Photosynthetic plants
  - Multicellular fungi
  - Thermophilic archaea
  - Multicellular animals
- Explain which of the kingdoms presented the greatest challenge to the acceptance of a six-kingdom system.
- Identify which of the following statements is false and correct the statement.
  - Brown and red algae are not closely related phylogenetically.
  - Chloroplasts in brown and red algae are monophyletic.
  - Brown algae gained chloroplasts by engulfing green algae (endosymbiosis).
  - None of the above statements are false.
- Which of the following events occurred first in eukaryotic evolution?
  - Endosymbiosis and mitochondria evolution
  - Endosymbiosis and chloroplast evolution
  - Compartmentalization and formation of the nucleus
  - Formation of multicellular organisms
- Given your understanding of phylogenetics, where would you place viruses in the tree of life?
  - Archaea
  - Fungi
  - Bacteria
  - None of the above

### APPLY

- As a researcher you discover a new species that is eukaryotic, motile, possesses a cell wall made of chitin, but lacks any evidence of a nervous system. Choose the kingdom of life that best aligns with this new species.
- Kingdom Plantae is being replaced by a new kingdom named Viridiplantae. Choose the evidence that justifies this change.
  - Molecular phylogenetics
  - Newly discovered fossils
  - Biochemical differences
  - All of the above
- Based on information in this chapter, choose which areas of research in plant biology have the greatest potential to increase our understanding of land plant evolution.
  - Photosynthetic pigments
  - Chloroplast endosymbiosis
  - Horizontal gene transfer
  - Changes in cell wall composition

### SYNTHESIZE

- The conditions on Mars, Jupiter's moon Europa, and Saturn's moon Titan mimic those that are believed to have occurred on the early Earth. Yet, these places are also different from our early planet. For example, both Europa and Titan are located far from the Sun. Suppose that someday in the future scientists discover bacteria on these moons that are very similar biochemically to the early bacteria on Earth. Explain how this information would support the theory of panspermia. What if the life was biochemically different?
- Construct a phylogeny that includes arthropods, hexapods, crustaceans, echinoderms, nematodes, mollusks, and annelids based on evidence in this chapter.
- You are part of a research team that has recently discovered evidence of a single-celled prokaryotic organism on Mars. As you begin your study of the organism, you wish to use a species from Earth as a comparison. Propose which domain of life you should obtain your reference species from and defend your choice.
- In the past, classification has relied primarily on the evolution of morphological characteristics. Modern approaches are relying more heavily on molecular analysis. Defend the claim that molecular approaches are very important in developing evolutionary hypotheses.

# Viruses

## Chapter Outline

---

- 27.1 The Nature of Viruses
- 27.2 Bacteriophage: Bacterial Viruses
- 27.3 Human Immunodeficiency Virus (HIV)
- 27.4 Other Viral Diseases
- 27.5 Prions and Viroids: Subviral Particles

## Introduction

---

We begin our exploration of the diversity of life with viruses. Viruses are genetic elements enclosed in protein; they are not considered organisms since they lack many of the features associated with life, including cellular structure, and independent metabolism or replication. For this reason viral particles are not called viral cells, but virions, and they are generally not described as living or dead but as active or inactive. Because of their disease-producing potential, however, viruses are important biological entities. The virus particles pictured here are responsible for causing influenza—flu for short. In the flu season of 1918 to 1919, an influenza pandemic killed approximately 20 to 50 million people worldwide, twice as many as were killed in combat during World War I. Other viruses cause such diseases as AIDS, SARS, and hemorrhagic fever, and some cause certain forms of cancer.

For more than four decades, viral studies have been thoroughly intertwined with those of genetics and molecular biology. Classic studies using viruses that infect bacteria (known as bacteriophage) have led to the discovery of restriction enzymes and the identification of nucleic acid, not protein, as the hereditary material. Currently, viruses are one of the principal tools used to experimentally carry genes from one organism to another. Applications of this technology could include treating genetic illnesses and fighting cancer.

## 27.1 The Nature of Viruses

### Learning Outcomes

1. Describe the different structures found in viruses.
2. Understand the basic mechanism of viral replication.

All viruses have the same basic structure—a core of nucleic acid surrounded by protein. This structure lacks cytoplasm, and it is not a cell. Individual viruses contain only a single type of nucleic acid, either DNA or RNA. The DNA or RNA genome may be linear or circular; single-stranded or double-stranded.

RNA viruses may be segmented, with multiple RNA molecules within a virion, or nonsegmented, with a single RNA molecule. Viruses are classified, in part, by the nature of their genomes: RNA viruses, DNA viruses, or retroviruses.

### Viruses are strands of nucleic acids encased in a protein coat

Nearly all viruses form a protein sheath, or **capsid**, around their nucleic acid core (figure 27.1). The capsid is composed of one to a few different protein molecules repeated many times. The repeating units are called capsomeres.

In several viruses, specialized enzymes are stored with the nucleic acid, inside the capsid. One example is reverse transcriptase, which is required for retroviruses to complete their cycle and is not found in the host. This enzyme is needed early in the infection process and is carried within each virion.

Many animal viruses have an *envelope* around the capsid that is rich in proteins, lipids, and glycoprotein molecules. The lipids

found in the envelope are derived from the host cell; however, the proteins found in a viral envelope are generally virally encoded.

### Viral hosts include virtually every kind of organism

Viruses occur as obligate intracellular parasites in every kind of organism that has been investigated for their presence. Viruses infect fungal cells, bacterial cells, and protists as well as cells of plants and animals; however, each type of virus can replicate in only a very limited number of cell types. A virus that infects bacteria would be ill-equipped to infect a human or plant cell.

The suitable cells for a particular virus are collectively referred to as its **host range**. Once inside a multicellular host, many viruses also exhibit **tissue tropism**, targeting only a specific set of cells. For example, rabies virus grows within neurons, and hepatitis virus replicates within liver cells. Once inside a host cell, some viruses, such as the highly dangerous Ebola virus, wreak havoc on the cells they infect; others produce little or no damage. Still other viruses remain dormant until a specific signal or event triggers their expression.

As one example, a person can get chicken pox as a child, recover, and develop the disease shingles decades later. Both chicken pox and shingles are caused by the same virus, varicella zoster. This virus can remain dormant, or *latent*, for years. Stresses to the immune system may trigger an outbreak of shingles in people who have had chicken pox in the past. This is caused by the same virus, but the infection may be called herpes zoster because the virus is actually a herpes virus.

Any given organism may often be susceptible to more than one kind of virus. This observation suggests that many more kinds of viruses may exist than there are kinds of organisms—perhaps trillions of different viruses. Only a few thousand viruses have been described at this point.

**Figure 27.1 Structure of virions.** Viruses are characterized as helical, icosahedral, binal, or polymorphic, depending on their symmetry. *a.* The capsid may have helical symmetry such as the tobacco mosaic virus (TMV). TMV infects plants and consists of 2130 identical protein molecules (*green*) that form a cylindrical coat around the single strand of RNA (*red*). *b.* The capsid of icosahedral viruses has 20 facets made of equilateral triangles. These viruses can come in many different sizes all based on the same basic shape. *c.* Bacteriophage come in a variety of shapes, but binal symmetry is exclusively seen in phages such as the T4 phage of *E. coli*. This form of symmetry is characterized by an icosahedral head, which contains the viral genome, and a helical tail. *d.* Viruses can also have an envelope surrounding the capsid such as the influenza virus. This gives the virus a polymorphic shape. This virus has eight RNA segments, each within a helical capsid.

## Viruses replicate by taking over host machinery

An infecting virus can be thought of as a set of instructions, not unlike a computer program. A cell is normally directed by chromosomal DNA-encoded instructions, just as a computer's operation is controlled by the instructions in its operating system. A virus is simply a set of instructions, the viral genome, that can trick the cell's replication and metabolic enzymes into making copies of the virus. Computer viruses get their name because they perform similar actions, taking over a computer and directing its activities. Like a computer with a virus, a cell with a virus is often damaged by infection.

Viruses can reproduce only when they enter cells. When they are outside of a cell, viral particles are called *virions* and are metabolically inert. Viruses lack ribosomes and the enzymes necessary for protein synthesis and most, if not all of the enzymes for nucleic acid replication. Inside cells, the virus hijacks the transcription and translation systems to produce viral proteins from *early genes*, which are the genes in the viral genome expressed first. This is followed by the expression of *middle genes* and eventually *late genes*. This cascade of gene expression leads to replication of viral nucleic acid and production of viral capsid proteins. The late genes generally code for proteins important in assembly and release of viral particles from a host cell.

## Most viruses come in two simple shapes

Most viruses have an overall structure that is either *helical* or *icosahedral*. Helical viruses, such as the tobacco mosaic virus in figure 27.1*a*, have a rodlike or threadlike appearance. Icosahedral viruses have a soccer ball shape, the geometry of which is revealed only under the highest magnification with an electron microscope.

The **icosahedron** is a structure with 20 equilateral triangular facets. Most animal viruses are icosahedral in basic struc-

**Figure 27.2 Icosahedral virion.** The poliovirus has icosahedral symmetry. The capsid is formed from multiple copies of four different proteins shown in different colors. (One protein is internal and cannot be seen.)

ture (figure 27.1*b*). The icosahedron is the basic design of the geodesic dome, and it is the most efficient symmetrical arrangement that subunits can take to form a shell with maximum internal capacity (figure 27.2).

Some viruses, such as the T-even bacteriophage shown in figure 27.3, are complex. Complex viruses have a *binial*, or

*a.*

*b.*

## Figure 27.3

### A bacterial virus.

Bacteriophage exhibit a complex structure.

*a.* Electron micrograph and *(b)* diagram of the structure of a T4 bacteriophage (some facets removed to reveal the interior).

**Figure 27.4** Viruses vary in size and shape. Note the dramatic differences in the size of a eukaryotic yeast cell, prokaryotic bacterial cells, and the many different viruses.

two-fold, symmetry that is not either purely icosahedral or helical. The T-even phage shown has a head structure that is an elongated icosahedron. A collar connects the head to a hollow tube with helical symmetry that ends in a complex baseplate with tail fibers. Although animal viruses do not have this binomial symmetry, some, such as the poxviruses, do have a complex multilayered capsid structure. Some enveloped viruses, such as influenza, are *polymorphic*, having no distinctive symmetry.

Viruses also vary greatly in size. As shown in figure 27.4, the very smallest viruses, such as the poliovirus, have actually been synthesized in a lab using nothing more than sequence data and a machine capable of synthesizing nucleic acids from nucleotides. The larger viruses, such as the poxviruses, generally carry more genes, have more complex structures, and tend to have a very short cycle time between entry of viral particles and release of newly formed virions.

### Viral genomes exhibit great variation

Viral genomes vary greatly in both type of nucleic acid and number of strands (table 27.1). Some viruses, including those that cause flu, measles, and AIDS, possess RNA genomes. Most RNA viruses are single-stranded and are replicated and assembled in the cytosol of infected eukaryotic cells. RNA virus replication is error-prone, leading to high rates of mutation. This makes them difficult targets for the host immune system, vaccines, and antiviral drugs.

In single-stranded RNA viruses, if the genome has the same base sequence as the mRNA used to produce viral proteins, then the genomic RNA can serve as the mRNA. Such viruses are called *positive-strand viruses*. In contrast, if the genome is complementary to the viral mRNA, then the virus is called a *negative-strand virus*.

A special class of RNA viruses, called *retroviruses*, have an RNA genome that is reverse-transcribed into DNA by the enzyme *reverse transcriptase*. The DNA fragments produced by reverse transcription are often integrated into a host's chromosomal DNA. *Human immunodeficiency virus (HIV)*, the agent that causes *acquired immune deficiency syndrome (AIDS)*, is a retrovirus. (We describe HIV in detail later on.)

Other viruses, such as the viruses causing smallpox and herpes, have DNA genomes. Most DNA viruses are double-stranded, and their DNA is replicated in the nucleus of eukaryotic host cells.

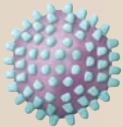

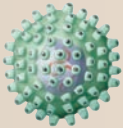

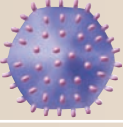

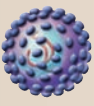

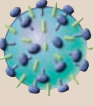

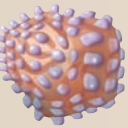

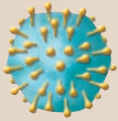

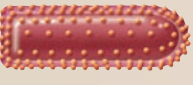

### Learning Outcomes Review 27.1

Viruses have a very simple structure that includes a nucleic acid genome encased in a protein coat. Viruses replicate by taking over a host's cell systems and are thus obligate intracellular parasites. Viruses show diverse genomes that are composed of DNA or RNA, which may be single- or double-stranded; most DNA viruses are double-stranded.

- Why can't viruses replicate outside of a cell?

**TABLE 27.1** Important Human Viral Diseases

Disease	Pathogen	Genome	Vector/Epidemiology
Chicken pox	Varicella-zoster virus 	Double-stranded DNA	Spread through contact with infected individuals. No cure. Rarely fatal. Vaccine approved in U.S. in early 1995. May exhibit latency leading to shingles.
Hepatitis B (viral)	Hepadnavirus 	Double-stranded DNA	Highly infectious through contact with infected body fluids. Approximately 1% of U.S. population infected. Vaccine available. No cure. Can be fatal.
Herpes	Herpes simplex virus 	Double-stranded DNA	Blisters; spread primarily through skin-to-skin contact with cold sores/blisters. Very prevalent worldwide. No cure. Exhibits latency—the disease can be dormant for several years.
Mononucleosis	Epstein–Barr virus 	Double-stranded DNA	Spread through contact with infected saliva. May last several weeks; common in young adults. No cure. Rarely fatal.
Smallpox	Variola virus 	Double-stranded DNA	Historically a major killer; the last recorded case of smallpox was in 1977. A worldwide vaccination campaign wiped out the disease completely.
AIDS	HIV 	(+) Single-stranded RNA (two copies)	Destroys immune defenses, resulting in death by opportunistic infection or cancer. For the year 2007, WHO estimated that 33.2 million people are living with AIDS, with an estimated 4.1 million new HIV infections and an estimated 2.8 million deaths.
Polio	Enterovirus 	(+) Single-stranded RNA	Acute viral infection of the CNS that can lead to paralysis and is often fatal. Prior to the development of Salk's vaccine in 1954, 60,000 people a year contracted the disease in the U.S. alone.
Yellow fever	Flavivirus 	(+) Single-stranded RNA	Spread from individual to individual by mosquito bites; a notable cause of death during the construction of the Panama Canal. If untreated, this disease has a peak mortality rate of 60%.
Ebola	Filoviruses 	(–) Single-stranded RNA	Acute hemorrhagic fever; virus attacks connective tissue, leading to massive hemorrhaging and death. Peak mortality is 50–90% if untreated. Outbreaks confined to local regions of central Africa.
Influenza	Influenza viruses 	(–) Single-stranded RNA (eight segments)	Historically a major killer (20–50 million died during 18 months in 1918–1919); wild Asian ducks, chickens, and pigs are major reservoirs. The ducks are not affected by the flu virus, which shuffles its antigen genes while multiplying within them, leading to new flu strains. Vaccines are available.
Measles	Paramyxoviruses 	(–) Single-stranded RNA	Extremely contagious through contact with infected individuals. Vaccine available. Usually contracted in childhood, when it is not serious; more dangerous to adults.
SARS	Coronavirus 	(–) Single-stranded RNA	Acute respiratory infection; an emerging disease, can be fatal, especially in the elderly. Commonly infected animals include bats, foxes, skunks, and raccoons. Domestic animals can be infected.
Rabies	Rhabdovirus 	(–) Single-stranded RNA	An acute viral encephalomyelitis transmitted by the bite of an infected animal. Fatal if untreated. Commonly infected animals include bats, foxes, skunks, and raccoons. Domestic animals can be infected.

## 27.2 Bacteriophage: Bacterial Viruses

### Learning Outcomes

1. Distinguish between lytic and lysogenic cycles in bacteriophage.
2. Describe how viruses can contribute DNA to their hosts.

Bacteriophage (both singular and plural) are viruses that infect bacteria. They are diverse, both structurally and functionally, and are united solely by their occurrence in bacterial hosts. Many of these types of bacteriophage, called *phage* for short, are large and complex, with relatively large amounts of DNA and proteins.

*E. coli*-infecting viruses were among the first bacteriophage to be discovered and are still some of the best studied. Some of these viruses that infect *E. coli* have been named as members of a “T” series (T1, T2, and so forth); others have been given different types of names. To illustrate the diversity of these viruses, T3 and T7 phage are icosahedral and have short tails. In contrast, the so-called T-even phage (T2, T4, and T6) have an icosahedral head, a capsid that consists primarily of three proteins, a connecting neck with a collar and long “whiskers,” a long tail, and a complex base plate (see figure 27.3).

### Archaeal viruses have diverse morphologies

Archaeal viruses were initially thought to be similar to bacterial viruses, but recent evidence argues against this. Surveys of viruses in several extreme environments dominated by archaeal species have uncovered an unexpected diversity of viral forms. In addition to the viral types described in the previous section, viruses with a two-tailed structure, with a bottle-shaped structure, and with a spindle-shaped structure have all been observed. All of these viruses have double-stranded DNA genomes, and most appear to be unrelated to any bacteriophage. The characterization of these viruses is in the early stages, so we will not discuss them further.

### Bacterial viruses exhibit two reproductive cycles

During the process of bacterial infection by phage T4, at least one of the tail fibers of the phage—they are normally held near the phage head by the “whiskers”—contacts proteins of the host bacterial cell wall. The other tail fibers set the phage perpendicular to the surface of the bacterium and bring the base plate into contact with the cell surface.

#### Contact with the host

Different phages may target different parts of the outer surface of a bacterial cell. This first step is called *attachment*, or *adsorption*. The next step, release of the phage genome into the host, is best understood in the binal phage, such as T4. Once contact is established, the tail contracts, and the tail tube passes through an opening that appears in the base plate, piercing the bacterial cell wall. The contents of the head, the DNA genome, are then injected into the host cytoplasm. This step is called *penetration*, or *injection*.

Once inside the bacterial cell a phage may immediately take over the cell’s replication and protein synthesis enzymes to synthesize viral components. This is the *synthesis* phase. Once the components are made, they are assembled (**assembly**) and mature virus particles are *released*, either through the action of enzymes that lyse the host cell or by budding through the host cell wall.

The time between adsorption and the formation of new viral particles is called an *eclipse period* because if a cell is lysed at this point, few if any active virions can be released.

#### The lytic cycle

When a virus lyses the infected host cell in which it is replicating, the reproductive cycle is referred to as a **lytic cycle** (figure 27.5, *left*). The basic steps of a lytic bacteriophage cycle are similar to those of a nonenveloped animal virus. The T-series bacteriophage are all **virulent**, or **lytic, phage**, multiplying within infected cells and eventually lysing (rupturing) them.

#### The lysogenic cycle

In contrast to the rather simple lytic cycles, some bacteriophage do not immediately kill the cells they infect, instead they integrate their nucleic acid into the genome of the infected host cell. This integration gives them a distinct advantage; integration allows a virus to be replicated along with the host cell’s DNA as the host divides. These viruses are called **temperate**, or **lysogenic, phage**. The DNA segment that is integrated into a host cell’s genome is called a *prophage*, and the resulting cell is called a *lysogen*.

Among the bacteriophage that do this is the binal phage lambda ( $\lambda$ ) of *E. coli*. Lambda may be the best studied biological particle; the complete sequence of its 48,502 bases has been determined. At least 23 proteins are associated with the development and maturation of phage  $\lambda$ , and other enzymes are involved in integrating this virus into the host genome.

When phage  $\lambda$  infects a cell, the early events constitute a genetic switch that will determine whether the virus will replicate and destroy the cell or become a lysogen and be passively replicated with the cell’s genome. This lysis/lysogeny “decision” depends on the expression of early genes. Early on, two regulatory proteins are produced that will compete for binding to sites on the phage’s DNA. Depending on which protein “wins” either the genes necessary for replication of the genome will be expressed beginning the lytic cycle, or the enzymes necessary for integrating the viral genome into the chromosome will be expressed and the **lysogenic cycle** initiated (figure 27.5, *right*).

A lysogenic phage has the expression of its genome repressed (see chapter 16) by one of the two viral regulatory proteins mentioned earlier. This is not a permanent state, however; in times of cell stress, the prophage can be derepressed, and the enzymes necessary for excision of the genome expressed. The viral genome then is in the same state as the initial stage of infection, and the lytic cycle can commence, leading to formation of viral particles and lysis of the cell.

The switch from a lysogenic prophage to a lytic cycle is called **induction** because it requires turning on the gene expression necessary for the lytic cycle. It can be stimulated in

**Figure 27.5 Lytic and lysogenic cycles of a bacteriophage.** In the lytic cycle the viral DNA directs the production of new viral particles by the host cell until the virus kills the cell by lysis. In the lysogenic cycle, the bacteriophage DNA is integrated into the host chromosome. This prophage is replicated along with the host DNA as the bacterium divides. It may persist as a prophage, or enter the lytic cycle and kill the cell. Bacteriophage not drawn to scale in this diagram.

the laboratory by stressors such as starvation or ultraviolet radiation. The molecular events of induction take advantage of host proteins that respond to stress to produce a protease that can destroy the repressor protein that is keeping the viral genome silent. The normal function of this protease is to degrade a host repressor that controls DNA repair genes. The two repressor proteins are similar enough that both are degraded by the protease.

## Bacteriophage can contribute genes to the host genome

During the integrated portion of a lysogenic reproductive cycle, a few viral genes may be expressed at the same time as host cell genes. Sometimes the expression of these genes has an important effect on the host cell, altering it in novel ways. When the phenotype or characteristics of the lysogenic bacterium is altered by the prophage, the alteration is called **phage conversion**.

### Phage conversion of the cholera-causing bacterium

The bacterium *Vibrio cholerae* usually exists in a harmless form, but a second, disease-causing form also occurs. In this latter

form, the bacterium is responsible for the deadly disease cholera, but how the bacteria changed from harmless to deadly was not known until recently.

Research now shows that a lysogenic bacteriophage that infects *V. cholerae* introduces into the host bacterial cell a gene that codes for the cholera toxin. This gene, along with the rest of the phage genome, becomes incorporated into the bacterial chromosome. The toxin gene is expressed along with the other host genes, thereby converting the benign bacterium to a disease-causing agent.

The receptors used by this toxin-encoding phage are pili (hairlike projections) found on the outer surface of *V. cholerae* (chapter 28); in recent experiments, it was determined that mutant bacteria that did not have pili were resistant to infection by the bacteriophage. This discovery has important implications in efforts to develop vaccines against cholera, which have been unsuccessful up to this point. Phage conversion could change any pili-expressing, nontoxicogenic *V. cholerae* into a toxin-producing, potentially deadly form.

Another example involved in human disease is the toxin found in *Corynebacterium diphtheriae*. This toxin is the product of phage conversion, as are the changes to the outer surface of certain infectious *Salmonella* species.

## Learning Outcomes Review 27.2

Bacteriophage are viruses that infect bacteria. They have two major types of life cycle: the lytic cycle that results in immediate death of the host, and the lysogenic cycle in which the virus becomes part of the host genome. This viral genome is then transmitted vertically by cell division. Under certain conditions the lysogenic phage can switch to the lytic cycle. Lysogenic phage contribute genes to the host, as is the case with *V. cholera*. The toxin responsible for the disease cholera came from a phage.

- What would be the result of a mutation in the  $\lambda$  repressor gene that resulted in a protein resistant to host protease?

## 27.3 Human Immunodeficiency Virus (HIV)

### Learning Outcomes

1. Explain how the HIV virus compromises the immune system.
2. Describe the disease AIDS.
3. Illustrate the different therapeutic options for AIDS.

A diverse array of viruses occurs among animals. A good way to gain a general idea of the characteristics of these viruses is to look at one animal virus in detail. Here we examine the virus responsible for a comparatively new and fatal viral disease, *acquired immune deficiency syndrome (AIDS)*.

### AIDS is caused by HIV

The disease now known as AIDS was first reported in the United States in 1981, although a few dozen people in the United States had likely died of AIDS prior to that time and had not been diagnosed. Frozen plasma samples and estimates based on evolutionary speed and current diversity of HIV strains trace the origins of HIV in the human population to Africa in the 1950s. It was not long before the infectious agent, a retrovirus, was identified by laboratories in France. Study of HIV revealed it to be closely related to a chimpanzee virus (simian immunodeficiency virus, SIV), suggesting a recent host expansion to humans from chimpanzees in central Africa.

Infected humans have varying degrees of resistance to HIV. Some have little resistance to infection and rapidly progress from having HIV-positive status to developing AIDS and eventually die. Others, even after repeated exposure, fail to become HIV-positive or may become HIV-positive without developing AIDS.

A relatively recent hypothesis to explain this great variability in susceptibility is genetic variation among these groups due to the selective pressure put on the human population by the smallpox virus (*variola major*) over the centuries. Because of

successful vaccination and immunization, smallpox has been eradicated from the human population; however, before its eradication, it caused billions of deaths worldwide.

In order for smallpox to infect a cell, the cell must have a receptor protein in its plasma membrane that the virus can bind to. Individuals with mutated receptors would have been more resistant to smallpox and would have passed their genes on to their offspring. It has been suggested that one of the receptors used by HIV, CCR5, is also a receptor for smallpox. It is known that people resistant to HIV infection have a mutation in the CCR5 gene. The historical appearance and distribution of this mutation in human populations correlates with the historical distribution of smallpox. The AIDS epidemic is discussed further in chapter 52.

### HIV infection compromises the host immune system

In AIDS patients, HIV primarily targets **CD4<sup>+</sup> cells**, particularly T-helper cells. **T-Helper cells** are responsible for mounting the immune response against foreign invaders, and their action is described more fully in chapter 52.

HIV infects and kills the CD4<sup>+</sup> cells until very few are left. Without these crucial immune system cells, the body cannot mount a defense against invading bacteria or viruses. AIDS patients die of infections that a healthy person could fight off. These diseases, called *opportunistic infections*, normally do not cause disease and are part of the progression from HIV infection to having AIDS.

Clinical symptoms typically do not begin to develop until after a long latency period, generally 8 to 10 years after the initial infection with HIV. Some individuals, however, may develop symptoms in as few as two years. During latency, HIV particles are not in circulation, but the virus can be found integrated within the genome of macrophages and CD4<sup>+</sup> T cells as a provirus (equivalent to a prophage in bacteria).

### HIV testing

HIV tests do not test for the presence of circulating virus but rather for the presence of antibody against HIV. Because only those people exposed to HIV in their bloodstream at one time or another would have anti-HIV antibodies, this screening provides an effective way to determine whether further testing is needed to confirm HIV-positive status.

### The spread of AIDS

Although carriers of HIV have no clinical symptoms during the long latency period, they are apparently fully infectious, which makes the spread of HIV very difficult to control. The reason HIV remains hidden for so long seems to be that its infection cycle continues throughout the 8- to 10-year latency period without doing serious harm to the infected person because of an effective immune response. Eventually, however, a random mutational event in the virus or a failure of the immune response allows the virus to quickly overcome the immune defense, beginning the course of AIDS.

## HIV infects key immune-system cells

The way in which HIV infects humans provides a good example of how animal viruses replicate (figure 27.6). Most other viral infections follow a similar course, although the details of entry and replication differ in individual cases.

### Attachment

When HIV is introduced into the human bloodstream, the virus particles circulate throughout the body but only infect CD4<sup>+</sup> cells. Most other animal viruses are similarly narrow in their requirements; hepatitis goes only to the liver, and rabies

to the brain. This tissue tropism is determined by the proteins found on a cell surface and on a viral surface.

For example, the common cold virus uses the ICAM-1 membrane protein as a receptor to enter cells. ICAM-1 is a protein that is up-regulated (increased) in times of immune activation and stress. So, the more inflammation and stress in an area, the more receptors exist for the virus to enter a cell and continue the disease process.

How does a virus such as HIV recognize a target cell? Recall from chapter 4 that every kind of cell in the human body has a specific array of cell-surface glycoprotein markers that serve to identify them to other, similar cells. Invading viruses take advantage of this to bind to specific cell types. Each HIV particle possesses a glycoprotein called gp120 on its surface that precisely fits the cell-surface marker protein CD4 on the surfaces of the immune system macrophages and T cells. Macrophages, another type of white blood cell, are infected first. Because macrophages commonly interact with CD4<sup>+</sup> T cells, this may be one way that the T cells

**Figure 27.6** The HIV infection cycle.

The cycle begins and ends with free HIV particles present in the bloodstream of its human host. These free viruses infect white blood cells that have CD4 receptors, cells called CD4<sup>+</sup> cells.

are infected. Several coreceptors also significantly affect the likelihood of viral entry into cells, including the CCR5 receptor, which is mutated in HIV-immune individuals.

### Entry of virus

After docking onto the CD4 receptor of a cell, HIV requires a coreceptor such as CCR5, to pull itself across the cell membrane. After gp120 binds to CD4, it goes through a conformational change that allows it to then bind the coreceptor. Receptor binding is thought to ultimately result in fusion of the viral and target cell membranes and entry of the virus through a fusion pore. The coreceptor, CCR5, is hypothesized to have been used by the smallpox virus as was mentioned earlier.

### Replication

Once inside the host cell, the HIV particle sheds its protective coat. This leaves viral RNA floating in the cytoplasm, along with the reverse transcriptase enzyme that was also within the virion. Reverse transcriptase synthesizes a double strand of DNA complementary to the virus RNA, often making mistakes and introducing new mutations. This double-stranded DNA then enters the nucleus along with a viral enzyme that incorporates the viral DNA into the host cell's DNA. After a variable period of dormancy the HIV provirus directs the host cell's machinery to produce many copies of the virus.

As is the case with most enveloped viruses, HIV does not directly rupture and kill the cells it infects. Instead, the new viruses are released from the cell by *budding*, a process much like exocytosis. HIV synthesizes large numbers of viruses in this way, challenging the immune system over a period of years. In contrast, naked viruses, those lacking an envelope, generally

lyse the host cell in order to exit. Some enveloped viruses may produce enzymes that damage the host cell enough to kill it or may produce lytic enzymes as well.

### Evolution of HIV during infection

During an infection, HIV is constantly replicating and mutating. The reverse transcriptase enzyme is less accurate than DNA polymerases, leading to a high mutation rate. Eventually, by chance, variants in the gene for gp120 arise that cause the gp120 protein to alter its second-receptor partner. This new form of gp120 protein will bind to a different second receptor, for example CXCR4, instead of CCR5. During the early phase of an infection, HIV primarily targets immune cells with the CCR5 receptor. Eventually the virus mutates to infect a broader range of cells. Ultimately, infection results in the destruction and loss of critical T-helper cells.

This destruction of T cells blocks the body's immune response and leads directly to the onset of AIDS, with cancers and opportunistic infections free to invade the defenseless victim. Most deaths due to AIDS are not a direct result of HIV, but are from other diseases that normally do not harm a host with a normal immune system.

### AIDS treatment targets different phases of the HIV life cycle

The federal Food and Drug Administration (FDA) currently lists 32 antiretroviral drugs that are used in AIDS therapy. These target four aspects of the HIV life cycle: viral entry, genome replication, integration of viral DNA, and maturation of HIV proteins (figure 27.7). Of these, the vast majority are

**Figure 27.7** Viral targets for therapeutic drugs. A simplified version of the HIV infection cycle is shown with the steps targeted for drug intervention. Four parts of the life cycle have been targeted: viral entry, genome replication, integration of the genome, and maturation of viral proteins. NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor.

inhibitors of the replication enzyme, reverse transcriptase, and the protease that is involved in maturation of proteins. Only two drugs block viral entry: one that blocks the fusion of virus with the cell membrane, and one that blocks the chemokine coreceptor CCR5. A single drug has also been approved that targets the integrase protein that integrates the viral genome into a chromosome.

### **Reverse transcriptase inhibitors**

The first drug licensed for clinical use was AZT, a reverse transcriptase inhibitor. This class of drugs falls into two categories: nucleotide or nucleoside reverse transcriptase inhibitors (NRTI) such as AZT, and nonnucleoside reverse transcriptase inhibitors (NNRTI). These drugs are selective for HIV (or other retroviruses) because reverse transcriptase is not a cellular enzyme. So although the NRTI drugs affect cellular enzymes, they inhibit reverse transcriptase at much lower doses. More than 17 RT inhibitors are currently approved by FDA.

### **Protease inhibitors**

The second class of drugs discovered to be effective in AIDS treatment were the protease inhibitors. These drugs target a protease that cleaves a polyprotein into the smaller proteins necessary for viral replication and assembly. Some of these drugs are actually a good example of the concept of rational drug design. Drug designers started with the protease enzyme, then targeted drugs at transition state analogues of this enzyme. There are now more than 10 of these drugs that have received FDA approval.

### **Blocking viral entry**

Two drugs have been approved by the FDA that block the entry of HIV into the cell. One of these, the fusion inhibitor, was approved in 2003. The drug blocks the fusion of the viral envelope with the plasma membrane of a target cell. This entry also requires recognizing the CD4 receptor protein, and a coreceptor such as CCR5. The coreceptor blocker is a new drug that was just approved in mid-2007.

### **Integrase inhibitors**

A number of companies have been working on drugs targeting the viral integrase protein. This protein catalyzes the integration reaction of the viral genome. One of these was approved in late 2007. At least one other is currently in testing for approval.

### **Combination therapy**

The most successful form of therapy has been to use combinations of the previously discussed drugs. The standard treatment regimen consists of a minimum of three active drugs: an NNRTI or protease inhibitor combined with two different NRTIs. This form of combination therapy has entirely eliminated the HIV virus from many patients' bloodstreams. All of these patients began to receive the combination drug therapy within three months of contracting the virus, before their bod-

ies had an opportunity to develop tolerance to any single drug. Widespread use of this *combination therapy*, otherwise known as *highly active antiretroviral therapy (HAART)* has cut the U.S. AIDS death rate by three-fourths since its introduction in the mid-1990s.

Unfortunately, this sort of combination therapy does not appear to actually eliminate HIV from the body. Although the virus disappears from the bloodstream, traces of it can still be detected in the patient's lymph tissue. When combination therapy is discontinued, virus levels in the bloodstream once again rise.

In addition to the search for new drugs to add to the mix of HAART, much effort has been put into simplifying the drug regimens. The more complex the regimen of drugs, the less likely that patients will stick with it. Thus drugs have been developed that combine two NRTIs into one dose, for example.

## **Vaccine development for HIV has been unsuccessful**

A large amount of effort has been put toward developing an anti-HIV vaccine. Thus far, this has been totally unsuccessful. A recent large-scale international HIV vaccine trial was halted when an early examination of data indicated that the vaccine was essentially useless for preventing infection or lowering viral load. This has led to a retooling of clinical trials to have periodic examination of data instead of waiting for endpoints, but has not helped in terms of the vaccine itself. This vaccine was a subunit vaccine in which a specific HIV protein was engineered into an adenovirus vector.

While the high mutation rate of HIV has always been seen as a problem for vaccine development, it appears that the reason for vaccine failures may be more basic, and harder to surmount. A vaccine needs to produce a strong cellular immune response, and thus far no trial HIV subunit vaccine has done this. The only type of vaccine in an animal system that has been shown to provide protection against infection was a vaccine made from attenuated SIV. Unfortunately over time, the attenuated virus was able to mutate into an infective virus, and the experimental animals eventually developed simian AIDS.

### **Learning Outcomes Review 27.3**

HIV is a retrovirus that enters cells via membrane fusion. The virus primarily infects host CD4<sup>+</sup> T cells, ultimately resulting in massive death of these cells, which thereby compromises the host's immune system. Most deaths result from cancer and infections that typically do not harm hosts with normal immune systems. Combination drug therapy is a treatment modality in developed countries, and much research is being done to develop vaccines or to find agents that can prevent infection.

- **Does combination therapy such as HAART represent a cure for AIDS?**

## 27.4 Other Viral Diseases

### Learning Outcomes

1. Explain why we need a new vaccine each year for influenza.
2. Illustrate where emerging viruses come from.

Humans have known and feared diseases caused by viruses for thousands of years. Among the diseases that viruses cause (see table 27.1) are influenza, smallpox, hepatitis, yellow fever, polio, AIDS, and SARS. In addition, viruses have been implicated in some cancers including leukemias. Viruses not only cause many human diseases, but also cause major losses in agriculture, forestry, and the productivity of natural ecosystems.

### The flu is caused by influenza virus

Perhaps the most lethal virus in human history has been the influenza virus. As mentioned earlier, some 20 to 50 million people worldwide died of flu within 18 months in 1918 and 1919.

### Types and subtypes

Flu viruses are enveloped segmented RNA viruses that infect animals. An individual flu virus resembles a rod studded with spikes composed of two kinds of protein. The three general “types” of flu virus are distinguished by their capsid protein, which surrounds the viral RNA segments and is different for each type: **Type A flu virus** causes most of the serious flu epidemics in humans and also occurs in mammals and birds. Type B and type C viruses are restricted to humans and rarely cause serious health problems.

Different strains of flu virus, called subtypes, differ in their protein spikes. One of these proteins, hemagglutinin (H), aids the virus in gaining access to the cell interior. The other, neuraminidase (N), helps the daughter viruses break free of the host cell once virus replication has been completed.

Parts of the H molecule contain “hotspots” that display an unusual tendency to change as a result of mutation of the viral RNA during imprecise replication. Point mutations cause changes in these spike proteins in 1 of 100,000 viruses during the course of each generation. These highly variable segments of the H molecule are targets against which the body’s antibodies are directed. These constantly changing H-molecule regions improve the reproductive capacity of the virus and hinder our ability to make effective vaccines.

Because of accumulating changes in the H and N molecules, different flu vaccines are required to protect against different subtypes. Type A flu viruses are currently classified into 13 distinct *H subtypes* and 9 distinct *N subtypes*, each of which requires a different vaccine to protect against infection. Thus, the type A virus that caused the 1918 influenza pandemic (that is, worldwide epidemic) has type 1H and type 1N and is designated A(H1N1).

### The importance of recombination

The greatest problem in combating flu viruses arises not through mutation, but through recombination. Viral RNA segments are readily reassorted by genetic recombination when two different subtypes simultaneously infect the same cell. This may put together novel combinations of H and N spikes unrecognizable by human antibodies specific for the old configuration.

Viral recombination of this kind seems to have been responsible for the three major flu pandemics that occurred in the 20th century, by producing drastic shifts in H–N combinations. The “Spanish flu” of 1918, A(H1N1), killed 20–50 million people worldwide. The Asian flu of 1957, A(H2N2), killed over 100,000 Americans. The Hong Kong flu of 1968, A(H3N2), infected 50 million people in the United States alone, of whom 70,000 died.

### Origin of new strains

It is no accident that new strains of flu usually originate in the Far East. The most common hosts of influenza virus are ducks, chickens, and pigs, which in Asia often live in close proximity to each other and to humans. Pigs are subject to infection by both bird and human strains of the virus, and individual animals are often simultaneously infected with multiple strains. This creates conditions favoring genetic recombination between strains, producing new combinations of H and N subtypes.

The Hong Kong flu, for example, arose from recombination between A(H3N8) from ducks and A(H2N2) from humans. The new strain of influenza, in this case A(H3N2), then passed back to humans, causing a pandemic in 1968–69.

In 1997, a form of avian influenza, A(H5N1), was discovered that could infect humans. Avian influenza, or “bird flu,” is highly contagious and deadly among domestic bird populations, and it is now clear that this H5N1 strain is transmitted between domestic birds, which live in close contact with humans, and wild birds that have worldwide migratory patterns. This new influenza variant has caused much concern because, while the number of infections worldwide is low, the mortality rate in these rare infections has been around 50%. However, these infections all appear to be transmitted from birds to humans, and it does not appear to spread by human-to-human contact.

While H5N1 captured the interest of the press worldwide, another viral reassortment occurred that has resulted in an actual pandemic. An A(H1N1) virus was isolated that appears to be the result of reassortment of human A(H3N2) and pig A(H1N1). Epidemiological studies indicate that this virus first appeared in an outbreak of influenza in Veracruz, Mexico.

The virus has since spread worldwide with the WHO raising the event to pandemic status in May, 2009. As of September, 2009, more than 300,000 cases have been reported worldwide. Fortunately, as of this writing, the pathogenicity of this virus is low, with a mortality rate of around 1.5%.

## New viruses emerge by infecting new hosts

Sometimes viruses that originate in one organism pass to another, thus expanding their host range. Often, this expansion is deadly to the new host. HIV, for example, is thought to have arisen in chimpanzees and relatively recently passed to humans. Influenza is fundamentally a bird virus. Viruses that originate in one organism and then pass to another and cause disease are called **emerging viruses**. They represent a considerable threat in an age when airplane travel potentially allows infected individuals to move about the world quickly, spreading an infection.

### Hantavirus

An emerging virus caused a sudden outbreak of a deadly pneumonia in the southwestern United States in 1993. This disease was traced to a species of **hantavirus** and was called the *sin nombre*, or *no-name, virus*. Hantavirus is a single-stranded RNA virus associated with rodents. This virus was eventually traced to deer mice. The deer mouse hantavirus is transmitted to humans through fecal and urine contamination in areas of human habitation. Controlling the deer mouse population has limited the disease.

### Hemorrhagic fever: Ebola

Sometimes the origin of an emerging virus is unknown, making an outbreak more difficult to control. Among the most lethal of emerging viruses are a collection of filamentous viruses arising in central Africa that cause severe hemorrhagic fever. With lethality rates in excess of 50%, these so-called **filoviruses** are among the most lethal infectious diseases known. One, **Ebola virus** (figure 27.8), has exhibited lethality rates in excess of 90% in isolated outbreaks in central Africa. The outbreak of Ebola virus in the summer of 1995 in Zaire killed 245 people out of 316 infected—a mortality rate of 78%. A recent (2004) outbreak of Ebola in Yambio, southern Sudan, caused 17 infections

**Figure 27.8 The Ebola virus.** This virus, with a fatality rate that can exceed 90%, appears sporadically in central Africa. The natural host of the virus currently is unknown.

**Figure 27.9 SARS coronavirus.** The 29,751-nucleotide SARS genome is composed of RNA and contains six principal genes:  $R_A$  and  $R_B$ , replicases; S, spike proteins; E, envelope glycoproteins; M, membrane glycoprotein; N, nucleocapsid protein.

and 7 deaths. This outbreak was rapidly contained by isolating patients from family members as soon as symptoms appeared. The natural host of Ebola is unknown.

### SARS

A recently emerged species of coronavirus (figure 27.9) was responsible for the 2003 worldwide outbreak of **severe acute respiratory syndrome (SARS)**, a respiratory infection with pneumonia-like symptoms that is fatal in over 8% of cases. When the 29,751-nucleotide RNA genome of the SARS coronavirus was sequenced, it proved to be a completely new form of coronavirus, not closely related to any of the three previously described forms.

Virologists suspect that the SARS coronavirus most likely came from civets (a weasel-like mammal) and possibly other wild animals that live in China and are eaten as delicacies. If the SARS virus indeed exists in natural populations, future outbreaks will be difficult to prevent without an effective vaccine. Recent data have implicated bats as the natural reservoir for SARS virus. The significance of this finding for control of the virus is unclear at present.

Genome sequences have been analyzed from SARS patients at various stages of the outbreak, and these analyses indicate that the virus's mutation rate is low, in marked contrast to HIV, another RNA virus. The stable genome of the SARS virus should make development of a SARS vaccine practical. The lessons learned from developing antiviral agents against other RNA viruses, such as HIV and influenza have helped develop drugs to treat SARS. Several anti-SARS agents and vaccines are currently being tested in laboratories across the world.

### Viruses can cause cancer

Through epidemiological studies and research, scientists have established a link between some viral infections and the subsequent development of cancer. Examples include the association between chronic hepatitis B infections and the development of liver cancer,

and the development of cervical carcinoma following infections with certain strains of human papillomaviruses (HPV).

Viruses may contribute to about 15% of all human cancer cases worldwide. They are capable of altering the growth properties of human cells they infect by triggering the expression of cancer-causing genes called oncogenes (see chapter 10). Changes in the normal function of these genes leads to cancer.

These changes can occur because viral proteins interfere with the regulation of oncogene expression. Alternatively, the integration of a viral genome into a host chromosome may disrupt a gene required to control the cell cycle. Viruses themselves may encode these oncogenes as well. Virus-induced cancer involves complex interactions with cellular genes and requires a series of events in order to develop. The association of viruses with some forms of cancer has led to research on vaccine development for the prevention of these cancers. In June 2006, the FDA approved the use of a new HPV vaccine in women and young girls from the age of 11 to prevent cervical cancer.

### Learning Outcomes Review 27.4

Many types of viruses have caused disease in humans for as long as we have recorded history. Some of these, such as influenza, have caused pandemics responsible for millions of deaths worldwide. Recombination is common in the influenza virus, making natural immunity and development of vaccines problematic. Emerging diseases can occur when viruses switch hosts, that is, jump from another species to humans. Hantavirus, Ebola, and SARS all fall into this category. Virus infection has also been linked to the development of certain cancers.

- Why does the effectiveness of flu shots vary from year to year?

## 27.5 Prions and Viroids: Subviral Particles

### Learning Outcomes

1. Explain why prion replication was a “heretical” concept.
2. Describe the mechanism of prion transmission.

For decades, scientists have been fascinated by a peculiar group of fatal brain diseases. These diseases have an unusual property: Years and often decades pass after infection before the disease is detected in infected individuals. The brains of infected individuals develop numerous small cavities as neurons die, producing a marked spongy appearance. Called *transmissible spongiform encephalopathies (TSEs)*, these diseases include scrapie in sheep; bovine spongiform encephalopathy (BSE), or “mad cow” disease in cattle; chronic wasting disease in deer and elk; and kuru, Creutzfeldt–Jakob disease (CJD), and variant Creutzfeldt–Jakob disease (vCJD) in humans.

TSEs can be transmitted experimentally by injecting infected brain tissue into a recipient animal’s brain. TSEs can also spread via tissue transplants and, apparently, tainted food. The disease kuru was once common in the Fore people of Papua New Guinea, because they practiced ritual cannibalism, eating the brains of infected individuals. Mad cow disease spread widely among the cattle herds of England in the 1990s because cows were fed bonemeal prepared from sheep and cattle carcasses to increase the protein content of their diet. Like the Fore, the British cattle were eating the tissue of cattle that had died of the disease.

In the years following the outbreak of BSE, there has been a significant increase in CJD incidence in England. Some cases appear to be genetic. Mysteriously, patients with no family history of CJD were being diagnosed with the disease. This led to the discovery of a new form of CJD called variant CJD, or vCJD, that is acquired from eating meat of BSE-infected animals. Concern exists that vCJD may be transmitted from person to person through blood products, similar to the transmission of HIV through blood and blood products.

### Prion replication was a heretical suggestion

In the 1960s, British researchers Tikvah Alper and John Stanley Griffith noted that infectious TSE preparations remained infectious even after exposure to radiation that would destroy DNA or RNA. They suggested that the infectious agent was a protein. They speculated that the protein could sometimes misfold, and then catalyze other proteins to do the same, the misfolding spreading like a chain reaction. This “heretical” suggestion was not accepted by the scientific community, because it violated a key tenet of molecular biology: Only DNA or RNA act as hereditary material, transmitting information from one generation to the next.

### Evidence has accumulated that prions cause TSEs

In the early 1970s, physician Stanley Prusiner began to study TSEs. Try as he might, Prusiner could find no evidence of nucleic acids or viruses in the infectious TSE preparations. He concluded, as Alper and Griffith had, that the infectious agent was a *protein*, which in a 1982 paper he named a **prion**, for “proteinaceous infectious particle.”

Prusiner went on to isolate a distinctive prion protein, and to amass evidence that prions play a key role in triggering TSEs. Every host tested to date expresses a normal prion protein (PrP<sup>c</sup>) in their cells. The disease-causing prions are the same protein, but folded differently (PrP<sup>sc</sup>). These misfolded proteins have been shown in vitro to serve as a template for normal PrP to misfold. The misfolded PrP proteins are very resistant to degradation, making it possible for them to pass through the acidic digestive tract intact and therefore to be transmitted by ingesting tainted food.

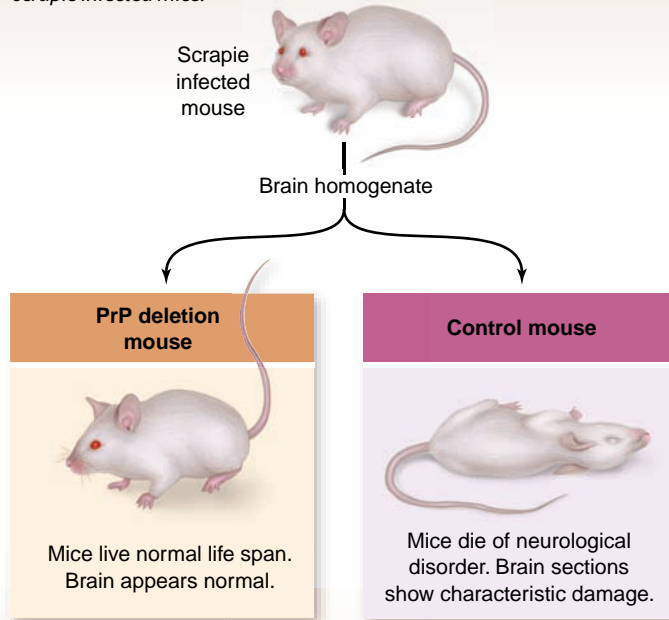

Experimental evidence has accumulated to support this idea. Injection of prions with different abnormal conformations into hosts leads to the same abnormal conformations as the parent prions. Mice genetically engineered to lack PrP<sup>c</sup> are

## SCIENTIFIC THINKING

**Hypothesis:** Normal cellular PrP protein is required for scrapie infection.

**Prediction:** Infection of mice lacking PrP with scrapie agent should not lead to scrapie.

**Test:** Construct "knockout" mice with PrP deleted. Inject PrP knockout mice, and control mice with normal PrP, with brain homogenates from scrapie infected mice.

**Result:** All control mice died with scrapie like neurological damage. Periodic sacrifice and histological examination showed normal disease progress. None of the PrP knockout mice showed any sign of neurological disorder.

**Conclusion:** Normal PrP protein is necessary for productive infection by scrapie infectious particle.

**Further Experiments:** What kind of experiment would conclusively prove that the infectious agent of scrapie is a misfolded PrP protein?

**Figure 27.10** Demonstration that normal prion protein is necessary for scrapie infectivity.

immune to TSE infection (figure 27.10). If brain tissue with the prion protein is grafted into the mice, the grafted tissue—but not the rest of the brain—can then be infected with TSE. However, infectious PrP has not been generated in vitro in quantities that would produce disease in nature. The mechanism of pathogenesis also remains controversial.

Prions have also been found in yeast and other fungi. Three different “genes” that behave in a nonmendelian fashion have all been shown to be prions in yeast. There has been greater progress in the in vitro conversion of normal cellular proteins to the prion form in the yeast system.

## Viroids are infectious RNA with no protein coat

**Viroids** are tiny, naked molecules of circular RNA, only a few hundred nucleotides long, that are important infectious disease agents in plants. A recent viroid outbreak killed over 10 million coconut palms in the Philippines. Despite their small size, viroids autonomously replicate without a helper virus, although they obviously use host proteins. Despite being nucleic acids, the important information they carry appears to be in their three-dimensional structure. There are also some intriguing hints that they might use the plant siRNA machinery to affect gene expression.

### Learning Outcomes Review 27.5

Prions and viroids are smaller and simpler than viruses. Prions are infectious particles that do not seem to contain any nucleic acid. They appear to be misfolded proteins that cause related cellular proteins to also misfold. Prions are the causative agent of TSEs. Viroids are infectious RNAs that are implicated in some plant diseases.

- *If prions are infectious proteins, then what is the form of genetic information that they carry?*

## Chapter Review

### 27.1 The Nature of Viruses

**Viruses are strands of nucleic acids encased in a protein coat.**

Viral genomes can consist of either DNA or RNA and can be classified as DNA viruses, RNA viruses, or retroviruses.

Most viruses have a protein sheath or capsid around their nucleic acid core. Many animal viruses have an envelope around the capsid composed of proteins that are virally encoded, lipids from the host cell, and glycoproteins.

Some viruses also have enzymes inside their capsid that are important in early infection.

**Viral hosts include virtually every kind of organism.**

Each virus has a limited host range, and many also exhibit tissue tropism.

**Viruses replicate by taking over host machinery.**

Viruses are obligate intracellular parasites lacking ribosomes and proteins needed for replication. Viruses take over host machinery and direct their own nucleic acid and protein synthesis.

**Most viruses come in two simple shapes.**

Viruses vary in size and come in two simple shapes: helical (rodlike) or icosahedral (spherical) (see figures 27.1 and 27.4).

### ***Viral genomes exhibit great variation.***

The DNA or RNA viral genome may be linear or circular, single- or double-stranded. RNA viruses may have multiple RNA molecules (segmented), or only one RNA molecule (nonsegmented). Retroviruses contain RNA that is transcribed into DNA by reverse transcriptase.

## **27.2 Bacteriophage: Bacterial Viruses**

### ***Archaeal viruses have diverse morphologies.***

### ***Bacterial viruses exhibit two reproductive cycles.***

The lytic cycle kills the host cell, whereas the lysogenic cycle incorporates the virus into the host genome as a prophage (see figure 27.5). A cell containing a prophage is called a lysogen.

The prophage can be induced by DNA damage and other environmental cues to reenter the lytic cycle.

For most phage, steps in infection include attachment, injection of DNA (penetration), macromolecular synthesis, assembly of new phage, and release of progeny phage.

### ***Bacteriophage can contribute genes to the host genome.***

Phage conversion occurs when foreign DNA is contributed to the host by a bacterial virus.

## **27.3 Human Immunodeficiency Virus (HIV)**

### ***AIDS is caused by HIV.***

Human immunodeficiency virus (HIV) causes acquired immunodeficiency syndrome (AIDS) (see figure 27.6).

### ***HIV infection compromises the host immune system.***

HIV specifically targets macrophages and CD4<sup>+</sup> cells, a type of helper T-lymphocyte cell. With the loss of these cells the body cannot fight off opportunistic infections, which ultimately lead to death.

### ***HIV infects key immune-system cells.***

The viral glycoprotein gp120 precisely fits on the cell-surface marker protein CD4<sup>+</sup> on macrophages and T cells. When HIV attaches to two receptors, CD4<sup>+</sup> and CCR5, receptor-mediated endocytosis is activated, bringing the HIV particle into the cell.

Once inside the cell, the protective coat is shed, releasing viral RNA and reverse transcriptase into the cytoplasm. Reverse transcriptase makes double-stranded DNA complementary to the viral RNA. This DNA may be incorporated into the host DNA as a provirus.

Replicated viruses are budded off the host cell by exocytosis.

HIV has a high mutation rate because the reverse transcriptase enzyme is much less accurate than DNA polymerases. Mutations lead to an altered glycoprotein gp120, which now binds instead

to the CXCR4 receptor found only on the surface of CD4<sup>+</sup> cells. Incorporation of the altered HIV particle leads to a rapid decline in T cells and immune response.

### ***AIDS treatment targets different phases of the HIV life cycle.***

Drugs target reverse transcriptase, a protease involved in protein maturation, viral entry, and the integration of the genome. Most approved drugs are reverse transcriptase and protease inhibitors.

Combination drug therapy using nucleoside analogues and protease inhibitors eliminates HIV from the bloodstream but not totally from the body.

### ***Vaccine development for HIV has been unsuccessful.***

Successful vaccines must elicit a strong immune response, and attempts to create immunity against a specific HIV subunit have failed. Attenuated viruses in animal tests have also proved capable of mutating into infectious forms.

## **27.4 Other Viral Diseases**

### ***The flu is caused by influenza virus.***

One of the most lethal viruses in human history is type A influenza virus. Influenza can also infect other mammals and birds.

Genes in influenza viruses undergo recombination frequently, so they are not recognized by antibodies against past infections. Each year the composition of flu vaccines must be changed.

### ***New viruses emerge by infecting new hosts.***

Viruses can extend their host range by jumping to another species. Examples include hantavirus, hemorrhagic fever, and SARS (see figure 27.9).

### ***Viruses can cause cancer.***

Viruses have been linked to formation of cancers, including liver cancer and cervical papillomas.

## **27.5 Prions and Viroids: Subviral Particles**

### ***Prion replication was a heretical suggestion.***

Prions are proteinaceous infectious particles consisting of a misfolded form of a protein. This misfolding catalyzes a chain reaction of misfolding in normal proteins, causing disease.

### ***Evidence has accumulated that prions cause TSEs (see figure 27.10).***

TSE disease-causing prions (PrP<sup>Sc</sup>) are the same protein as the normal version (PrP<sup>C</sup>) but misfolded.

### ***Viroids are infectious RNA with no protein coat.***

Viroids are circular, naked molecules of RNA that infect plants. They use host protein to replicate.

## **Review Questions**

### **UNDERSTAND**

1. The reverse transcriptase enzyme is active in which class of viruses?
  - a. Positive-strand RNA viruses
  - b. Double-stranded DNA viruses
  - c. Retroviruses
  - d. Negative-strand RNA viruses
2. Which of the following is not part of a virus?
  - a. Capsid
  - b. Ribosomes
  - c. Genetic material
  - d. All of the above are found in viruses.

- Which of the following is common in animal viruses but not in bacteriophage?
  - DNA
  - Capsid
  - Envelope
  - Icosahedral shape
- Which of the following would not be part of the life cycle of a lytic virus?
  - Macromolecular synthesis
  - Attachment to host cell
  - Assembly of progeny virus
  - Integration into the host genome
- A process by which a virus may change a benign bacteria into a virulent strain is called
  - induction.
  - phage conversion.
  - lysogeny.
  - replication.
- Prior to entry, the \_\_\_\_\_ glycoprotein of the HIV virus recognizes the \_\_\_\_\_ receptor on the surface of the macrophage.
  - CCR5; gp120
  - CXCR4; CCR5
  - CD4; CCR5
  - gp120; CD4
- The use of multiple drugs in HAART to treat AIDS has
  - completely removed the virus from infected individuals.
  - reduced the viral level in the bloodstream to undetectable levels.
  - been a complete failure.
  - been supplanted by the new HIV vaccine.
- Phage conversion in which viruses add genes to a bacterial cell can be considered to be a form of
  - standard inheritance.
  - horizontal gene transfer.
  - vertical gene transfer.
  - parasitism.
- According to the prion hypothesis, the infectious agent for scrapie must have “genetic” information in
  - the sequence of amino acids in the scrapie protein.
  - the sequence of bases in the scrapie gene.
  - the three-dimensional structure of the scrapie prion.
  - all of the above.
- The difficulty designing a single flu vaccine that will work forever is that influenza
  - is an RNA virus.
  - is a DNA virus.
  - both mutates and can be recombined to form new viruses.
  - infects only humans.
- The SARS outbreak is an example of
  - a virus jumping from one species to another.
  - mutation of a virus that only infects humans.
  - how viruses can disable the human immune system.
  - two viruses combining to form a new virus.

## APPLY

- The varying degrees of resistance to HIV in populations has been suggested to be related to the patterns of smallpox outbreaks over human history. This explanation hinges on
  - the similarity in the genomes of the two viruses.
  - the fact that both viruses use reverse transcriptase.
  - both viruses using the same receptor to bind to host cells.
  - the fact that both viruses compromise the immune system.
- The idea of a protein that was an infectious agent was heretical because
  - proteins are not that important in cells.
  - proteins are not the informational molecules in cells.
  - the function of proteins does not depend on their structure.
  - proteins require nucleic acids for their function.
- Bacterial viruses and animal viruses are similar in that they both
  - have only DNA as genetic material.
  - have only RNA as genetic material.
  - require host functions for some aspect of their life cycle.
  - do not require any host proteins.
- The drugs used against HIV in AIDS therapy are not effective against the flu because
  - HIV is an RNA virus and influenza is a DNA virus.
  - HIV is a DNA virus and influenza is an RNA virus.
  - the two viruses have different sized genomes.
  - the proteins targeted by HIV drugs are not found in influenza.

## SYNTHESIZE

- E. coli* lysogens derived from infection by phage  $\lambda$  can be induced to form progeny viruses by exposure to radiation. The inductive event is the destruction of a repressor protein that keeps the prophage genome unexpressed. What might be the normal role of the protein that recognizes and destroys the  $\lambda$  repressor?
- Most biologists believe that viruses evolved following the origin of the first cells. Defend or critique this concept.
- Much effort has been expended to produce a vaccine for HIV. To date, this has not been successful. Why has this been such a difficult task? Are any other viruses equally resistant to a vaccine, and are the reasons the same? Why do you think that we could make a vaccine against the smallpox virus that allowed us to completely eradicate this virus?
- What do we mean by the term “emerging virus”? How is this a medical problem, and what is a recent example?
- How might phage  $\lambda$  be used to transfer *E. coli* genes between different bacterial cells? Could this be used to transfer any gene?

# Chapter 28

## Prokaryotes

### Chapter Outline

- 28.1 The First Cells
- 28.2 Prokaryotic Diversity
- 28.3 Prokaryotic Cell Structure
- 28.4 Prokaryotic Genetics
- 28.5 Prokaryotic Metabolism
- 28.6 Human Bacterial Disease
- 28.7 Beneficial Prokaryotes

### Introduction

One of the hallmarks of living organisms is their cellular organization. You learned earlier that living things come in two basic cell types: prokaryotes and eukaryotes. To review, prokaryotes lack the membrane-bounded nucleus found in all eukaryotes, and they also have a much less complex cellular structure, lacking many of the organelles seen in eukaryotes (chapter 4). Prokaryotes are considerably smaller and more numerous than their eukaryotic counterparts. If we examined a human being closely, we would discover that for every single cell of the human body there are approximately 10 prokaryotic cells—and there are trillions of human cells.

Prokaryotic microbes play an important role in global ecology as well. Most biologists think prokaryotes were the first organisms to evolve. The diversity of eukaryotic organisms that currently live on Earth could not exist without prokaryotes because they make possible many of the essential functions of ecosystems. Prokaryotic photosynthesis, for example, is thought to have been the source for the oxygen in the ancient Earth's atmosphere, and it still contributes significantly to oxygen production today. An understanding of prokaryotes is essential to understanding all life on Earth, past and present.

## 28.1 The First Cells

### Learning Outcomes

1. Explain the evidence for the earliest cells.
2. Describe possible pathways of carbon fixation by early life forms.

As no human was present at the formation of life, we are left with indirect evidence for the earliest life-forms. The most direct evidence we have are fossils, but these can be difficult to interpret, especially since we are looking for microscopic evidence of life. We also can analyze the composition of carbon-containing rocks to look for signs of life acting on organic material, as indicated by a change in isotopic ratios. Finally, we can look for the presence of organic chemicals, which are of biological origin.

### Microfossils indicate that the first cells were probably prokaryotic

Evidence of life in the form of microfossils is difficult both to find and to interpret. Rocks older than 3 billion years are rarely unchanged by geologic action over time. Two main formations of 3.5- to 3.8-billion-year-old rocks have been found that are mostly intact: the Kaapvaal craton in South Africa and the Pilbara craton in western Australia. (A *craton* is a rock layer of undisturbed continental crust.) Structures have been found in each of these formations and others that are interpreted to be biological in origin. Although this interpretation has been controversial, the accumulation of evidence over time favors these structures as being true fossil cells.

Microfossils are fossilized forms of microscopic life. Many microfossils are small (1–2  $\mu\text{m}$  in diameter) and appear to be single-celled, lack external appendages, and have little evidence of internal structure (figure 28.1). Thus, microfossils seem to resemble present-day prokaryotes.

The currently oldest microfossils are 3.5 billion years old. The claim that these microfossils are the remains of liv-

**Figure 28.1 Evidence of bacterial fossils.** Rocks approximately 3.5 billion years old to 1 billion years old have tiny fossils resembling bacterial cells embedded within them.

**Figure 28.2 Stromatolites.** Mats of bacterial cells that trap mineral deposits and form the characteristic dome shapes seen here.

ing organisms is supported by isotopic data (described shortly) and by spectroscopic analysis that indicates they do contain complex carbon molecules. Whether these microscopic structures are true fossil cells is still controversial, and the identity of the prokaryotic groups represented by the various microfossils is still unclear. Arguments have been made for various bacteria, including cyanobacteria (described later on) being the microfossils in question, but definitive interpretation is difficult.

In addition to these microfossils, indirect evidence for ancient life can be found in the form of sedimentary deposits called **stromatolites**. These structures are commonly interpreted as a combination of sedimentary deposits and precipitated material that are held in place by mats of microorganisms. The microorganisms that make up the mats are thought to be cyanobacteria. Formations of stromatolites are as old as 2.7 billion years. Because relatively modern stromatolites are also known, the formation and biological nature of these structures is less contentious (figure 28.2).

### Isotopic data indicate that carbon fixation is an ancient process

Another way to ask when life began is to look for the signature of living systems in the geological record. Living systems alter their environments, and sometimes this change can be detected. The most obvious change is that living systems are selective in the isotopes of carbon in compounds they use. Living organisms incorporate carbon-12 into their cells before any other carbon isotope, and thus they can alter the ratios of these isotopes in the atmosphere. They also have a higher level of carbon-12 in their fossilized bodies than does the nonorganic rock around them.

Much work has been done on dating and analyzing carbon compounds in the oldest rocks, looking for signatures of life. Although this work is controversial, it has been argued that carbon signatures indicate carbon fixation, the incorporation of inorganic carbon into organic form, was active as long as 3.8 BYA.

## 28.2 Prokaryotic Diversity

### Learning Outcomes

1. Differentiate among archaea, bacteria, and eukarya.
2. Describe the basic features of bacteria and archaea.
3. Explain classification methods for prokaryotes.

The ancient fixation of carbon happened via four possible pathways. The most common pathway for carbon fixation is the Calvin cycle (see chapter 8). This is the pathway used by cyanobacteria, algae, and modern land plants that perform oxygenic photosynthesis using two photosystems. The Calvin cycle is also active in green and purple sulfur bacteria that perform anoxygenic photosynthesis using a single photosystem. This anoxygenic form of photosynthesis could account for ancient carbon fixation.

To date, the entire Calvin cycle has not been demonstrated in the domain Archaea, although the key enzyme for this pathway has been identified in a few archaeal isolates. Instead, some archaea use a reductive version of the Krebs cycle (see chapter 7). This pathway of carbon fixation is also used by some lithotrophic bacteria, which derive energy from the oxidation of inorganic compounds, and by the green sulfur bacteria. Two other pathways may also occur in the lithotrophs, archaea, and the green nonsulfur bacteria. Evidence suggests that the ability to fix carbon has evolved multiple times over the course of evolution.

### Some hydrocarbons found in ancient rocks may have biological origins

Another way to look for evidence of ancient life is to look for organic molecules, which are clearly of biological origin; such molecules are called *biomarkers*. Although the process sounds simple, it has proved difficult to find such markers. One type of biomarker molecule is hydrocarbons, which are derived from the fatty acid tails of lipids. These can be analyzed for their carbon isotope ratios to indicate biological origin. The analysis of extractable hydrocarbons from the Pilbara formation in Australia found lipids that are indicative of cyanobacteria as long ago as 2.7 billion years. The search for definitive chemical markers for living systems in the oldest rocks and in meteorites is an area of intense interest.

Arguments for the oldest microfossils have been supported by analysis of the carbon isotope ratios in carbonaceous material from the same formations. If these fossils indeed represent living cells, it implies that life was much more abundant 3.5 BYA than previously thought. Although much of this work is still being debated, it pushes the possible origin of life back well beyond 3.5 BYA.

#### Learning Outcomes Review 28.1

Evidence for the earliest cells exists in microfossils. The earliest microfossils are controversial, but they are at least 3.5 billion years old. Other evidence for early life includes isotopic ratios that are skewed by biological activity. The Calvin cycle and a reductive version of the Krebs cycle, as well as other pathways, appear to have led to carbon fixation in ancient life. Some hydrocarbons appear to be biomarkers and may therefore also indicate ancient life forms.

- When we are looking for life on Mars, what kind of evidence would be the most convincing?

Although thousands of different kinds of prokaryotes are currently recognized, many thousands more await proper identification. New molecular techniques have allowed scientists to identify and study microorganisms without culturing them. As a result, microbiologists have discovered thousands of new species that were never discovered or characterized because they could not be maintained in culture.

It is estimated that only between 1 and 10% of all prokaryotic species are known and characterized, leaving between 90 and 99% unknown and undescribed. Every place microbiologists look, new species are being discovered, often altering the way we think about prokaryotes. In the 1970s and 1980s, a new type of prokaryote was identified and analyzed that eventually led to the division of prokaryotes into two groups: the *Archaea* (formerly called Archaeobacteria) and the *Bacteria* (sometimes also called Eubacteria).

Archaea and bacteria are the oldest, structurally simplest, and most abundant forms of life. They are also the only organisms with prokaryotic cellular organization. Prokaryotes were abundant for over a billion years before eukaryotes appeared in the world. Early photosynthetic bacteria (cyanobacteria) altered the Earth's atmosphere by producing oxygen, which stimulated extreme bacterial and eukaryotic diversity.

Prokaryotes are ubiquitous and live everywhere eukaryotes do; they are also able to thrive in places no eukaryote could live. Bacteria and archaea have been found in deep-sea caves, volcanic rims, and deep within glaciers. Some of the extreme environments in which prokaryotes can be found would be lethal to any other life-form.

Many archaea are *extremophiles*. They live in hot springs that would cook other organisms, in hypersaline environments that would dehydrate other cells, and in atmospheres rich in otherwise-toxic gases such as methane or hydrogen sulfide. They have even been recovered living beneath 435 m of ice in Antarctica!

These harsh environments may be similar to the conditions present on the early Earth when life first began. It is likely that prokaryotes evolved to dwell in these harsh conditions early on and have retained the ability to exploit these areas as the rest of the atmosphere has changed.

### Prokaryotes are fundamentally different from eukaryotes

Prokaryotes differ from eukaryotes in numerous important features. These differences represent some of the most fundamental distinctions that separate any groups of organisms.

**Unicellularity.** With a few exceptions prokaryotes are fundamentally single-celled). In some types, individual cells adhere to one another within a matrix and form filaments; however, the cells retain their individuality. Cyanobacteria, in particular, are likely to form such associations, but their cytoplasm is not directly interconnected, as is often the case in multicellular eukaryotes. These filaments do have a common cell wall, however, making it difficult to isolate single cells.

In their natural environments, most bacteria appear to be capable of forming a complex community of different species called a **biofilm**. Although not a multicellular organism, a biofilm is more resistant to antibiotics, desiccation, and other environmental stressors than is a simple colony of a single type of microbe, such as a laboratory culture.

**Cell size.** As new species of prokaryotes are discovered, investigators are finding that the size of prokaryotic cells varies tremendously, by as much as five orders of magnitude. The largest bacterial cells currently characterized are from *Thiomargarita namibia*. A single cell from this species is up to 750  $\mu\text{m}$  across, which is visible to the naked eye and is roughly the size of the eye of a bumblebee. Most prokaryotic cells, however, are only 1  $\mu\text{m}$  or less in diameter, whereas most eukaryotic cells are well over 10 times bigger. This generality is misleading, however, because there are very small eukaryotes as well as very large prokaryotes.

**Chromosomes.** Eukaryotic cells have a membrane-bounded nucleus containing linear chromosomes made up of both nucleic acids and histone proteins. Prokaryotes do not have membrane-bounded nuclei; instead they usually have a single circular chromosome made up of DNA and histone proteins in a *nucleoid* region of the cell. An exception to this single chromosome includes *Vibrio cholerae*, which has two circular chromosomes. Prokaryotic cells often have accessory DNA molecules called plasmids as well. Plasmids are genetic elements that can sometimes be transferred between prokaryotic cells.

**Cell division and genetic recombination.** Cell division in eukaryotes takes place by mitosis and involves spindles made up of microtubules. Cell division in prokaryotes takes place mainly by binary fission (see chapter 10), which is also a form of asexual reproduction. True sexual reproduction occurs only in eukaryotes and involves the production of haploid gametes that fuse to form a diploid zygote that grows to adulthood, producing more gametes and starting the cycle over again (see chapter 11).

Despite their asexual mode of reproduction, prokaryotes do have mechanisms that lead to the transfer of genetic material and generation of genetic diversity. These mechanisms are collectively called *horizontal gene transfer* and are not a form of reproduction.

**Internal compartmentalization.** In eukaryotes, the enzymes for cellular respiration are packaged in mitochondria. In prokaryotes, the corresponding enzymes are not packaged separately, but instead are bound to the cell membranes or are in the cytosol. The cytoplasm of prokaryotes, unlike

that of eukaryotes, contains no internal compartments and no membrane-bounded organelles. Ribosomes are found in both prokaryotes and eukaryotes, but differ significantly in structure. (See chapter 4 for a review of cell structure.)

**Flagella.** Prokaryotic flagella are simple in structure, composed of a single fiber of the protein flagellin. Eukaryotic flagella and cilia are complex, having a 9 + 2 structure of microtubules (see figure 4.23). Bacterial flagella also function differently, being rigid and spinning like propellers, whereas eukaryotic flagella have a whiplike motion (described in more detail later and in figure 28.8).

**Metabolic diversity.** Only one kind of photosynthesis occurs in eukaryotes, and it involves the release of oxygen. Photosynthetic bacteria have two basic patterns of photosynthesis: *oxygenic*, producing oxygen, and *anoxygenic*, nonoxygen producing. Anoxygenic photosynthesis involves the formation of products such as sulfur and sulfate instead of oxygen.

Prokaryotic cells can also be *chemolithotrophic*, meaning that they use the energy stored in chemical bonds of inorganic molecules to synthesize carbohydrates; eukaryotes are not capable of this metabolic process.

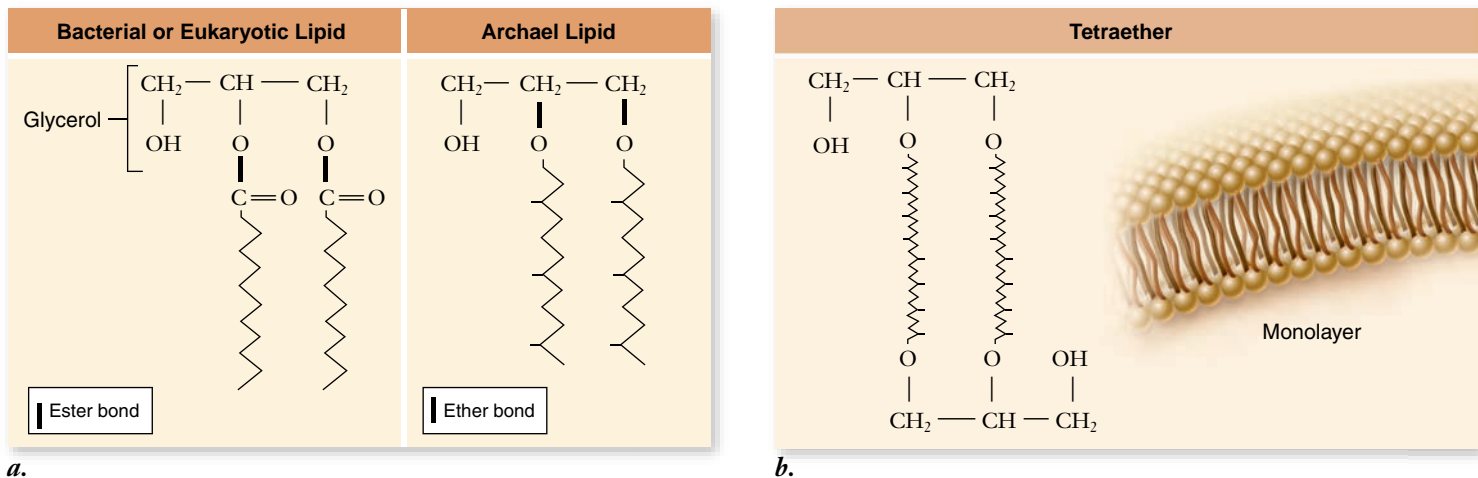

## Despite similarities, bacteria and archaea differ fundamentally

Archaea and bacteria are similar in that both have a prokaryotic cellular structure, but they vary considerably at the biochemical and molecular levels. They differ in four key areas: plasma membranes, cell walls, DNA replication, and gene expression.

**Plasma membranes.** All prokaryotes have plasma membranes with a fluid mosaic architecture (see chapter 5). The plasma membranes of archaea differ from both bacteria and eukaryotes. Archaeal membrane lipids are composed of glycerol linked to hydrocarbon chains by ether linkages, not the ester linkages seen in bacteria and eukaryotes (figure 28.3a). These hydrocarbons may also be branched, and they may be organized as tetraethers that form a monolayer instead of a bilayer (figure 28.3b).

In the case of some hyperthermophiles, the majority of the membrane may be this tetraether monolayer. This structural feature is part of what allows these archaeans to withstand high temperatures.

**Cell wall.** Both kinds of prokaryotes typically have cell walls covering the plasma membrane that strengthen the cell. The cell walls of bacteria are constructed, minimally, of **peptidoglycan**, which is formed from carbohydrate polymers linked together by peptide cross-bridges. The peptide cross-bridges also contain D-amino acids, which are never found in cellular protein. The cell walls of archaea lack peptidoglycan, although some have **pseudomurein**, which is similar to peptidoglycan in structure and function. This wall layer is also a carbohydrate polymer with peptide cross-bridges, but the carbohydrates are different, and the peptide cross-bridge

**Figure 28.3 Archaea membrane lipids.** *a.* Archaea membrane lipids are formed on a glycerol skeleton similar to bacterial and eukaryotic lipids, but the hydrocarbon chains are connected to the glycerol by ether linkages not ester linkages. The hydrocarbons can also be branched and even contain rings. *b.* These lipids can also form as tetraethers instead of diethers. The tetraether forms a monolayer as it includes two polar regions connected by hydrophobic hydrocarbons.

structure also differs. Other archaeal cell walls have been found to be composed of a variety of proteins and carbohydrates, making generalizations difficult.

**DNA replication.** Although both archaea and bacteria have a single replication origin, the nature of this origin and the proteins that act there are quite different. Archaeal initiation of DNA replication is more similar to that of eukaryotes (see chapter 14).

**Gene expression.** The machinery used for gene expression also differs between archaea and bacteria. The archaea may have more than one RNA polymerase, and these enzymes more closely resemble the eukaryotic RNA polymerases than they do the single bacterial RNA polymerase. Some of the translation machinery is also more similar to that of eukaryotes (see chapter 15).

## Most prokaryotes have not been characterized

Prokaryotes are not easily classified according to their forms, and only recently has enough been learned about their biochemical and metabolic characteristics to develop a satisfactory overall classification scheme comparable to that used for other organisms.

### Early classification characteristics

Early systems for classifying prokaryotes relied on differential stains such as the Gram stain and differences in the observable phenotype of the organism. Key characteristics once used in classifying prokaryotes were

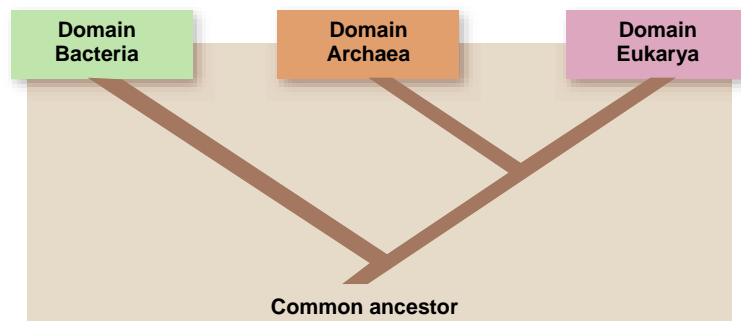

1. photosynthetic or nonphotosynthetic
2. motile or nonmotile
3. unicellular or colony-forming or filamentous
4. formation of spores or division by transverse binary fission
5. importance as human pathogens or not

### Molecular approaches to classification

With the development of genetic and molecular approaches, prokaryotic classifications may help reflect true evolutionary relatedness. Molecular approaches include

1. the analysis of the amino acid sequences of key proteins
2. the analysis of nucleic acid–base sequences by establishing the percent of guanine (G) and cytosine (C)
3. nucleic acid hybridization, which is essentially the mixing of single-stranded DNA from two species and determining the amount of base-pairing (closely related species will have more bases pairing)
4. gene and RNA sequencing, especially looking at ribosomal RNA
5. whole-genome sequencing

The three-domain, or Woese, system of phylogeny (figure 28.4) relies on all of these molecular methods, but emphasizes the comparison of rRNA sequences to establish the evolutionary relatedness of all organisms. The rRNA sequences were chosen for their high degree of evolutionary

**Figure 28.4 The three domains of life.** The two prokaryotic domains, Archaea and Bacteria, are not closely related, though both are prokaryotes. In many ways (see text), archaea more closely resemble eukaryotes than bacteria. This tree is based on rRNA sequences.

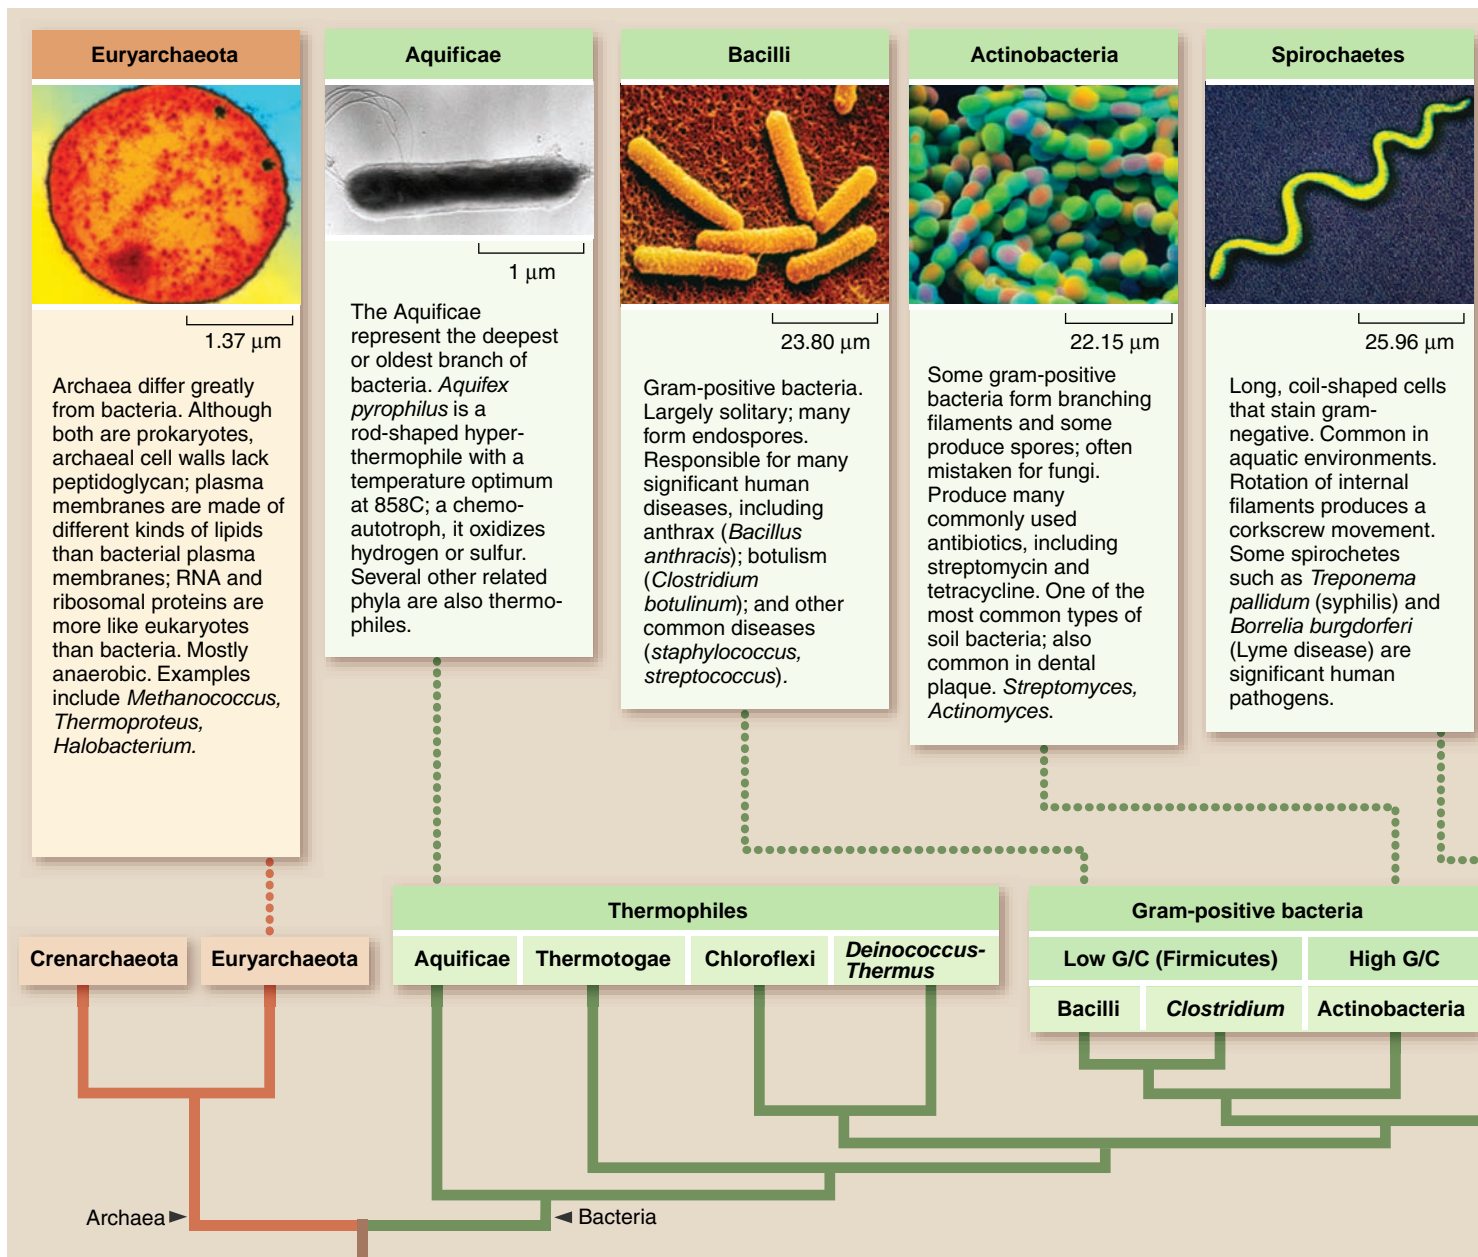

conservation to ask questions about these most ancient splits in the tree of life.

Based on these sorts of molecular data, several groupings of prokaryotes have been proposed. The most widely accepted is that presented in *Bergey's Manual of Systematic Bacteriology*, second edition, which is being published in 5 volumes, 3 of which have been completed (figure 28.5). At the same time, large scale sequencing of randomly sampled collections of bacteria show an incredible amount of diversity. While it has always been challenging to assign bacteria to species, these new data indicate that the vast majority of bacteria have never been cultured and studied in any detail. The field is in a state of flux as attempts are made to define the nature of bacterial species.

### Learning Outcomes Review 28.2

Compared with eukaryotes, prokaryotes are distinctly different, lacking both a membrane-bounded nucleus and diverse organelles. Prokaryotes also reproduce by binary fission. Bacteria and archaea are clearly different from each other based on both structure and metabolism. Classification of prokaryotes had been based on physical characteristics, and it has now been aided by the use of DNA analysis; but a vast number of prokaryotes remain unidentified because they cannot be cultured.

- What features distinguish archaea from both bacteria and eukaryotes?

**Figure 28.5** Some major clades of prokaryotes. The classification adopted here is that of *Bergey's Manual of Systematic Bacteriology*, second edition, 2001. G/C refers to %G/C in genome.

## 28.3 Prokaryotic Cell Structure

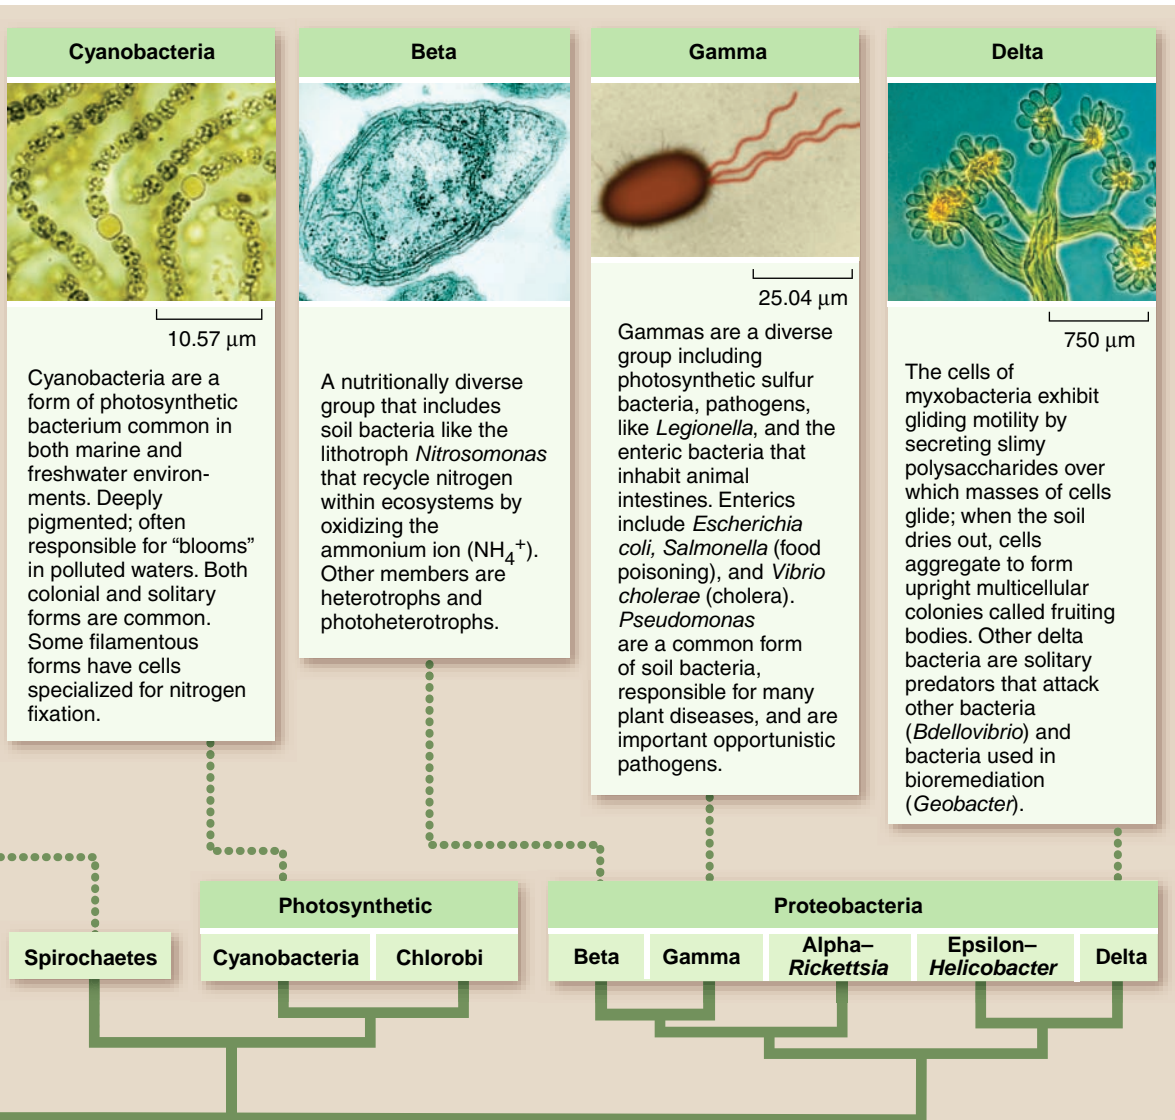

### Learning Outcomes

1. Describe the general features common to all prokaryotic cells.
2. Explain the differences between gram-positive and gram-negative bacterial cells.
3. Describe the features that distinguish different kinds of prokaryotic cells.

Prokaryotic cells are relatively simple, but they can be categorized based on cell shape. They also have some variations in structure that give them different staining properties for certain dyes. Other features are found in some types of cells but not in others.

### Prokaryotes have three basic forms: rods, cocci, and spirals

Although it is an oversimplification, it is useful to divide bacteria based on easily definable morphologies. Most prokaryotes exhibit one of three basic shapes: rod-shaped, often called a

*bacillus* (plural, *bacilli*); *coccus* (plural, *cocci*), spherical- or ovoid-shaped; and *spirillum* (plural, *spirilla*), long and helical-shaped; these bacteria are also called *spirochetes*.

© Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited

The bacterial cell wall is the single most important contributor to cell shape. Bacteria that normally lack cell walls, such as the mycoplasmas, do not have a set shape.

As diverse as their shapes may be, prokaryotic cells also have many different methods to move through their environment. A *flagellum* or several flagella may be found on the outer surface of many prokaryotic cells. These structures are used to propel the organisms in a fluid environment. Some rod-shaped and spherical bacteria form colonies, adhering end-to-end after they have divided, forming chains. Some bacterial cells change into stalked structures or grow long, branched filaments. Some filamentous bacteria are capable of a gliding motion on solid surfaces, often combined with rotation around a longitudinal axis.

## Prokaryotes have a tough cell wall and other external structures

The prokaryotic cell wall is often complex, consisting of many layers. Minimally it consists of peptidoglycan, a polymer unique to bacteria. This polymer forms a rigid network of polysaccharide strands cross-linked by peptide side chains. It is an important structure because it maintains the shape of the cell and protects the cell from swelling and rupturing in hypotonic solutions, which are most commonly found in the environment. The archaea do not possess peptidoglycan, but some have a similar structure called pseudomurein, or pseudo-peptidoglycan.

### Gram-positive and gram-negative bacteria

Two types of bacteria can be identified using a staining process called the **Gram stain**, hence their names. **Gram-positive** bacteria have a thicker peptidoglycan wall and stain a purple color, whereas the more common **gram-negative** bacteria contain less peptidoglycan and do not retain the purple-colored dye. These gram-negative bacteria can be stained with a red counterstain and then appear dark pink (figure 28.6).

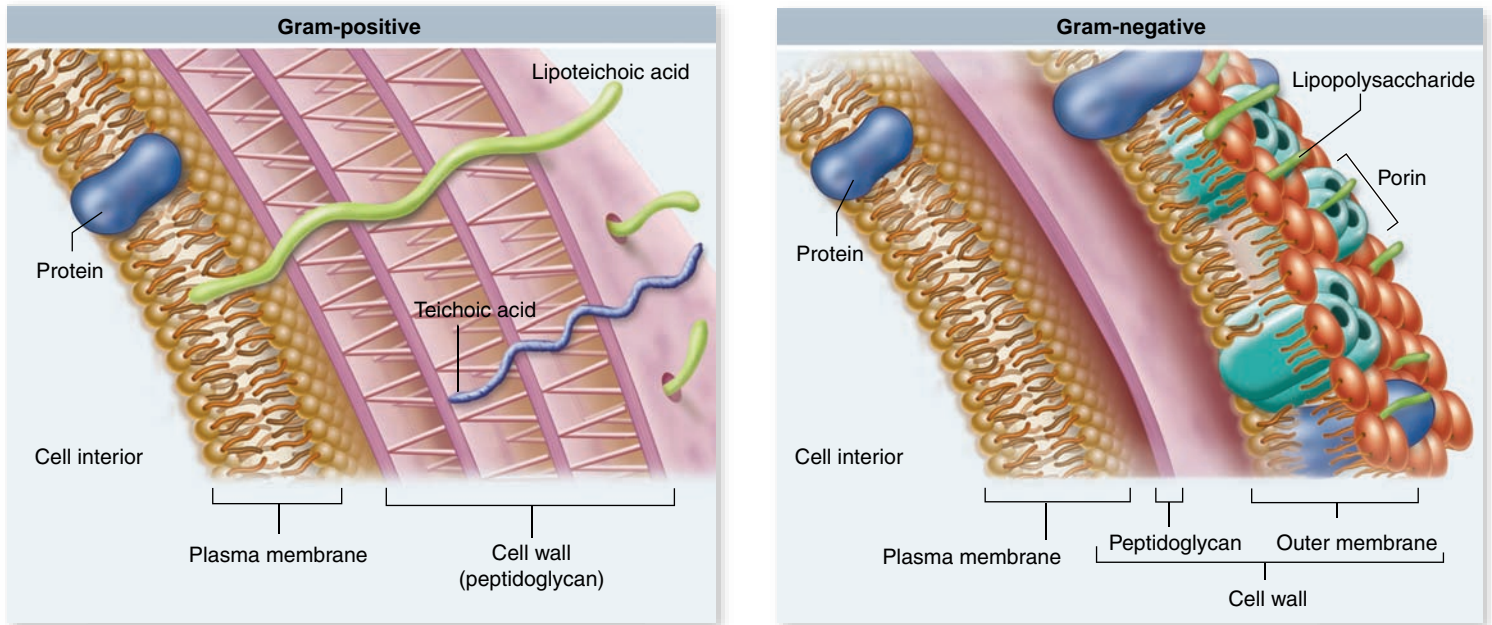

In the gram-positive bacteria, the peptidoglycan forms a thick, complex network around the outer surface of the cell. This network also contains lipoteichoic and teichoic acid, which protrudes from the cell wall. In the gram-negative bacteria, a thin layer of peptidoglycan is sandwiched between the plasma membranes and a second outer membrane (figure 28.7). The outer membrane contains large molecules

*a.*

**Figure 28.6 The Gram stain.** *a.* The thick peptidoglycan (PG) layer encasing gram-positive bacteria traps crystal violet dye, so the bacteria appear purple in a gram-stained smear (named after Hans Christian Gram—Danish bacteriologist, 1853–1938—who developed the technique). Because gram-negative bacteria have much less peptidoglycan (located between the plasma membrane and an outer membrane), they do not retain the crystal violet dye and so exhibit the red counterstain (usually a safranin dye). *b.* A micrograph showing the results of a Gram stain with both gram-positive and gram-negative cells.

**Figure 28.7** The structure of gram-positive and gram-negative cell walls. The gram-positive cell wall is much simpler, composed of a thick layer of cross-linked peptidoglycan chains. Molecules of lipoteichoic acid and teichoic acid are also embedded in the wall and exposed on the surface of the cell. The gram-negative cell wall is composed of multiple layers. The peptidoglycan layer is thinner than in gram-positive bacteria and is surrounded by an additional membrane composed of lipopolysaccharide. Porin proteins form aqueous pores in the outer membrane. The space between the outer membrane and peptidoglycan is called the periplasmic space.

of **lipopolysaccharide**, lipids with polysaccharide chains attached. The outer membrane layer makes gram-negative bacteria resistant to many antibiotics that interfere with cell-wall synthesis in gram-positive bacteria. For example, penicillin acts to inhibit the cross-linking of peptidoglycan in a gram-positive cell wall, killing growing bacterial populations.

### S-layer

In some bacteria and archaea, an additional protein or glycoprotein layer forms a rigid paracrystalline surface called an *S-layer* outside of the peptidoglycan or outer membrane layers of gram-positive and gram-negative bacteria, respectively. Among the archaea, the S-layer is almost universal and can be found outside of a pseudopeptidoglycan layer or, in contrast to the bacteria, may be the only rigid layer surrounding the cell. The functions of S-layers are diverse and variable but often involve adhesion to surfaces or protection.

### The capsule

In some bacteria, an additional gelatinous layer, the **capsule**, surrounds the other wall layers. A capsule enables a prokaryotic cell to adhere to surfaces and to other cells, and, most important, to evade an immune response by interfering with recognition by phagocytic cells. Therefore, a capsule often contributes to the ability of bacteria to cause disease.

### Bacterial flagella and pili

Many kinds of prokaryotes have slender, rigid, helical flagella composed of the protein **flagellin** (figure 28.8). These flagella range from 3 to 12  $\mu\text{m}$  in length and are very thin—only 10 to 20 nm thick. They are anchored in the cell wall and spin like a propeller, moving the cell through a liquid environment.

Bacterial cells that have lost the genes for flagellin are not able to swim.

**Pili** (singular, *pilus*) are other hairlike structures that occur on the cells of some gram-negative prokaryotes. They are shorter than prokaryotic flagella and about 7.5 to 10 nm

**Figure 28.8** The flagellar motor of a gram-negative bacterium. *a.* A protein filament, composed of the protein flagellin, is attached to a protein rod that passes through a sleeve in the outer membrane and through a hole in the peptidoglycan layer to rings of protein anchored in the cell wall and plasma membrane, like rings of ball bearings. The rod rotates when the inner protein ring attached to the rod turns with respect to the outer ring fixed to the cell wall. The inner ring is an  $\text{H}^+$  ion channel, a proton pump that uses the flow of protons into the cell to power the movement of the inner ring past the outer one. The membrane wall anchor of the flagellum is called the basal body. *b.* Electron micrograph of bacterial flagellum.

thick. Pili are more important in adhesion than movement, and they also have a role in exchange of genetic information (discussed later).

### Endospore formation

Some prokaryotes are able to form **endospores**, developing a thick wall around their genome and a small portion of the cytoplasm when they are exposed to environmental stress. These endospores are highly resistant to environmental stress, especially heat, and when environmental conditions improve, they can germinate and return to normal cell division to form new individuals after decades or even centuries.

The bacteria that cause tetanus, botulism, and anthrax are all capable of forming spores. With a puncture wound, tetanus endospores may be driven deep into the skin where conditions are favorable for them to germinate and cause disease, or even death.

### The interior of prokaryotic cells is organized

The most fundamental characteristic of prokaryotic cells is their simple interior organization. Prokaryotic cells lack the extensive functional compartmentalization seen within eukaryotic cells, but they do have the following structures:

**Internal membranes.** Many prokaryotes possess invaginated regions of the plasma membrane that function in respiration or photosynthesis (figure 28.9).

**Nucleoid region.** Prokaryotes lack nuclei and generally do not possess linear chromosomes. Instead, their genes are encoded within a single double-stranded ring of DNA that is highly condensed to form a visible region of the cell known as the **nucleoid region**. Many prokaryotic cells also possess plasmids, which as described earlier are small, independently replicating circles of DNA. Plasmids contain only a few genes, and although these genes may

confer a selective advantage, they are not essential for the cell's survival.

**Ribosomes.** Prokaryotic ribosomes are smaller than those of eukaryotes and differ in protein and RNA content. Antibiotics such as tetracycline and chloramphenicol can tell the difference, however—they bind to prokaryotic ribosomes and block protein synthesis, but they do not bind to eukaryotic ribosomes.

### Learning Outcomes Review 28.3

The three basic shapes of prokaryotes are rod-shaped, spherical, and spiral-shaped. Bacteria have a cell wall containing peptidoglycan, which is the basis for the Gram stain. Gram-positive bacteria have a thick cell wall, relative to gram-negative species. Many also have an external capsule. Some bacteria have flagella and pili. Some can form heat-resistant endospores. Although prokaryotes do not have membrane-bounded organelles, the interior of the cell is organized and may include infolding of the plasma membrane. Prokaryotic DNA is localized in a nucleoid region.

- What would be the simplest method to determine whether two bacteria belong to the same species?

## 28.4 Prokaryotic Genetics

### Learning Outcomes

1. Contrast the mechanisms of DNA exchange in prokaryotes.
2. Explain genetic mapping in *E. coli*.
3. Describe how genetics explains the spread of antibiotic resistance.

**Figure 28.9** Prokaryotic cells often have complex internal membranes. *a.* This aerobic bacterium exhibits extensive respiratory membranes (long dark curves that hug the cell wall) within its cytoplasm not unlike those seen in mitochondria. *b.* This cyanobacterium has thylakoid-like membranes (ripple-like shapes along the edges and in the center) that provide a site for photosynthesis.

In sexually reproducing populations, traits are transferred vertically from parent to child. Prokaryotes do not reproduce sexually, but they can exchange DNA between different cells. This horizontal gene transfer occurs when genes move from one cell to another by **conjugation**, requiring cell-to-cell contact, or by means of viruses (*transduction*). Some species of bacteria can also pick up genetic material directly from the environment (*transformation*).

All of these processes have been observed in archaea, but the study of archaeal genetics is still in its infancy because of the difficulty in culturing most species. We concentrate here on bacterial systems, primarily *E. coli*, which has been studied extensively.

### Conjugation depends on the presence of a conjugative plasmid

Plasmids may encode functions that can confer an advantage to the cell, such as antibiotic resistance, on which natural selection can operate—but they are not required for normal function. In some cases, plasmids can be transferred from one cell to another via conjugation. The best known plasmid capable of transfer is called the **F plasmid**, for fertility factor; cells containing F plasmids are termed **F<sup>+</sup>** cells, and cells that lack the F plasmid

**Figure 28.10** Conjugation bridge and transfer of F plasmid between  $F^+$  and  $F^-$  cell. *a.* The electron micrograph shows two *E. coli* cells caught in the act of conjugation. The connection between the cells is the extended F pilus. *b.*  $F^-$  cells are converted to  $F^+$  cells by the transfer of the F plasmid. The cells are joined by a conjugation bridge and the plasmid is replicated in the donor cell, displacing one parental strand. The displaced strand is transferred to the recipient cell then replicated. After successful transfer, the recipient cell becomes an  $F^+$  cell capable of expressing genes for the F pilus and acting as a donor.

are  $F^-$  cells. The F plasmid occurs in *E. coli* and, like all plasmids, acts as an independent genetic entity that nevertheless depends on the cell for replication. Studies involving the F plasmid were critical to our current understanding of bacterial genetics and the organization of the *E. coli* chromosome.

### F plasmid transfer

The F plasmid contains a DNA replication origin and several genes that promote its transfer to other cells. These genes encode protein subunits that assemble on the surface of the bacterial cell, forming a hollow pilus that is necessary for the transfer process (figure 28.10*a*).

First, the F plasmid binds to a site on the interior of the  $F^+$  cell just beneath the pilus, now called a *conjugation bridge*. Then, by a process called *rolling-circle replication*, the F plasmid begins to copy its DNA at the binding point. As it is replicated, the displaced single strand of the plasmid passes into the other cell. There, a complementary strand is added, creating a new, stable F plasmid (figure 28.10*b*).

### Recombination between the F plasmid and host chromosome

The F plasmid can integrate into the host chromosome by recombining with it (see chapter 13). The molecular events in this process are similar to events during meiosis in eukaryotes when crossing over (recombination) exchanges material between chromosomes. This process is also called homologous recombination. In the case of the F plasmid and the *E. coli* chromosome, a single recombination event between two circles produces a larger circle, consisting of the chromosome and the integrated plasmid. This integration is actually mediated by host-encoded proteins, but it takes advantage of regions in the F plasmid called insertion sequences (IS) that also exist in the *E. coli* chromosome. These IS elements are actually transposable elements that probably moved from the chromosome to the F plasmid.

When the F plasmid is integrated into the chromosome, the cell is called an **Hfr cell** for high frequency of recombination (figure 28.11), because now transfer by the F plasmid will include chromosomal DNA. The site on the F plasmid where transfer initiates is located in the middle of the integrated plasmid, so that the entire chromosome would have to be transferred to also

**Figure 28.11** Integration and excision of F plasmid.

The F plasmid contains short insertion sequences (IS) that also exist in the chromosome. This allows the plasmid to pair with the chromosome, and a single recombination event between two circles leads to a larger circle. This integrates the plasmid into the chromosome, creating an Hfr cell, as shown on the left. The process is reversible because the IS sequences in the integrated plasmid can pair, and now a recombination event will return the two circles and convert the Hfr back to an  $F^+$  cell as shown on the right.

transfer all of the integrated plasmid. The transfer of the entire chromosome takes around 100 minutes, and the conjugation bridge is usually broken before that time. This leads to transfer of portions of donor chromosome that can then replace regions of the recipient chromosome by homologous recombination. This occurs by *two* recombination events between the linear piece and the circular chromosome, similar to a double crossover in eukaryotic meiosis.

Geneticists have taken advantage of this process to map the order of genes in the *E. coli* chromosome. Genes close to the origin of transfer are transferred early in the process, and those far from the origin are transferred later. If the process of mating is experimentally interrupted at different times, then gene order can be mapped based on time of entry of each gene (figure 28.12). The entry of genes can be detected by using a donor with wild-type alleles that can replace mutant alleles in the recipient by homologous recombination as described. These experiments have shown that the *E. coli* chromosome is indeed circular, and the genetic map is therefore circular. The units of the map are minutes, and the entire map is 100 minutes long.

The F plasmid can also excise itself by reversing the integration process. In this case, the IS elements bounding the integrated plasmid pair and now a single recombination event will restore the two circles (see figure 28.11). If excision is inaccurate, the F plasmid can pick up some chromosomal DNA in the process. This creates what is called an F' plasmid that can then be transferred rapidly and in its entirety to another cell. In this case, the cell already has the same genetic material in its chromosome as that carried by the F'. This makes the cell a **partial diploid**, sometimes called a **merodiploid**. Merodiploids can be used to determine if new isolated mutations are alleles of known genes. This is done by using wild types of alleles of known genes of the F' plasmid to provide normal function heterozygous to unknown mutant alleles in the chromosome.

## Viruses transfer DNA by transduction

Horizontal transfer of DNA can also be mediated by bacteriophage. In **generalized transduction**, virtually any gene can be transferred between cells; in **specialized transduction**, only a few genes are transferred.

### Generalized transduction

Generalized transduction can be thought of as an accident of the biology of some types of lytic phage (see chapter 27). In these viruses, after the viral genome is replicated and the phage head is constructed, the phage packaging machinery stuffs DNA into the phage head until no more fits, so-called headfull packaging. Sometimes the phage begins with bacterial DNA instead of phage DNA and packages this DNA into a phage head (figure 28.13). When this viral particle goes on to infect another cell, it injects the bacterial DNA into the infected cell instead of viral DNA. This DNA can then be incorporated into the recipient chromosome by homologous recombination. Similar to transfer by Hfr cells described earlier, two recombination events are necessary to integrate the linear piece of DNA into the circular chromosome (see figure 28.13).

Generalized transduction has also been used for mapping purposes in *E. coli*, although the logic is different from that in

## SCIENTIFIC THINKING

**Hypothesis:** Conjugation using Hfr strains involves the linear transfer of information from donor to recipient cell.

**Prediction:** If there is a linear transfer of information, then different markers should appear in a time sequence.

**Test:** Mating strains are agitated at time points to break the conjugation bridge, then plated to determine genotype.

### Data from Interrupted Mating

### Genetic Map

**Result:** The different genes from the donor strain appear in a linear time sequence.

**Conclusion:** The transfer of genetic information is linear. This sequence can be used to construct a genetic map ordering the genes on the chromosomes.

**Further Experiments:** Can other methods of DNA exchange also be used for genetic mapping?

## Figure 28.12 Interrupted mating experiment allows construction of genetic map.

conjugation. In transduction, the closer together two genes are, the more likely it is that they will be transferred in a single transduction event. This can be expressed mathematically as the *cotransduction frequency*. Correlation of maps from the two

**Figure 28.13 Transduction by generalized transducing phage.** When some phage infect cells, they degrade the host DNA into pieces. When the phage package their DNA, they can package host DNA in place of phage DNA to produce a transducing phage as shown on the top. When a transducing phage infects a cell, it injects host DNA that can then be integrated into the host genome by homologous recombination. With a linear piece of DNA, it requires two recombination events, which replace the chromosomal DNA with the transducing DNA as shown on the bottom. If the new allele is different from the old, the cell's phenotype will change.

methods allows an empirical conversion between cotransduction frequency and minutes in the genetic map.

### Specialized transduction

Specialized transduction is limited to phage that exhibit a lysogenic life cycle (see chapter 27). The prototype for this is phage  $\lambda$  from *E. coli*. When  $\lambda$  infects a cell and its genome integrates into the host chromosome, it does not destroy the cell but is passed on by cell division. This integration event is similar to the integration of the F plasmid, except that in the case of  $\lambda$  the recombination is a site-specific event mediated by phage-encoded proteins.

In this lysogenic state, the phage is called a prophage and it is dormant. The prophage encodes the functions necessary to eventually excise itself and undergo lytic growth, leading to the death of the cell. If this excision event is imprecise, it may take some chromosomal DNA with it, in the process making a specialized transducing phage. These phage carry both phage genes and chromosomal genes, unlike generalized transducing phage that carry only chromosomal DNA.

Because the phage head can carry only as much DNA as is found in the phage genome, imprecise excision results in deletion of phage genes. Thus specialized transducing phage may be defective if genes necessary for phage growth are lost in the process.

Specialized transducing phage particles can then integrate into the chromosome, just like wild-type phage, also making the cell diploid for the genes carried by the phage. Phage particles that can integrate as prophages may become trapped in the host genome if the genes necessary for excision become defective by mutation or are lost. The *E. coli* genome contains a number of such cryptic prophage, some of which encode functions important to the cell and must now be considered part of the host genome.

### Transformation is the uptake of DNA directly from the environment

Transformation is a naturally occurring process in some species, such as the bacteria that were studied by Frederick Griffith (see chapter 14). Griffith discovered the process despite not knowing what chemical component was transferred. Transformation occurs when one bacterial cell has died and ruptured,

**Figure 28.14 Natural transformation.** Natural transformation occurs when one cell dies and releases its contents to the surrounding environment. The DNA is usually fragmented, and small pieces can be taken up by other, living cells. The DNA taken up can replace chromosomal DNA by homologous recombination as in conjugation and transduction. If the new DNA contains different alleles from the chromosome, the phenotype of the cell changes, possibly providing a selective advantage.

spilling its fragmented DNA into the surrounding environment. This DNA can be taken up by another cell and incorporated into its genome, thereby transforming it (figure 28.14). When the uptake occurs under natural conditions, it is termed natural transformation. Some species of both gram-positive and gram-negative bacteria exhibit natural transformation, although the mechanisms seem to differ between the groups.

The proteins involved in the process of natural transformation are all encoded by the bacterial chromosome. The implication is that natural transformation may be the only one of the mechanisms of DNA exchange that evolved as part of normal cellular machinery. The transfer of chromosomal DNA by either conjugation or transduction can be thought of as accidents of plasmid or phage biology, respectively.

Transformation is also important in molecular cloning, but *E. coli* does not exhibit natural transformation. When transformation is accomplished in the laboratory it is called artificial transformation. Artificial transformation is useful for cloning and DNA manipulation (see chapter 17).

### Antibiotic resistance can be transferred by resistance plasmids

Some conjugative plasmids pick up antibiotic resistance genes, becoming resistance plasmids, or **R plasmids**. The rapid transfer of newly acquired, antibiotic resistance genes by plasmids has been an important factor in the appearance of the resistant strains of the pathogen *Staphylococcus aureus* discussed in the next section.

The means by which resistance plasmids acquire antibiotic resistance genes is often through transposable elements, which were described in chapter 18. These elements can move from chromosome to chromosome or from plasmid to chromosome and back again, and they can transfer antibiotic resistance genes in the process. If a conjugative plasmid picks up these genes, then the bacterium carrying it has a selective advantage in the presence of those antibiotics.

An important example in terms of human health involves the Enterobacteriaceae, the family of bacteria to which the common intestinal bacterium *E. coli* belongs. This family contains many pathogenic bacteria, including the organisms that

cause dysentery, typhoid, and other major diseases. At times, some of the genetic material from these pathogenic species is exchanged with or transferred to *E. coli* by transmissible plasmids or bacteriophage. Because of its abundance in the human digestive tract, *E. coli* poses a special threat if it acquires harmful traits, as seen by the outbreaks of the food-borne O157:H7 strain of *E. coli*. Infection with this strain of *E. coli* can lead to serious illness. This is a new strain of *E. coli* that evolved by acquiring genes for pathogenic traits. Evidence suggests this occurred by both transduction and the acquisition of a large virulence plasmid by conjugation.

### Variation can also arise by mutation

Just as with any organism, mutations can arise spontaneously in bacteria. Certain factors, especially those that damage DNA, such as radiation, ultraviolet light, and various chemicals, increase the likelihood of mutation.

A typical bacterium such as *E. coli* contains about 5000 genes. The probability of mutation occurring by chance is about in one out of every million copies of a gene. With 5000 genes in a bacterium, we can predict that approximately 1 out of every 200 bacteria will have a mutation. With adequate food and nutrients, a population of *E. coli* can double in 20 minutes. Because bacteria multiply so rapidly, mutations can spread rapidly in a population and can change the characteristics of that population in a relatively short time.

In the laboratory, bacteria are grown on different substrates, called *growth media*, that reflect their nutritional needs. For a particular species, the medium that contains only those nutrients required for wild-type growth is termed a *minimal medium*. A mutant that can no longer survive on minimal medium and needs particular nutritional supplements, such as an amino acid, is called an **auxotroph**. **Replica plating** allows identification of bacterial auxotrophs from a master plate of rich growth media by isolating individual colonies and observing their growth (or failure to grow) on different supplemented media. The technique is somewhat like using a rubber stamp—an impression of colonies growing in a Petri plate is made on a velvet surface, and then this surface is pressed onto different

media in other plates. The impression contains many thousands if not millions of cells from each colony—and each colony has grown from a single cell. In this way, a bacterium with a highly specific mutation can be isolated, identified, and grown.

The ability of prokaryotes to change rapidly in response to new challenges often has adverse effects on humans. A number of antibiotic-resistant strains of the bacterium *Staphylococcus aureus* (termed methicillin-resistant *Staphylococcus aureus*, or MRSA) had been known in hospital settings for some time. More recently these have been observed in infections out of the hospital setting, so-called community acquired MRSA.

Of most concern among these strains is **vancomycin-resistant *Staphylococcus aureus*** (VRSA). This appears to have arisen rapidly by mutation and is alarming because vancomycin is the drug of last resort, making these strains and the infections they cause very difficult to stop. *Staphylococcus* infections, or “staph” infections for short, provide an excellent example of the way in which mutation and intensive selection can bring about rapid change in bacterial populations.

### Learning Outcomes Review 28.4

Prokaryotic DNA exchange is horizontal, from donor cell to recipient cell. DNA can be exchanged by conjugation via plasmids, by transduction via viruses, and by transformation through the direct uptake of DNA from the environment. These forms of DNA exchange can be used experimentally to map genes. Variation in prokaryotes also arises by mutation. Extensive use of antibiotics has led to selection for resistant organisms. Resistance genes can be transferred, rapidly spreading resistance.

- How does transfer of genetic information in bacteria differ from eukaryotic sex?

## 28.5 Prokaryotic Metabolism

### Learning Outcomes

1. Describe the different ways that prokaryotes acquire energy and carbon.
2. Explain how bacterial proteins can cause disease in humans.

The variation seen in prokaryotes manifests itself most noticeably in biochemical rather than morphological diversity. Wide variation has been found in the types of metabolism prokaryotes exhibit, especially in the means by which they acquire energy and carbon.

### Prokaryotes acquire carbon and energy in four basic ways

Prokaryotes have evolved many mechanisms to acquire the energy and carbon they need for growth and reproduction. Many are *autotrophs* that obtain their carbon from inorganic CO<sub>2</sub>.

Other prokaryotes are *heterotrophs* that obtain at least some of their carbon from organic molecules, such as glucose. Depending on the method by which they acquire energy, autotrophs and heterotrophs are categorized as follows:

**Photoautotrophs.** Many bacteria carry out photosynthesis, using the energy of sunlight to build organic molecules from carbon dioxide. The **cyanobacteria** use chlorophyll *a* as the key light-capturing pigment and H<sub>2</sub>O as an electron donor, releasing oxygen gas as a by-product. They are therefore oxygenic, and their method of photosynthesis is very similar to that found in algae and plants.

Other bacteria use bacteriochlorophyll as their light-capturing pigment and H<sub>2</sub>S as an electron donor, leaving elemental sulfur as the by-product. These bacteria do not produce oxygen (anoxygenic) and have a simpler method of photosynthesis. These are the purple and green sulfur bacteria.

Archaeal species also carry out photosynthesis, the simplest form known. This involves a single protein, bacteriorhodopsin, that uses energy from light to translocate protons across a membrane. This then provides a proton motive force for ATP synthesis. Recent surveys of microbial diversity in marine ecosystems using DNA sequencing have found a new relative of the rhodopsin family called proteorhodopsin. First found in a bacterial species, these proteorhodopsins are quite widespread, found in bacterial, archaeal, and even algal species. This raises the possibility that photosynthesis in marine systems may be more widespread and complex than previously thought.

**Chemolithoautotrophs.** Some prokaryotes obtain energy by oxidizing inorganic substances. Nitrifiers, for example, oxidize ammonia or nitrite to obtain energy, producing the nitrate that is taken up by plants. This process is called **nitrification**, and it is essential in terrestrial ecosystems because plants primarily absorb nitrogen in the form of nitrate.

Other chemolithoautotrophs oxidize sulfur, hydrogen gas, and other inorganic molecules. On the dark ocean floor at depths of 2500 m, entire ecosystems subsist on prokaryotes that oxidize hydrogen sulfide as it escapes from thermal vents.

**Photoheterotrophs.** The so-called purple and green nonsulfur bacteria use light as their source of energy but obtain carbon from organic molecules, such as carbohydrates or alcohols that have been produced by other organisms.

**Chemoheterotrophs.** The majority of prokaryotes obtain both carbon atoms and energy from organic molecules. These include decomposers and most pathogens. Human beings and all nonphotosynthetic eukaryotes are chemoheterotrophs as well.

### Some bacteria can attack other cells directly

Invading pathogens of the genera *Yersinia* can introduce proteins directly into host cells by a specialized form of secretion. (*Yersinia pestis* is the bacterial species responsible for bubonic plague.) Most proteins secreted by gram-negative

## 28.6 Human Bacterial Disease

### Learning Outcomes

1. Describe common human bacterial pathogens.
2. Explain how bacteria can cause ulcers.
3. Identify sexually transmitted diseases caused by bacteria.

bacteria have special signal sequences that allow them to pass through the bacterium's double membrane. The proteins secreted by *Yersinia* lacked a key signal sequence that two known secretion mechanisms require for transport. The proteins must therefore have been secreted by means of a third type of system, which researchers called the *type III system*. This kind of system acts like a kind of molecular syringe allowing the pathogen to inject proteins directly into the cytoplasm of host cells.

As more bacterial species are studied, the genes coding for the type III system are turning up in other gram-negative animal pathogens, and even in more distantly related plant pathogens. The genes seem more closely related to one another than are the bacteria. Furthermore, the genes are similar to those that code for bacterial flagella.

These proteins are used to transfer other virulence proteins, such as toxins, into nearby eukaryotic cells. Given the similarity of the type III genes to the genes that code for flagella, the transfer proteins may form a flagellum-like structure that shoots virulence proteins into the host cells. Once in the eukaryotic cells, the virulence proteins affect the host's response to the pathogen.

In *Yersinia*, proteins secreted by the type III system are injected into macrophages; the proteins disrupt signals that tell the macrophages to engulf bacteria. *Salmonella* and *Shigella* use their type III proteins to enter the cytoplasm of eukaryotic cells, and thus they are protected from the immune system of their host. The proteins secreted by certain strains of *E. coli* alter the cytoskeleton of nearby intestinal eukaryotic cells, resulting in a bulge onto which the bacterial cells can tightly bind.

### Bacteria are costly plant pathogens

Although the majority of commercially relevant plant pathogens are fungi, many diseases of plants are associated with particular heterotrophic bacteria. Almost every kind of plant is susceptible to one or more kinds of bacterial disease, including blights, soft rots, and wilts. Fire blight, which destroys pear and apple trees and related plants, is a well-known example of bacterial disease.

The early symptoms of these plant diseases vary, but they are commonly manifested as spots of various sizes on the stems, leaves, flowers, or fruits. Most bacteria that cause plant diseases are members of the group of rod-shaped gram-negative bacteria known as pseudomonads.

### Learning Outcomes Review 28.5

Prokaryotes exhibit amazing metabolic diversity with both autotrophic and heterotrophic species. Photoautotrophs use light as an energy source; chemolithoautotrophs oxidize inorganic compounds. Photoheterotrophs use light as an energy source and organic compounds as carbon sources. Chemoheterotrophs use organic compounds for both energy and carbon. Bacterial animal pathogens attack host cells with toxic proteins that disrupt the host's immune response, among other effects.

- Why is metabolism a better way than morphology to characterize prokaryotes?

In the early 20th century, before the discovery and widespread use of antibiotics, infectious diseases killed nearly 20% of all U.S. children before they reached the age of five. Sanitation and antibiotics considerably improved the situation. In recent years, however, we have seen the appearance or reappearance of many bacterial diseases, including cholera, leprosy, tetanus, bacterial pneumonia, whooping cough, diphtheria, and Lyme disease (table 28.1). Members of the genus *Streptococcus* are associated with scarlet fever, rheumatic fever, pneumonia, "flesh-eating disease," and other infections. Tuberculosis, another bacterial disease, is still a leading cause of death in humans worldwide.

Bacteria have many different methods to spread through a susceptible population. Tuberculosis and many other bacterial diseases of the respiratory tract are mostly spread through the air in droplets of mucus or saliva. Diseases such as typhoid fever, paratyphoid fever, and bacillary dysentery are spread by fecal contamination of food or water. Lyme disease and Rocky Mountain spotted fever are spread to humans by tick vectors.

### Tuberculosis has infected humans for all of recorded history

Tuberculosis (TB) has been a scourge to humanity for thousands of years. There is evidence that peoples from ancient Egypt and pre-Columbian South America died from TB; the TB bacillus (*Mycobacterium tuberculosis*) has been identified in prehistoric mummies. TB afflicts the respiratory system, thwarts the immune system, and is easily transmitted from person to person through the air.

#### The spread of tuberculosis

Currently, about one-third of all people worldwide are regularly exposed to *Mycobacterium tuberculosis*. An estimated 9.27 million new cases were diagnosed, and 1.8 million deaths occurred in 2007. In 2006, the World Health Organization reported the incidence of TB falling in five of six WHO regions, but the numbers continue to rise in Africa driven by the spread of HIV.

Since the mid-1980s, the United States has experienced a resurgence of TB. This peaked in the mid-1990s and has been declining since, although the rate of decline is leveling off. The latest statistics from the CDC indicate 13,300 TB cases in 2007, down from 13,754 cases in 2006.

#### Tuberculosis treatment

Most TB patients are placed on multiple, expensive antibiotics for six to twelve months. Alarming outbreaks of **multidrug-resistant**

**TABLE 28.1** Important Human Bacterial Diseases

Disease	Pathogen	Vector/Reservoir	Epidemiology
Anthrax	<i>Bacillus anthracis</i>	Animals, including processed skins	Bacterial infection that can be transmitted through contact or ingestion. Rare except in sporadic outbreaks. May be fatal.
Botulism	<i>Clostridium botulinum</i>	Improperly prepared food	Contracted through ingestion or contact with wound. Produces acute toxic poison; can be fatal.
Chlamydia	<i>Chlamydia trachomatis</i>	Humans, sexually transmitted disease (STD)	Urogenital infections with possible spread to eyes and respiratory tract. Increasingly common over past 20 years.
Cholera	<i>Vibrio cholerae</i>	Human feces, plankton	Causes severe diarrhea that can lead to death by dehydration; 50% peak mortality rate if untreated. A major killer in times of crowding and poor sanitation; over 100,000 died in Rwanda in 1994 outbreak.
Dental caries	<i>Streptococcus mutans</i> , <i>Streptococcus sobrinus</i>	Humans	A dense collection of these bacteria on the surface of teeth leads to secretion of acids that destroy minerals in tooth enamel; sugar alone does not cause caries.
Diphtheria	<i>Corynebacterium diphtheriae</i>	Humans	Acute inflammation and lesions of respiratory mucous membranes. Spread through respiratory droplets. Vaccine available.
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Humans only	STD, on the increase worldwide. Usually not fatal.
Hansen disease (leprosy)	<i>Mycobacterium leprae</i>	Humans, feral armadillos	Chronic infection of the skin; worldwide incidence about 10–12 million, especially in southeast Asia. Spread through contact with infected individuals.
Lyme disease	<i>Borrelia burgdorferi</i>	Ticks, deer, small rodents	Spread through bite of infected tick. Lesion followed by malaise, fever, fatigue, pain, stiff neck, and headache.
Peptic ulcers	<i>Helicobacter pylori</i>	Humans	Originally thought to be caused by stress or diet, most peptic ulcers now appear to be caused by this bacterium; good news for ulcer sufferers because it can be treated with antibiotics.
Plague	<i>Yersinia pestis</i>	Fleas of wild rodents: rats and squirrels	Killed one-fourth of the population of Europe in the 14th century; endemic in wild rodent populations of the western United States today.
Pneumonia	<i>Streptococcus</i> , <i>Mycoplasma</i> , <i>Chlamydia</i> , <i>Haemophilus</i>	Humans	Acute infection of the lungs; often fatal without treatment. Vaccine for streptococcal pneumonia available.
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Humans	An acute bacterial infection of the lungs, lymph, and meninges. Its incidence is on the rise, complicated by the development of new strains of the bacterium that are resistant to antibiotics.
Typhoid fever	<i>Salmonella typhi</i>	Humans	A systemic bacterial disease of worldwide incidence. Fewer than 500 cases a year are reported in the United States. Spread through contaminated water or foods (such as improperly washed fruits and vegetables). Vaccines are available for travelers.
Typhus	<i>Rickettsia typhi</i>	Lice, rat fleas, humans	Historically a major killer in times of crowding and poor sanitation; transmitted from human to human through the bite of infected lice and fleas. Peak untreated mortality rate of 70%.

(MDR) strains of TB have occurred, however, in the United States and worldwide. These MDR strains are resistant to most of the best available anti-TB medications. MDR TB is of particular concern because it requires much more time and is more expensive to treat. Also, it is more likely to prove fatal.

This spread of MDR TB is likely due to the extremely long course of antibiotics required to treat the disease. Patients often quit taking the antibiotics before completing the course, setting up conditions in their bodies to allow drug-resistant bacteria to thrive.

The basic principles of TB treatment and control are to make sure all patients complete a full course of medication, so that all of the bacteria causing the infection are killed and drug-resistant strains do not develop. Great efforts are being made to ensure that high-risk individuals who are infected but not yet

sick receive preventive therapy under observation. Such programs are approximately 90% effective in reducing the likelihood of developing active TB and spreading it to others. These efforts are having an effect, since the disease is on the decline in the United States, decreasing by 3.3% from 2006 to 2007.

### Bacterial biofilms are involved in tooth decay

Bacteria and other organisms may form mixed cultures on certain surfaces that are extremely difficult to treat. On teeth, this biofilm, or plaque, consists largely of bacterial cells surrounded by a polysaccharide matrix. Most of the bacteria in plaque are filaments of rod-shaped cells classified as various species of *Actinomyces*, which extend out perpendicular to the surface of the tooth. Many other bacterial species are also present in plaque.

Tooth decay, or dental caries, is caused by the bacteria present in the plaque, which persist especially in places that are difficult to reach with a toothbrush. Diets that are high in simple sugars are especially harmful to teeth because certain bacteria, notably *Streptococcus sobrinus* and *S. mutans*, ferment the sugars to lactic acid. This acid production reduces the pH in the area around the plaque, breaking down the structure of the hydroxyapatite that makes tooth enamel hard. As the enamel degenerates, the remaining soft matrix of the tooth becomes vulnerable to bacterial attack.

## Bacteria can cause ulcers

Bacteria can also be the cause of disease states that on the surface appear to have no infectious basis. Peptic ulcer disease is due to craterlike lesions in the gastrointestinal tract that are exposed to peptic acid. Ulcers can be caused by drugs, such as nonsteroidal anti-inflammatory drugs, and also by some tumors of the pancreas that cause an oversecretion of peptic acid. In 1982, a bacterium named *Campylobacter pylori* (now named *Helicobacter pylori*) was isolated from gastric juices. Over the years evidence has accumulated that this bacterium is actually the causative agent in the majority of cases of peptic ulcer disease.

Antibiotic therapy can now eliminate *H. pylori*, treating the cause of the disease, and not just the symptoms. The discovery of the action of this bacterial species illustrates how even disease states that appear to be unrelated to infectious disease may actually be caused by cryptic (unknown) infection.

## Many sexually transmitted diseases are bacterial

A number of bacteria cause sexually transmitted diseases (STDs), three particularly important examples of which are gonorrhea, syphilis, and chlamydia (figure 28.15).

**Figure 28.15** Trends in sexually transmitted diseases in the United States.

### Inquiry question

How is it possible for the incidence of one STD (chlamydia) to rise as another (gonorrhea) falls?

## Gonorrhea

*Gonorrhea* is one of the most prevalent communicable diseases in North America. Caused by the bacterium *Neisseria gonorrhoeae*, gonorrhea can be transmitted through sexual intercourse or any other sexual contact in which body fluids are exchanged, such as oral or anal intercourse. It can also pass from mother to baby during delivery through the birth canal.

The incidence of gonorrhea has been on the decline in the United States, but it remains a serious threat worldwide. Of particular concern is the appearance of antibiotic-resistant strains of *N. gonorrhoeae*.

## Syphilis

*Syphilis*, a very destructive STD, was once prevalent and deadly but is now less common due to the advent of blood-screening procedures and antibiotics. Syphilis is caused by a spirochete bacterium, *Treponema pallidum*, transmitted during sexual intercourse or through direct contact with an open syphilis chancre sore. The bacterium can also be transmitted from a mother to her fetus, often causing damage to the heart, eyes, and nervous system of the baby.

Once inside the body, the disease progresses in four distinct stages. The first, or primary stage, is characterized by the appearance of a small, painless, often unnoticed sore called a *chancre*. The chancre resembles a blister and occurs at the location where the bacterium entered the body about three weeks following exposure. This stage of the disease is highly infectious, and an infected person may unwittingly transmit the disease to others. This sore heals without treatment in approximately four weeks, deceptively indicating a “cure” of the disease, although the bacterium remains in the body.

The second stage of syphilis, or secondary syphilis, is marked by a rash, a sore throat, and sores in the mouth. The bacteria can be transmitted at this stage through kissing or contact with an open sore. Commonly at this point, the disease enters the third stage, a latent period. This latent stage of syphilis is symptomless and may last for several years. At this point, the person is no longer infectious, but the bacteria are still present in the body, attacking the internal organs.

The final stage of syphilis is the most debilitating, as the damage done by the bacteria in the third stage becomes evident. Sufferers at this stage of syphilis experience heart disease, mental deficiency, and nerve damage, which may include loss of motor functions or blindness.

## Chlamydia

*Chlamydia* is caused by an unusual bacterium. *Chlamydia trachomatis* is genetically a bacterium but is an obligate intracellular parasite, much like a virus in this respect. It is susceptible to antibiotics but it depends on its host to replicate its genetic material. The bacterium is transmitted through vaginal, anal, or oral intercourse with an infected person.

Chlamydia is called the “silent STD” because women usually experience no symptoms until after the infection has become established. In part because of this symptomless nature, the incidence of chlamydia has skyrocketed, increasing from 142 cases per 100,000 population in 1988 to 544 cases per 100,000 population in 2007.

The effects of an established chlamydia infection on the female body are extremely serious. Chlamydia can cause pelvic inflammatory disease (PID), which can lead to sterility and sometimes death.

It has recently been established that infection of the male or female reproductive tract by chlamydia can cause heart disease. Chlamydiae produce a peptide similar to one produced by cardiac muscle. As the body's immune system tries to fight off the infection, it recognizes and reacts to this peptide. The similarity between the bacterial and cardiac peptides confuses the immune system, and T cells attack cardiac muscle fibers, inadvertently causing inflammation of the heart and other problems.

Within the last few years, two types of tests for chlamydia have been developed. The treatment for the disease is antibiotics, usually tetracycline, which can penetrate the eukaryotic plasma membrane to attack the bacterium. Any woman who experiences the symptoms associated with this STD or who is at risk of developing an STD should be tested for the presence of the chlamydia bacterium; otherwise, her fertility may be at risk.

### Learning Outcomes Review 28.6

Many human diseases are due to bacterial infection, including tuberculosis, streptococcal and staphylococcal infection, and sexually transmitted diseases. The causative agent of most peptic ulcers is *Helicobacter pylori*, an inhabitant of the digestive tract. Bacteria are responsible for many STDs, including gonorrhea, syphilis, and chlamydia. In many cases symptoms of infection disappear although the disease is still present, and all can have serious consequences if untreated, especially for women.

- Why is infection by most pathogens not fatal?

## 28.7 Beneficial Prokaryotes

### Learning Outcomes

1. Recognize the role of prokaryotes in the global cycling of elements.
2. Describe examples of bacterial/eukaryote symbiosis.
3. Explain how bacteria can be used for bioremediation.

Prokaryotes were largely responsible for creating the current properties of the atmosphere and the soil through billions of years of their activity. Today, they still affect the Earth and human life in many important ways.

### Prokaryotes are involved in cycling important elements

Life on Earth is critically dependent on the cycling of chemical elements between organisms and the physical environments in which they live—that is, between the living and nonliving elements of ecosystems. Prokaryotes, algae, and fungi play many key roles in this chemical cycling, a process discussed in detail in chapter 58.

### Decomposition

The carbon, nitrogen, phosphorus, sulfur, and other atoms of biological systems all have come from the physical environment, and when organisms die and decay, these elements all return to it. The prokaryotes and fungi that carry out the decomposition portion of chemical cycles, releasing a dead organism's atoms to the environment, are called *decomposers*.

### Fixation

Other prokaryotes play important roles in fixation, the other half of chemical cycles, helping to return elements from inorganic forms to organic forms that heterotrophic organisms can use.

**Carbon.** The role of photosynthetic prokaryotes in fixing carbon is obvious. The organic compounds that plants, algae, and photosynthetic prokaryotes produce from CO<sub>2</sub> pass up through food chains to form the bodies of all the ecosystem's heterotrophs. Ancient cyanobacteria are thought to have added oxygen to the Earth's atmosphere as a by-product of their photosynthesis. Modern photosynthetic prokaryotes continue to contribute to the production of oxygen.

**Nitrogen.** Less obvious, but no less critical to life, is the role of prokaryotes in recycling nitrogen. The nitrogen in the Earth's atmosphere is in the form of N<sub>2</sub> gas. A triple covalent bond links the two nitrogen atoms and is not easy to break. Among the Earth's organisms, only a very few species of prokaryotes are able to accomplish this feat, reducing N<sub>2</sub> to ammonia (NH<sub>3</sub>), which is used to build amino acids and other nitrogen-containing biological molecules. When the organisms that contain these molecules die, decomposers return nitrogen to the soil as ammonia. This is then converted to nitrate (NO<sub>3</sub><sup>-</sup>) by nitrifying bacteria, making nitrogen available for plants. The nitrate can also be converted back into molecular nitrogen by *denitrifiers* that return the nitrogen to the atmosphere, completing the cycle.

To fix atmospheric nitrogen, prokaryotes employ an enzyme complex called nitrogenase, encoded by a set of genes called *nif* ("nitrogen fixation") genes. The nitrogenase complex is extremely sensitive to oxygen and is found in a wide range of free-living prokaryotes.

In aquatic environments, nitrogen fixation is carried out largely by cyanobacteria such as *Anabaena*, which forms long chains of cells. Because the nitrogen fixation process is strictly anaerobic, individual cyanobacteria cells may develop into *heterocysts*, specialized nitrogen-fixing cells impermeable to oxygen.

In soil, nitrogen fixation occurs in the roots of plants that harbor symbiotic colonies of nitrogen-fixing bacteria. These associations include *Rhizobium* (a genus of proteobacteria; see figure 28.5) with legumes, *Frankia* (an actinomycete) with many woody shrubs, and *Anabaena* with water ferns.

### Prokaryotes may live in symbiotic associations with eukaryotes

Many prokaryotes live in symbiotic association with eukaryotes. **Symbiosis** refers to the ecological relationship between different species that live in direct contact with each other. The symbiotic

association of nitrogen-fixing bacteria with plant roots is an example of *mutualism*, a form of symbiosis in which both parties benefit. The bacteria supply the plant with useful nitrogen, and the plant supplies the bacteria with sugars and other organic nutrients (see chapter 39).

Many bacteria live symbiotically within the digestive tracts of animals, providing nutrients to their hosts. Cattle and other grazing mammals are unable to digest cellulose in the grass and plants they eat because they lack the required cellulase enzyme. Colonies of cellulase-producing bacteria inhabiting the gut allow cattle to digest their food (see chapter 48 for a fuller account). Similarly, humans maintain large colonies of bacteria in the large intestine that produce vitamins—particularly B<sub>12</sub> and K—that the body cannot make.

Many bacteria inhabit the outer surfaces of animals and plants without doing damage. These associations are examples of *commensalism*, in which one organism (the bacterium) receives benefits while the animal or plant is neither benefited nor harmed.

*Parasitism* is a form of symbiosis in which one member (in this case, the bacterium) benefits, and the other (the infected animal or plant) is harmed. Infection might be considered a form of parasitism.

## Bacteria are used in genetic engineering

Because the genetic code is universal, a gene from a human can be inserted into a bacterial cell, and the bacterium produces a human protein. The use of bacteria in genetic engineering was discussed in chapter 17, and it is a large part of modern molecular biology.

In addition to the production of pharmaceutical agents such as insulin, discussed in chapter 17, applying genetic engineering methods to produce improved strains of bacteria for commercial use holds promise for the future. Bacteria are now widely used as “biofactories” in the commercial production of a variety of enzymes, vitamins, and antibiotics. Immense cultures of bacteria, often genetically modified to enhance performance, are used to produce commercial acetone and other industrially important compounds.

## Bacteria can be used for bioremediation

The use of organisms to remove pollutants from water, air, and soil is called *bioremediation*. The normal functioning of sewage treatment plants depends on the activity of microorganisms. In sewage treatment plants, the solid matter from raw sewage is broken down by bacteria and archaea naturally present in the sewage. The end product, methane gas (CH<sub>4</sub>) is often used as an energy source to heat the treatment plant.

Biostimulation, that is, the addition of nutrients such as nitrogen and phosphorus sources, has been used to encourage the growth of naturally occurring microbes that can degrade crude oil spills. This approach was used successfully to clean up the Alaskan shoreline after the crude oil spill of the Exxon Valdez in 1998. Similarly, biostimulation has been used to encourage the growth of naturally occurring microbial flora in contaminated groundwater. Current efforts include those concentrated on the use of endogenous microbes such as *Geobacter* (see figure 28.5) to eliminate radioactive uranium from groundwater contaminated during the cold war.

Chlorinated compounds released into the environment by a variety of sources are another serious pollutant. Some bacteria can actually use these compounds for energy by performing reductive dehalogenation that is linked to electron transport, a process termed *halorespiration*. Although still at the development stage, the use of such bacteria to remove halogenated compounds from toxic waste holds great promise.

### Learning Outcomes Review 28.7

Prokaryotes are vital to ecosystems for both recycling elements and fixation, or making elements available in organic form. Bacteria are involved in fixation of both carbon and nitrogen and are the only organisms that can fix nitrogen. These nitrogen-fixing bacteria may live in symbiotic association with plants. Bacteria are a key component of waste treatment, and they are also being used in bioremediation to remove toxic compounds introduced into the environment.

- Does the information about nitrogen fixation shed any light on the practice of crop rotation?

## Chapter Review

### 28.1 The First Cells

**Microfossils indicate that the first cells were probably prokaryotic.**

The oldest microfossils are 3.5 billion years old. Stromatolites, a combination of sedimentary deposits and precipitated materials, are as old as 2.7 billion years.

**Isotopic data indicate that carbon fixation is an ancient process.**

Relatively higher levels of carbon-12 in fossils compared with neighboring rocks indicate the action of ancient carbon fixation.

**Some hydrocarbons found in ancient rocks may have biological origins.**

Biomarkers such as lipids indicate that cyanobacteria are at least 2.7 billion years old.

### 28.2 Prokaryotic Diversity

**Prokaryotes are fundamentally different from eukaryotes.**

Prokaryotic features include unicellularity, small circular DNA, division by binary fission, lack of internal compartmentalization, a singular flagellum, and metabolic diversity.

**Despite similarities, bacteria and archaea differ fundamentally.**

Bacteria and archaea differ in four key areas: plasma membranes, cell walls, DNA replication, and gene expression.

Archaeal lipids have ether instead of ester linkages and can form tetraether monolayers. The cell walls of bacteria contain peptidoglycans, but those of archaea do not.

Both bacteria and archaea DNA have a single replication origin, but the origin and the replication proteins are different. Archaeal initiation of DNA replication and RNA polymerases are more like those of eukaryotes.

**Most prokaryotes have not been characterized.**

Nine clades of prokaryotes have been found so far, but many bacteria have not been studied (see figure 28.5).

## 28.3 Prokaryotic Cell Structure

**Prokaryotes have three basic forms: rods, cocci, and spirals.**

**Prokaryotes have a tough cell wall and other external structures.**

Bacteria are classified as gram-positive or gram-negative based on the Gram stain (see figure 28.6). Gram-positive bacteria have a thick peptidoglycan layer in the cell wall that contains teichoic acid (see figure 28.7). Gram-negative bacteria have a thin peptidoglycan layer and an outer membrane containing lipopolysaccharides in their cell wall (see figure 28.7).

Some bacteria have a gelatinous layer, the capsule, enabling the bacterium to adhere to surfaces and evade an immune response.

Many bacteria have a slender, rigid, helical flagellum composed of flagellin, which can rotate to drive movement (see figure 28.8). Some bacteria have hairlike pili that have roles in adhesion and exchange of genetic information.

Some bacteria form highly resistant endospores in response to environmental stress.

**The interior of prokaryotic cells is organized.**

In prokaryotes, invaginated regions of the plasma membrane function in respiration and photosynthesis. The nucleoid region contains a compacted circular DNA with no bounding membrane.

Prokaryotic ribosomes are smaller than those of eukaryotes and some antibiotics work by binding to these ribosomes, blocking protein synthesis.

## 28.4 Prokaryotic Genetics

**Conjugation depends on the presence of a conjugative plasmid.**

DNA can be exchanged by conjugation (see figure 28.10), which depends on the presence of conjugative plasmids like the F plasmid in *E. coli*. The F<sup>+</sup> donor cell transfers the F plasmid to the F<sup>-</sup> recipient cell.

The F plasmid can also integrate into the bacterial genome. Excision may be imprecise, so that the F plasmid carries genetic information from the host.

**Viruses transfer DNA by transduction (see figure 28.13).**

Generalized transduction occurs when viruses package host DNA and transfer it on subsequent infection. Specialized transduction is limited to lysogenic phage.

**Transformation is the uptake of DNA directly from the environment (see figure 28.14).**

Transformation occurs when cells take up DNA from the surrounding medium. It can be induced artificially in the laboratory.

**Antibiotic resistance can be transferred by resistance plasmids.**

R plasmids have played a significant role in the appearance of strains resistant to antibiotics, such as *S. aureus* and *E. coli* O157:H7.

**Variation can also arise by mutation.**

Mutations can occur spontaneously in bacteria due to radiation, UV, and various chemicals.

## 28.5 Prokaryotic Metabolism

**Prokaryotes acquire carbon and energy in four basic ways.**

Photoautotrophs carry out photosynthesis and obtain carbon from carbon dioxide. Chemolithoautotrophs obtain energy by oxidizing inorganic substances. Photoheterotrophs use light for energy but obtain carbon from organic molecules. Chemoheterotrophs, the largest group, obtain carbon and energy from organic molecules.

**Some bacteria can attack other cells directly.**

Some bacteria release proteins through their cell walls, and these proteins may transfer other, virulent proteins into eukaryotic cells.

**Bacteria are costly plant pathogens.**

Gram-negative bacteria known as pseudomonads are responsible for most plant diseases.

## 28.6 Human Bacterial Disease (see table 28.1)

Bacterial diseases are spread through mucus or saliva droplets, contaminated food and water, and insect vectors.

**Tuberculosis has infected humans for all of recorded history.**

Tuberculosis continues to be a major public health problem. Treatment requires a long course of antibiotics.

**Bacterial biofilms are involved in tooth decay.**

**Bacteria can cause ulcers.**

Most stomach ulcers are caused by infection with *Helicobacter pylori*.

**Many sexually transmitted diseases are bacterial.**

The potentially dangerous sexually transmitted diseases gonorrhea, syphilis, and chlamydia are caused by bacteria.

## 28.7 Beneficial Prokaryotes

**Prokaryotes are involved in cycling important elements.**

Prokaryotes are involved in the recycling of carbon and nitrogen; only bacteria can fix nitrogen.

**Prokaryotes may live in symbiotic associations with eukaryotes.**

**Bacteria are used in genetic engineering.**

Genetically engineered prokaryotes can be used to produce human pharmaceutical agents and other useful products.

**Bacteria can be used for bioremediation.**

## Review Questions

### UNDERSTAND

- Which of the following would be an example of a biomarker?
  - A microfossil found in a meteorite
  - A hydrocarbon found in an ancient rock layer
  - An area that is high in carbon-12 concentration in a rock layer
  - A newly discovered formation of stromatolites
- A cell that can use energy from the sun, and CO<sub>2</sub> as a carbon source is a
  - photoautotroph.
  - chemoautotroph.
  - photoheterotroph.
  - chemoheterotroph.
- Gram-positive (+) and gram-negative (-) bacteria are characterized by differences in
  - the cell wall: gram+ have peptidoglycan, gram- have pseudo-peptidoglycan.
  - the plasma membrane: gram+ have ester-linked lipids, gram- have ether-linked lipids.
  - the cell wall: gram+ have a thick layer of peptidoglycan and gram- have an outer membrane.
  - chromosomal structure: gram+ have circular chromosomes, gram- have linear chromosomes.
- Which of the following characteristics is unique to the archaea?
  - A fluid mosaic model of plasma membrane structure
  - The use of an RNA polymerase during gene expression
  - Ether-linked phospholipids
  - A single origin of DNA replication
- The horizontal transfer of DNA using a plasmid is an example of
  - generalized transduction.
  - binary fission.
  - transformation.
  - conjugation.
- The disease tuberculosis is
  - caused by a bacterial pathogen.
  - an emerging disease that is now worldwide.
  - caused by a viral pathogen.
  - not treatable with antibiotics.
- Prokaryotes participate in the global cycling of
  - proteins and nucleic acids.
  - carbon and nitrogen.
  - carbohydrates and lipids.
  - all of the above.

### APPLY

- Which of the following is typically not associated with a prokaryote?
  - Horizontal transfer of genetic information
  - A lack of internal compartmentalization
  - Multiple, linear chromosomes
  - A cell size of 1 μm
- The mechanisms of DNA exchange in prokaryotes share the feature of
  - vertical transmission of information.
  - horizontal transfer of information.
  - requiring cell contact.
  - the presence of a plasmid in one cell.
- The cell wall in both gram-positive and gram-negative cells is
  - composed of phospholipids.

- a target for antibiotics that affect peptidoglycan synthesis.
  - composed of peptidoglycan.
  - surrounded by a membrane.
- The three domains of life
    - represent variations of the same basic cell type.
    - include two different basic cell types.
    - consist of three different basic cell types.
    - describe current cells but say nothing about their history.
  - Ulcers and tooth decay do not appear related, but in fact both
    - are due to eating particular kinds of foods.
    - are caused by viral infection.
    - are caused by environmental factors.
    - can be due to bacterial infection.
  - Bacteria lack independent internal membrane systems, but are able to perform photosynthesis and respiration, both of which use membranes. They are able to perform these functions because
    - they actually have internal membranes, but only for these functions.
    - invaginations of the plasma membrane can provide an internal membrane surface.
    - they take place outside of the cell between the membrane and the cell wall.
    - they use protein-based structures to take the place of internal membranes.
  - Plants cannot fix nitrogen, yet some plants do not need nitrogen from the soil. This is because
    - of a symbiotic association with a bacterium that can fix nitrogen.
    - these plants are the exceptions that can fix nitrogen.
    - they have been infected by a parasitic virus that can fix nitrogen.
    - they are able to obtain nitrogen from the air.

### SYNTHESIZE

- If a new form of carbon fixation was discovered that was not biased toward carbon-12, would this affect our analysis of the earliest evidence for life?
- Frederick Griffith's experiments (see chapter 14) played an important role in showing that DNA is the genetic material. Griffith showed that dead virulent bacteria mixed with live nonvirulent bacteria could cause pneumonia in mice. Live rough bacteria could also be cultured from the infected mice. The difference between the two strains is a polysaccharide capsule found in the smooth strain. Given what you have learned in this chapter, how would you explain these observations?
- In the 1960s, it was common practice to prescribe multiple antibiotics to fight bacterial infections. It is also often the case that patients do not always take the entire "course" of their antibiotics. Antibiotic resistance genes are often found on conjugative plasmids. How do these factors affect the evolution of antibiotic resistance and of resistance to multiple antibiotics in particular?
- Soil-based nitrogen-fixing bacteria appear to be highly vulnerable to exposure to UV radiation. Suppose that the ozone level continues to be depleted, what are the long-term effects on the planet?

# Chapter 29

## Protists

### Chapter Outline

- 29.1** Eukaryotic Origins and Endosymbiosis
- 29.2** Defining Protists
- 29.3** Diplomonads and Parabasalids:  
Flagellated Protists Lacking Mitochondria
- 29.4** Euglenozoa: A Diverse Group in Which Some  
Members Have Chloroplasts
- 29.5** Alveolata: Protists with Submembrane Vesicles
- 29.6** Stramenopila: Protists with Fine Hairs
- 29.7** Rhodophyta: Red Algae
- 29.8** Choanoflagellida: Possible Animal Ancestors
- 29.9** Protists Without a Clade

### Introduction

For more than half of the long history of life on Earth, all life was microscopic. The biggest organisms that existed for over 2 billion years were single-celled bacteria fewer than 6  $\mu\text{m}$  thick. These prokaryotes lacked internal membranes, except for invaginations of surface membranes in photosynthetic bacteria.

The first evidence of a different kind of organism is found in tiny fossils in rock 1.5 billion years old. These fossil cells are much larger than bacteria (up to 10 times larger) and contain internal membranes and what appear to be small, membrane-bounded structures. The complexity and diversity of form among these single cells is astonishing. The step from relatively simple to quite complex cells marks one of the most important events in the evolution of life, the appearance of a new kind of organism, the eukaryote. Eukaryotes that are clearly not animals, plants, or fungi have been lumped together and called protists.

## 29.1 Eukaryotic Origins and Endosymbiosis

### Learning Outcomes

1. List the defining features of eukaryotes.
2. Define endosymbiosis and explain how it relates to the evolution of mitochondria and chloroplasts.
3. Explain why mitosis is not believed to have evolved all at once.

Eukaryotic cells are distinguished from prokaryotes by the presence of a cytoskeleton and compartmentalization that includes a nuclear envelope and organelles. The exact sequence of events that led to large, complex eukaryotic cells is unknown, but several key events are agreed upon. Loss of a rigid cell wall allowed membranes to fold inward, increasing surface area. Membrane flexibility also made it possible for one cell to engulf another.

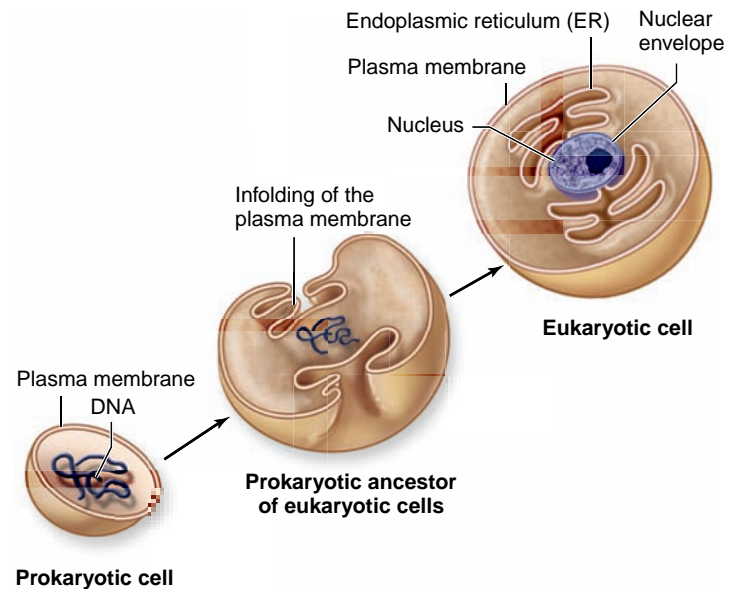

### Fossil evidence dates the origins of eukaryotes

Indirect chemical traces hint that eukaryotes may go as far back as 2.7 billion years, but no fossils as yet support such an early appearance. In rocks about 1.5 billion years old, we begin to see the first microfossils that are noticeably different in appearance from the earlier, simpler forms, none of which were more than 6  $\mu\text{m}$  in diameter (figure 29.1). These cells are much larger than those of prokaryotes and have internal membranes and thicker walls.

These early fossils mark a major event in the evolution of life: A new kind of organism had appeared. These new cells are called eukaryotes, from the Greek words meaning “true nucleus,” because they possess an internal structure called a nucleus. All organisms other than prokaryotes are eukaryotes.

**Figure 29.1** Early eukaryotic fossil. Fossil algae that lived in Siberia 1 BYA.

**Figure 29.2** Origin of the nucleus and endoplasmic reticulum. Many prokaryotes today have infoldings of the plasma membrane (see also figure 27.6). The eukaryotic internal membrane system, called the endoplasmic reticulum (ER), and the nuclear envelope may have evolved from such infoldings of the plasma membrane, encasing the DNA of prokaryotic cells that gave rise to eukaryotic cells.

In the sections that follow, the origins of eukaryotic internal structure are considered. Keep in mind that, as discussed in chapter 24, horizontal gene transfer occurred frequently while eukaryotic cells were evolving. Eukaryotic cells evolved not only through horizontal gene transfer, but through infolding of membranes and engulfing other cells. Today’s eukaryotic cell is the result of cutting and pasting of DNA and organelles from different species.

### The nucleus and ER arose from membrane infoldings

Many prokaryotes have infoldings of their outer membranes extending into the cytoplasm that serve as passageways to the surface. The network of internal membranes in eukaryotes is called the endoplasmic reticulum (ER), and the nuclear envelope, an extension of the ER network that isolates and protects the nucleus, is thought to have evolved from such infoldings (figure 29.2).

### Mitochondria evolved from engulfed aerobic bacteria

Bacteria that live within other cells and perform specific functions for their host cells are called *endosymbiotic bacteria*. Their widespread presence in nature led biologist Lynn Margulis in the early 1970s to champion the theory of endosymbiosis, which was first proposed by Konstantin

**Figure 29.3 The theory of endosymbiosis.** Scientists propose that ancestral eukaryotic cells, which already had an internal system of membranes, engulfed aerobic bacteria, which then became mitochondria in the eukaryotic cell. Chloroplasts also originated this way, with eukaryotic cells engulfing photosynthetic bacteria.

Mereschkowsky in 1905. Endosymbiosis means living together in close association.

Endosymbiosis, a concept that is now widely accepted, suggests that a critical stage in the evolution of eukaryotic cells involved endosymbiotic relationships with prokaryotic organisms. According to this theory, energy-producing bacteria may have come to reside within larger bacteria, eventually evolving into what we now know as mitochondria (figure 29.3). Possibly the original host cell was anaerobic with hydrogen-dependent metabolic pathways. The symbiont had a form of respiration that produced  $H_2$ . The host depended on the symbiont for  $H_2$  under anaerobic conditions and was able later to adapt to an  $O_2$ -rich atmosphere using the symbiont's respiratory pathways.

## Chloroplasts evolved from engulfed photosynthetic bacteria

Photosynthetic bacteria may have come to live within other larger bacteria, leading to the evolution of chloroplasts, the photosynthetic organelles of plants and algae (see figure 29.3). The history of chloroplast evolution is an example of the care that must be taken in phylogenetic studies. All chloroplasts are likely derived from a single line of cyanobacteria, but the organisms that host these chloroplasts are not monophyletic. This apparent paradox is resolved by considering the possibility of secondary, and even tertiary endosymbiosis. Figure 26.8 explains how red and green algae both obtained their chloroplasts by engulfing photosynthetic cyanobacteria. The brown algae most likely obtained their chloroplasts by engulfing one or more red algae, a process called **secondary endosymbiosis** (figure 29.4). (As mentioned, green algae are considered in the following chapter even though they are protists.)

A phylogenetic tree based only on chloroplast gene sequences from red and green algae reveals an incredibly close evolutionary relationship. This tree is misleading, however, because it is not possible to tell just from these data how

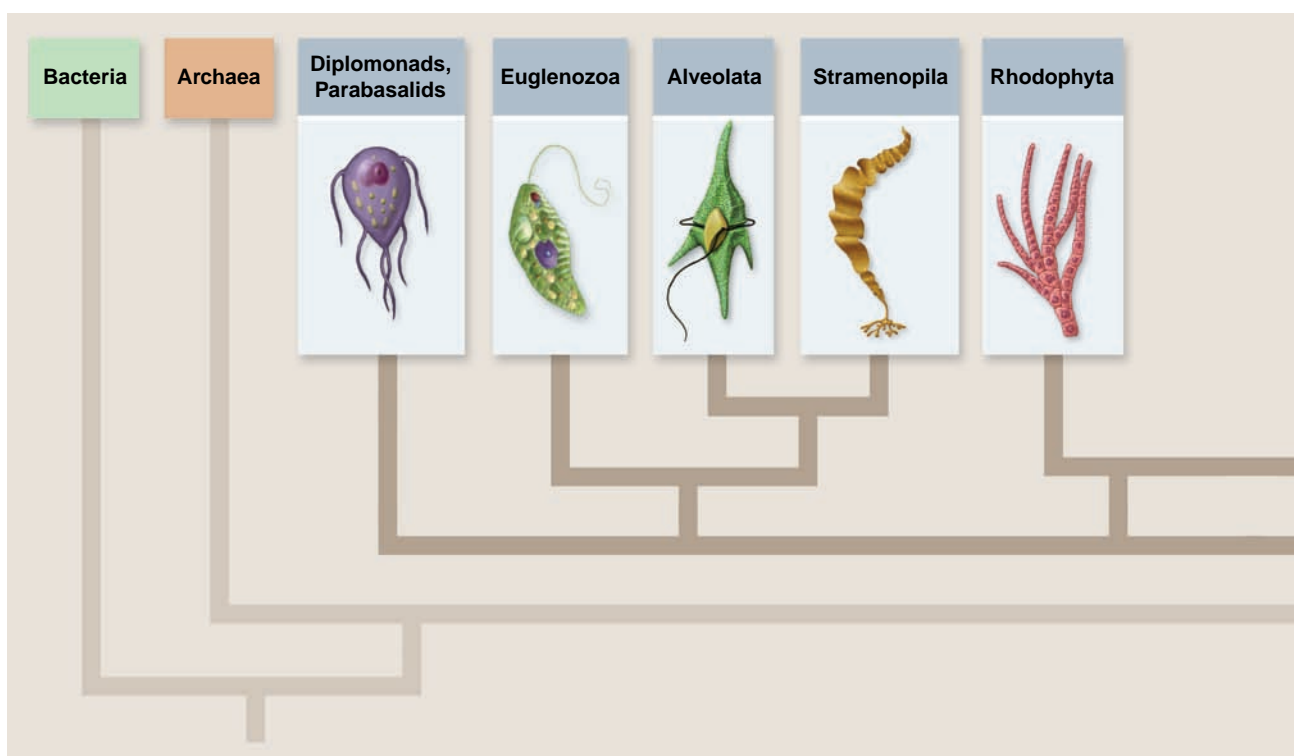

**Figure 29.4 Endosymbiotic origins of chloroplasts in red and brown algae.**

much the two algal lines had diverged at the time they engulfed the same line of cyanobacteria. Morphological and chemical traits are more helpful than chloroplast gene sequences in sorting out red and green algal relations. More data and analyses are still needed to confirm the position of red algae in figure 29.5.

## Endosymbiosis is supported by a range of evidence

The fact that we now witness so many symbiotic relationships lends general support to the endosymbiotic theory. Even stronger support comes from the observation that present-day organelles such as mitochondria and chloroplasts contain their own DNA, which is remarkably similar to the DNA of bacteria in size and character. During the billion and a half years in which mitochondria have existed as endosymbionts within eukaryotic cells, most of their genes have been transferred to the chromosomes of the host cells—but not all. Each mitochondrion still has its own genome, a circular, closed molecule of DNA similar to that found in bacteria, on which are located genes encoding the essential proteins of oxidative metabolism. These genes are transcribed within the mitochondrion, using mitochondrial ribosomes that are smaller than those of eukaryotic cells, very much like bacterial ribosomes in size and structure. Many antibiotics that inhibit protein synthesis in bacteria also inhibit protein synthesis in mitochondria and chloroplasts, but not in the cytoplasm. Chloroplasts and mitochondria replicate via binary fission, not mitosis, further supporting bacterial origins.

**Figure 29.5 The challenge of protistan classification.** Our understanding of the evolutionary relationships among protists is currently in flux. The most recent data support seven major, monophyletic groups within the protists. Consider this a working model, not fact. The green algae (Chlorophyta) are not truly monophyletic in that another branch, Streptophyta, gave rise to the land plants. Protist lineages are shaded in blue.

## Mitosis evolved in eukaryotes

The mechanisms of mitosis and cytokinesis, now so common among eukaryotes, did not evolve all at once. Traces of very different, and possibly intermediate, mechanisms survive today in some of the eukaryotes. In fungi and in some groups of protists, for example, the nuclear membrane does not dissolve, as it does in plants, animals, and most other protists, and mitosis is confined to the nucleus. When mitosis is complete in these organisms, the nucleus divides into two daughter nuclei, and only then does the rest of the cell divide. We do not know whether mitosis without nuclear membrane dissolution represents an intermediate step on the evolutionary journey, or simply a different way of solving the same problem. We cannot see the interiors of dividing cells well enough in fossils to be able to trace the history of mitosis.

### Learning Outcomes Review 29.1

Eukaryotes are organisms that contain a nucleus and other membrane-bounded organelles. Endoplasmic reticulum and the nuclear membrane are believed to have evolved from infoldings of the outer membranes. According to the endosymbiont theory, mitochondria and chloroplasts evolved from engulfed bacteria that remained intact. Mitochondria, chloroplasts, and centrioles have their own DNA, which is similar to that of prokaryotes. Mitosis did not evolve all at once; different mechanisms persist in different organisms.

- What evidence supports the endosymbiont theory?

### Inquiry question

? How could you distinguish between primary and secondary endosymbiosis by looking at micrographs of cells with chloroplasts?

## 29.2 Defining Protists

### Learning Outcomes

1. Describe the feature that distinguishes protists from other eukaryotes.
2. Define monophyletic.
3. Describe the various kinds of protist cell surfaces.
4. List the two main means of locomotion used by protists.
5. Distinguish between phototrophs, phagotrophs, and osmotrophs.

*Protists* are the most diverse of the four kingdoms in the domain Eukarya. Protists are united on the basis of a single negative characteristic: They are eukaryotes that are not fungi, plants, or animals. In all other respects, they vary considerably, with no unifying features. Many are unicellular, but numerous colonial and multicellular groups also exist. Most are microscopic, but some are as large as trees. They represent all symmetries and exhibit all types of nutrition. The origin of eukaryotes, which began with ancestral protists, is among the most significant events in the evolution of life.

### Protista is not monophyletic

One of the most important statements we can make about the kingdom Protista is that it is paraphyletic and not a kingdom at all; as a matter of convenience, single-celled eukaryotic organ-

isms have typically been grouped together and called protists. This lumps 200,000 different and only distantly related forms together. The “single-kingdom” classification of the Protista is artificial and not representative of any evolutionary relationships. You may be wondering why biologists continue to refer to the protista as a kingdom and why we have a chapter devoted to the protists. While we wait for the evolutionary relationships among protists to be sorted out, lumping the protists together allows us to explore the biology of a number of fascinating eukaryotes that might otherwise disappear from the pages of your textbook.

### Monophyletic clades have been identified among the protists

Applications of a variety of molecular methods are providing insights into the relationships among protists. Many questions about how to classify the protists are being addressed with these techniques. Are protists best considered as several different kingdoms, each of equal rank with animals, plants, and fungi? Are some of the protists actually members of other kingdoms? While these questions continue to be debated, new information is becoming available concerning which organisms among the protists are most likely to be monophyletic.

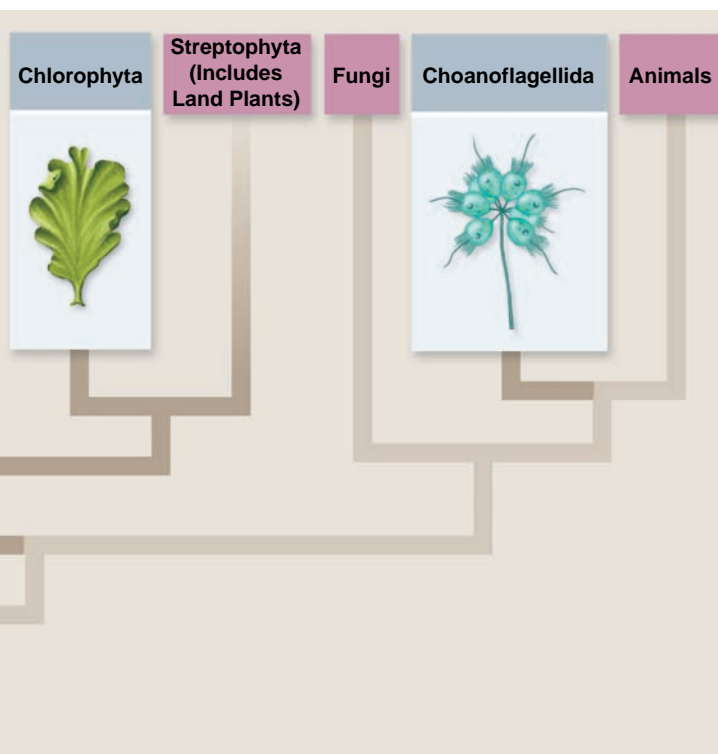

In this chapter, we group the 15 major protist phyla into seven major monophyletic groups, based on our current understanding of phylogeny (figure 29.5). Although these lineages may change, this approach allows us to examine groups with many shared traits. Keep in mind that about 60 of the protist lineages cannot yet be placed on the tree of life with any confidence! Protists exemplify the challenges and excitement of the revolutionary changes in taxonomy and phylogeny we explored in chapter 26. Understanding the evolution of protists is key to understanding the origins of plants, fungi, and animals.

Because green algae and land plants form a monophyletic clade, the green algae are explored in more detail in the following chapter on plant diversity. The characteristics of green algae and land plants are best understood when considered in concert because of their shared evolutionary history. The remaining six monophyletic clades that are loosely called protists are examined in this chapter.

### Protist cell surfaces vary widely

Protists possess a varied array of cell surfaces. Some protists, such as amoebas, are surrounded only by their plasma membrane. All other protists have a plasma membrane with an extracellular matrix (ECM) deposited on the outside of the membrane. Some ECMs form strong cell walls; for instance, diatoms and foraminifera secrete glassy shells of silica.

Many protists with delicate surfaces are capable of surviving unfavorable environmental conditions. How do they manage to survive so well? They form cysts, which are dormant forms with resistant outer coverings in which cell metabolism is more or less completely shut down. Not all cysts are so sturdy, however. Vertebrate parasitic amoebas, for example, form cysts that are quite resistant to gastric acidity, but will not tolerate desiccation or high temperature.

## Protists have several means of locomotion

Movement in protists is also accomplished by diverse mechanisms. Protists move chiefly by either flagellar rotation or pseudopodial movement. Many protists wave one or more flagella to propel themselves through the water, and others use banks of short, flagella-like structures called cilia to create water currents for their feeding or propulsion. Pseudopods (Greek, meaning “false feet”) are the chief means of locomotion among amoebas, whose pseudopods are large, blunt extensions of the cell body called lobopodia. Other related protists extend thin, branching protrusions called filopodia. Still other protists extend long, thin pseudopods called axopodia supported by axial rods of microtubules. Axopodia can be extended or retracted. Because the tips can adhere to adjacent surfaces, the cell can move by a rolling motion, shortening the axopodia in front and extending those in the rear.

## Protists have a range of nutritional strategies

Protists can be heterotrophic or autotrophic. Some autotrophic protists are photosynthetic and are called **phototrophs**. Others are heterotrophs that obtain energy from organic molecules synthesized by other organisms.

Among the heterotrophic protists are some called *phagotrophs*, which ingest visible particles of food by pulling them into intracellular vesicles called food vacuoles or phagosomes. Lysosomes fuse with the food vacuoles, introducing enzymes that digest the food particles within. Digested molecules are absorbed across the vacuolar membrane.

Protists that ingest food in soluble form are called *osmotrophs*. Another example of the protists’ tremendous nutritional flexibility is seen in *mixotrophs*, protists that are both phototrophic and heterotrophic.

## Protists reproduce asexually and sexually

Protists typically reproduce asexually, although some have an obligate sexual reproductive phase and others undergo sexual reproduction at times of stress, including food shortages.

### Asexual reproduction

**Asexual reproduction** involves mitosis, but the process often differs from the mitosis in multicellular animals. For example, the nuclear membrane often persists throughout mitosis, with the microtubular spindle forming within it.

In some species, a cell simply splits into nearly equal halves after mitosis. Sometimes the daughter cell is considerably smaller than its parent and then grows to adult size—a type of cell division called **budding**. In *schizogony*, common among some protists, cell division is preceded by several nuclear divisions. This allows cytokinesis to produce several individuals almost simultaneously.

### Sexual reproduction

Most eukaryotic cells also possess the ability to reproduce sexually, something prokaryotes cannot do at all. Meiosis (see chapter 11) is a major evolutionary innovation that arose in ancestral protists and allows for the production of haploid cells from diploid cells. Sexual reproduction is the process of pro-

ducing offspring by fertilization, the union of two haploid cells. The great advantage of sexual reproduction is that it allows for frequent genetic recombination, which generates the variation that is the starting point of evolution. Not all eukaryotes reproduce sexually, but most have the capacity to do so. The evolution of meiosis and sexual reproduction contributed to the tremendous explosion of diversity among the eukaryotes.

## Protists are the bridge to multicellularity

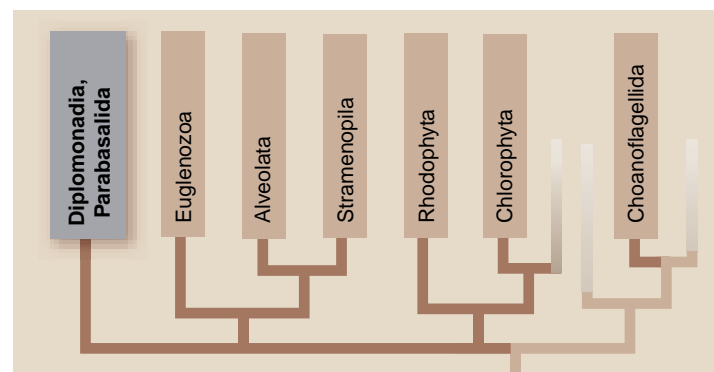

Diversity was also promoted by the development of *multicellularity*. Some single eukaryotic cells began living in association with others, in colonies. Eventually, individual members of the colony began to assume different duties, and the colony began to take on the characteristics of a single individual. Multicellularity has arisen many times among the eukaryotes. Practically every organism big enough to be seen with the unaided eye, including all animals and plants, is multicellular. The great advantage of multicellularity is that it fosters specialization; some cells devote all of their energies to one task, other cells to another. Few innovations have had as great an influence on the history of life as the specialization made possible by multicellularity.

### Learning Outcomes Review 29.2

A monophyletic group is one in which all members have a single common ancestor. Protista is paraphyletic, however, so it is not really a kingdom. The major protist phyla have been grouped into seven major monophyletic groups. All protists have plasma membranes, but other cell-surface components, such as deposited extracellular material (ECM), are highly variable. Protists mainly use flagella or pseudopodial movement to propel themselves. Phototrophic protists carry out photosynthesis; phagotrophs ingest food particles; and osmotrophs ingest dissolved nutrients. Sexual reproduction is common, but asexual reproduction also occurs in many groups. Multicellular organisms likely arose from colonial protists.

- Why is Kingdom Protista considered to be a paraphyletic group?
- What would be the advantage of movement by pseudopodia?

## 29.3 Diplomonads and Parabasalids: Flagellated Protists Lacking Mitochondria

## Learning Outcomes

1. List the main features of diplomonads and parabasalids.
2. Give examples of diplomonads and parabasalids.

What was the first eukaryote like? We cannot be sure, but the *diplomonads* and the *parabasalids* likely had early eukaryotic ancestors. Although these groups have similar features, their differences put them into separate clades.

### Diplomonads have two nuclei

Diplomonads are unicellular and move with flagella. This group lacks mitochondria, but has two nuclei. *Giardia intestinalis* is an example of a diplomonad (figure 29.6). *Giardia* is a parasite that can pass from human to human via contaminated water and cause diarrhea. Mitochondrial genes are found in their nuclei, leading to the conclusion that *Giardia* evolved from aerobes. Electron micrographs of *Giardia* cells stained with mitochondrial-specific antibodies reveal degenerate mitochondria. Thus, *Giardia* is unlikely to represent an early protist.

### Parabasalids have undulating membranes

Parabasalids contain an intriguing array of species. Some live in the gut of termites and digest cellulose, the main component of the termite's wood-based diet. The symbiotic relationship is one layer more complex because these parabasalids have a symbiotic relationship with bacteria that also aid in the digestion of cellulose. The persistent activity of these three symbiotic organisms from three different kingdoms can lead to the collapse of a home built of wood or recycle tons of fallen trees in a forest. Another parabasalid, *Trichomonas vaginalis*, causes a sexually transmitted disease in humans.

Parabasalids have undulating membranes that assist in locomotion (figure 29.7). Like diplomonads, parabasalids also

**Figure 29.6** *Giardia intestinalis*. This parasitic diplomonad lacks a mitochondrion.

**Figure 29.7** Undulating membrane characteristic of parabasalids. Vaginitis can be caused by this parasite species, *Trichomonas vaginalis*.

use flagella to move and lack mitochondria. The lack of mitochondria in both groups is now believed to be a derived rather than an ancestral trait.

## Learning Outcomes Review 29.3

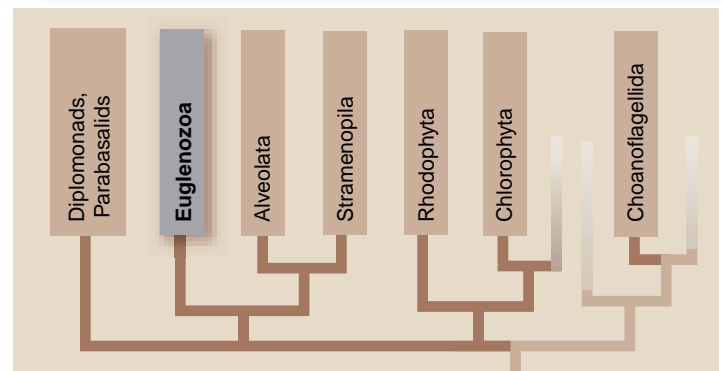

The ancestors of diplomonads and parabasalids are likely to be among the earliest eukaryotes. Diplomonads lack mitochondria but may contain mitochondrial genes. They are unicellular, have two nuclei, and move with flagella; an example is *Giardia*. Parabasalids also lack mitochondria and use flagella and undulating membranes for locomotion; an example is *Trichomonas*.

- In what type of habitat would it be useful to use undulating membranes for locomotion?

## 29.4 Euglenozoa: A Diverse Group in Which Some Members Have Chloroplasts

### Learning Outcomes

1. Explain why Euglenozoa cannot be classified as either plants or animals.
2. Describe the distinguishing feature of kinetoplastids.

Among their distinguishing features, a number of the *Euglenozoa* have acquired chloroplasts through endosymbiosis. None of the algae are closely related to Euglenozoa, a reminder that endosymbiosis is widespread.

### Euglenoids are free-living eukaryotes with anterior flagella

**Euglenoids** diverged early and were among the earliest free-living eukaryotes to possess mitochondria. Euglenoids clearly illustrate the impossibility of distinguishing “plants” from “animals” among the protists. About one-third of the approximately 40 genera of euglenoids have chloroplasts and are fully autotrophic; the others lack chloroplasts, ingest their food, and are heterotrophic.

Some euglenoids with chloroplasts may become heterotrophic in the dark; the chloroplasts become small and non-functional. If they are put back in the light, they may become green within a few hours. Photosynthetic euglenoids may sometimes feed on dissolved or particulate food.

Individual euglenoids range from 10 to 500  $\mu\text{m}$  long and vary greatly in form. Interlocking proteinaceous strips arranged in a helical pattern form a flexible structure called the *pellicle*, which lies within the plasma membrane of the euglenoids. Because its pellicle is flexible, a euglenoid is able to change its shape.

Reproduction in this phylum occurs by mitotic cell division. The nuclear envelope remains intact throughout the process of mitosis. No sexual reproduction is known to occur in this group.

### ***Euglena*, the best known euglenoid**

In *Euglena* (figure 29.8), the genus for which the phylum is named, two flagella are attached at the base of a flask-shaped opening called the *reservoir*, which is located at the anterior end of the cell. One of the flagella is long and has a row of very fine, short, hairlike projections along one side. A second, shorter flagellum is located within the reservoir but does not emerge from it. Contractile vacuoles collect excess water from all parts of the organism and empty it into the reservoir, which apparently helps regulate the osmotic pressure within the or-

ganism. The stigma, which also occurs in the green algae (phylum Chlorophyta), helps these photosynthetic organisms move toward light.

Cells of *Euglena* contain numerous small chloroplasts. These chloroplasts, like those of the green algae and plants, contain chlorophylls *a* and *b*, together with carotenoids. Although the chloroplasts of euglenoids differ somewhat in structure from those of green algae, they probably had a common origin. *Euglena*'s photosynthetic pigments are light-sensitive (figure 29.9). It seems likely that euglenoid chloroplasts ultimately evolved from a symbiotic relationship through ingestion of green algae. Recent phylogenetic evidence indicates that *Euglena* had multiple origins within the Euglenoids, and the concept of a single *Euglena* genus is now being debated.

### **Kinetoplastids are parasitic**

A second major group within the Euglenozoa is the *kinetoplastids*. The name kinetoplastid refers to a unique, single mitochondrion in each cell. The mitochondria have two types of DNA: minicircles and maxicircles. (Remember that prokaryotes have circular DNA, and mitochondria had prokaryotic origins.) This mitochondrial DNA is responsible for very rapid glycolysis and also for an unusual kind of editing of the RNA by guide RNAs encoded in the minicircles.

### **Trypanosomes: Disease-causing kinetoplastids**

Parasitism has evolved multiple times within the kinetoplastids. Trypanosomes are a group of kinetoplastids that cause many serious human diseases, the most familiar being trypanosomiasis, also known as African sleeping sickness, which causes extreme lethargy and fatigue (figure 29.10).

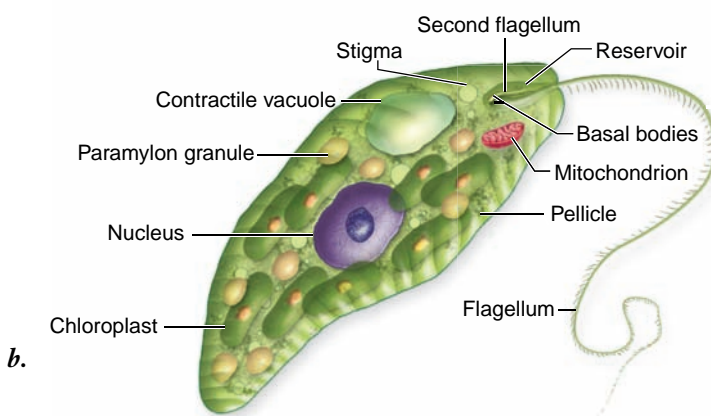

Leishmaniasis, which is transmitted by sand flies, is a trypanosomic disease that causes skin sores and in some cases can affect internal organs, leading to death. About 1.5 million new cases are reported each year. The rise in leishmaniasis in South America correlates with the move of infected individuals from rural to urban environments, where there is a greater chance of spreading the parasite.

Chagas disease is caused by *Trypanosoma cruzi*. At least 90 million people, from the southern United States to Argentina, are at risk of contracting *T. cruzi* from small wild mammals that carry the parasite and can spread it to other mammals and humans through skin contact with urine and feces. Blood transfusions have also increased the spread of the infection. Chagas disease can lead to severe cardiac and digestive problems in humans and domestic animals, but it appears to be tolerated in the wild mammals.

Control is especially difficult because of the unique attributes of these organisms. For example, tsetse fly-transmitted trypanosomes have evolved an elaborate genetic mechanism for repeatedly changing the antigenic nature of their protective glycoprotein coat, thus dodging the antibodies their hosts produce against them (see chapter 52). Only a single one out of some 1000 variable-surface glycoprotein (VSG) genes is expressed at a time. A VSG gene is usually duplicated and moved to 1 of about 20 expression sites near the telomere where it is transcribed. Only one expression site is transcribed at a time.

**Figure 29.8**  
**Euglenoids.**

*a.* Micrograph of *Euglena gracilis*.  
*b.* Diagram of *Euglena*.  
Paramylon granules are areas where food reserves are stored.

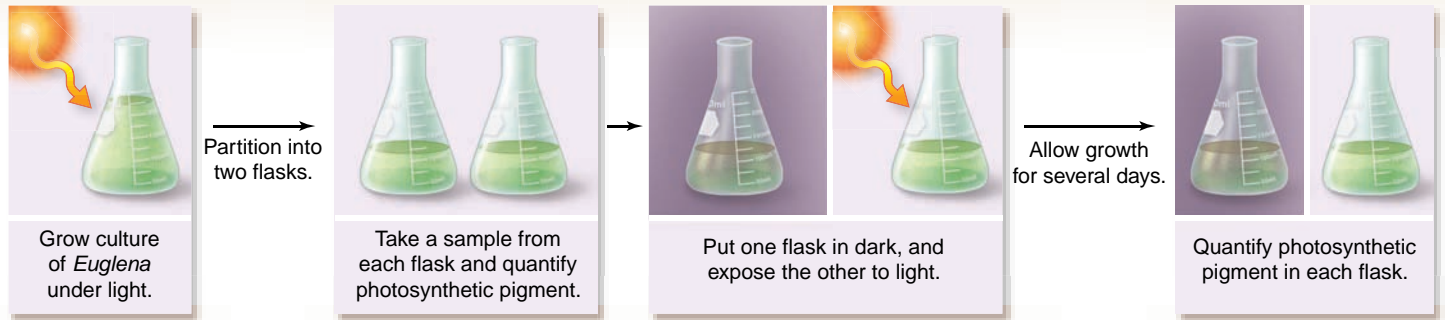

## SCIENTIFIC THINKING

**Hypothesis:** *Euglena* cells do not retain photosynthetic pigments in a dark environment.

**Prediction:** Photosynthetic pigments will be degraded when light-grown *Euglena* cells are transferred to the dark and new pigment will not be produced.

**Test:** Grow *Euglena* under normal light conditions. Transfer the culture to two flasks. Take a sample from each flask and measure the amount of photosynthetic pigments in each. Maintain one flask in the light and transfer the other to the dark. After several days, extract the photosynthetic pigments from each flask, and compare amounts with each other and with initial levels.

**Result:** Photosynthetic pigment levels are lower in the dark-grown flask than in the light-grown one. Pigment levels in the dark-grown flask are lower than at the beginning of the experiment. Pigment levels in the light-grown flask are unchanged.

**Conclusion:** The hypothesis is supported. Maintenance of *Euglena* in the dark resulted in a loss of photosynthetic pigment. Pigments were degraded in the dark-grown flask.

**Further Experiments:** Transfer dark-grown flasks back to the light and measure changes in pigment levels over time. Are original pigment levels restored after growth in light?

**Figure 29.9** Effect of light on *Euglena* photosynthetic pigments.

In the guts of the flies that spread them, trypanosomes are noninfective. When they are ready to transfer to the skin or bloodstream of their host, trypanosomes migrate to the salivary glands and acquire the thick coat of glycoprotein antigens that protect them from the host's antibodies. Later, when they are taken up by a tsetse fly, the trypanosomes again shed their coats.

The production of vaccines against such a system is complex, but tests are under way. Releasing sterilized flies to impede the reproduction of populations is another technique being tried to control the fly population. Traps made of dark cloth and scented like cows, but poisoned with insecticides, have likewise proved effective.

The recent sequencing of the genomes of the three kinetoplastids described earlier revealed a core of common genes in all three, as described in chapter 24. The devastating toll of all

three on human life could be alleviated by the development of a single drug targeted at one or more of the core proteins shared by the three parasites.

### Learning Outcomes Review 29.4

The Euglenozoa were among the earliest protists to contain mitochondria. This group contains phototrophs and heterotrophs. Some members have chloroplasts that remain nonfunctional unless light is present, and some phototrophs may feed if food particles are present. The kinetoplastids contain a single mitochondrion with two types of DNA and the ability to edit RNA with RNA guides. Trypanosomes are disease-causing kinetoplastids.

## 29.5 Alveolata: Protists with Submembrane Vesicles

### Learning Outcomes

1. Identify the distinguishing feature of the members of Alveolata.
2. Describe the swimming motion of a dinoflagellate.
3. Explain the function of the apical complex in Apicomplexans.

Members of the **Alveolata** include the *dinoflagellates*, *apicomplexans*, and *ciliates*, all of which have a common lineage but diverse modes of locomotion. One common trait is the presence of flattened vesicles called alveoli (hence the name alveolata) stacked in a continuous layer below their plasma membranes (figure 29.11). The alveoli may function in membrane transport, similar to Golgi bodies.

### Dinoflagellates are photosynthesizers with distinctive features

Most dinoflagellates are photosynthetic unicells with two flagella. Dinoflagellates live in both marine and freshwater environments. Some dinoflagellates are luminous and contribute to the twinkling or flashing effects seen in the sea at night, especially in the tropics.

The flagella, protective coats, and biochemistry of dinoflagellates are distinctive, and the dinoflagellates do not appear to be directly related to any other phylum. Plates made of a cellulose-like material, often encrusted with silica, encase the dinoflagellate cells (figure 29.12). Grooves at the junctures of these plates usually house the flagella, one encircling the cell like a belt, and the other perpendicular to it. By beating in their grooves, these flagella cause the dinoflagellate to spin as it moves.

Most dinoflagellates have chlorophylls *a* and *c*, in addition to carotenoids, so that in the biochemistry of their chloroplasts, they resemble the diatoms and the brown algae. Possibly this lineage acquired such chloroplasts by forming endosymbiotic relationships with members of those groups.

**Figure 29.11** Alveoli are a continuum of vesicles just below the plasma membrane of dinoflagellates, apicomplexans, and ciliates. The apical complex of apicomplexans forces the parasite into host cells.

### Red tide: Overgrowth of dinoflagellates

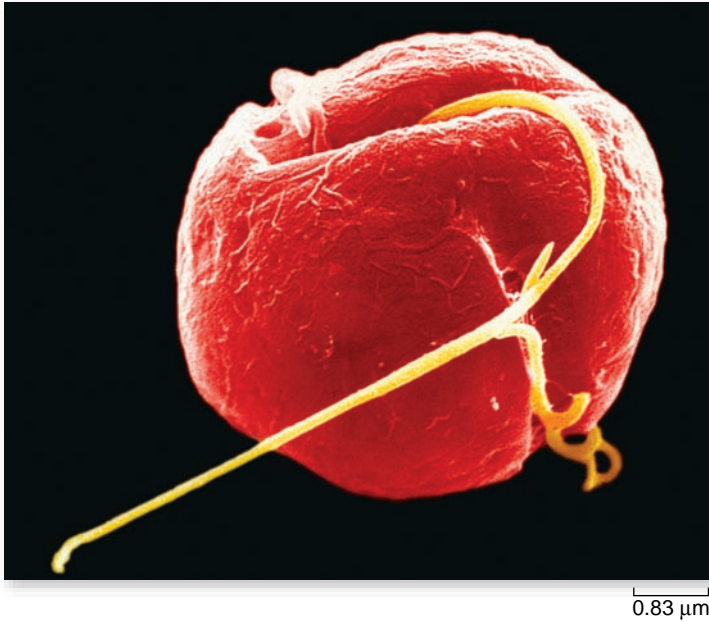

The poisonous and destructive “red tides” that occur frequently in coastal areas are often associated with great population explosions, or “blooms,” of dinoflagellates, whose pigments color the water (figure 29.13). Red tides have a profound, detrimental effect on the fishing industry worldwide. Some 20 species of dinoflagellates produce powerful toxins that inhibit the diaphragm and cause respiratory failure in many vertebrates. When the toxic dinoflagellates are abundant, many fishes, birds, and marine mammals may die.

Although sexual reproduction does occur under starvation conditions, dinoflagellates reproduce primarily by asexual cell division. Asexual cell division relies on a unique form of mitosis in which the permanently condensed chromosomes divide within a permanent nuclear envelope. After the numerous chromosomes duplicate, the nucleus divides into two daughter nuclei.

Also, the dinoflagellate chromosome is unique among eukaryotes in that the DNA is not generally complexed with

**Figure 29.12** Some dinoflagellates. *Noctiluca*, which lacks the heavy cellulose armor characteristic of most dinoflagellates, is one of the bioluminescent organisms that cause the waves to sparkle in warm seas. In the other three genera, the shorter, encircling flagellum is seen in its groove, with the longer one projecting away from the body of the dinoflagellate. (Not drawn to scale.)

**Figure 29.13 Red tide.** Although small in size, huge populations of dinoflagellates, including this *Gymnodinium* species, can color the sea red and release toxins into the water.

histone proteins. In all other eukaryotes, the chromosomal DNA is complexed with histones to form nucleosomes, structures that represent the first order of DNA packaging in the nucleus (chapter 10). How dinoflagellates maintain distinct chromosomes with a small amount of histones remains a mystery.

## Apicomplexans include the malaria parasite

Apicomplexans are spore-forming parasites of animals. They are called apicomplexans because of a unique arrangement of fibrils, microtubules, vacuoles, and other cell organelles at one end of the cell, termed an *apical complex* (see figure 29.11). The apical complex is a cytoskeletal and secretory complex that enables the apicomplexan to invade its host. The best known apicomplexan is the malarial parasite *Plasmodium*. (The use of the genome sequence of the parasite and the mosquito that carries it is discussed in chapter 24.)

### *Plasmodium* and malaria

*Plasmodium* glides inside the red blood cells of its host with amoeboid-like contractility. Like other apicomplexans, *Plasmodium* has a complex life cycle involving sexual and asexual phases and alternation between different hosts, in this case mosquitoes (*Anopheles gambiae*) and humans (figure 29.14). Even though *Plasmodium* has mitochondria, it grows best in a low-O<sub>2</sub>, high-CO<sub>2</sub> environment.

Efforts to eradicate malaria have focused on (1) eliminating the mosquito vectors; (2) developing drugs to poison the parasites that have entered the human body; and (3) developing vaccines. From the 1940s to the 1960s, wide-scale applications of dichlorodiphenyltrichloroethane (DDT) killed mosquitoes in the United States, Italy, Greece, and certain areas of Latin America. For a time, the worldwide elimination of malaria appeared possible. But this hope was soon crushed by the development of DDT-resistant mosquitoes in many regions. Furthermore, the use of DDT has had serious

**Figure 29.14**  
**The life cycle of *Plasmodium*.**

*Plasmodium*, the apicomplexan that causes malaria, has a complex life cycle that alternates between mosquitoes and mammals.

**Figure 29.15**  
Gregarine entering a cell.

environmental consequences. In addition to the problems with resistant strains of mosquitoes, strains of *Plasmodium* have appeared that are resistant to the drugs historically used to kill them, including quinine.

An experimental vaccine containing a surface protein of one malaria-causing parasite, *P. falciparum*, seems to induce the immune system to defend against future infections. In tests, six out of seven vaccinated people did not get malaria after being bitten by mosquitoes that carried *P. falciparum*. Many are hopeful that this new vaccine may be able to fight malaria. (Chapter 24 contains a discussion of the genome sequences of both *Plasmodium* and its mosquito vector.)

### Gregarines

Gregarines are another group of apicomplexans that use their distinctive apical complex to attach themselves in the intestinal epithelium of arthropods, annelids, and mollusks. Most of the gregarine body, aside from the apical complex, is in the intestinal cavity, and nutrients appear to be obtained through the apicomplex attachment to the cell (figure 29.15).

### Toxoplasma

Using its apical complex, *Toxoplasma gondii* invades the epithelial cells of the human gut. Most individuals infected with the parasite mount an immune response, preventing any permanent damage. In the absence of a fully functional immune system, however, *Toxoplasma* can damage brain (figure 29.16), heart, and skeletal tissues, in addition to gut and lymph tissue, during extended infections. Individuals with AIDS are particularly susceptible to *Toxoplasma* infection. If a pregnant woman touches a cat litter box, *Toxoplasma* parasites from the cat can, if ingested, cross the placental barrier and harm the developing fetus with an immature immune system.

**Figure 29.16**  
Micrograph of a cyst filled with *Toxoplasma*.

*Toxoplasma* can enter the brain and form cysts filled with slowly replicating parasites.

## Ciliates are characterized by their mode of locomotion

As the name indicates, most ciliates feature large numbers of cilia (tiny beating hairs). These heterotrophic, unicellular protists are 10 to 3000 μm long. Their cilia are usually arranged either in longitudinal rows or in spirals around the cell. Cilia are anchored to microtubules beneath the plasma membrane (see chapter 5), and they beat in a coordinated fashion. In some groups, the cilia have specialized functions, becoming fused into sheets, spikes, and rods that may then function as mouths, paddles, teeth, or feet.

The ciliates have a pellicle, a tough but flexible outer covering, that enables them to squeeze through or move around obstacles.

### Micronucleus and macronucleus

All known ciliates have two different types of nuclei within their cells: a small **micronucleus** and a larger **macronucleus** (figure 29.17). Macronuclei divide by mitosis and are essential for the physiological function of the well-known ciliate *Paramecium*. The micronucleus of some individuals of *Tetrahymena pyriformis*, a common laboratory species, was experimentally removed in the 1930s, and their descendants continue to reproduce asexually to this day! *Paramecium*, however, is not immortal. The cells divide asexually for about 700 generations and then die if sexual reproduction has not occurred. The micronucleus in ciliates is evidently needed only for sexual reproduction.

### Vacuoles

Ciliates form vacuoles for ingesting food and regulating water balance. Food first enters the gullet, which in *Paramecium* is lined with cilia fused into a membrane (see figure 29.17). From the gullet, the food passes into food vacuoles, where enzymes and hydrochloric acid aid in its digestion. Afterward, the vacuole empties its waste contents through a special pore in the pellicle called the *cytoproct*, which is essentially an exocytotic

**Figure 29.17** *Paramecium*. The main features of this ciliate include cilia, two nuclei, and numerous specialized organelles.

**Figure 29.18** Life cycle of *Paramecium*. In sexual reproduction, two mature cells fuse in a process called conjugation.

vesicle that appears periodically when solid particles are ready to be expelled.

The contractile vacuoles, which regulate water balance, periodically expand and contract as they empty their contents to the outside of the organism.

### Conjugation: Exchange of micronuclei

Like most ciliates, *Paramecium* undergoes a sexual process called conjugation, in which two individual cells remain attached to each other for up to several hours (figure 29.18).

*Paramecia* have multiple mating types. Only cells of two different genetically determined mating types can conjugate. Meiosis in the micronuclei produces several haploid micronuclei, and the two partners exchange a pair of their micronuclei through a cytoplasmic bridge between them.

In each conjugating individual, the new micronucleus fuses with one of the micronuclei already present in that individual, resulting in the production of a new diploid micronucleus. After conjugation, the macronucleus in each cell disintegrates, and the new diploid micronucleus undergoes mitosis, thus giving rise to two new identical diploid micronuclei in each individual.

One of these micronuclei becomes the precursor of the future micronuclei of that cell, while the other micronucleus undergoes multiple rounds of DNA replication, becoming the new macronucleus. This complete segregation of the genetic

material is unique to the ciliates and makes them ideal organisms for the study of certain aspects of genetics.

### "Killer" strains

*Paramecium* strains that kill other, sensitive strains of *Paramecium* long puzzled researchers. Initially, killer strains were believed to have genes coding for a substance toxic to sensitive strains. The true source of the toxin turned out to be an endosymbiotic bacterium in the "killer" strains. If this bacterium is engulfed by a "nonkiller" strain, the toxin is released, and the sensitive *Paramecium* dies.

### Learning Outcomes Review 29.5

All members of the Alveolata contain flattened vesicles called alveoli. Dinoflagellates have pairs of flagella arranged perpendicular to each other, which causes them to swim with a spinning motion. Blooms of dinoflagellates cause red tides. Apicomplexans are animal parasites that produce a structure called an apical complex, which is composed of cytoskeleton and secretory structures and aids in penetrating their host. The ciliates are unicellular, heterotrophic protists with cilia used for feeding and propulsion.

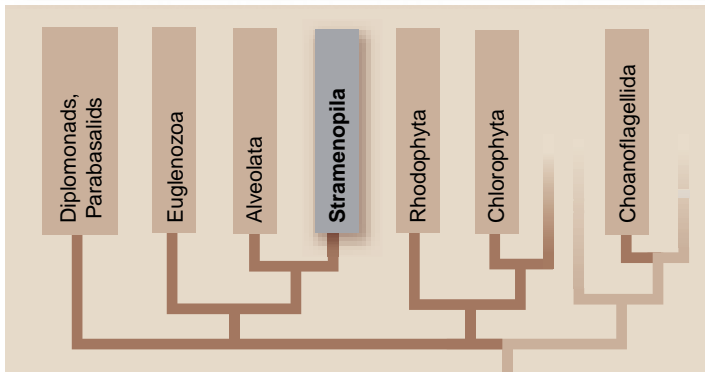

- What would be a major difficulty in finding a poison to fight the malaria-causing protist *Plasmodium*?

## 29.6 Stramenopila: Protists with Fine Hairs

### Learning Outcomes

1. Describe the characteristic features of the Stramenopila.
2. Describe the composition of the unique shells of diatoms.
3. Explain how the oomycetes are distinguished from other protists.

Stramenopiles include *brown algae*, *diatoms*, and the *oomycetes* (water molds). The name *stramenopila* refers to unique, fine hairs (figure 29.19) found on the flagella of members of this group, although a few species have lost their hairs during evolution.

### Brown algae include large seaweeds

Brown algae are the most conspicuous seaweeds in many northern regions (figure 29.20). The life cycle of the brown algae is marked by an alternation of generations between a multicellular sporophyte (diploid) and a multicellular gametophyte (haploid) (figure 29.21). Some sporophyte cells go through meiosis and produce spores. These spores germinate and undergo mitosis to produce the large individuals we recognize, such as the

**Figure 29.19** Stramenopiles have very fine hairs on their flagella.

**Figure 29.20** Brown algae. The giant kelp, *Macrocystis pyrifera*, grows in relatively shallow water along the coasts throughout the world and provides food and shelter for many different kinds of organisms.

kelps. The gametophytes are often much smaller, filamentous individuals, perhaps a few centimeters in width.

Even in an aquatic environment, transport can be a challenge for the very large brown algal species. Distinctive transport cells that stack one upon the other enhance transport within some species (see figure 23.10). However, even though the large kelp look like plants, it is important to realize that they do not contain the complex tissues such as xylem that are found in plants.

### Diatoms are unicellular organisms with double shells

Diatoms, members of the phylum Chrysophyta, are photosynthetic, unicellular organisms with unique double shells made of opaline silica, which are often strikingly marked (figure 29.22). The shells of diatoms are like small boxes with lids, one half of the shell fitting inside the other. Their chloroplasts, containing chlorophylls *a* and *c*, as well as carotenoids, resemble those of the brown algae and dinoflagellates. Diatoms produce a unique carbohydrate called chrysolaminarin.

**Figure 29.21** Life cycle of *Laminaria*, a brown alga. Multicellular haploid and diploid stages are found in this life cycle, although the male and female gametophytes are quite small.

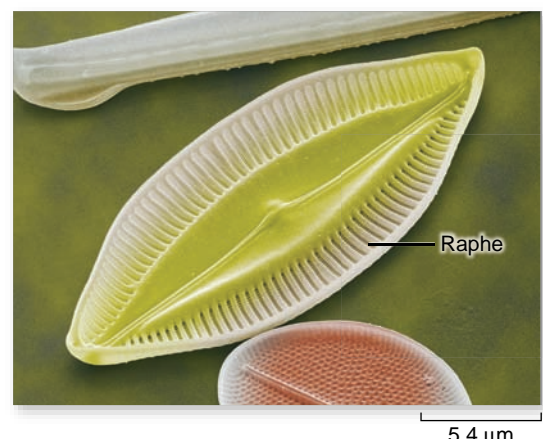

Some diatoms move by using two long grooves, called *raphe*s, which are lined with vibrating fibrils (figure 29.23). The exact mechanism is still being unraveled and may involve the ejection of mucopolysaccharide streams from the raphe that propel the diatom. Pencil-shaped diatoms can slide back and forth over each other, creating an ever-changing shape.

### Oomycetes, the “water molds,” have some pathogenic members

All oomycetes are either parasites or saprobes (organisms that live by feeding on dead organic matter). At one time, these organisms were considered fungi, which is the origin of the term *water mold* and why their name contains *-mycetes*.

**Figure 29.22** Diatoms. These different radially symmetrical diatoms have unique silica, two-part shells.

**Figure 29.23** Diatom raphe are lined with fibrils that aid in locomotion.

They are distinguished from other protists by the structure of their motile spores, or zoospores, which bear two unequal flagella, one pointed forward and the other backward. Zoospores are produced asexually in a sporangium. Sexual reproduction involves the formation of male and female reproductive organs that produce gametes. Most oomycetes are found in water, but their terrestrial relatives are plant pathogens.

*Phytophthora infestans*, which causes late blight of potatoes, was responsible for the Irish potato famine of 1845 and 1847. During the famine, about 400,000 people starved to death or died of diseases complicated by starvation and about 2 million Irish immigrated to the United States and elsewhere.

Another oomycete, *Saprolegnia*, is a fish pathogen that can cause serious losses in fish hatcheries. When these fish are released into lakes, the pathogen can infect amphibians and kill millions of amphibian eggs at a time at certain locations. This pathogen is thought to contribute to the phenomenon of amphibian decline.

### Learning Outcomes Review 29.6

Most members of the Stramenopila have fine hairs on their flagella. Brown algae are large seaweeds that provide food and habitat for marine organisms. They undergo an alternation of generations. Diatoms are unicellular with silica in their cell walls, which forms a shell with two halves. Some can propel themselves. Oomycetes are unique in the production of zoospores that bear two unequal flagella.

- How could you distinguish between the sporophyte and the gametophyte of a brown alga?

**Figure 29.24** Red algae come in many forms and sizes.

This lineage lacks flagella and centrioles, and has the accessory photosynthetic pigments phycoerythrin, phycocyanin, and allophycocyanin, which are arranged within structures called *phycobilisomes*. They reproduce using alternation of generations.

The origin of the over 7000 species of Rhodophyta has been a source of controversy. Evidence supporting very early eukaryotic origins and a common ancestry with green algae has been considered. Molecular comparisons of the chloroplasts in red and green algae support a single endosymbiotic origin for both.

Comparisons of the nuclear DNA coding for the large subunit of RNA polymerase II from two red algae, a green alga, and another protist support the conclusion that the Rhodophyta emerged before the evolutionary lineage that led to plants, animals, and fungi.

How can we reconcile the data from plastid and nuclear DNA? The host cells and the cyanobacterial symbionts probably did not follow congruent evolutionary pathways. The host cell that gave rise to red algae may have been distinct from the one that gave rise to plants. One possibility is that different host cells engulfed the same bacterial symbiont. Tentatively, we will treat Rhodophyta and Chlorophyta (the green algae; see chapter 30) as sister clades based on the substantial amount of chloroplast data.

### Learning Outcomes Review 29.7

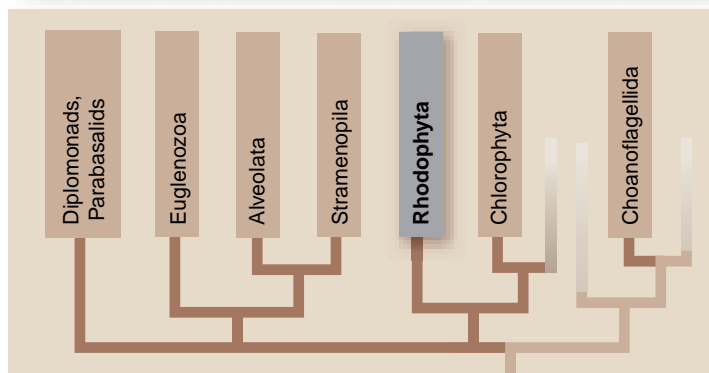

Red algae vary greatly in size and produce accessory pigments that may give them a red color. They lack centrioles and flagella, and they reproduce using an alternation of generations. Humans use red algae as a food and a thickening agent. The evolutionary origin of red algae is a subject of controversy.

- Why would you expect to get different results from analysis of nuclear DNA versus plastid DNA?

## 29.7 Rhodophyta: Red Algae

### Learning Outcomes

1. List the major characteristics of red algae.
2. Describe how humans use red algae.

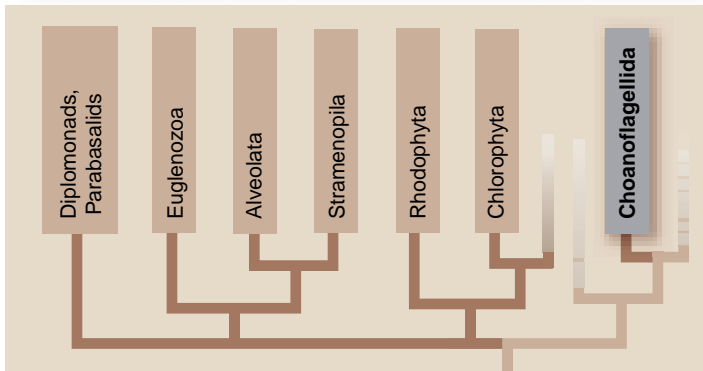

**Rhodophyta**, the red algae, range in size from microscopic organisms to *Schizymenia borealis* with blades as long as 2 m (figure 29.24). Sushi rolls are wrapped in nori, a red alga. Red algal polysaccharides are used commercially to thicken ice cream and cosmetics.

## 29.8 Choanoflagellida: Possible Animal Ancestors

### Learning Outcome

1. Describe the evolutionary significance of the choanoflagellates.

*Choanoflagellates* are most like the common ancestor of the sponges and, indeed, all animals. Choanoflagellates have a single emergent flagellum surrounded by a funnel-shaped, contractile collar composed of closely placed filaments, a structure that is exactly matched in the sponges, which are animals. These protists feed on bacteria strained out of the water by their collar. Colonial forms resemble freshwater sponges (figure 29.25).

The close relationship of choanoflagellates to animals was further demonstrated by the strong homology between a surface receptor (a tyrosine kinase receptor) found in choanoflagellates and sponges. This surface receptor initiates a signaling pathway involving phosphorylation (see chapter 9).

### Learning Outcome Review 29.8

The choanoflagellates are believed to be the closest relatives of animals. Colonial forms are similar to freshwater sponges, and both organisms have a homologous cell surface receptor.

- What other types of studies might connect choanoflagellates with sponges?

**Figure 29.25**  
Colonial choanoflagellates resemble their close animal relatives, the sponges.

## 29.9 Protists Without a Clade

### Learning Outcomes

1. Explain how amoebas move.
2. Distinguish between the shells of most foraminifera and those of diatoms.
3. Distinguish between cellular and plasmodial slime molds.

Many protists remain to be placed on the tree of life. The following examples are of particular importance to human health and the environment.

### Amoebas are paraphyletic

So far, we have organized the protists based on their closest relatives. Some lineages vary tremendously if you consider just a single trait. For example, the stramenopiles include autotrophic, marine algae, and terrestrial plant pathogens. As seen in chapter 25, it is also possible for unrelated organisms to acquire similar traits. That is the case with amoebas, which have similar cell morphology, but are not monophyletic.

#### *Rhizopoda: True amoebas*

Amoebas move from place to place by means of their pseudopods. Pseudopods are flowing projections of cytoplasm that extend and pull the amoeba forward or engulf food particles. An amoeba puts a pseudopod forward and then flows into it (figure 29.26). Microfilaments of actin and myosin similar to those found in muscles are associated with these movements. The pseudopods can form at any point on the cell body so that it can move in any direction.

#### *Actinopoda: Radiolarians*

The pseudopods of amoeboid cells give them truly amorphous bodies. One group, however, has more distinct structures. Members of the phylum Actinopoda, often called *radiolarians*, secrete glassy exoskeletons made of silica. These skeletons give the unicellular organisms a distinct shape, exhibiting either bilateral or radial symmetry. The shells of different species form many elaborate and beautiful shapes, with pseudopods extruding outward

**Figure 29.26**  
*Amoeba proteus*. The projections are pseudopods; an amoeba moves by flowing into them.

**Figure 29.27** *Actinosphaerium* with needle-like pseudopods.

along spiky projections of the skeleton (figure 29.27). Microtubules support these cytoplasmic projections.

### Foraminifera fossils created huge limestone deposits

Members of the phylum Foraminifera are heterotrophic marine protists. They range in diameter from about 20  $\mu\text{m}$  to several centimeters. They resemble tiny snails and can form 3-m-deep layers in marine sediments. Characteristic of the group are pore-studded shells (called *tests*) composed of organic materials usually reinforced with grains of calcium carbonate, sand, or even plates from shells of echinoderms or spicules (minute needles of calcium carbonate) from sponge skeletons.

Depending on the building materials they use, foraminifera may have shells of very different appearance. Some of them are brilliantly colored red, salmon, or yellow-brown.

Most foraminifera live in sand or are attached to other organisms, but two families consist of free-floating planktonic organisms. Their tests may be single-chambered, but are more often multichambered, and they sometimes have a spiral shape resembling that of a tiny snail. Thin cytoplasmic projections called *podia* emerge through openings in the tests (figure 29.28).

**Figure 29.28** A representative of the foraminifera. Podia, thin cytoplasmic projections, extend through pores in the calcareous test, or shell, of this living foram.

Podia are used for swimming, gathering materials for the tests, and feeding. Foraminifera eat a wide variety of small organisms.

The life cycles of foraminifera are extremely complex, involving alternation between haploid and diploid generations. Foraminifera have contributed massive accumulations of their tests to the fossil record for more than 200 million years. Because of the excellent preservation of their tests and the striking differences among them, forams are very important as geological markers. The pattern of occurrence of different forams is often used as a guide in searching for oil-bearing strata. Limestones all over the world, including the famous White Cliffs of Dover in southern England, are often rich in forams (figure 29.29).

### Slime molds exhibit “group behavior”

**Slime molds** originated at least three distinct times, and the three lineages are very distantly related. Like water molds, these organisms were once considered fungi. We will explore two lineages: the plasmodial slime molds, which are huge, single-celled, multinucleate, oozing masses, and the cellular slime molds, in which single cells combine and differentiate, creating an early model of multicellularity.

#### Plasmodial slime molds

Plasmodial slime molds stream along as a **plasmodium**, a non-walled, multinucleate mass of cytoplasm that resembles a moving mass of slime (figure 29.30). This form is called the *feeding phase*, and the plasmodia may be orange, yellow, or another color.

Plasmodia show a back-and-forth streaming of cytoplasm that is very conspicuous, especially under a microscope. They are able to pass through the mesh in cloth or simply to flow around or through other obstacles. As they move, they engulf and digest bacteria, yeasts, and other small particles of organic matter.

A multinucleated *Plasmodium* cell undergoes mitosis synchronously, with the nuclear envelope breaking down, but only at late anaphase or telophase. Centrioles are absent.

**Figure 29.29** White Cliffs of Dover. The limestone that forms these cliffs is composed almost entirely of fossil shells of protists, including foraminifera.

**Figure 29.30** A plasmodial protist. This multinucleate pretzel slime mold, *Hemitrachia serpula*, moves about in search of the bacteria and other organic particles that it ingests.

When either food or moisture is in short supply, the plasmodium migrates relatively rapidly to a new area. Here it stops moving and either forms a mass in which spores differentiate or divides into a large number of small mounds, each of which produces a single, mature **sporangium**, the structure in which spores are produced. These sporangia are often beautiful and extremely complex in form (figure 29.31). The spores are highly resistant to unfavorable environmental influences and may last for years if kept dry.

### Cellular slime molds

The cellular slime molds have become an important group for the study of cell differentiation because of their relatively simple developmental systems (figure 29.32). The individual organisms behave as separate amoebas, moving through the soil and ingesting bacteria. When food becomes scarce, the individuals aggregate to form a moving “slug.” Cyclic adenosine monophosphate (cAMP) is sent out in pulses by some of the

**Figure 29.31** Sporangia of a plasmodial slime mold. These *Arcyria* sporangia are found in the phylum Myxomycota.

cells, and other cells move in the direction of the cAMP to form the slug. In the cellular slime mold *Dictyostelium discoideum*, this slug goes through morphogenesis to make stalk and spore cells. The spores then go on to form a new amoeba if they land in a moist habitat.

### Learning Outcomes Review 29.9

Amoebas such as Rhizopodia and Actinopoda are polyphyletic. They move with the aid of pseudopods. Many members of the foraminifera occupy marine habitats. Most of them have calcium carbonate shells responsible for large fossil deposits of limestone, whereas most diatoms have silica shells. At least three lineages of slime mold exist. Cellular slime molds are multicellular, and plasmodial slime molds consist of large multinucleate single cells.

- *Would you say that cellular slime molds are closely related to plasmodial slime molds?*

**Figure 29.32** Development in *Dictyostelium discoideum*, a cellular slime mold. 1. First, a spore germinates, forming an amoeba that feeds and reproduces until the food runs out. At that point, amoebas aggregate and move toward a fixed center. 2. The aggregated amoebas begin to form a mound. 3. The mound produces a tip and begins to fall sideways. 4. Next, the aggregate forms a multicellular “slug,” 2–3 mm long, that migrates toward light. 5. The slug stops moving and a process called culmination begins. Cells differentiate into stalk and spore cells. 6. In the mature fruiting body, amoebas become encysted as spores.

## Chapter Review

### 29.1 Eukaryotic Origins and Endosymbiosis

*Protista is not monophyletic.*

Protists are the most diverse of the four kingdoms in the domain Eukarya; however, Kingdom Protista is polyphyletic.

*Monophyletic clades have been identified among the protists.*

The correct classification of protists is under debate. Seven major monophyletic groups are considered in this chapter.

*Fossil evidence dates the origins of eukaryotes.*

Although eukaryotes may have arisen earlier, the fossil evidence of their appearance dates back to 1.5 BYA.

*The nucleus and ER arose from membrane infoldings.*

*Mitochondria evolved from engulfed aerobic bacteria.*

According to the theory of endosymbiosis, ancestral eukaryotic cells engulfed aerobic bacteria, which then became mitochondria.

*Chloroplasts evolved from engulfed photosynthetic bacteria.*

Chloroplasts are believed to have arisen when ancestral eukaryotic cells engulfed photosynthetic bacteria.

*Endosymbiosis is supported by a range of evidence.*

Centrioles may have also arisen by endosymbiosis. In support of endosymbiosis, several organelles are found to contain their own DNA, which closely resembles that of prokaryotes.

*Genes have migrated from endosymbiotic organelles.*

Many genes in the mitochondria have moved into the eukaryotic nucleus over time.

*Mitosis evolved in eukaryotes.*

Mechanisms of mitosis vary among organisms, suggesting that the process did not evolve all at once.

### 29.2 Defining Protists

*Protista is not monophyletic.*

*Monophyletic clades have been identified among the protists.*

*Protist cell surfaces vary widely.*

Extracellular material (ECM) may cover the plasma membrane.

*Protists have several means of locomotion.*

Protists mainly use flagella or pseudopods for locomotion, although many other means of propulsion are found.

*Protists have a range of nutritional strategies.*

Protists include phototrophs, heterotrophs, (phagotrophs or osmotrophs), and mixotrophs capable of both modes.

*Protists reproduce asexually and sexually.*

Protists can reproduce asexually by mitosis, budding, or schizogony. They may also carry out sexual reproduction.

*Protists are the bridge to multicellularity.*

Colonial protists may be the precursors of multicellular organisms.

### 29.3 Diplomonads and Parabasalids: Flagellated Protists Lacking Mitochondria

*Diplomonads have two nuclei.*

Diplomonads are unicellular, move with flagella, and have two nuclei.

*Parabasalids have undulating membranes.*

Parabasalids use flagella and undulating membranes for locomotion.

### 29.4 Euglenozoa: A Diverse Group in Which Some Members Have Chloroplasts

*Euglenoids are free-living eukaryotes with anterior flagella.*

Euglenoids can produce chloroplasts to carry out photosynthesis in the light. They contain a pellicle and move via anterior flagella.

*Kinetoplastids are parasitic.*

Kinetoplastids are parasitic and are distinctive in having a single, unique mitochondrion with two types of circular DNA.

### 29.5 Alveolata: Protists with Submembrane Vesicles

*Dinoflagellates are photosynthesizers with distinctive features.*

Dinoflagellates have pairs of flagella arranged so that they swim with a spinning motion. Blooms of dinoflagellates cause red tides.

*Apicomplexans include the malaria parasite.*

Apicomplexans are spore-forming animal parasites. They have a unique arrangement of organelles at one end of the cell, called the apical complex, which is used to invade the host.

*Ciliates are characterized by their mode of locomotion.*

Ciliates are unicellular, heterotrophic protists that use numerous cilia for feeding and propulsion. Each cell has a macronucleus and a micronucleus. Micronuclei are exchanged during conjugation.

### 29.6 Stramenopila: Protists with Fine Hairs

*Brown algae include large seaweeds.*

Brown algae are typically large seaweeds that undergo an alternation of generations, producing gametophyte and sporophyte stages.

*Diatoms are unicellular organisms with double shells.*

Diatoms have silica in their cell walls. Each diatom produces two overlapping glassy shells that fit like a box and lid.

*Oomycetes, the "water molds," have some pathogenic members.*

Oomycetes are parasitic and are unique in the production of asexual spores (zoospores) that bear two unequal flagella.

### 29.7 Rhodophyta: Red Algae

Red algae produce accessory pigments that may give them a red color. They lack centrioles and flagella, and they reproduce using an alternation of generations.

### 29.8 Choanoflagellida: Possible Animal Ancestors

Colonial choanoflagellates are structurally similar to freshwater sponges, and molecular similarities have been found.

### 29.9 Protists Without a Clade

*Amoebas are paraphyletic.*

Amoebas have formed through several lineages. Two main groups are Rhizopoda and Actinopoda (radiolarians).

*Foraminifera fossils created huge limestone deposits.*

The Foraminifera are heterotrophic marine protists with pore-studded shells primarily formed by deposit of calcium carbonate.

*Slime molds exhibit "group behavior."*

Two of the three lineages of slime molds are the plasmodial slime molds and the cellular slime molds. All can aggregate to form a moving "slug" that produces spores.

## Review Questions

### UNDERSTAND

- Fossil evidence of eukaryote dates back to *Hemitrichia serpula*
  - 2.5 BYA.
  - 1.5 BYA.
  - 2.5 MYA.
  - 1.5 MYA.
- DNA is not found in this organelle.
  - Endoplasmic reticulum
  - Nucleus
  - Chloroplast
  - Centriole
  - Mitochondrion
- The products of budding are
  - two cells of equal size.
  - two cells, one of which is smaller than the other.
  - many cells of equal size.
  - many cells of variable size.
- Both diplomonads and parabasalids
  - contain chloroplasts.
  - have multinucleate cells.
  - lack mitochondria.
  - have silica in their cell walls.
- Trypanosomes are examples of
  - euglenoids.
  - diplomonads.
  - parabasalids.
  - kinetoplastids.
- The function of the apical complex in Apicomplexans is to
  - propel the cell through water.
  - penetrate host tissue.
  - absorb food.
  - detect light.
- If a cell contains a pellicle, it
  - can change shape readily.
  - is shaped like a sphere.
  - is shaped like a torpedo.
  - must have a contractile vacuole.
- Stramenopila are
  - tiny flagella.
  - large cilia.
  - small hairs on flagella.
  - pairs of large flagella.
- Choose all of the following that exhibit an alternation of multicellular generations.
  - Dinoflagellates
  - Brown algae
  - Red algae
  - Diatoms
- Choose all of the following that are photosynthetic.
  - Diatoms
  - Ciliates
  - Apicomplexans
  - Dinoflagellates
- Which is most likely the ancestor of animals?
  - Trypanosomes
  - Diplomonads
  - Ciliates
  - Choanoflagellates
- When food is scarce, cells of this organism communicate with each other to form a multicellular slug.
  - Cellular slime molds
  - True amoebas
  - Foraminifera
  - Diatoms

### APPLY

- Analyze the following statements and choose the one that most accurately supports the endosymbiotic theory.
  - Mitochondria rely on mitosis for replication.
  - Chloroplasts contain DNA but translation does not occur in chloroplasts.
  - Vacuoles have double membranes.
  - Antibiotics that inhibit protein synthesis in bacteria can have the same effect on mitochondria.
- Determine which feature of the choanoflagellates was likely the most significant for the evolution of animals?
  - Flagellum with a funnel-shaped, contractile collar also found in sponges
  - A tyrosine kinase receptor on the surface of choanoflagellates that has strong homology to fungi
  - A colonial form that resembles some fungi
  - Eyespots that are similar to ribbonworms
- Examine the life cycle of cellular slime molds, and determine which feature affords the greatest advantage for surviving food shortages.
  - Cellular slime molds produce spores when starved.
  - Cellular slime molds are saprobes.
  - A diet of bacteria ensures there will never be a shortage of food.
  - Cellular slime molds use cAMP to guide each other to food sources.

### SYNTHESIZE

- Modern taxonomic treatments rely heavily on phylogenetic data to classify organisms. In the past, taxonomists often used a morphological species concept, in which species were defined based on similarities in growth form. Give an example to show how a morphological species concept would group a set of protists differently than a phylogenetic species concept would.
- Three methods have been used to try to eradicate malaria. One is to eliminate the mosquito vectors of the parasite, a second is to kill the parasites after they entered the human body, and the third is to develop a vaccine against the parasite, allowing the human immune system to provide protection from the disease. Which do you suppose is the most promising in the long run? Why? Think about both the biology of the disease and the efficacy of carrying out each of the methods on a large scale.
- Design an experiment to demonstrate that cells of cellular slime molds are attracted to cyclic-AMP. Then, design a follow-up experiment to determine whether they are always attracted to cAMP or only when resources are scarce.

## Chapter 30

## Green Plants

## Chapter Outline

- 30.1 Defining Plants
- 30.2 Chlorophytes and Charophytes: Green Algae
- 30.3 Bryophytes: Dominant Gametophyte Generation
- 30.4 Tracheophyte Plants: Roots, Stems, and Leaves
- 30.5 Lycophytes: Dominant Sporophyte Generation and Vascular Tissue
- 30.6 Pterophytes: Ferns and Their Relatives
- 30.7 The Evolution of Seed Plants
- 30.8 Gymnosperms: Plants with “Naked Seeds”
- 30.9 Angiosperms: The Flowering Plants

## Introduction

Colonization of land by plants fundamentally altered the history of life on Earth. A terrestrial environment offers abundant CO<sub>2</sub> and solar radiation for photosynthesis. But for at least 500 million years, the lack of water and higher ultraviolet (UV) radiation on land confined green algal ancestors to an aquatic environment. Evolutionary innovations for reproduction, structural support, and prevention of water-loss are key in the story of plant adaptation to land. The evolutionary shift on land to life cycles dominated by a diploid generation masks recessive mutations arising from higher UV exposure. As a result, larger numbers of alleles persist in the gene pool, creating greater genetic diversity. Numerous evolutionary solutions to terrestrial challenges have resulted in over 300,000 species of plants dominating all terrestrial communities today, from forests to alpine tundra and from agricultural fields to deserts. Plants affect almost every aspect of our lives, from improving environmental quality to providing pharmaceuticals, food, fuels, building materials, and clothing. This chapter explores the evolutionary history and strategies of the green plants.

## 30.1 Defining Plants

## Learning Outcomes

1. Explain the relationship between the different algae clades and plants.
2. Describe the haplodiplontic life cycle.
3. Distinguish between a sporophyte and a gametophyte.
4. Identify two major environmental challenges for land plants and associated adaptations.

As you saw in chapter 26, the phylogenetic revolution has completely altered our definition of a plant. We now know that all green algae and the land plants shared a common ancestor a little over 1 BYA, and the two groups are now recognized as a kingdom or crown group referred to as the Viridiplantae, or simply, the green plants. DNA sequence data are consistent with the claim that a single individual gave rise to all plants. Thus, plants are all members of the Viridiplantae, extending an older definition of plants to include the green algae.

Plants are photoautotrophic, but not all photoautotrophs are members of the Viridiplantae. The definition of a plant is broad, but it excludes the red and brown algae. All

algae—red, brown, and green—shared a primary endosymbiotic event 1.5 BYA. But sharing an ancestral chloroplast lineage is not the same as being monophyletic. Red and green algae last shared a common ancestor about 1.4 BYA. Brown algae became photosynthetic through endosymbiosis with a eukaryotic red alga that had itself already acquired a photosynthetic cyanobacterium, as described in the preceding chapter.

Plants are also not fungi, which are more closely related to metazoan animals (see chapter 32). Fungi, however, were essential to the colonization of land by plants, enhancing plants' nutrient uptake from the soil.

## Land plants evolved from freshwater algae

Some saltwater algae evolved to thrive in a freshwater environment. Just a single species of freshwater green algae gave rise to the entire terrestrial plant lineage, from mosses through the flowering plants (angiosperms). Given the incredibly harsh conditions of life on land, it is not surprising that all land plants share a single common ancestor. Exactly what this ancestral alga was is still a mystery, but close relatives, members of the charophytes, exist in freshwater lakes today.

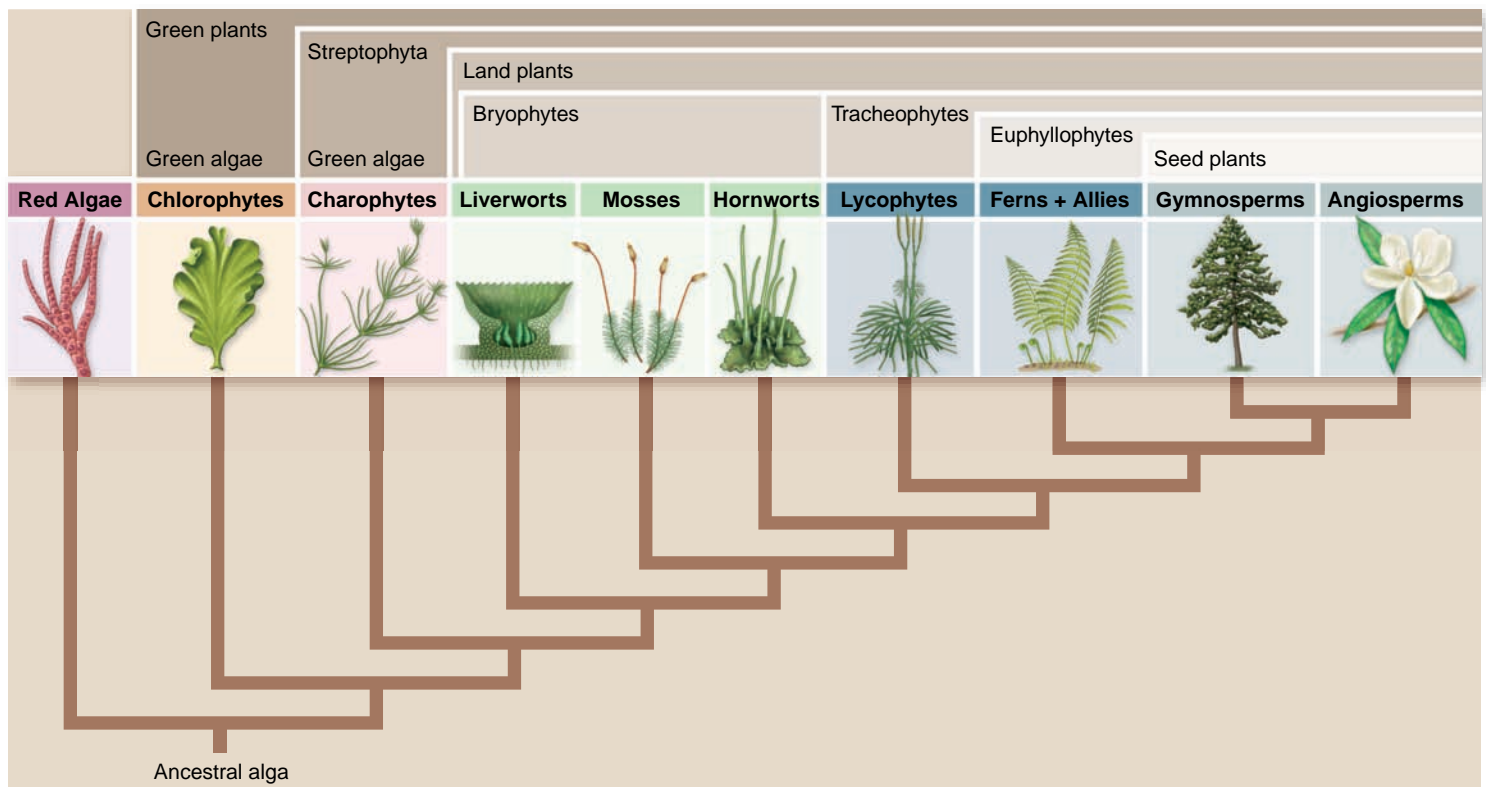

The green algae split into two major clades: the chlorophytes, which never made it to land, and the charophytes, which are sister to all the land plants (figure 30.1). Land plants, although diverse, have certain characteristics in common. Unlike the charophytes, land plants have multicellular haploid and diploid stages. Diploid embryos are also land plant innovations.

Over time, the trend has been toward more embryo protection and a smaller haploid stage in the life cycle.

## Land plants have adapted to terrestrial life

Unlike their freshwater ancestors, most land plants have only limited amounts of water available. As an adaptation to living on land, most plants are protected from desiccation—the tendency of organisms to lose water to the air—by a waxy surface material called the cuticle that is secreted onto their exposed surfaces. The cuticle is relatively impermeable, preventing water loss. This solution, however, limits the gas exchange essential for respiration and photosynthesis. Gas diffusion into and out of a plant occurs through tiny mouth-shaped openings called **stomata** (singular, *stoma*), which allows water to diffuse out at the same time. Chapter 36 describes how stomata can be closed at times to limit water loss.

Moving water within plants is a challenge that increases with plant size. Members of the land plants can be distinguished based on the presence or absence of **tracheids**, specialized cells that facilitate the transport of water and minerals (see chapter 36). Tracheophytes have specialized transport cells called tracheids and have evolved highly efficient transport systems: water-conducting xylem and food-conducting phloem strands of tissues in their stems, roots, and leaves. Some plants that grow in aquatic environments, including water lilies, have tracheids. Aquatic tracheophytes had terrestrial ancestors that adapted back to a watery environment.

**Figure 30.1** Green plant phylogeny.

Terrestrial plants are exposed to higher intensities of UV irradiation than aquatic algae, increasing the chance of mutation. Diploid genomes mask the effect of a single, deleterious allele. All land plants have both haploid and diploid generations, and the evolutionary shift toward a dominant diploid generation allows for greater genetic variability to persist in terrestrial plants.

Most multicellular Viridiplantae have haplodiplontic life cycles. Many multicellular green algae and all land plants have haplodiplontic life cycles and undergo mitosis after both gamete fusion and meiosis. The result is a multicellular haploid individual and a multicellular diploid individual—unlike in the human life cycle, in which gamete fusion directly follows meiosis. Humans have a **diploptic** life cycle, meaning that only the diploid stage is multicellular; by contrast, the land plant life cycle is **haplodiplontic**, having multicellular haploid and diploid stages.

## The haplodiplontic cycle produces alternation of generations

The basic haplodiplontic cycle is summarized in figure 30.2. Many brown, red, and green algae are also haplodiplontic. Humans produce gametes via meiosis, but land plants actually produce gametes by *mitosis* in a multicellular, haploid individual. The diploid generation, or **sporophyte**, alternates with the haploid generation, or **gametophyte**. Sporophyte means “spore plant,” and gametophyte means “gamete plant.” These terms indicate the kinds of reproductive cells the respective generations produce.

The diploid sporophyte produces haploid spores (not gametes) by meiosis. Meiosis takes place in structures called sporangia, where diploid **spore mother cells (sporocytes)** undergo meiosis, each producing four haploid **spores**. Spores

**Figure 30.2** A generalized multicellular plant life cycle. Note that both haploid and diploid individuals can be multicellular. Also, spores are produced by meiosis, while gametes are produced by mitosis.

are the first cells of the gametophyte generation. Spores divide by mitosis, producing a multicellular, haploid gametophyte.

The haploid gametophyte is the source of gametes. When the gametes fuse, the zygote they form is diploid and is the first cell of the next sporophyte generation. The zygote grows into a diploid sporophyte by mitosis and produces sporangia in which meiosis ultimately occurs.

## The relative sizes of haploid and diploid generations vary

All land plants are haplodiplontic; however, the haploid generation consumes a much larger portion of the life cycle in mosses and ferns than it does in gymnosperms and angiosperms. In mosses, liverworts, and ferns, the gametophyte is photosynthetic and free-living. When you look at mosses, what you see is largely gametophyte tissue; the sporophytes are usually smaller, brownish or yellowish structures attached to the tissues of the gametophyte. In other plants, the gametophyte is usually nutritionally dependent on the sporophyte. When you look at a gymnosperm or angiosperm, such as most trees, the largest, most visible portion is a sporophyte.

Although the sporophyte generation can get very large, the size of the gametophyte is limited in all plants. The gametophyte generation of mosses produces gametes at its tips. The egg is stationary, and sperm lands near the egg in a droplet of water. If the moss were the height of a sequoia, not only would vascular tissue be needed for conduction and support, but the sperm would have to swim up the tree! In contrast, the small gametophyte of the fern develops on the forest floor where gametes can meet. Tree ferns are especially abundant in Australia; the haploid spores the sporophyte trees produce fall to the ground and develop into gametophytes.

Having completed an overview of plant life cycles, we next consider the major plant groups within Viridiplantae. As we proceed, you will see a reduction of the gametophyte from group to group, a loss of multicellular **gametangia** (structures in which gametes are produced), and increasing specialization for life on land, including the remarkable structural adaptations of the flowering plants, which are the dominant plants today.

### Learning Outcomes Review 30.1

All algae acquired chloroplasts necessary for photosynthesis, but green algae diverged from red algae after that event. A single freshwater green alga successfully invaded land; its descendants eventually developed reproductive strategies, conducting systems, stomata, and cuticles as adaptations. Green plants (Viridiplantae) include all green algae and the land plants. Most plants have a haplodiplontic life cycle, a haploid form alternates with a diploid form in a single organism. Diploid sporophytes produce haploid spores by meiosis. Each spore can develop into a haploid gametophyte by mitosis; the gametophyte form produces haploid gametes, again by mitosis. When the gametes fuse, the diploid sporophyte is formed once more.

- How would you distinguish a small aquatic tracheophyte from a freshwater alga?
- What distinguishes gamete formation in plants from gamete formation in humans?

## 30.2 Chlorophytes and Charophytes: Green Algae

### Learning Outcomes

1. Explain why chlorophytes are considered close relatives of land plants.
2. Explain why charophytes are considered the closest relatives of land plants.

Green algae have two distinct lineages: the chlorophytes, discussed here, and another lineage, the **streptophytes**, that gave rise to the land plants (see figure 30.1). The chlorophytes are of special interest here because of their unusual diversity and lines of specialization. The chlorophytes have an extensive fossil record dating back 900 million years. Modern chlorophytes closely resemble land plants, especially in their chloroplasts, which are biochemically similar to those of the plants. They contain chlorophylls *a* and *b*, as well as carotenoids.

**Figure 30.3**  
***Chlamydomonas* life cycle.**

This single-celled chlorophyte has both asexual and sexual reproduction. Unlike multicellular green plants, gamete fusion is not followed by mitosis. © Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited

### Chlorophytes can be unicellular

Early green algae probably resembled *Chlamydomonas reinhardtii*, diverging from land plants over 1 BYA (figure 30.3). Individuals are microscopic (usually less than 25  $\mu\text{m}$  long), green, and rounded, and they have two flagella at the anterior end. They are soil dwellers that move rapidly in water by beating their flagella in opposite directions. Most individuals of *Chlamydomonas* are haploid. *Chlamydomonas* reproduces asexually as well as sexually, but because it is always unicellular the life cycle is not haplodiplontic (see figure 30.3).

Several lines of evolutionary specialization have been derived from organisms such as *Chlamydomonas*, including the evolution of nonmotile, unicellular green algae. *Chlamydomonas* is capable of retracting its flagella and settling down as an immobile unicellular organism if the pond in which it lives dries out. Some common algae found in soil and bark, such as *Chlorella*, are essentially like *Chlamydomonas* in this trait, but they do not have the ability to form flagella.

Genome-sequencing projects are providing new insights into the evolution of the Viridiplantae. A comparison of the 6968 protein families predicted by the *Chlamydomonas* genome were compared with a red algal genome and two streptophyte genomes (moss and *Arabidopsis*). Of these proteins, 172 are found only in the Viridiplantae. Comparing these conserved proteins in the green plants will provide new information about the evolution of the green plants.

### Colonial chlorophytes have some cell specialization

Multicellularity arose many times in the eukaryotes. Colonial chlorophytes provide examples of cellular specialization, an aspect of multicellularity. A line of specialization from cells like those of *Chlamydomonas* concerns the formation of motile, colonial organisms. In these genera of green algae, the *Chlamydomonas*-like cells retain some of their individuality.

The most elaborate of these organisms is *Volvox* (figure 30.4), a hollow sphere made up of a single layer of

**Figure 30.4** *Volvox*. This chlorophyte forms a colony where some cells specialize for reproduction.

500 to 60,000 individual cells, each cell having two flagella. Only a small number of the cells are reproductive. Some reproductive cells may divide asexually, bulge inward, and give rise to new colonies that initially remain within the parent colony. Others produce gametes.

## Multicellular chlorophytes can have haplodiplontic life cycles

Haplodiplontic life cycles are found in some chlorophytes and the streptophytes, which include both charophytes and land plants. *Ulva*, a multicellular chlorophyte, has identical gametophyte and sporophyte generations that consist of flattened sheets two cells thick (figure 30.5). Unlike the charophytes, none of the ancestral chlorophytes gave rise to land plants.

**Figure 30.5 Life cycle of *Ulva*.** This chlorophyte alga has a haplodiplontic life cycle. The gametophyte and sporophyte are multicellular and identical in appearance.

### Inquiry question

? Are *Ulva* gametes formed by meiosis? Explain your response.

**Figure 30.6 *Chara*, a member of the Charales, and *Coleochaete*, a member of the Coleochaetales, represent the two clades most closely related to land plants.**

## Charophytes are the closest relatives to land plants

Charophytes, a clade of streptophytes, are also green algae, and they are distinguished from chlorophytes by their close phylogenetic relationship to the land plants. Charophytes have haplontic life cycles, indicating that the evolution of a diplontic embryo and haplodiplontic life cycle occurred after the move onto land.

Identifying which of the charophyte clades is sister (most closely related) to the land plants puzzled biologists for a long time. The charophyte algae fossil record is scarce. Currently, the molecular evidence from rRNA and DNA sequences favors the charophytes as the green algal clade in the streptophytes.

The two candidate Charophyta clades have been the Charales, with about 300 species, and the Coleochaetales, with about 30 species (figure 30.6). Both lineages are primarily freshwater algae, but the Charales are huge, relative to the microscopic Coleochaetales. Both clades have similarities to land plants. *Coleochaete* and its relatives have cytoplasmic linkages between cells called *plasmodesmata*, which are found in land plants. The species *Chara* in the Charales undergoes mitosis and cytokinesis like land plant cells. Sexual reproduction in both relies on a large, nonmotile egg and flagellated sperm. These gametes are more similar to those of land plants than many charophyte relatives. Both charophyte clades form green mats around the edges of freshwater ponds and marshes. One species must have successfully inched its way onto land through adaptations to drying.

## Learning Outcomes Review 30.2

The chlorophytes have chloroplasts very similar to those of land plants. Specializations in this group include the evolution of nonmotile, unicellular species that can tolerate drying and formation of colonial organisms that exhibit a degree of cell specialization. Charophytes are the green algae that are most likely sister to the land plants based on molecular evidence, morphology, and reproduction.

- What major barrier must be overcome for sexual reproduction of land-based organisms?

## 30.3 Bryophytes: Dominant Gametophyte Generation

### Learning Outcome

1. Describe adaptations of bryophytes for terrestrial environments.

Bryophytes are the closest living descendants of the first land plants. Plants in this group are also called nontracheophytes because they lack the derived transport cell called a *tracheid*.

Fossil evidence and molecular systematics can be used to reconstruct early terrestrial plant life.

Water and gas availability were limiting factors. These plants likely had little ability to regulate internal water levels and likely tolerated desiccation, traits found in most extant mosses, although some are aquatic.

Algae, including the Charales, lack roots. Fungi and early land plants cohabitated, and the fungi formed close associations with the plants that enhanced water uptake. The tight symbiotic relationship between fungi and plants, called **mycorrhizal associations**, are also found in many existing bryophytes. More information on mycorrhizal fungi is found in chapter 31.

### Bryophytes are unspecialized but successful in many environments

The approximately 24,700 species of bryophytes are simple but highly adapted to a diversity of terrestrial environments, even deserts. Most bryophytes are small; few exceed 7 cm in height. Bryophytes have conducting cells other than tracheids for water and nutrients. The tracheid is a derived trait that characterizes the tracheophytes, all land plants but the bryophytes.

Bryophytes are sometimes called nonvascular plants, but *non-tracheophyte* is a more accurate term because they do have conducting cells of different types.

Scientists now agree that bryophytes consist of three quite distinct clades of relatively unspecialized plants: liverworts, mosses, and hornworts. Their gametophytes are photosynthetic and are more conspicuous than the sporophytes. Sporophytes are attached to the gametophytes and depend on them nutritionally in varying degrees. Some of the sporophytes are completely enclosed within gametophyte tissue; others are not and usually turn brownish or straw-colored at maturity. Like ferns and certain other vascular (tracheophyte) plants, bryophytes require water (such as rainwater) to reproduce sexually, tracing back to their aquatic origins. It is not surprising that they are especially common in moist places, both in the tropics and temperate regions.

### Liverworts are an ancient phylum

The Old English word *wyrt* means “plant” or “herb.” Some common liverworts (phylum Hepaticophyta) have flattened gametophytes with lobes resembling those of liver—hence the name “liverwort.” Although the lobed liverworts are the best known representatives of this phylum, they constitute only about 20% of the species (figure 30.7). The other 80% are leafy and superficially resemble mosses. The gametophytes are prostrate instead of erect, and the rhizoids are one-celled.

Some liverworts have air chambers containing upright, branching rows of photosynthetic cells, each chamber having a pore at the top to facilitate gas exchange. Unlike stomata, the pores are fixed open and cannot close.

Sexual reproduction in liverworts is similar to that in mosses. Lobed liverworts may form gametangia in umbrella-like structures. Asexual reproduction occurs when lens-shaped pieces of tissue that are released from the gametophyte grow to form new gametophytes.

**Figure 30.7** A common liverwort, *Marchantia* (phylum Hepaticophyta). The microscopic sporophytes are formed by fertilization within the tissues of the umbrella-shaped structures that arise from the surface of the flat, green, creeping gametophyte.

## Mosses have rhizoids and water-conducting tissue

Unlike other bryophytes, the gametophytes of mosses typically consist of small, leaflike structures (not true leaves, which contain vascular tissue) arranged spirally or alternately around a stemlike axis (figure 30.8); the axis is anchored to its substrate by means of rhizoids. Each rhizoid consists of several cells that absorb water, but not nearly the volume of water that is absorbed by a vascular plant root.

Moss leaflike structures have little in common with leaves of vascular plants, except for the superficial appearance of the green, flattened blade and slightly thickened midrib that runs lengthwise down the middle. Only one cell layer thick (except at the midrib), they lack vascular strands and stomata, and all the cells are haploid.

Water may rise up a strand of specialized cells in the center of a moss gametophyte axis. Some mosses also have specialized food-conducting cells surrounding those that conduct water.

### Moss reproduction

Multicellular gametangia are formed at the tips of the leafy gametophytes (figure 30.9). Female gametangia (**archegonia**) may develop either on the same gametophyte as the male gametangia (**antheridia**) or on separate plants. A single egg is produced in the swollen lower part of an archegonium, whereas numerous sperm are produced in an antheridium.

When sperm are released from an antheridium, they swim with the aid of flagella through a film of dew or rainwater to the archegonia. One sperm (which is haploid) unites with an egg (also haploid), forming a diploid zygote. The zygote divides by mitosis and develops into the sporophyte, a slender, basal stalk with a swollen capsule, the *sporangium*, at its tip. As the

**Figure 30.8** A hair-cup moss, *Polytrichum* (phylum **Bryophyta**). The leaflike structures belong to the gametophyte. Each of the yellowish-brown stalks with a capsule, or sporangium, at its summit is a sporophyte.

**Figure 30.9** Life cycle of a typical moss. The majority of the life cycle of a moss is in the haploid state. The leafy gametophyte is photosynthetic, but the smaller sporophyte is not and is nutritionally dependent on the gametophyte. Water is required to carry sperm to the egg.

sporophyte develops, its base is embedded in gametophyte tissue, its nutritional source.

The sporangium is often cylindrical or club-shaped. Spore mother cells within the sporangium undergo meiosis, each producing four haploid spores. In many mosses at maturity, the top of the sporangium pops off, and the spores are released. A spore that lands in a suitable damp location may germinate and grow, using mitosis, into a threadlike structure, which branches to form rhizoids and “buds” that grow upright. Each bud develops into a new gametophyte plant consisting of a leafy axis.

### Moss distribution

In the Arctic and the Antarctic, mosses are the most abundant plants. The greatest diversity of moss species, however, is found in the tropics. Many mosses are able to withstand prolonged periods of drought, although mosses are not common in deserts.

Most mosses are highly sensitive to air pollution and are rarely found in abundance in or near cities or other areas with high levels of air pollution. Some mosses, such as the peat mosses (*Sphagnum*), can absorb up to 25 times their weight in

water and are valuable commercially as a soil conditioner or as a fuel when dry.

### The moss genome

Moss plants can survive extreme water loss—an adaptive trait in the early colonization of land that has been lost from vegetative tissues of tracheophytes (figure 30.10). Desiccation toler-

#### SCIENTIFIC THINKING

**Hypothesis:** Desiccation tolerance genes in moss and flowering plants first appeared in a common ancestor.

**Prediction:** The late embryogenesis abundant (LEA) protein gene, a desiccation tolerance gene, from flowering plants will be expressed in moss plants when they experience severe water loss.

**Test:** Isolate RNA from moss plants that have not been water stressed (control), have been dehydrated to 84% water loss, and have been dehydrated to 95% water loss. Load a gel with equal amounts of RNA from each treatment. Probe the gel with a cDNA sequence for the LEA gene that is labeled.

**Conclusion:** Moss and flowering plants share a gene that is expressed under water stress conditions.

**Further Experiments:** Are other stress genes shared by bryophytes and flowering plants? Repeat the experiment with other stress-induced genes.

**Figure 30.10** Moss and flowering plants share desiccation tolerance genes.

**Figure 30.11** Hornworts (phylum Anthocerotophyta).

Hornwort sporophytes are seen in this photo. Unlike the sporophytes of other bryophytes, most hornwort sporophytes are photosynthetic.

ance and phylogenetic position were among the traits that led researchers to sequence the genome of the moss *Physcomitrella patens* as being the first streptophyte that is not a seed plant. Although the moss genome is a single genome bracketed by *Chlamydomonas* and the flowering plant *Arabidopsis*, many evolutionary hints are hidden within it. Evidence indicates the loss of genes associated with a watery life, including flagellar arms, which have completely vanished in the flowering plants. Genes associated with tolerance of terrestrial stresses, including temperature and water availability, are absent in *Chlamydomonas* and present in moss. The genome data add rich sets of traits to be used in phylogenetic analyses.

### Hornworts developed stomata

The origin of hornworts (phylum Anthocerotophyta) is a puzzle. They are most likely among the earliest land plants, yet the earliest hornwort fossil spores date from the Cretaceous period (65 to 145 MYA), when angiosperms were emerging.

The small hornwort sporophytes resemble tiny green broom handles or horns, rising from filmy gametophytes usually less than 2 cm in diameter (figure 30.11). The sporophyte base is embedded in gametophyte tissue, from which it derives some of its nutrition. However, the sporophyte has stomata to regulate gas exchange, is photosynthetic, and provides much of the energy needed for growth and reproduction. Hornwort cells usually have a single large chloroplast.

#### Learning Outcome Review 30.3

The bryophytes exhibit adaptations to terrestrial life. Moss adaptations include rhizoids to anchor the moss body and to absorb water, and water-conducting tissues. Mosses are found in a variety of habitats, and some can survive droughts. Hornworts developed stomata that can open and close to regulate gas exchange.

- What might account for the abundance of mosses in the Arctic and Antarctic?

## 30.4 Tracheophyte Plants: Roots, Stems, and Leaves

### Learning Outcomes

1. Explain the evolutionary significance of tracheids.
2. Analyze the claim that roots, stems, and leaves are evolutionary innovations unique to tracheophytes.

The first tracheophytes with a relatively complete record belonged to the phylum Rhyniophyta. We are not certain what the earliest of these vascular plants looked like, but fossils of *Cooksonia* provide some insight into their characteristics (figure 30.12).

*Cooksonia*, the first known vascular land plant, appeared in the late Silurian period about 420 MYA, but is now extinct. It was successful partly because it encountered little competition as it spread out over vast tracts of land. The plants were only a few centimeters tall and had no roots or leaves. They consisted of little more than a branching axis, the branches forking evenly and expanding slightly toward the tips. They were **homosporous** (producing only one type of spore). Sporangia formed at branch tips. Other ancient vascular plants that followed evolved more complex arrangements of sporangia.

### Vascular tissue allows for distribution of nutrients

*Cooksonia* and the other early plants that followed it became successful colonizers of the land by developing efficient water- and food-conducting systems called *vascular tissues*. These tissues con-

**Figure 30.12** *Cooksonia*, the first known vascular land plant. This fossil represents a plant that lived some 420 MYA. *Cooksonia* belongs to phylum Rhyniophyta, consisting entirely of extinct plants. Its upright, branched stems, which were no more than a few centimeters tall, terminated in sporangia, as seen here. It probably lived in moist environments such as mudflats, had a resistant cuticle, and produced spores typical of vascular plants.

sist of strands of specialized cylindrical or elongated cells that form a network throughout a plant, extending from near the tips of the roots, through the stems, and into true leaves, defined by the presence of vascular tissue in the blade. One type of vascular tissue, **xylem**, conducts water and dissolved minerals upward from the roots; another type of tissue, **phloem**, conducts sucrose and hormones throughout the plant. Vascular tissue enables enhanced height and size in the tracheophytes. It develops in the sporophyte, but (with a few exceptions) not in the gametophyte. (Vascular tissue structure is discussed more fully in chapter 38.) A cuticle and stomata are also characteristic of vascular plants.

### Inquiry question

- ? Explain why tracheophytes may have had a selective advantage during the evolution of land plants.

### Tracheophytes include seven extant phyla grouped in three clades

Three clades of vascular plants exist today: (1) lycophytes (club mosses), (2) pterophytes (ferns and their relatives), and (3) seed plants. Advances in molecular systematics have changed the way we view the evolutionary history of vascular plants. Whisk ferns and horsetails were long believed to be distinct phyla that were transitional between bryophytes and vascular plants. Phylogenetic evidence now shows they are the closest living relatives to ferns, and they are grouped as pterophytes.

Tracheophytes dominate terrestrial habitats everywhere, except for the highest mountains and the tundra. The haplodiplontic life cycle persists, but the gametophyte has been reduced in size relative to the sporophyte during the evolution of tracheophytes. A similar reduction in multicellular gametangia has occurred as well.

### Stems evolved prior to roots

Fossils of early vascular plants reveal stems, but no roots or leaves. The earliest vascular plants, including *Cooksonia*, had transport cells in their stems, but the lack of roots limited the size of these plants.

### Roots provide structural support and transport capability

True roots are found only in the tracheophytes. Other, somewhat similar structures enhance either transport or support in non-tracheophytes, but only roots have a dual function—providing both transport and support. Lycophytes diverged from other tracheophytes before roots appeared, based on fossil evidence. It appears that roots evolved at least two separate times.

### Leaves evolved more than once

Leaves increase surface area of the sporophyte, enhancing photosynthetic capacity. Lycophytes have single vascular strands supporting relatively small leaves called lycophylls. True leaves, called euphylls, are found only in ferns and seed plants, having distinct origins from lycophylls (figure 30.13). Lycophylls may have resulted from vascular tissue penetrating small, leafy protuberances on stems. Euphylls most likely arose from branching stems that became webbed with leaf tissue.

**Figure 30.13** Evolution of leaves.

About 400 million years separates the appearance of vascular tissue and the wide euphyll leaf—a curiously large amount of time. The current hypothesis is that a 90% drop in atmospheric CO<sub>2</sub> 360 MYA allowed for the increase in leaf size because of an increase in the number of stomata on a leaf. Large, horizontal leaves capture 200% more radiation than thin, axial leaves. Although beneficial for photosynthesis, larger leaves correspondingly increase leaf temperature, which can be lethal. Stomatal openings in the leaf enhance the movement of water out of the leaf, thereby cooling it. The density of stomata on leaf surfaces correlates with CO<sub>2</sub> concentration, as the stomatal openings are essential for gas exchange. As the atmospheric CO<sub>2</sub> levels dropped, plants could not obtain sufficient CO<sub>2</sub> for photosynthesis. In the low-CO<sub>2</sub> atmosphere, natural selection favored plants with higher stomatal densities. Higher stomatal densities favored larger leaves with a photosynthetic advantage that did not overheat. Leaves up to 120 mm wide

**Figure 30.14** Land plant innovations.

and 160 mm long have been identified in the fossil record from that time period.

## Seeds are another innovation in some phyla

Seeds are highly resistant structures well suited to protecting a plant embryo from drought and to some extent from predators. In addition, almost all seeds contain a supply of food for the young plant. Lycophytes and pterophytes do not have seeds.

Fruits in the flowering plants (angiosperms) add a layer of protection to seeds and attract animals that assist in seed dispersal, expanding the potential range of the species. Flowers allow plants to

secure the benefits of wide outcrossing in promoting genetic diversity. Before moving on to the specifics of lycophytes and pterophytes, review the evolutionary history of terrestrial innovations in the land plants illustrated in figure 30.14. The advantages conferred by seeds have led to the current dominance of seed plants in terrestrial environments.

### Learning Outcomes Review 30.4

Most tracheophytes have well-developed vascular tissues, including tracheids, that enable efficient delivery of water and nutrients throughout the organism. They also exhibit specialized roots, stems, leaves, cuticles, and stomata. Many produce seeds, which protect and nourish embryos.

- Why would vascular tissue be prevalent in the sporophyte, but not the gametophyte, generation?

## 30.5 Lycophytes: Dominant Sporophyte Generation and Vascular Tissue

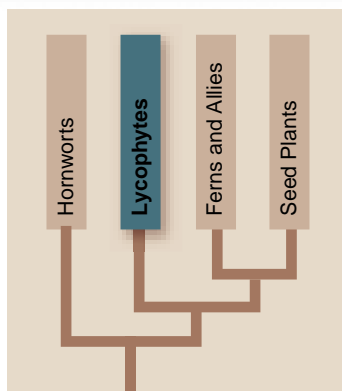

### Learning Outcome

1. Explain features that differentiate lycophytes from bryophytes.

The earliest vascular plants lacked seeds. Members of four phyla of living vascular plants also lack seeds, as do at least three other phyla known only from fossils. As we explore the adaptations of the vascular plants, we focus on both reproductive strategies and the advantages of increasingly complex transport systems.

The lycophytes (club mosses) are relic species of an ancient past when vascular plants first evolved (figure 30.15). They are the sister group to all vascular plants. Several genera of club mosses, some of them treelike, became extinct about 270 MYA. Today, club mosses are worldwide in distribution but are most abundant in the tropics and moist temperate regions.

Members of the 12 to 13 genera and about 1150 living species of club mosses superficially resemble true mosses, but once their internal vascular structure and reproductive pro-

**Figure 30.15** A club moss. *Selaginella moellendorffii*'s sporophyte generation grows on moist forest floors.

cesses became known, it was clear that they are unrelated to mosses. The sporophyte stage is the dominant (obvious) stage; sporophytes have leafy stems that are seldom more than 30 cm long.

*Selaginella moellendorffii* is a lycophyte whose genome is now being analyzed. Comparisons with the moss genome will help us understand more about genes that are important in a dominant sporophyte generation and in the evolution of vascular tissue. Are the genes new or were they co-opted from the gametophyte generation?

### Learning Outcome Review 30.5

Lycophytes are basal to all other vascular plants. Although they superficially resemble bryophytes, they contain tracheid-based vascular tissues, and their reproductive cycle is like that of other vascular plants; however, they lack vascularized leaves.

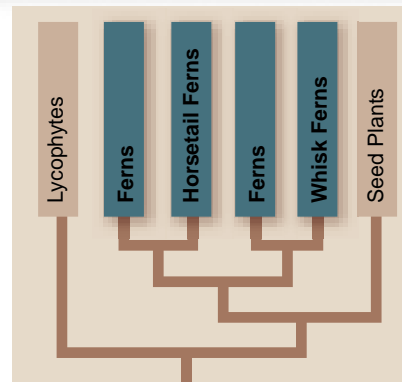

- What events might have contributed to the extinction of large club mosses 270 MYA?

## 30.6 Pterophytes: Ferns and Their Relatives

### Learning Outcomes

1. List the features exhibited by pterophytes.
2. Contrast pterophyte and moss sporophytes.

The phylogenetic relationships among ferns and their near relations are still being sorted out. A common ancestor gave rise to two clades: One clade diverged to produce a line of ferns and horsetails; the other diverged to yield another line of ferns and whisk ferns—ancient-looking plants.

Whisk ferns and horsetails are close relatives of ferns. Like lycophytes and bryophytes, they all form antheridia and archegonia. Free water is required for the process of fertilization, during which the sperm, which have flagella, swim to and unite with the eggs. In contrast, most seed plants have nonflagellated sperm.

### Whisk ferns lost their roots and leaves secondarily

In whisk ferns, which occur in the tropics and subtropics, the sporophytic generation consist merely of evenly forking green stems without roots (figure 30.16). The two or three species of

**Figure 30.16**

**A whisk fern.** Whisk ferns have no roots or leaves. The green, photosynthetic stems have yellow sporangia attached.

**Figure 30.17**

**A horsetail, *Equisetum telmateia*.** This species forms two kinds of erect stems; one is green and photosynthetic, and the other, which terminates in a spore-producing “cone,” is mostly light brown.

the genus *Psilotum* do, however, have tiny, green, spirally arranged flaps of tissue lacking veins and stomata. Another genus, *Tmesipteris*, has more leaflike appendages. Currently, systematists believe that whisk ferns lost leaves and roots when they diverged from others in the fern lineage.

Given the simple structure of whisk ferns, it was particularly surprising to discover that they are monophyletic with ferns. The gametophytes of whisk ferns are essentially colorless and are less than 2 mm in diameter, but they can be up to 18 mm long. They form symbiotic associations with fungi, which furnish their nutrients. Some develop elements of vascular tissue and have the distinction of being the only gametophytes known to do so.

### **Horsetails have jointed stems with brushlike leaves**

The 15 living species of horsetails are all homosporous. They constitute a single genus, *Equisetum*. Fossil forms of *Equisetum* extend back 300 million years to an era when some of their relatives were treelike. Today, they are widely scattered around the world, mostly in damp places. Some that grow among the coastal redwoods of California may reach a height of 3 m, but most are less than a meter tall (figure 30.17).

Horsetail sporophytes consist of ribbed, jointed, photosynthetic stems that arise from branching underground *rhizomes* with roots at their nodes. A whorl of nonphotosynthetic, scalelike leaves emerges at each node. The hollow stems have silica deposits in the epidermal cells of the ribs, and the interior parts of the stems have two sets of vertical, tubular canals. The larger outer canals, which alternate with the ribs, contain air, while the smaller inner canals opposite the ribs contain water. Horsetails are also called scouring rushes because pioneers of the American West used them to scrub pans.

### **Ferns have fronds that bear sori**

**Ferns** are the most abundant group of seedless vascular plants, with about 11,000 living species. Recent research indicates that they may be the closest relatives to the seed plants.

The fossil record indicates that ferns originated during the Devonian period about 350 MYA and became abundant and varied in form during the next 50 million years. Their apparent ancestors were established on land as much as 375 MYA. Rainforests and swamps of lycopsid and fern trees growing in the Eastern United States and Europe over 300 MYA formed the coal currently being mined. Today, ferns flourish in a wide range of habitats throughout the world; however, about 75% of the species occur in the tropics.

The conspicuous sporophytes may be less than a centimeter in diameter (as in small aquatic ferns such as *Azolla*), or more than 24 m tall, with leaves up to 5 m or longer in the tree ferns (figure 30.18). The sporophytes and the much smaller

**Figure 30.18**

**A tree fern (phylum Pterophyta) in the forests of Malaysia.**

The ferns are by far the largest group of seedless vascular plants.

**Figure 30.19** Life cycle of a typical fern.

Both the gametophyte and sporophyte are photosynthetic and can live independently. Water is necessary for fertilization. Sperm are released on the underside of the gametophyte and swim in moist soil to neighboring gametophytes. Spores are dispersed by wind.

gametophytes, which rarely reach 6 mm in diameter, are both photosynthetic.

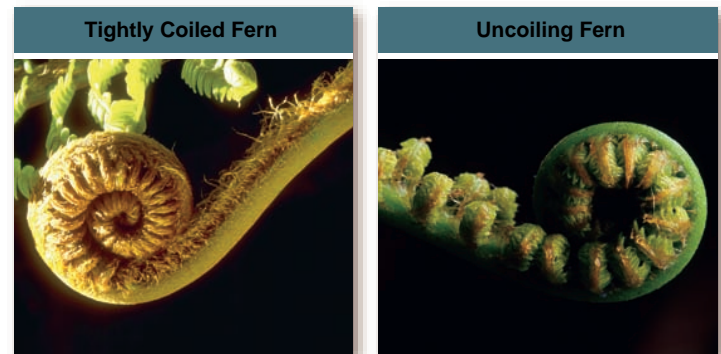

The fern life cycle (figure 30.19) differs from that of a moss primarily in the much greater development, independence, and dominance of the fern's sporophyte. The fern sporophyte is structurally more complex than the moss sporophyte, having vascular tissue and well-differentiated roots, stems, and leaves. The gametophyte, however, lacks the vascular tissue found in the sporophyte.

**Fern morphology**

Fern sporophytes, like horsetails, have rhizomes. Leaves, referred to as *fronds*, usually develop at the tip of the rhizome as tightly rolled-up coils ("fiddleheads") that unroll and expand (figure 30.20). Fiddleheads are considered a delicacy in several cuisines, but some species contain secondary compounds linked to stomach cancer.

Many fronds are highly dissected and feathery, making the ferns that produce them prized as ornamental garden plants. Some ferns, such as *Marsilea*, have fronds that resemble a four-

leaf clover, but *Marsilea* fronds still begin as coiled fiddleheads. Other ferns produce a mixture of photosynthetic fronds and nonphotosynthetic reproductive fronds that tend to be brownish in color.

**Figure 30.20** Fern "fiddlehead." Fronds develop in a coil and slowly unfold on ferns, including the tree fern fronds in these photos.

### Fern reproduction

Ferns produce distinctive sporangia, usually in clusters called **sori** (singular, *sorus*), typically on the underside of the fronds. Sori are often protected during their development by a transparent, umbrella-like covering. (At first glance, one might mistake the sori for an infection on the plant.) Diploid spore mother cells in each sporangium undergo meiosis, producing haploid spores.

At maturity, the spores are catapulted from the sporangium by a snapping action, and those that land in suitable damp locations may germinate, producing gametophytes that are often heart-shaped, are only one cell layer thick (except in the center), and have rhizoids that anchor them to their substrate. These rhizoids are not true roots because they lack vascular tissue, but they do aid in transporting water and nutrients from the soil. Flask-shaped archegonia and globular antheridia are produced on either the same or a different gametophyte. The multicellular archegonia provide some protection for the developing embryo.

The sperm formed in the antheridia have flagella, with which they swim toward the archegonia when water is present,

often in response to a chemical signal secreted by the archegonia. One sperm unites with the single egg toward the base of an archegonium, forming a zygote. The zygote then develops into a new sporophyte, completing the life cycle (see figure 30.19).

The developing fern embryo has substantially more protection from the environment than a charophyte zygote, but it cannot enter a dormant phase to survive a harsh winter the way a seed plant embryo can. Although extant ferns do not produce seeds, seed fern fossils have been found that date back 365 million years. The seed ferns are not actually pterophytes, but gymnosperms. Of the seven tracheophyte phyla (table 30.1), only two—gymnosperms and angiosperms—produce seeds.

### Learning Outcomes Review 30.6

Ferns and their relatives have a large and conspicuous sporophyte with vascular tissue. Many have well-differentiated roots, stems, and leaves (fronds). The gametophyte generation is small and lacks vascular tissue.

- **What would be the advantage of silica deposits in stems, as is found in horsetails?**

TABLE 30.1		The Seven Phyla of Extant Vascular Plants

TABLE 30.1

The Seven Phyla of Extant Vascular Plants, *continued*

Phylum	Examples	Key Characteristics	Approximate Number of Living Species
<i>S E E D P L A N T S</i>			
Coniferophyta	Conifers (including pines, spruces, firs, yews, redwoods, and others)		Heterosporous seed plants. Sperm not motile; conducted to egg by a pollen tube. Leaves mostly needlelike or scalelike. Trees, shrubs. About 50 genera. Many produce seeds in cones. 601
Cycadophyta	Cycads		Heterosporous. Sperm flagellated and motile but confined within a pollen tube that grows to the vicinity of the egg. Palmlike plants with pinnate leaves. Secondary growth slow compared with that of the conifers. Ten genera. Seeds in cones. 206
Gnetophyta	Gnetophytes		Heterosporous. Sperm not motile; conducted to egg by a pollen tube. The only gymnosperms with vessels. Trees, shrubs, vines. Three very diverse genera ( <i>Ephedra</i> , <i>Gnetum</i> , <i>Welwitschia</i> ). 65
Ginkgophyta	<i>Ginkgo</i>		Heterosporous. Sperm flagellated and motile but conducted to the vicinity of the egg by a pollen tube. Deciduous tree with fan-shaped leaves that have evenly forking veins. Seeds resemble a small plum with fleshy, foul-smelling outer covering. One genus. 1
Anthophyta	Flowering plants (angiosperms)		Heterosporous. Sperm not motile; conducted to egg by a pollen tube. Seeds enclosed within a fruit. Leaves greatly varied in size and form. Herbs, vines, shrubs, trees. About 14,000 genera. 250,000

## 30.7 The Evolution of Seed Plants

### Learning Outcomes

1. List the evolutionary advantages of seeds.
2. Distinguish between pollen and sperm in seed plants.

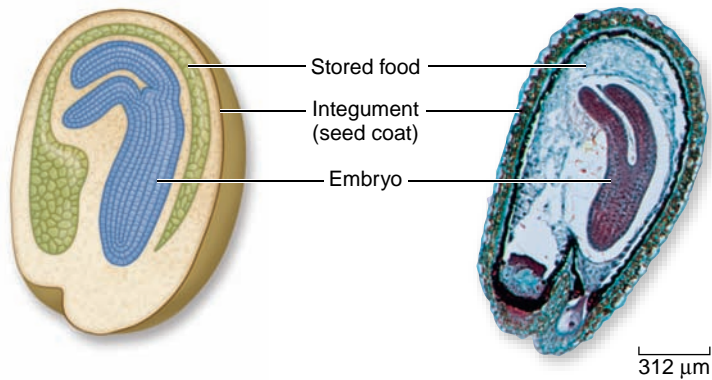

The history of the land plants is replete with evolutionary innovations allowing the ancestors of aquatic algae to colonize the harsh and varied terrestrial terrains. Early innovations made survival on land possible, later followed by an explosion of plant life that continues to change the land and atmosphere, and support terrestrial animal life. Seed-producing plants have come to dominate the terrestrial landscape over the last several hundred million years. Much of the remarkable success of seed plants, both gymnosperms and angiosperms, can be attributed to the evolution of the seed, an innovation that protects and provides food for delicate embryos. Seeds allow embryos to “stop the clock” and germinate after a harsh winter or extremely dry season has passed.

Fruits, a later innovation, enhanced the dispersal of embryos across a broader landscape.

Seed plants, which have additional embryo protection, first appeared about 305 to 465 MYA and were the ancestors of gymnosperms and angiosperms. Seed plants appear to have evolved from spore-bearing plants known as **progymnosperms**. Progymnosperms shared several features with modern gymnosperms, including secondary vascular tissues (which allow for an increase in girth later in development). Some progymnosperms had leaves. Their reproduction was very simple, and it is not certain which particular group of progymnosperms gave rise to seed plants.

### The seed protects the embryo

From an evolutionary and ecological perspective, the seed represents an important advance. The embryo is protected by an extra layer or two of sporophyte tissue called the **integument**, creating the **ovule** (figure 30.21). Within the ovule, the megasporangium divides meiotically, producing a haploid megaspore. The megaspore produces the egg that combines with the sperm, resulting in the zygote. Seeds also contain a food supply for the developing embryo.

**Figure 30.21** Cross-section of an ovule.

During development, the integuments harden to produce the seed coat. In addition to protecting the embryo from drought, the seed can be easily dispersed. Perhaps even more significantly, the presence of seeds introduces into the life cycle a dormant phase that allows the embryo to survive until environmental conditions are favorable for further growth.

### A pollen grain is the male gametophyte

Seed plants produce two kinds of gametophytes—male and female—each of which consists of just a few cells. Pollen grains, multicellular male gametophytes, are conveyed to the egg in the female gametophyte by wind or by a pollinator. In some seed plants, the sperm moves toward the egg through a growing **pollen tube**. This eliminates the need for external water. In contrast to the seedless plants, the whole male gametophyte, rather than just the sperm, moves to the female gametophyte.

A female gametophyte forms within the protection of the integuments, collectively forming the ovule. In angiosperms, the ovules are completely enclosed within additional diploid sporophyte tissue. The ovule and the surrounding, protective tissue are called the ovary. The ovary develops into the fruit.

#### Learning Outcomes Review 30.7

A common ancestor that had seeds gave rise to the gymnosperms and the angiosperms. Seeds protect the embryo, aid in dispersal, and can allow for an extended pause in the life cycle. Seed plants produce male and female gametophytes; the male gametophyte is a pollen grain, which is carried to the female gametophyte by wind or other means. The sperm is within the pollen grain.

- Why is water not essential for fertilization in seed plants?

## 30.8 Gymnosperms: Plants with “Naked Seeds”

#### Learning Outcomes

1. Describe the distinguishing features of a gymnosperm.
2. List the four groups of living gymnosperms.

Seeds distinguish the gymnosperms from the pterophytes. There are four groups of living **gymnosperms**, namely coniferophytes, cycadophytes, gnetophytes, and ginkgophytes, all of which lack the flowers and fruits of angiosperms. In all of them, the ovule, which becomes a seed, rests exposed on a scale (a modified shoot or leaf) and is not completely enclosed by sporophyte tissues at the time of pollination. The name *gymnosperm* literally means “naked seed.” Although the ovules are naked at the time of pollination, the seeds of gymnosperms are sometimes enclosed by other sporophyte tissues by the time they are mature.

Details of reproduction vary somewhat in gymnosperms, and their forms vary greatly. For example, cycads and *Ginkgo* have motile sperm, whereas conifers and gnetophytes have sperm with no flagella. All sperm are carried within a pollen tube. The female cones range from tiny, woody structures weighing less than 25 g and having a diameter of a few millimeters, to massive structures produced in some cycads, weighing more than 45 kg and growing to lengths of more than a meter.

### Conifers are the largest gymnosperm phylum

The most familiar gymnosperms are **conifers** (phylum Coniferophyta), which include pines (figure 30.22), spruces, firs, cedars, hemlocks, yews, larches, cypresses, and others. The coastal redwood (*Sequoia sempervirens*), a conifer native to northwestern California and southwestern Oregon, is the tallest living vascular plant; it may attain a height of nearly 100 m (300 ft). Another conifer, the bristlecone pine (*Pinus longaeva*) of the White Mountains of California, is the oldest living tree; one specimen is 4900 years of age.

Conifers are found in the colder temperate and sometimes drier regions of the world. Various species are sources of timber, paper, resin, taxol (used to treat cancer), and other economically important products.

### Pines are an exemplary conifer genus

More than 100 species of pines exist today, all native to the northern hemisphere, although the range of one species does extend a

**Figure 30.22** Conifers.

Longleaf pines, *Pinus palustris*, in Florida are representative of the Coniferophyta, the largest phylum of gymnosperms.

little south of the equator. Pines and spruces, which belong to the same family, are members of the vast coniferous forests that lie between the arctic tundra and the temperate deciduous forests and prairies to their south. During the past century, pines have been extensively planted in the southern hemisphere.

### Pine morphology

Pines have tough, needlelike leaves produced mostly in clusters of two to five. Among the conifers, only pines have clustered leaves. The leaves, which have a thick cuticle and recessed stomata, represent an evolutionary adaptation for retarding water loss. This strategy is important because many of the trees grow in areas where the topsoil is frozen for part of the year, making it difficult for the roots to obtain water.

The leaves and other parts of the sporophyte have canals into which surrounding cells secrete resin. The resin deters insect and fungal attacks. The resin of certain pines is harvested commercially for its volatile liquid portion, called *turpentine*, and for the solid *rosin*, which is used on bowed stringed instruments. The wood of pines lacks some of the more rigid cell types found in other trees, and it is considered a “soft” rather than a “hard” wood. The thick bark of pines is an adaptation for surviving fires and subzero temperatures. Some cones actually depend on fire to open them, releasing seeds to reforest burned areas.

### Reproductive structures

All seed plants produce two types of spores that give rise to two types of gametophytes (figure 30.23). The male gametophytes (pollen grains) of pines develop from microspores, which are produced in male cones that develop in clusters of 30 to 70, typically at the tips of the lower branches; there may be hundreds of such clusters on any single tree.

The male pine cones generally are 1 to 4 cm long and consist of small, papery scales arranged in a spiral or in whorls. A pair of microsporangia form as sacs within each scale. Numerous microspore mother cells in the microsporangia undergo meiosis, each becoming four microspores. The microspores develop into four-celled pollen grains with a pair of air sacs that give them added buoyancy when released into the air. A single cluster of male pine cones may produce more than a million pollen grains.

Female pine cones typically are produced on the upper branches of the same tree that produces male cones. Female cones are larger than male cones, and their scales become woody.

Two ovules develop toward the base of each scale. Each ovule contains a megasporangium called the **nucellus**. The nucellus itself is completely surrounded by a thick layer of cells called the integument that has a small opening (the **micropyle**) toward one end. One of the layers of the integument later

**Figure 30.23**  
**Life cycle of a typical pine.** The male and female gametophytes are dramatically reduced in size in these plants. Wind generally disperses the male gametophyte (pollen), which produces sperm. Pollen tube growth delivers the sperm to the egg on the female cone. Additional protection for the embryo is provided by the integument, which develops into the seed coat.

becomes the seed coat. A single megaspore mother cell within each megasporangium undergoes meiosis, becoming a row of four megaspores. Three of the megaspores break down, but the remaining one, over the better part of a year, slowly develops into a female gametophyte. The female gametophyte at maturity may consist of thousands of cells, with two to six archegonia formed at the micropylar end. Each archegonium contains an egg so large it can be seen without a microscope.

### Fertilization and seed formation

Female cones usually take two or more seasons to mature. At first they may be reddish or purplish in color, but they soon turn green, and during the first spring, the scales spread apart. While the scales are open, pollen grains carried by the wind drift down between them, some catching in sticky fluid oozing out of the micropyle. The pollen grains within the sticky fluid are slowly drawn down through the micropyle to the top of the nucellus, and the scales close shortly thereafter.

The archegonia and the rest of the female gametophyte are not mature until about a year later. While the female gametophyte is developing, a pollen tube emerges from a pollen grain at the bottom of the micropyle and slowly digests its way through the nucellus to the archegonia. During growth of the pollen tube, one of the pollen grain's four cells, the *generative cell*, divides by mitosis, with one of the resulting two cells dividing once more. These last two cells function as sperm. The germinated pollen grain with its two sperm is the mature male gametophyte, a very limited haploid phase compared with fern gametophytes.

About 15 months after pollination, the pollen tube reaches an archegonium and discharges its contents into it. One sperm unites with the egg, forming a zygote. The other sperm and cells of the pollen grain degenerate. The zygote develops into an embryo within the seed. After dispersal and germination of the seed, the young sporophyte of the next generation develops into a tree.

### Cycads resemble palms, but are not flowering plants

**Cycads** (phylum Cycadophyta) are slow-growing gymnosperms of tropical and subtropical regions. The sporophytes of most of the 100 known species resemble palm trees (figure 30.24a) with

trunks that can attain heights of 15 m or more. Unlike palm trees, which are flowering plants, cycads produce cones and have a life cycle similar to that of pines.

The female cones, which develop upright among the leaf bases, are huge in some species and can weigh up to 45 kg. The sperm of cycads, although formed within a pollen tube, are released within the ovule to swim to an archegonium. These sperm are the largest sperm cells among all living organisms. Several species of cycads are facing extinction in the wild and soon may exist only in botanical gardens.

### Gnetophytes have xylem vessels

There are three genera and about 65 living species of gnetophytes (phylum Gnetophyta). They are the only gymnosperms with vessels in their xylem. **Vessels** are a particularly efficient conducting cell type that is a common feature in angiosperms.

The members of the three genera differ greatly from one another in form. One of the most bizarre of all plants is *Welwitschia*, which occurs in the Namib and Mossamedes deserts of southwestern Africa (figure 30.24b). The stem is shaped like a large, shallow cup that tapers into a taproot below the surface. It has two strap-shaped, leathery leaves that grow continuously from their base, splitting as they flap in the wind. The reproductive structures of *Welwitschia* are conelike, appear toward the bases of the leaves around the rims of the stems, and are produced on separate male and female plants.

More than half of the gnetophyte species are in the genus *Ephedra*, which is common in arid regions of the western United States and Mexico. Species are found on every continent except Australia. The plants are shrubby, with stems that superficially resemble those of horsetails, being jointed and having tiny, scale-like leaves at each node. Male and female reproductive structures may be produced on the same or different plants.

The drug ephedrine, widely used in the treatment of respiratory problems, was in the past extracted from Chinese species of *Ephedra*, but it has now been largely replaced with synthetic preparations (pseudoephedrine). Because ephedrine found in herbal remedies for weight loss was linked to strokes and heart attacks, it was withdrawn from the market in April of 2004. Sales restrictions were placed on pseudoephedrine-containing products in 2006 because it can be used to manufacture the illegal drug methamphetamine.

a. A cycad, *Cycas circinalis*.  
 b. *Welwitschia mirabilis* represents one of the three genera of gnetophytes.  
 c. Maidenhair tree, *Ginkgo biloba*, the only living representative of the phylum Ginkgophyta.

## Learning Outcomes

1. List the defining features of angiosperms.
2. Describe the roles of some animals in the angiosperm life cycle.
3. Explain double fertilization and its outcome.

The best known species of the third genus, *Gnetum*, is a tropical tree, but most species are vinelike. All species have broad leaves similar to those of angiosperms. One *Gnetum* species is cultivated in Java for its tender shoots, which are cooked as a vegetable.

## Only one species of the ginkgophytes remains extant

The fossil record indicates that members of the ginkgophytes (phylum Ginkgophyta) were once widely distributed, particularly in the northern hemisphere; today, only one living species, *Ginkgo biloba*, remains (figure 30.24c). This tree, which sheds its leaves in the fall, was first encountered by Europeans in cultivation in Japan and China; it apparently no longer exists in the wild.

Like the sperm of cycads, those of *Ginkgo* have flagella. The ginkgo is **dioecious**—that is, the male and female reproductive structures are produced on separate trees. The fleshy outer coverings of the seeds of female ginkgo plants exude the foul smell of rancid butter, caused by the presence of butyric and isobutyric acids. As a result, male plants vegetatively propagated from shoots are preferred for cultivation. Because of its beauty and resistance to air pollution, *Ginkgo* is commonly planted along city streets.

## Learning Outcomes Review 30.8

Gymnosperms are mostly cone-bearing seed plants. In gymnosperms, the ovules are not completely enclosed by sporophyte tissue at pollination, and thus have “naked seeds.” The four groups of gymnosperms are conifers, cycads, gnetophytes, and ginkgophytes.

- What adaptation do conifers exhibit to capture wind-borne pollen?

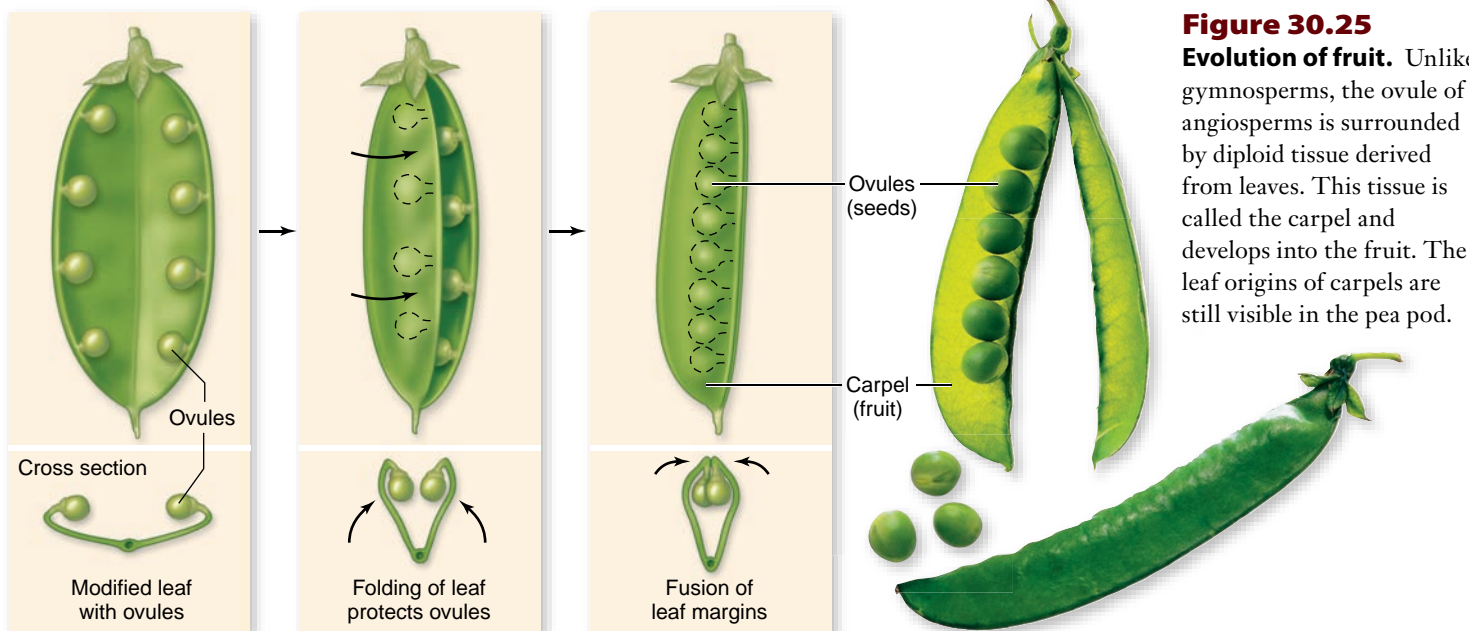

The 270,000 known species of flowering plants are called **angiosperms** because their ovules, unlike those of gymnosperms, are enclosed within diploid tissues at the time of pollination. The *carpel*, a modified leaf that encapsulates seeds, develops into the fruit, a unique angiosperm feature (figure 30.25). Although some gymnosperms, including the yew (*Taxus* spp.), have fleshlike tissue around their seeds, it is of a different origin and not a true fruit.

## Angiosperm origins are a mystery

The origins of the angiosperms puzzled even Darwin (he referred to their origin as an “abominable mystery”). Recent fossil pollen and plants accompanied by molecular sequence data have provided exciting clues about basal angiosperms, indicating origins as early as 145 to 208 MYA.

In the remote Liaoning province of China, a complete angiosperm fossil that is at least 125 million years old has been found (figure 30.26). The fossil may represent a new, basal, and

**Figure 30.25**  
**Evolution of fruit.** Unlike gymnosperms, the ovule of angiosperms is surrounded by diploid tissue derived from leaves. This tissue is called the carpel and develops into the fruit. The leaf origins of carpels are still visible in the pea pod.

**Figure 30.26 Fossil of basal angiosperm.**

*Archaeofructus* fossil with multiseeded carpels (fruits) and stamens. This is the oldest known angiosperm in the fossil record, estimated to be between 122 and 145 million years.

extinct angiosperm family, Archaeofructaceae, with two species: *Archaeofructus liaoningensis* and *A. sinensis*. *Archaeofructus* was an herbaceous, aquatic plant. This family is proposed to be the sister clade to all other angiosperms, but there is a lively debate about the validity of this claim.

**Figure 30.27 An ancient living angiosperm, *Amborella trichopoda*.** This plant is believed to be the closest living relative to the original angiosperm.

*Archaeofructus* fossils have both male and female reproductive structures; however, they lack the sepals and petals that evolved in later angiosperms to attract pollinators. The fossils were so well preserved that fossil pollen could be examined using scanning electron microscopy. Although *Archaeofructus* is ancient, it is unlikely to be the very first angiosperm. Still, the incredibly well-preserved fossils provide valuable detail on angiosperms in the Upper Jurassic to Lower Cretaceous period, when dinosaurs roamed the Earth.

Consensus has also been growing on the most basal living angiosperm—*Amborella trichopoda* (figure 30.27). *Amborella*, with small, cream-colored flowers, is even more primitive than water lilies. This small shrub, found only on the island of New Caledonia in the South Pacific, is the last remaining species of the earliest extant lineage of the angiosperms that arose about 135 MYA.

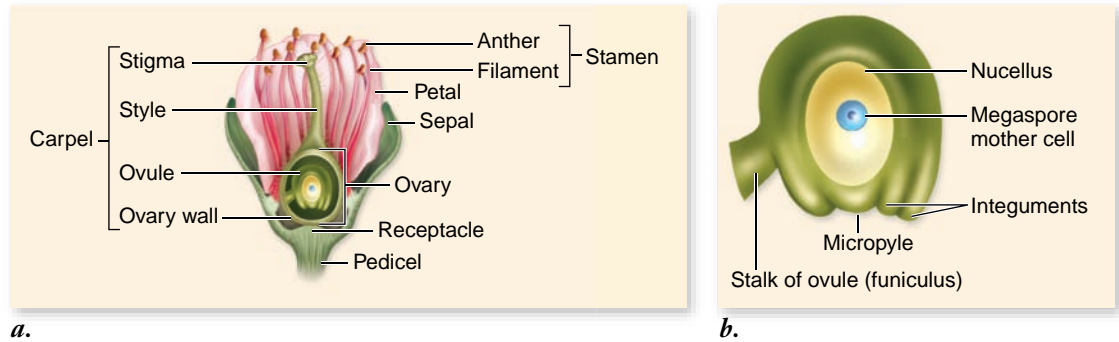

Although *Amborella* is not the original angiosperm, it is sufficiently close that studying its reproductive biology may help us understand the early radiation of the angiosperms. The angiosperm phylogeny reflects an evolutionary hypothesis that is driving new research on angiosperm origins (figure 30.28).

**Figure 30.28 *Archaeofructus* may be the sister clade to all other angiosperms.** All members of the *Archaeofructus* lineage are extinct, leaving *Amborella* as the most basal, living angiosperm. Gymnosperms species labels are shaded green.

### Figure 30.29 Diagram of an angiosperm flower.

*a.* The main structures of the flower are labeled. *b.* Details of an ovule. The ovary as it matures will become a fruit; as the ovule's outer layers (integuments) mature, they will become a seed coat.

## Flowers house the gametophyte generation of angiosperms

Flowers are considered to be modified stems bearing modified leaves. Regardless of their size and shape, they all share certain features (figure 30.29). Each flower originates as a **primordium** that develops into a bud at the end of a stalk called a pedicel. The pedicel expands slightly at the tip to form the receptacle, to which the remaining flower parts are attached.

### Flower morphology

The other flower parts typically are attached in circles called **whorls**. The outermost whorl is composed of **sepals**. Most flowers have three to five sepals, which are green and somewhat leaflike. The next whorl consists of **petals** that are often colored, attracting pollinators such as insects, birds, and some small mammals. The petals, which also commonly number three to five, may be separate, fused together, or missing altogether in wind-pollinated flowers.

The third whorl consists of **stamens** and is collectively called the androecium. This whorl is where the male gametophytes, pollen, are produced. Each stamen consists of a pollen-bearing **anther** and a stalk called a **filament**, which may be missing in some flowers.

At the center of the flower is the fourth whorl, the **gynoecium**, where the small female gametophytes are housed; the gynoecium consists of one or more **carpels**. The first carpel is believed to have been formed from a leaflike structure with ovules along its margins. Primitive flowers can have several to many separate carpels, but in most flowers, two to several carpels are fused together. Such fusion can be seen in an orange sliced in half; each segment represents one carpel.

### Structure of the carpel

A carpel has three major regions (see figure 30.29*a*). The **ovary** is the swollen base, which contains from one to hundreds of ovules; the ovary later develops into a **fruit**. The tip of the carpel is called a **stigma**. Most stigmas are sticky or feathery, causing pollen grains that land on them to adhere. Typically, a neck or stalk called a **style** connects the stigma and the ovary; in some flowers, the style may be very short or even missing.

Many flowers have nectar-secreting glands called *nectaries*, often located toward the base of the ovary. Nectar is a fluid containing sugars, amino acids, and other molecules that attracts insects, birds, and other animals to flowers.

## Most species use flowers to attract pollinators and reproduce

Eudicots (about 175,000 species) include the great majority of familiar angiosperms—almost all kinds of trees and shrubs, snapdragons, mints, peas, sunflowers, and other plants. Monocots (about 65,000 species) include the lilies, grasses, cattails, palms, agaves, yuccas, orchids, and irises and share a common ancestor with the eudicots (see figure 30.28). Some of the monocots, including maize, rely on wind rather than pollinators to reproduce.

## The angiosperm life cycle includes double fertilization

During development of a flower bud, a single megaspore mother cell in the ovule undergoes meiosis, producing four megaspores (figure 30.30). In most flowering plants, three of the megaspores soon disappear; the nucleus of the remaining megaspore divides mitotically, and the cell slowly expands until it becomes many times its original size.

### The female gametophyte

While the expansion of the megaspore is occurring, each of the daughter nuclei divides twice, resulting in eight haploid nuclei arranged in two groups of four. At the same time, two layers of the ovule, the integuments, differentiate and become the *seed coat* of a seed. The integuments, as they develop, form the micropyle, a small gap or pore at one end that was described earlier (see figure 30.29*b*).

One nucleus from each group of four migrates toward the center, where they function as polar nuclei. Polar nuclei may fuse together, forming a single diploid nucleus, or they may form a single cell with two haploid nuclei. Cell walls also form around the remaining nuclei. In the group closest to the micropyle, one cell functions as the egg; the other two nuclei are called synergids. At the other end, the three cells are now called antipodals; they have no apparent function and eventually break down and disappear.

The large sac with eight nuclei in seven cells is called an embryo sac; it constitutes the female gametophyte. Although it is completely dependent on the sporophyte for nutrition, it is a multicellular, haploid individual.

**Figure 30.30 Life cycle of a typical angiosperm.** As in pines, external water is no longer required for fertilization. In most species of angiosperms, animals carry pollen to the carpel. The outer wall of the carpel forms the fruit, which often entices animals to disperse the seed.

### Pollen production

While the female gametophyte is developing, a similar but less complex process takes place in the anthers (see figure 30.30). Most anthers have patches of tissue (usually four) that eventually become chambers lined with nutritive cells. The tissue in each patch is composed of many diploid microspore mother cells that undergo meiosis more or less simultaneously, each producing four microspores.

The four microspores at first remain together as a quartet, or tetrad, and the nucleus of each microspore divides once; in most species, the microspores of each quartet then separate. At the same time, a two-layered wall develops around each microspore. As the microspore-containing anther continues to mature, the wall between adjacent pairs of chambers breaks down, leaving two larger sacs. At this point, the binucleate microspores have become pollen grains.

The outer pollen grain wall layer often becomes beautifully sculptured, and it contains chemicals that may react with others in a stigma to signal whether development of the male gametophyte should proceed to completion. The pollen grain has areas called *apertures*, through which a pollen tube may later emerge.

### Pollination and the male gametophyte

**Pollination** is simply the mechanical transfer of pollen from its source (an anther) to a receptive area (the stigma of a flowering plant). Most pollination takes place between flowers of different plants and is brought about by insects, wind, water, gravity, bats, and other animals. In as many as one-quarter of all angiosperms, however, a pollen grain may be deposited directly on the stigma of its own flower, and self-pollination occurs. Pollination may or may not be followed by *fertilization*, depending on the genetic compatibility of the pollen grain and the flower on whose stigma it has landed.

If the stigma is receptive, the pollen grain's dense cytoplasm absorbs substances from the stigma and bulges through an aperture. The bulge develops into a pollen tube that responds to chemical and mechanical stimuli that guide it to the embryo sac. It follows a diffusion gradient of the chemicals and grows down through the style and into the micropyle. The pollen tube usually takes several hours to two days to reach the micropyle, but in a few instances, the journey may take up to a year. Pollen tube growth is more rapid in angiosperms than

gymnosperms. Rapid pollen tube growth rate is an innovation that is believed to have preceded fruit development and been essential in the origins of angiosperms (see figure 30.31)

One of the pollen grain's two cells, the *generative cell*, lags behind. Its nucleus divides in the pollen grain or in the pollen tube, producing two sperm cells. Unlike sperm in mosses, ferns, and some gymnosperms, the sperm of flowering plants have no flagella. At this point, the pollen grain with its tube and sperm has become a mature male gametophyte.

### Double fertilization and seed production

As the pollen tube enters the embryo sac, it destroys a synergid in the process and then discharges its contents. Both sperm are functional, and an event called **double fertilization** follows. One sperm unites with the egg and forms a zygote, which develops into an embryo sporophyte plant. The other sperm and the two polar nuclei unite, forming a triploid primary endosperm nucleus.

The primary endosperm nucleus begins dividing rapidly and repeatedly, becoming triploid endosperm tissue that may soon consist of thousands of cells. Endosperm tissue can become an extensive part of the seed in grasses such as corn, and it provides nutrients for the embryo in most flowering plants (see figure 37.11).

Until recently, the nutritional, triploid endosperm was believed to be the ancestral state in angiosperms. A recent analysis of extant, basal angiosperms revealed that diploid endosperms were also common. The female gametophyte in these species has four, not eight nuclei. At the moment, it is unclear whether diploid or triploid endosperms are the most primitive.

### Inquiry question

If the endosperm failed to develop in a seed, how do you think the fitness of that seed's embryo would be affected? Explain your answer.

### Germination and growth of the sporophyte

As mentioned earlier, a seed may remain dormant for many years, depending on the species. When environmental conditions become favorable, the seed undergoes germination, and the young sporophyte plant emerges. Again depending on the species, the sporophyte may grow and develop for many years before becoming capable of reproduction, or it may quickly grow and produce flowers in a single growing season.

We present a more detailed description of reproduction in plants in chapter 42.

### Learning Outcomes Review 30.9

Angiosperms are characterized by ovules that at pollination are enclosed within an ovary at the base of a carpel, a structure unique to the phylum; a fruit develops from the ovary. Evolutionary innovations of angiosperms include flowers to attract pollinators, fruits to protect embryos and aid in their dispersal, and double fertilization, which provides endosperm to help nourish the embryo.

- What advantage does an angiosperm gain by producing a fruit that animals eat?

## SCIENTIFIC THINKING

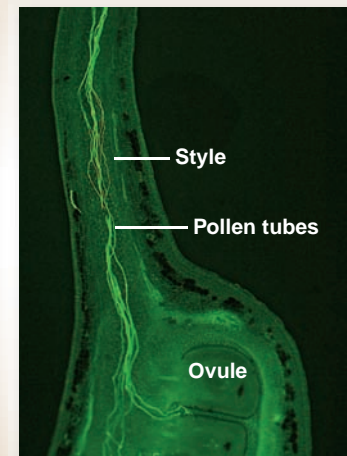

**Hypothesis:** An increase in pollen tube growth accompanied angiosperm origins.

**Prediction:** The time from pollination to fertilization will be greater in gymnosperms than angiosperms that are sister to the ancestral angiosperm and also more derived angiosperms.

**Test:** Pollinate three angiosperm species, including *Amborella*, that are most closely related to the first angiosperm. At different time intervals, cut sections of the carpel and observe pollen tube position under a fluorescent microscope. Calculate and compare the rate of pollen tube growth with results published for gymnosperms and more derived angiosperms.

Species	Pollen Tube Growth Rate ( $\mu\text{m}/\text{hour}$ )
<b>Close relatives of ancestral angiosperm</b>	
<i>Amborella trichopoda</i>	80
<i>Nuphar polysepala</i>	589
<i>Austrobaileya scandens</i>	271
<b>Derived angiosperms</b>	
<i>Petunia inflata</i>	900
<i>Zea mays</i> (maize)	10,000
<b>Gymnosperms</b>	
<i>Gnetum gnemon</i>	6
<i>Ginkgo biloba</i>	0.31

Pollen Tube Growth Rate of *Amborella trichopoda*

**Conclusion:** An increase in pollen tube growth rate is found in angiosperms most closely related to the ancestral angiosperm, supporting the hypothesis.

**Further Experiments:** Develop a hypothesis to explain the difference in pollen tube growth rates among the tested angiosperms. Is there a correlation between the distance a pollen tube must travel to fertilize an egg and the rate of growth? How could you test your hypothesis?

**Figure 30.31** Rapid pollen tube growth accompanied the origin of angiosperms.

## Chapter Review

### 30.1 Defining Plants

#### *Land plants evolved from freshwater algae.*

All green plants arose from a single freshwater green algal species (see figure 30.1). The charophytes are the sister clade of the land plants.

Green algae and the land plants are placed in the kingdom Viridiplantae.

#### *Land plants have adapted to terrestrial life.*

Land plants have two major characteristics: protected embryos and multicellular haploid and diploid phases. A waxy cuticle, stomata, and specialized cells for transport of water and minerals enhance survival.

Most multicellular Viridiplantae have haplodiplontic life cycles.

Plants have a haplodiplontic life cycle with multicellular diploid sporophytes and haploid gametophytes (see figure 30.2).

#### *The haplodiplontic cycle produces alternation of generations.*

#### *The relative sizes of haploid and diploid generations vary.*

As some plants became more complex, the sporophyte stage became the dominant phase.

### 30.2 Chlorophytes and Charophytes: Green Algae (see figure 30.5)

The chlorophytes gave rise to aquatic algae; the streptophytes include the group that gave rise to land plants.

#### *Chlorophytes can be unicellular.*

Unicellular chlorophytes include *Chlamydomonas*, which has two flagella, and *Chlorella*, which has no flagella and reproduces asexually.

#### *Colonial chlorophytes have some cell specialization.*

*Volvox* is an example of a colonial green alga; some cells specialize for producing gametes or for asexual reproduction.

#### *Multicellular chlorophytes can have haplodiplontic life cycles.*

*Ulva* has sporophyte and gametophyte generations; however, the chlorophytes did not give rise to land plants.

#### *Charophytes are the closest relatives to land plants.*

Both candidate Streptophyta clades—Charales and Coleochaetales—exhibit plasmodesmata, cytoplasmic links between cells. They also undergo mitosis and cytokinesis like terrestrial plants.

### 30.3 Bryophytes: Dominant Gametophyte Generation

#### *Bryophytes are unspecialized but successful in many environments.*

Bryophytes consist of three distinct clades: liverworts, mosses, and hornworts. Bryophytes do not have true roots or tracheids, but do have conducting cells for movement of water and nutrients.

In liverworts and mosses, the nonphotosynthetic sporophyte is nutritionally dependent on the gametophyte.

#### *Liverworts are an ancient phylum.*

The gametophyte of some liverworts is flattened and has lobes that resemble those of the liver. They produce upright structures that contain the gametangia.

#### *Mosses have rhizoids and water-conducting tissue.*

Mosses exhibit alternation of generations and have widespread distribution. Many are able to withstand droughts.

#### *Hornworts developed stomata.*

Stomata in the sporophyte can open and close to regulate gas exchange. The sporophyte is also photosynthetic.

### 30.4 Tracheophyte Plants: Roots, Stems, and Leaves (see table 30.1)

#### *Vascular tissue allows for distribution of nutrients.*

The evolution of tracheids allowed more efficient vascular systems to develop. This vascular tissue develops in the sporophyte.

Vascular plants have a much reduced gametophyte.

#### *Tracheophytes include seven extant phyla grouped in three clades.*

The vascular plants found today exist in three clades: lycophytes, pterophytes, and seed plants.

#### *Stems evolved prior to roots.*

#### *Roots provide structural support and transport capability.*

#### *Leaves evolved more than once.*

Lycophytes have small leaves called lycophylls that lack vascularization.

True leaves (euphylls) are found only in ferns and seed plants and have origins different from lycophylls.

#### *Seeds are another innovation in some phyla.*

Seeds are resistant structures that protect the embryo from desiccation and to some extent from predators.

### 30.5 Lycophytes: Dominant Sporophyte Generation and Vascular Tissue

Lycophyte ancestors were the earliest vascular plants and were among the first plants to have a dominant sporophyte generation.

### 30.6 Pterophytes: Ferns and Their Relatives (see figure 30.17)

Ancestors of the pterophytes gave rise to two clades: one line of ferns and horsetails, and a second line of ferns and whisk ferns.

Pterophytes require water for fertilization and are seedless.

#### *Whisk ferns lost their roots and leaves secondarily.*

The sporophyte of a whisk fern consists of evenly forking green stems without roots.

#### *Horsetails have jointed stems with brushlike leaves.*

Scalelike leaves of horsetail sporophytes emerge in a whorl. The stems have silica deposits in epidermal cells of their ribs.

#### *Ferns have fronds that bear sori.*

The leaves of ferns, called fronds, develop as tightly rolled coils that unwind to expand. Sporangia called sori develop on the underside of the fronds. The gametophyte is often heart shaped and can live independently.

### 30.7 The Evolution of Seed Plants

#### *The seed protects the embryo.*

An extra layer of sporophyte tissue surrounds the embryo, creating the ovule, which later hardens. The seed protects the embryo, helps it resist drying out, and allows a dormant stage that pauses the life cycle until environmental conditions are favorable.

#### *A pollen grain is the male gametophyte.*

The gametophytes of seed plants consist of only a few cells. Pollen grains are male gametophytes; each pollen grain contains sperm cells. Water is not required for fertilization. The female gametophyte develops within an ovule that forms the seed.

## 30.8 Gymnosperms: Plants with “Naked Seeds” (see figure 30.23)

Gymnosperms have ovules that are not completely enclosed in sporophyte (diploid) tissue at the time of pollination.

The four groups of gymnosperms are coniferophytes, cycadophytes, gnetophytes, and ginkgophytes; all lack flowers and true fruits.

### **Conifers are the largest gymnosperm phylum.**

Conifers include pines, spruces, firs, cedars, and many other groups. Both the tallest and the oldest vascular plants are conifers.

### **Pines are an exemplary conifer genus.**

Pines have tough, needlelike leaves in clusters of two to five. They produce male and female cones.

In the male cones, microspore mother cells in the microsporangia give rise to microspores that then develop into four-celled pollen grains, the male gametophytes.

In the female cones, a megasporangium (nucellus) produces a single megaspore mother cell that becomes four megaspores; three of these break down, and the remaining one develops into a female gametophyte, which produces archegonia that carry eggs.

Upon fertilization, a pollen tube emerges from the pollen grain and grows through the nucellus. Eventually two sperm cells migrate through the tube, and one unites with the egg; the other disintegrates.

### **Cycads resemble palms, but are not flowering plants.**

Most cycads can reach heights of 15 m or more. Cycads, unlike palms, produce cones; in some species the female cones are huge. Their life cycle is like that of conifers.

### **Gnetophytes have xylem vessels.**

Xylem vessels, a common feature in angiosperms, are highly efficient conducting cells. Gnetophytes are the only gymnosperms that have them.

This group includes the strange *Welwitschia* genus of southwestern Africa and the numerous worldwide *Ephedra* species.

### **Only one species of the ginkgophytes remains extant.**

*Ginkgo biloba* is a gymnosperm with broad leaves that it sheds in the fall. It is dioecious, and the fleshy seeds of the female tree have a foul odor.

## 30.9 Angiosperms: The Flowering Plants (see figure 30.28)

Angiosperms are distinct from gymnosperms and other plants because their ovules are enclosed within diploid tissue called the ovary at the time of fertilization, and they form fruits.

### **Angiosperm origins are a mystery.**

No one is certain how the angiosperms arose, although the extinct family Archaefructaceae may have been a sister clade. The earliest extant angiosperm appears to be *Amborella trichopoda*, found on the island of New Caledonia.

### **Flowers house the gametophyte generation of angiosperms.**

Flowers are considered to be modified stems that bear modified leaves. Flower parts are organized into four whorls: sepals, petals, androecium, and gynoecium (see figure 30.29a).

The male androecium consists of the stamens where haploid pollen, the male gametophyte, is produced.

The female gynoecium consists of one or more carpels that contain the female gametophyte. The carpel has three major regions: the ovary, which later becomes the fruit; the stigma, which is the tip of the carpel; and the style, a stalk that connects the stigma and ovary.

### **Most species use flowers to attract pollinators and reproduce.**

Many angiosperm flowers have nectaries near the base of the ovary that produce nectar containing nutrients and other molecules. Nectar and scent attracts animal pollinators, which carry pollen from one flower to another; some angiosperms are wind pollinated, however.

### **The angiosperm life cycle includes double fertilization.**

The megaspore produces eight haploid nuclei. The female gametophyte consists of a large embryo sac with the eight nuclei in seven cells. The egg and the two polar nuclei (in a single cell) are most important.

After landing on a receptive stigma, a pollen grain develops a pollen tube that grows toward the embryo sac. Eventually, two sperm pass through this tube. One fuses with the egg to form a zygote, and the other unites with the polar bodies to form a triploid endosperm nucleus that develops into endosperm to nourish the embryo.

## Review Questions

### UNDERSTAND

- Which of the following plant structures is not matched to its correct function?
  - Stomata—allow gas transfer
  - Tracheids—allow the movement of water and minerals
  - Cuticle—prevents desiccation
  - All of the above are matched correctly.
- Which of the following genera most likely directly gave rise to the land plants?
  - Volvox*
  - Cblamydomonas*
  - Ulva*
  - Chara*

- Which of the following would not be found in a bryophytes?
  - Mycorrhizal associations
  - Rhizoids
  - Tracheid cells
  - Photosynthetic gametophytes
- Which of the following statements is correct regarding the bryophytes?
  - The bryophytes represent a monophyletic clade.
  - The sporophyte stage of all bryophytes is photosynthetic.
  - Archegonium and antheridium represent haploid structures that produce reproductive cells.
  - Stomata are common to all bryophytes.

- The lack of seeds is a characteristic of all
  - lycophytes.
  - conifers.
  - tracheophytes.
  - gnetophytes.
- Which of the following adaptations allows plants to pause their life cycle until environmental conditions are optimal?
  - Stomata
  - Phloem and xylem
  - Seeds
  - Flowers
- Which of the following gymnosperms possesses a form of vascular tissue that is similar to that found in the angiosperms?
  - Cycads
  - Gnetophytes
  - Ginkgophytes
  - Conifers
- In a pine tree, the microspores and megaspores are produced by the process of
  - fertilization.
  - mitosis.
  - fusion.
  - meiosis.
- Which of the following terms is *not* associated with a male portion of a plant?
  - Megaspore
  - Antheridium
  - Pollen grains
  - Microspore
- Which of the following potentially represents the oldest known living species of angiosperm?
  - Cooksonia*
  - Chlamydomonas*
  - Archaeofructus*
  - Amborella*
- angiosperm pollen tubes grow more quickly than gymnosperm pollen tubes.
- angiosperms have nectaries.
- In double fertilization, one sperm produces a diploid \_\_\_\_\_, and the other produces a triploid \_\_\_\_\_.
  - zygote; primary endosperm
  - primary endosperm; microspore
  - antipodal; zygote
  - polar nuclei; zygote
- Apply your understanding of angiosperms to identify which innovations likely contributed to the tremendous success of angiosperms.
  - Homospory in angiosperms
  - Fruits that attract animal dispersers
  - Cones that protect the seed
  - Dominant gametophyte generation
- Comparing stems of two plant specimens under the microscope, you identify vessels in one sample and conclude the specimen
  - with vessels must be an angiosperm.
  - with vessels is either *Ephedra* or a cycad.
  - without vessels is a pterophyte.
  - without vessels must be a tracheophyte.
- In a flower after fertilization, the following tissues are diploid:
  - carpel, integuments, and megaspore mother cell.
  - carpel, integuments, and megaspore.
  - carpel, megaspore, and zygote.
  - carpel, megaspore mother cell, and endosperm.

## APPLY

- Compare what happens to a spore mother cell as it gives rise to a spore with what happens to a spore as it gives rise to a gametophyte.
  - The spore mother cell and the spore both go through meiosis.
  - The spore mother cell and the spore both go through mitosis.
  - The spore mother cell goes through mitosis and the spore goes through meiosis.
  - The spore mother cell goes through meiosis and the spore goes through mitosis.
- How could a plant without roots obtain sufficient nutrients from the soil?
  - It cannot, all land plants have roots.
  - Mychorrizal fungi associate with the plant and assist with the transfer of nutrients.
  - Charophytes associate with the plant and assist with the transfer of nutrients.
  - It relies on its xylem in the absence of a root.
- A major innovation of land plants is embryo protection. How is a moss embryo protected from desiccation?
  - By the seed
  - By the antheridium
  - By the archegonium
  - By the lycophyll
- Reproduction in angiosperms can occur more quickly than in gymnosperms because
  - gymnosperm sperm requires water to swim to the egg.
  - flowers always increase the rate of reproduction.

## SYNTHESIZE

- You have access to the sequenced genomes for moss and the lycophyte *Selaginella*. Your goal in analyzing the data is to write a ground-breaking paper that answers an important question about the evolution of plants. What question would you try to answer?
- You have been hired as a research assistant to investigate the origins of the angiosperms, specifically the boundary between a gymnosperm and an angiosperm. Which characteristics would you use to clearly define a new fossil as a gymnosperm? An angiosperm?
- Assess the benefits and drawbacks of self-pollination for a flowering plant? Explain your answer.
- The relationship between flowering plants and pollinators is often used as an example of coevolution. Many flowering plant species have flower structures that are adaptive to a single species of pollinator. Evaluate the benefits and drawbacks of using such a specialized relationship.

# Chapter 31

## Fungi

### Chapter Outline

- 31.1 Defining Fungi
- 31.2 Microsporidia: Unicellular Parasites
- 31.3 Chytridiomycota and Relatives: Fungi with Flagellated Zoospores
- 31.4 Zygomycota: Fungi That Produce Zygotes
- 31.5 Glomeromycota: Asexual Plant Symbionts
- 31.6 Basidiomycota: The Club (Basidium) Fungi
- 31.7 Ascomycota: The Sac (Ascus) Fungi
- 31.8 Ecology of Fungi
- 31.9 Fungal Parasites and Pathogens

### Introduction

The fungi, an often overlooked group of unicellular and multicellular organisms, have a profound influence on ecology and human health. Along with bacteria, they are important decomposers and disease-causing organisms. Fungi are found everywhere—from the tropics to the tundra and in both terrestrial and aquatic environments. Fungi made it possible for plants to colonize land by associating with rootless stems and aiding in the uptake of nutrients and water. Mushrooms and toadstools are the multicellular spore-producing part of fungi that grow rapidly under proper conditions. A single *Armillaria* fungus can cover 15 hectares underground and weigh 100 tons, making it the largest organism in the world based on area. Some puffball fungi are almost a meter in diameter and may contain 7 trillion spores—enough to circle the Earth's equator!

Yeasts are used to make bread and beer, but other fungi cause disease in plants and animals. These fungal killers are particularly problematic because fungi are animals' closest relatives. Drugs that can kill fungi often have toxic effects on animals, including humans. In this chapter we present the major groups of this intriguing life form.

### 31.1 Defining Fungi

#### Learning Outcomes

1. Identify characteristics that distinguish fungi from other eukaryotes.
2. Compare mitosis in fungi and animals.
3. Explain why fungi are useful for bioremediation.

Mycologists, scientists who study fungi as well as fungi-like protists, believe there may be as many as 1.5 million fungal species. Fungi exist either as single-celled yeasts or in multicellular form with several different cell types. Their reproduction may be either sexual or asexual, and they exhibit an unusual form of mitosis. They are specialized to extract and absorb nutrients from their surroundings through external secretion of enzymes. Recent phylogenetic analysis of DNA sequences and protein sequences indicates that fungi are more closely related to animals than to plants. Fossils and molecular data indicate that animals and fungi last shared a common ancestor at least 460 MYA, but inconsistencies remain. The oldest

**Figure 31.1 Seven major phyla of fungi.** All phyla, except Zygomycota, are monophyletic. *a.* Microsporidia, including *Encephalitozoon cuniculis*, are animal parasites. *b.* *Allomyces arbuscula*, a water mold, is a blastocladiomycete. *c.* *Pilobolus*, a zygomycete, grows on animal dung and also on culture medium. Stalks about 10 mm long contain dark, spore-bearing sacs. *d.* Neocallimastigales, including *Piromyces communis*, decompose cellulose in the rumens of herbivores. *e.* Some chytrids, including members of the genus *Rhizophydium*, parasitize green algae. *f.* Spores of *Glomus intraradices*, a glomeromycete associated with roots. *g.* *Amanita muscaria*, the fly agaric, is a toxic basidiomycete. *h.* The cup fungus *Cookeina tricholoma* is an ascomycete from the rain forest of Costa Rica. In the cup fungi, the spore-producing structures line the cup; in basidiomycetes that form mushrooms such as *Amanita*, they line the gills beneath the cap of the mushroom. All visible structures of fungi, including the ones shown here, arise from an extensive network of filamentous hyphae that penetrates and is interwoven with the substrate on which they grow.

fossil resembles extant members of the genus *Glomus* that arose within the Glomeromycota. One DNA analysis placed the animal/fungal divergence at 1.5500 BYA. This latter estimate is not generally accepted, but many researchers believe that the last common ancestor existed around close to 670 MYA based on an analysis of multiple genes. The last common ancestor with animals was a single cell, and unique solutions to multicellularity evolved both in fungi and in animals.

The phylogenetic relationships among fungi have been the cause of much debate. Traditionally, four fungal phyla were recognized, based primarily on characteristics of the cells undergoing meiosis: Chytridiomycota (“chytrids”), Zygomycota (“zygomycetes”), Ascomycota (“ascomycetes”), and Basidiomycota (“basidiomycetes”). The chytrids and zygomycetes are not monophyletic.

The understanding of fungal phylogeny is going through rapid and exciting changes, aided by increasing molecular sequence data (figure 31.1 and table 31.1). In 2007, mycologists agreed on seven monophyletic phyla: Microsporidia, Blastocladiomycota, Neocallimastigomycota, Chytridiomycota, Glomeromycota, Basidiomycota, and Ascomycota (see figure 31.1). Blastomycetes and neocallimastigomycetes were formerly grouped with the chytrids. The Microsporidia are sister to all other fungi, but there is disagreement as to whether or not they are true fungi.

In reading the chapter you will find that phyla with common characteristics are sometimes grouped under one heading. Phylogenies are included as reminders of the evolutionary relationships among phyla. Not all fungi are currently assigned to a monophyletic clade, yet their biology is fascinating.

TABLE 31.1		Fungi	
Group	Typical Examples	Key Characteristics	Approximate Number of Living Species
Chytridiomycota	<i>Allomyces</i>	Aquatic, flagellated fungi that produce haploid gametes in sexual reproduction or diploid zoospores in asexual reproduction.	1000
Zygomycota	<i>Rhizopus</i> , <i>Pilobolus</i>	Multinucleate hyphae lack septa, except for reproductive structures; fusion of hyphae leads directly to formation of a zygote in zygosporangium, in which meiosis occurs just before it germinates; asexual reproduction is most common.	1050
Glomeromycota	<i>Glomus</i>	Form arbuscular mycorrhizae. Multinucleate hyphae lack septa. Reproduce asexually.	150
Ascomycota	Truffles, morels	In sexual reproduction, ascospores are formed inside a sac called an ascus; asexual reproduction is also common.	45,000
Basidiomycota	Mushrooms, toadstools, rusts	In sexual reproduction, basidiospores are borne on club-shaped structures called basidia; asexual reproduction occurs occasionally.	22,000

### Figure 31.2 A septum.

This transmission electron micrograph of a section through a hypha of an ascomycete shows a pore through which the cytoplasm streams.

## The body of a fungus is a mass of connected hyphae

Some hyphae are continuous or branching tubes filled with cytoplasm and multiple nuclei. Other hyphae are typically made up of long chains of cells joined end-to-end and divided by cross-walls called septa (singular, *septum*). The septa rarely form a complete barrier, except when they separate the reproductive cells. Even fungi with septa can be considered one long cell.

Cytoplasm characteristically flows or streams freely throughout the hyphae, passing through major pores in the septa (figure 31.2). Because of this streaming, proteins synthesized throughout the hyphae may be carried to their actively growing tips. As a result, fungal hyphae may grow very rapidly when food and water are abundant and the temperature is optimum. For example, you may have seen mushrooms suddenly appear in a lawn overnight after a rain in summer.

### The mycelium

A mass of connected hyphae is called a **mycelium** (plural, *mycelia*). (This word and the term mycology, the study of fungi, are both derived from the Greek word *mykes*, meaning fungi.) The mycelium of a fungus (figure 31.3) constitutes a system that may, in the aggregate, be many meters long. This mycelium grows into the soil, wood, or other material and digestion of the material begins quickly. In two of the four major groups of fungi, reproductive structures formed of interwoven hyphae, such as mushrooms, puffballs, and morels, are produced at certain stages of the life cycle. These structures expand rapidly because of rapid inflation of the hyphae.

### Cell walls with chitin

The cell walls of fungi are formed of polysaccharides, including chitin. In contrast, cell walls of plants and many protists contain cellulose, not chitin. Chitin is a modified cellulose consisting of linked glucose units to which nitrogen groups have been added; this polymer is then cross-linked with proteins. Chitin is the same material that makes up the major portion of the hard shells, or exoskeletons, of arthropods, a group of animals that includes insects and crustaceans (chapter 34). Chitin is one of

the shared traits that has led scientists to believe that fungi and animals are more closely related than fungi and plants.

## Fungal cells may have more than one nucleus

Fungi are different from most animals and plants in that each cell (or hypha) can house one, two, or more nuclei. A hypha that has only one nucleus is called **monokaryotic**; a cell with two nuclei is **dikaryotic**. In a dikaryotic cell, the two haploid nuclei exist independently. Dikaryotic hyphae have some of the genetic properties of diploids, because both genomes are transcribed.

Sometimes, many nuclei intermingle in the common cytoplasm of a fungal mycelium, which can lack distinct cells. If a dikaryotic or multinucleate hypha has nuclei that are derived from two genetically distinct individuals, the hypha is called **heterokaryotic**. Hyphae whose nuclei are genetically similar to one another are called **homokaryotic**.

## Mitosis is not followed by cell division

Mitosis in multicellular fungi differs from that in most other organisms. Because of the linked nature of the cells, the cell

**Figure 31.3 Fungal mycelium.** This mycelium, composed of hyphae, is growing through leaves on the forest floor in Maryland.

**Figure 31.4**  
**Fungal spores.**  
Scanning electron micrograph of fungal spores from *Aspergillus*.

itself is not the relevant unit of reproduction; instead, the nucleus is. The nuclear envelope does not break down and reform; instead, the spindle apparatus is formed *within* it.

Centrioles are absent in all fungi except chytrids; instead, fungi regulate the formation of microtubules during mitosis with small, relatively amorphous structures called *spindle plaques*. This unique combination of features strongly suggests that fungi originated from some unknown group of single-celled eukaryotes with these characteristics.

## Fungi can reproduce both sexually and asexually

Many fungi are capable of producing both sexual and asexual spores. When a fungus reproduces sexually, two haploid hyphae of compatible mating types may come together and fuse.

### The dikaryon stage

In animals, plants, and some fungi, the fusion of two haploid cells during reproduction immediately results in a diploid cell ( $2n$ ). But in other fungi, namely basidiomycetes and ascomycetes, an intervening dikaryotic stage ( $1n + 1n$ ) occurs before the parental nuclei fuse and form a diploid nucleus. In ascomycetes, this dikaryon stage is brief, occurring in only a few cells of the sexual reproductive structure. In basidiomycetes, however, it can last for most of the life of the fungus, including both the feeding and sexual spore-producing structures.

### Reproductive structures

Some fungal species produce specialized mycelial structures to house the production of spores. Examples are the mushrooms we see above ground, the “shelf” fungus that appears on the trunks of dead trees, and puffballs, which can house billions of spores.

As noted previously, the cytoplasm in fungal hyphae normally flows through perforated septa or moves freely in their absence. Reproductive structures are an important exception to this general pattern. When reproductive structures form, they are cut off by complete septa that lack perforations or that have perforations that soon become blocked.

### Spores

Spores are the most common means of reproduction among fungi. They may form as a result of either asexual or sexual processes, and they are often dispersed by the wind. When spores land in a suitable place, they germinate, giving rise to a new fungal mycelium.

Because the spores are very small, between 2 and 75  $\mu\text{m}$  in diameter (figure 31.4), they can remain suspended in the air for a long time. Unfortunately, many of the fungi that cause diseases in plants and animals are spread rapidly by such means. The spores of other fungi are routinely dispersed by insects or other small animals. A few fungal phyla retain the ancestral flagella and have motile zoospores.

Biologists had believed for a long time that the worldwide presence of fungal species could be accounted for, on an evolutionary timescale, by the almost limitless, long-distance dispersal of fungal spores. Recent biogeographic studies, however, have examined the phylogenetic relationships among fungi in distant parts of the world and disproved this long-held assumption.

## Fungi are heterotrophs that absorb nutrients

All fungi obtain their food by secreting digestive enzymes into their surroundings and then absorbing the organic molecules produced by this external digestion. The fungal body plan reflects this approach. Unicellular fungi have the greatest surface area-to-volume ratio of any fungus, maximizing the surface area for absorption. Extensive networks of hyphae also provide an enormous surface area for absorptive nutrition in a fungal mycelium.

Many fungi are able to break down the cellulose in wood, cleaving the linkages between glucose subunits and then absorbing the glucose molecules as food. Most fungi also digest lignin, an insoluble organic compound that strengthens plant cell walls. The specialized metabolic pathways of fungi allow them to obtain nutrients from dead trees and from an extraordinary range of organic compounds, including tiny roundworms called nematodes (figure 31.5a).

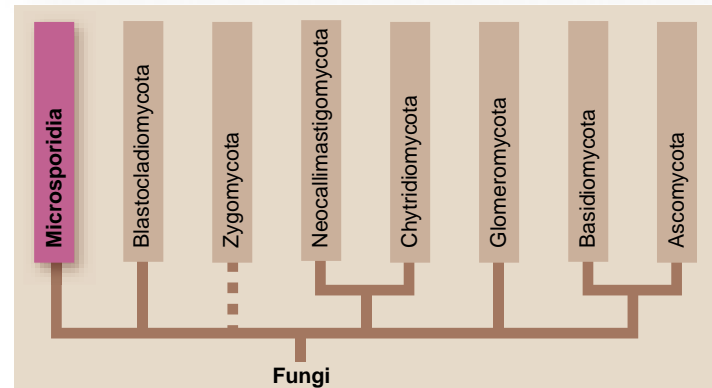

**Figure 31.5 Carnivorous fungi.** *a.* Fungus obtaining nutrients from a nematode. *b.* The oyster mushroom *Pleurotus ostreatus* not only decomposes wood but also immobilizes nematodes, which the fungus uses as a source of nitrogen.

## 31.2 Microsporidia: Unicellular Parasites

### Learning Outcomes

1. Explain characteristics that led microsporidians to be classified as protists.
2. Describe evidence for placing microsporidians with fungi.

The mycelium of the edible oyster mushroom *Pleurotus ostreatus* (figure 31.5b) excretes a substance that paralyzes nematodes that feed on the fungus. When the worms become sluggish and inactive, the fungal hyphae envelop and penetrate their bodies. Then the fungus secretes digestive juices and absorbs the nematode's nutritious contents, just like it would from a plant source.

This fungus usually grows within living trees or on old stumps, obtaining the bulk of its glucose through the enzymatic digestion of cellulose and lignin from plant cell walls. The nematodes it consumes apparently serve mainly as a source of nitrogen—a substance almost always in short supply in biological systems. Other fungi are even more active predators than *Pleurotus*, snaring, trapping, or firing projectiles into nematodes, rotifers, and other small animals on which they prey.

Because of their ability to break down almost any carbon-containing compound—even jet fuel—fungi are of interest for use in bioremediation, using organisms to clean up soil or water that is environmentally contaminated. As one example, some fungal species can remove selenium, an element that is toxic in high accumulations, from soils by combining it with other harmless volatile compounds.

### Learning Outcomes Review 31.1

Fungi are more closely related to animals than to plants. Many, but not all, fungi form seven monophyletic phyla. A fungus consists of a mass of hyphae (cells) termed a mycelium; cell walls contain the polysaccharide chitin. Mitosis in fungi divides the nucleus but not the hypha itself. Sexual reproduction may occur when hyphae of two different mating types fuse. Haploid nuclei from each type may persist separately in some groups, termed a dikaryon stage. Spores are produced sexually or asexually and are spread by wind or animals. Fungi secrete digestive enzymes externally and then absorb the products of the digestion. Fungi can break down almost any organic compound.

- What differentiates fungi from animals, since both are heterotrophs?
- What protects hyphae from being digested by the fungus's own secreted enzymes?

Microsporidia are obligate, intracellular, animal parasites, long thought to be protists. The lack of mitochondria led biologists to believe that microsporidians were in a deep branch of protists that diverged before endosymbiosis led to mitochondria. Genome sequencing of the microsporidian *Encephalitozoon cuniculi* revealed genes related to mitochondrial functions within the tiny 2.9-Mb genome. Finding mitochondrial genes led to the hypothesis that microsporidia ancestors had mitochondria, and that greatly reduced, mitochondrion-derived organelles exist in microsporidia. Coupled with phylogenies derived from analyses of new sequence data, microsporidia have been tentatively moved from the protists to the fungi.

*E. cuniculi* and other microsporidia commonly cause disease in immunosuppressed patients, such as those with AIDS and people who have received organ transplants. Microsporidians infect hosts with their spores, which contain a polar tube (figure 31.6). The polar tube extrudes the contents of the spore

**Figure 31.6** Polar tube of an *E. cuniculi* spore infects cells.

into the cell and the parasite sets up housekeeping in a vacuole. *E. cuniculi* infects intestinal and neuronal cells, leading to diarrhea and neurodegenerative disease. Understanding the phylogenetic placement of the microsporidia is important in identifying effective disease treatments.

### Learning Outcomes Review 31.2

Microsporidia lack mitochondria; however, the presence of mitochondrial genes indicates that at one time an ancestral form possessed them. As obligate parasites, microsporidia cause diseases in animals, including humans.

- How would you distinguish a microsporidian from the parasitic protistan Plasmodium?

## 31.3 Chytridiomycota and Relatives: Fungi with Flagellated Zoospores

### Learning Outcomes

1. Distinguish between blastocladiomycetes and microsporidians.
2. Explain the meaning of “chytrid.”
3. Discuss possible uses of neocallimastigomycetes.

Members of phylum Chytridiomycota, the **chytridiomycetes** or **chytrids**, are aquatic, flagellated fungi that are closely related to ancestral fungi. Motile zoospores are a distinguishing character of this fungal group. Chytrid has its origins in the Greek word

**Figure 31.7 Zoospore release.** The potlike structure (*chytridion* in Greek) containing the zoospores gives chytrids their name.

*chytridion*, meaning “little pot,” referring to the structure that releases the flagellated zoospores (figure 31.7).

Chytrids include *Batrachochytrium dendrobatidis*, which has been implicated in the die-off of amphibians. Other chytrids have been identified as plant pathogens (figure 31.8). Traditionally the blastocladiomycetes and the neocallimastigomycetes have been grouped with the chytrids. Recent phylogenetic inferences have accorded the two groups their own phyla. Both proposed phyla are discussed here because of their many similarities with the chytrids.

### Blastocladiomycota have single flagella

Blastocladiomycetes have unflagellated zoospores. Blastocladiomycetes, neocallimastigomycetes, and chytridiomycetes were originally grouped as a single phylum because they all have flagella that have been lost in other groups, except the microsporidians. Inclusion of multiple genes in phylogenetic analyses has established that the three groups form three separate, monophyletic phyla.

**Figure 31.8 Chytridiomycota can be plant pathogens.** *Rhizophyidium granulosporum* sporangia on a filament of the green algae *Oedogonium*.

**Figure 31.9**

**Allomyces, a blastocladiomycete that grows in the soil.**

**a.** The spherical sporangia can produce either diploid zoospores via mitosis or haploid zoospores via meiosis. **b.** Life cycle of *Allomyces*, which has both haploid and diploid multicellular stages (alternation of generations).

*Allomyces* is a typical blastocladiomycete genus. A water mold, it exhibits a true haplodiplontic life cycle (figure 31.9). Reproduction in *Allomyces* species is enhanced by the secretion of a pheromone, a long-distance chemical signal, from the female gametes that attracts male gametes. Pheromones are similar to hormones, but work between organisms, rather than within organisms. The *Allomyces* pheromone is called sirenin (after the Sirens in Greek mythology) and was the first fungal sex hormone to be identified chemically.

Unlike microsporidia, which lack mitochondria, *A. macrogynus* has giant mitochondria in its zoospores. Each flagellated zoospore contains a single giant mitochondrion that is fragmented into several normal-sized organelles in vegetative cells.

## Neocallimastigomycota digest cellulose in ruminant herbivores

Within the rumens of mammalian herbivores, **neocallimastigomycetes** enzymatically digest the cellulose and lignin of the plant biomass in their grassy diet. Sheep, cows, kangaroos, and elephants all depend on these fungi to obtain sufficient calories. These anaerobic fungi have greatly reduced mitochondria that lack cristae. Their zoospores have multiple flagella. “Mastig” in *Neocallimastigomycota* is Latin for “whips,” referencing the multiple flagella.

The genus *Neocallimastix* can survive on cellulose alone. Genes encoding digestive enzymes such as cellulase made their way into the *Neocallimastix* genomes via horizontal gene transfer from bacteria. Horizontal gene transfer is covered in chapter 26.

The many enzymes that neocallimastigomycetes use to digest cellulose and lignin in plant cell walls may be useful in biofuel production from cellulose. Although it is possible to obtain ethanol from cellulose, breaking down the cellulose is a major technical hurdle. The use of neocallimastigomycetes fungi to produce cellulosic ethanol is a promising, cost-effective approach.

### Learning Outcomes Review 31.3

Three closely related phyla, Chytridiomycota, Blastocladiomycota, and Neocallimastigomycota have flagellated zoospores. Chytrid refers to the potlike shape of the structure releasing the zoospores. *Allomyces*, a representative blastocladiomycete, has unflagellated zoospores with giant mitochondria, and a haplodiplontic life cycle. Neocallimastigomycetes acquired cellulases from bacteria. They aid ruminant animals in digesting cellulose from plants and may be useful in production of biofuels.

- What two features differentiate blastocladiomycetes from microsporidians?

## 31.4 Zygomycota: Fungi That Produce Zygotes

### Learning Outcomes

1. Describe the defining feature of the zygomycetes.
2. Explain the advantage of zygospore formation.

**Zygomycetes** (phylum Zygomycota) include only about 1050 named species, but they are incredibly diverse. The zygomycota are not monophyletic, but are included in this chapter as a group while research on their evolutionary history continues. Among them are some of the more common bread molds, which have been assigned to the monophyletic subphylum Mucoromycotina (figure 31.10), as well as a variety of others

found on decaying organic material, including strawberries and other fruits. A few human pathogens are in this group.

### In sexual reproduction, zygotes form inside a zygosporangium

The zygomycetes lack septa in their hyphae except when they form sporangia or gametangia (structures in which spores or gametes are produced). The group is named after a characteristic feature of the sexual phase of the life cycle, the formation of diploid zygote nuclei.

Sexual reproduction begins with the fusion of gametangia, which contain numerous nuclei. The gametangia are cut off from the hyphae by complete septa. These gametangia may be formed on hyphae of different mating types or on a single hypha.

The haploid nuclei fuse to form a diploid zygote nucleus, a process called karyogamy. The area where the fusion has taken

place develops into a zygosporangium (figure 31.10*b*), within which a **zygospore** develops. The zygospore, which may contain one or more diploid nuclei, acquires a thick coat that helps the fungus survive conditions not favorable for growth.

Meiosis, followed by mitosis, occurs during the germination of the zygospore, which releases haploid spores. Haploid hyphae grow when these haploid spores germinate. Except for the zygote nuclei, all nuclei of the zygomycetes are haploid.

### Asexual reproduction is more common

Asexual reproduction occurs much more frequently than sexual reproduction in the zygomycetes. During asexual reproduction, hyphae produce clumps of erect stalks, called **sporangiophores**. The tips of the sporangiophores form sporangia, which are separated by septa. Thin-walled haploid spores are produced within the sporangia. These spores are shed above the food substrate, in a position where they may be picked up by the wind and dispersed to a new food source.

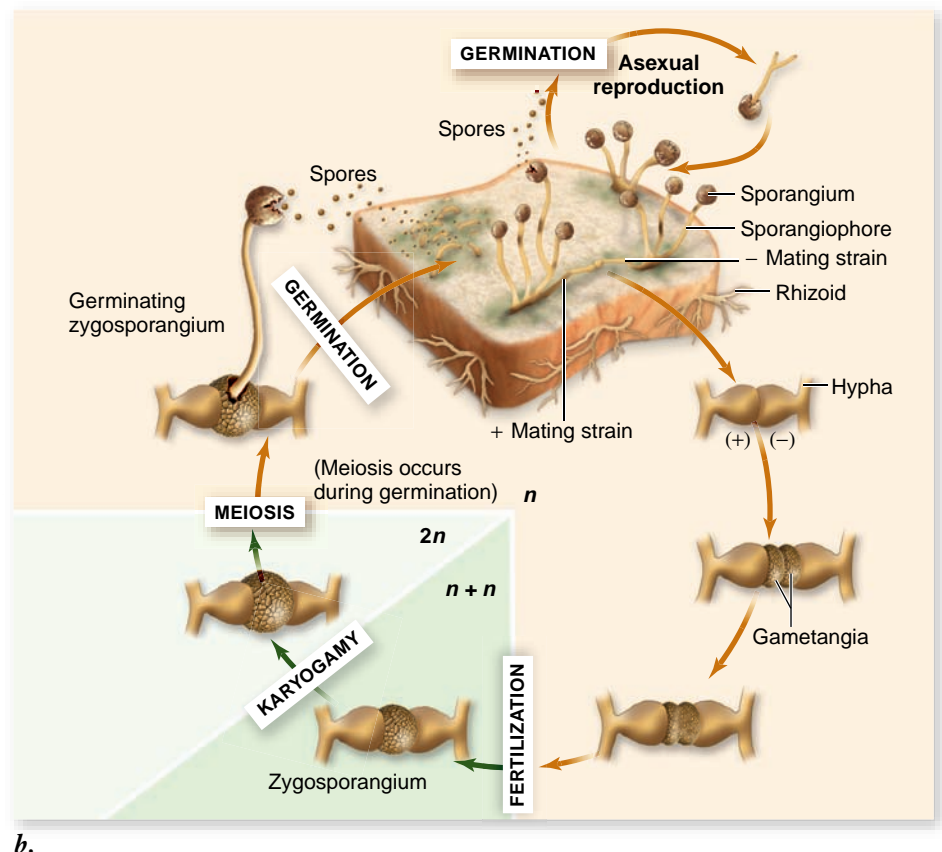

#### Learning Outcomes Review 31.4

Zygomycetes are named for the production of diploid zygote nuclei by fusion of haploid nuclei, a process called karyogamy. The hyphae of zygomycetes are multinucleate, with septa only where gametangia or sporangia are separated. Many zygomycetes form characteristic resting structures called zygosporangia, which contain zygospores that are able to withstand harsh conditions.

- Under what conditions would you expect a zygomycete to produce zygospores rather than haploid spores?

**Figure 31.10** *Rhizopus*, a zygomycete that grows on simple sugars. This fungus is often found on moist bread or fruit. *a.* The dark, spherical, spore-producing sporangia are on hyphae about 1 cm tall. The rootlike hyphae (rhizoids) anchor the sporangia. *b.* Life cycle of *Rhizopus*. The Zygomycota group is named for the zygosporangia characteristic of *Rhizopus*. The (+) and (-) denote mating types.

## 31.5 Glomeromycota: Asexual Plant Symbionts

### Learning Outcome

1. Explain why Glomeromycota is now considered separate from Zygomycota.

The glomeromycetes, a tiny group of fungi with approximately 150 described species, likely made the evolution of terrestrial plants possible. Tips of hyphae grow within the root cells of most trees and herbaceous plants, forming a branching structure that allows nutrient exchange. The intracellular associations with plant roots are called **arbuscular mycorrhizae**. The specifics of arbuscular mycorrhizal associations and other forms of mycorrhizal interactions are detailed in section 31.8.

Glomeromycetes cannot survive in the absence of a host plant. The symbiotic relationship is mutualistic, with the glomeromycetes providing essential minerals, especially phosphorous, and the plants providing carbohydrates.

The glomeromycetes are challenging to characterize, in part, because there is no evidence of sexual reproduction. These fungi exemplify our emerging understanding of fungal phylogeny. Like zygomycetes, glomeromycetes lack septae in their hyphae and were once grouped with the zygomycetes. However, comparisons of DNA sequences of small-subunit rRNAs reveal that glomeromycetes are a monophyletic clade that is phylogenetically distinct from zygomycetes. Unlike zygomycetes, glomeromycetes lack zygospores. Glomeromycota originated at least 600 to 620 MYA, well before the split of the Ascomycota and Basidiomycota, which we will consider next.

### Learning Outcome Review 31.5

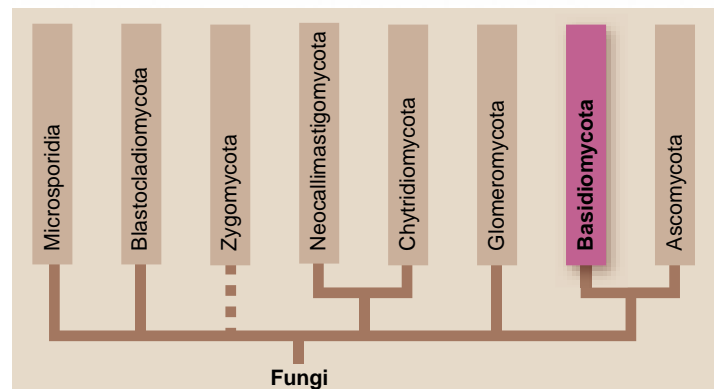

Glomeromycetes are a monophyletic fungal lineage based on analysis of small-subunit rRNAs. Their obligate symbiotic relationship with the roots of many plants appears to be ancient and may have made it possible for terrestrial plants to evolve.

- Why do glomeromycetes require a host plant?

## 31.6 Basidiomycota: The Club (Basidium) Fungi

### Learning Outcomes

1. Explain which cells in the life cycle of a basidiomycete are diploid.
2. Distinguish between primary and secondary mycelium in basidiomycetes.

The basidiomycetes (phylum Basidiomycota) include some of the most familiar fungi. Among the basidiomycetes are not only the mushrooms, toadstools, puffballs, jelly fungi, and shelf fungi, but also many important plant pathogens, including rusts and smuts (figure 31.11*a*). Rust infections resemble rusting metals, and smut infections appear black and powdery due to the spores. Many mushrooms are used as food, but others are hallucinogenic or deadly poisonous.

### Basidiomycetes sexually reproduce within basidia

Basidiomycetes are named for their characteristic sexual reproductive structure, the club-shaped **basidium** (plural, *basidia*). Karyogamy (fusion of two nuclei) occurs within the basidium, giving rise to the only diploid cell of the life cycle (figure 31.11*b*). Meiosis occurs immediately after karyogamy. In the basidiomycetes, the four haploid products of meiosis are incorporated into **basidiospores**. In most members of this phylum, the basidiospores are borne at the end of the basidia on slender projections (sterigmata).

### The secondary mycelium of basidiomycetes is heterokaryotic

The life cycle of a basidiomycete continues with the production of monokaryotic hyphae after spore germination. These hyphae lack septa early in development. Eventually, septa form between the nuclei of the monokaryotic hyphae. A basidiomycete mycelium made up of monokaryotic hyphae is called a *primary mycelium*.

a.

### Figure 31.11 Basidiomycetes.

a. The death cap mushroom, *Amanita phalloides*. When eaten, these mushrooms are usually fatal. b. Life cycle of a basidiomycete. The basidium is the reproductive structure.

b.

Different mating types of monokaryotic hyphae may fuse, forming a dikaryotic mycelium, or *secondary mycelium*. Such a mycelium is heterokaryotic, with two nuclei representing the two different mating types, between each pair of septa. This stage is the dikaryon stage described earlier as being a distinguishing feature of fungi. It is found in both the ascomycetes and the basidiomycetes. The two phyla are grouped as the subkingdom Dikarya because of this commonality. The maintenance of two genomes in the heterokaryon allows for more genetic plasticity than in a diploid cell with one nucleus. One genome may compensate for mutations in the other.

The **basidiocarps**, or mushrooms, are formed entirely of secondary (dikaryotic) mycelium. Gills, sheets of tissue on the undersurface of the cap of a mushroom, produce vast numbers of minute spores. It has been estimated that a mushroom with a cap measuring 7.5 cm in diameter produces as many as 40 million spores per hour!

#### Learning Outcomes Review 31.6

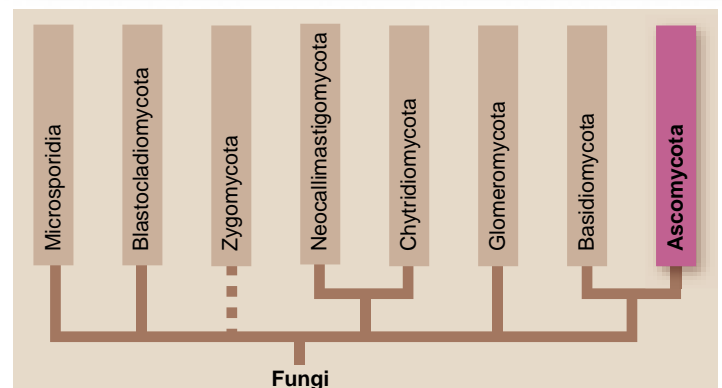

Basidiomycetes undergo karyogamy, after which meiosis occurs within club-shaped basidia. The primary mycelium consists of monokaryotic hyphae resulting from spore germination. The secondary mycelium of basidiomycetes is the dikaryon stage, in which two nuclei exist within a single hyphal segment.

- What distinguishes a dikaryotic cell from a diploid cell?

## 31.7 Ascomycota: The Sac (Ascus) Fungi

### Learning Outcomes

1. Compare the ascomycetes and the basidiomycetes
2. List the ways ascomycetes affect humans.

The phylum **Ascomycota** contains about 75% of the known fungi. Among the ascomycetes are such familiar and economically important fungi as bread yeasts, common molds,

morels (figure 31.12a), cup fungi (figure 31.12b), and truffles. Also included in this phylum are many serious plant pathogens, including those that produce chestnut blight, *Cryphonectria parasitica*, and Dutch elm disease, *Ophiostoma ulmi*. Penicillin-producing ascomycetes are in the genus *Penicillium*.

## Sexual reproduction occurs within the ascus

The ascomycetes are named for their characteristic reproductive structure, the microscopic, saclike **ascus** (plural, *asci*). Karyogamy, the production of the only diploid nucleus of the ascomycete life cycle (figure 31.12c), occurs within the ascus. The structure of an ascus differs from that of a basidium, although functionally the two are identical.

Asci are differentiated within a structure made up of densely interwoven hyphae, corresponding to the visible portions of a morel or cup fungus, called the **ascocarp**. Meiosis immediately follows karyogamy, forming four haploid daughter nuclei. These usually divide again by mitosis, producing eight haploid nuclei that become walled **ascospores**. The as-

cospores of the ascomycetes are borne internally in asci instead of externally as in basidiospores.

In many ascomycetes, the ascus becomes highly turgid at maturity and ultimately bursts, often at a preformed area. When this occurs, the ascospores may be thrown as far as 31 cm, an amazing distance considering that most ascospores are only about 10  $\mu\text{m}$  long. This would be equivalent to throwing a baseball (diameter 7.5 cm) 1.25 km—about 10 times the length of a home run!

## Asexual reproduction occurs within conidiophores

Asexual reproduction is very common in the ascomycetes. It takes place by means of **conidia** (singular, *conidium*), asexual spores cut off by septa at the ends of modified hyphae called conidiophores. Conidia allow for the rapid colonization of a new food source. Many conidia are multinucleate. The hyphae of ascomycetes are divided by septa, but the septa are perforated, and the cytoplasm flows along the length of each hypha. The septa that cut off the asci and conidia are initially perforated, but later become blocked.

c.

## Some ascomycetes have yeast morphology

Most yeasts are ascomycetes with a single-celled lifestyle. Most of yeasts' reproduction is asexual and takes place by cell fission or budding, when a smaller cell forms from a larger one (figure 31.13). Sometimes two yeast cells fuse, forming one cell containing two nuclei. This cell may then function as an ascus, with karyogamy followed immediately by meiosis. The resulting ascospores function directly as new yeast cells.

The ability of yeasts to ferment carbohydrates, breaking down glucose to produce ethanol and carbon dioxide, is fundamental in the production of bread, beer, and wine. About four billion of these tiny, powerful organisms can fit in a teaspoon. Many different strains of yeast have been domesticated and selected for these processes, using the sugars in rice, barley, wheat, and corn. Wild yeasts—ones that occur naturally in the areas where wine is made—were important in wine making historically, but domesticated cultured yeasts are normally used now.

Wild yeast, often *Candida milleri*, is still important in making sourdough bread. Unlike most breads that are made with pure cultures of yeast, sourdough uses an active culture of wild yeast and bacteria that generate acid. This culture is maintained, and small amounts—"starter" cultures—are used for each batch of bread. The combination of yeast and acid-producing bacteria is needed for fermentation and gives sourdough bread its unique flavor.

The most important yeast in baking, brewing, and wine making is *Saccharomyces cerevisiae*. This yeast has been used by humans throughout recorded history. Yeast is also employed as a nutritional supplement because it contains high levels of B vitamins and because about 50% of yeast is protein.

## Ascomycete genetics and genomics have practical applications

Yeast is a long-standing model system for genetic research. It was the first eukaryote to be manipulated extensively by the techniques of genetic engineering, and they still play the lead-

**Figure 31.13 Budding in *Saccharomyces*.** As shown in this scanning electron micrograph, the cells tend to hang together in chains, a feature that calls to mind the derivation of single-celled yeasts from multicellular ancestors.

ing role as models for research in eukaryotic cells. In 1996, the genome sequence of *S. cerevisiae*, the first eukaryote to be sequenced entirely, was completed. The yeast two-hybrid system has been an important component of research on protein interactions (see chapter 17).

The fungal genome initiative is now under way to provide sequence information on other fungi. More than 25 fungi have been or are being sequenced. These fungi were selected based on their effects on human health, including plant pathogens that threaten our food supply.

The ascomycetes *Coccidioides posadasii* and its relative *C. immitis* were included because they are endemic in soil in the southwestern portion of the United States, can cause a fatal infection called coccidioidomycosis ("valley fever"), and have been considered a possible bioterrorism threat. In the United States the annual infection rate is about 100,000 individuals, although only a small percentage of infected individuals die.

A second important criterion in selecting which fungi to sequence was the potential to provide information on fungal evolution. This new information will complement and expand our understanding of the diverse fungal kingdom.

### Learning Outcomes Review 31.7

Ascomycetes undergo karyogamy within a characteristic saclike structure, the ascus. The function of the ascus is therefore identical to that of the basidium, although they are structurally different. Meiosis follows, resulting in the production of ascospores. Yeasts within this group generally reproduce asexually by budding. Ascomycetes include both beneficial forms used as foods, and in the production of foods, and harmful forms responsible for diseases and spoilage. Many ascomycetes are employed in scientific research.

- *Coccidioidomycosis* is caused by inhaling spores; it often occurs in farmworkers in the Southwest United States. What would help prevent this disease?

## 31.8 Ecology of Fungi

### Learning Outcomes

1. Identify a trait that contributes to the value of fungi in symbiotic relationships.
2. Describe the living components of a lichen.
3. List examples of fungal associations with different organisms.

Fungi, together with bacteria, are the principal decomposers in the biosphere. They break down organic materials and return the substances locked in those molecules to circulation in the ecosystem. Fungi can break down cellulose and lignin, an insoluble organic compound that is one of the major constituents of wood. By breaking down such substances, fungi release carbon,

nitrogen, and phosphorus from the bodies of living or dead organisms and make them available to other organisms.

In addition to their role as decomposers, fungi have entered into fascinating relationships with a variety of life forms. Interactions between different species are described in chapter 57 where we discuss community ecology, but we cover fungal relationships briefly here because of their unique character.

## Fungi have a range of symbioses

The interactions, or symbioses, between fungi and other living organisms fall into a broad range of categories. In some cases, the symbiosis is an **obligate symbiosis** (essential for survival), and in other cases it is a **facultative symbiosis** (the fungus can survive without the host). Within a group of closely related fungi, several different types of symbiosis can be found.

First, here is a summary of ways in which living things can interact. **Pathogens** and **parasites** gain resources from their host, but they have a negative effect on the host that can even lead to death. The difference between pathogens and parasites is that pathogens cause disease, but parasites do not, except in extreme cases.

**Commensal** relationships benefit one partner but do not harm the other. Fungi that are in a **mutualistic** relationship benefit both themselves and their hosts. Many of these relationships are described in the discussion that follows.

## Endophytes live inside plants and may protect plants from parasites

Endophytic fungi live inside plants, actually in the intercellular spaces. Found throughout the plant kingdom, many of these relationships may be examples of parasitism or commensalism.

There is growing evidence that some of these fungi protect their hosts from herbivores by producing chemical toxins or deterrents. Most often, the fungus synthesizes alkaloids that protect the plant. As you will learn in chapter 40, plants also synthesize a wide range of alkaloids, many of which serve to defend the plant.

One way to assess whether an endophyte is enhancing the health of its host plant is to grow plots of plants with and without the same endophyte. An experiment with perennial ryegrass, *Lolium perenne*, demonstrated that it is more resistant to aphid feeding when an endophytic fungus, *Neotyphodium*, is present (figure 31.14).

## Lichens are an example of symbiosis between different kingdoms

**Lichens** (figure 31.15) are symbiotic associations between a fungus and a photosynthetic partner. Although many lichens are excellent examples of mutualism, some fungi are parasitic on their photosynthetic host.

### Composition of a lichen

Ascomycetes are the fungal partners in all but about 20 of the approximately 15,000 species of lichens estimated to exist. Most of the visible body of a lichen consists of its fungus, but between

## SCIENTIFIC THINKING

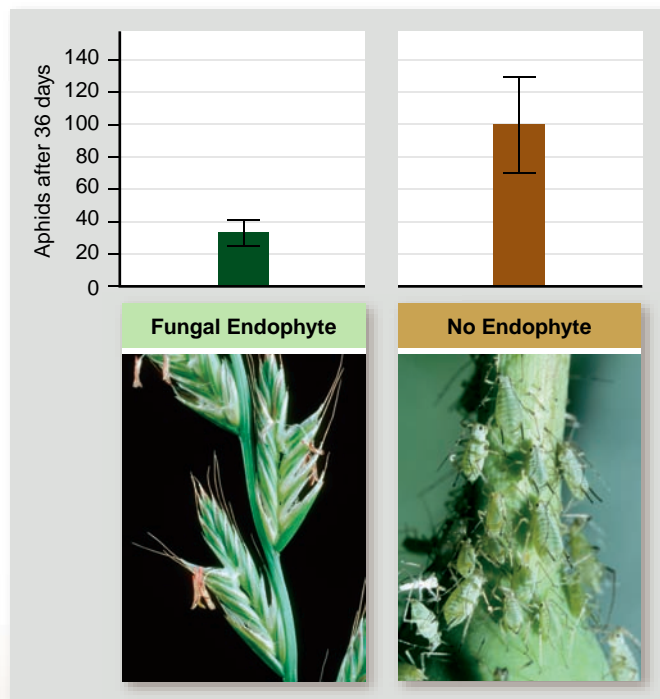

**Hypothesis:** Endophytic fungi can protect their host from herbivory.

**Prediction:** There will be fewer aphids (*Rhopalosiphum padi*, an herbivore) on perennial ryegrass (*Lolium perenne*) infected with endophytic fungi than on uninfected ryegrass.

**Test:** Place five adult aphids on each pot of 2-week-old grass plants with and without endophytic fungi. Place pots in perforated bags and grow for 36 days. Count the number of aphids in each pot.

**Result:** Significantly more aphids were found on the uninfected grass plants.

**Conclusion:** Endophytic fungi protect host plants from herbivory.

**Further Experiments:** How do you think the fungi protect the plants from herbivory? If they secrete chemical toxins, could you use this basic experimental design to test specific fungal compounds?

**Figure 31.14** Effect of the fungal endophyte *Neotyphodium* on the aphid population living on perennial ryegrass (*Lolium perenne*).

**Figure 31.15** Lichens are found in a variety of habitats. *a.* A fruticose lichen, growing in the soil. *b.* A foliose (“leafy”) lichen, growing on the bark of a tree in Oregon. *c.* A crustose lichen, growing on rocks leading to the breakdown of rock into soil.

the filaments of that fungus are cyanobacteria, green algae, or sometimes both (figure 31.16).

Specialized fungal hyphae penetrate or envelop the photosynthetic cell walls within them and transfer nutrients directly to the fungal partner. Note that although fungi penetrate the cell wall, they do not penetrate the plasma membrane. Biochemical signals sent out by the fungus apparently direct its cyanobacterial or green algal component to produce metabolic substances that it does not produce when growing independently of the fungus.

The fungi in lichens are unable to grow normally without their photosynthetic partners, and the fungi protect their partners from strong light and desiccation. When fungal components of lichens have been experimentally isolated from their photosynthetic partner, they survive, but grow very slowly.

**Figure 31.16** Stained section of a lichen. This section shows fungal hyphae (purple) more densely packed into a protective layer on the top and, especially, the bottom layer of the lichen. The blue cells near the upper surface of the lichen are those of a green alga. These cells supply carbohydrate to the fungus.

### Ecology of lichens

The durable construction of the fungus combined with the photosynthetic properties of its partner have enabled lichens to invade the harshest habitats—the tops of mountains, the farthest northern and southern latitudes, and dry, bare rock faces in the desert. In harsh, exposed areas, lichens are often the first colonists, breaking down the rocks and setting the stage for the invasion of other organisms.

Lichens are often strikingly colored because of the presence of pigments that probably play a role in protecting the photosynthetic partner from the destructive action of the sun’s rays. These same pigments may be extracted from the lichens and used as natural dyes. The traditional method of manufacturing Scotland’s famous Harris tweed used fungal dyes.

Lichens vary in sensitivity to pollutants in the atmosphere, and some species are used as bioindicators of air quality. Their sensitivity results from their ability to absorb substances dissolved in rain and dew. Lichens are generally absent in and around cities because of automobile traffic and industrial activity, but some are adapted to these conditions. As pollution decreases, lichen populations tend to increase.

### Mycorrhizae are fungi associated with roots of plants

The roots of about 90% of all plant families have species that are involved in mutualistic symbiotic relationships with certain kinds of fungi. It has been estimated that these fungi probably amount to 15% of the total weight of the world’s plant roots. Associations of this kind are termed **mycorrhizae**, from the Greek words for fungus and root.

The fungi in mycorrhizal associations function as extensions of the root system. The fungal hyphae dramatically increase the amount of soil contact and total surface area for absorption. When mycorrhizae are present, they aid in the direct transfer of phosphorus, zinc, copper, and other mineral nutrients from the soil into the roots. The plant, on the other hand, supplies organic carbon to the fungus, so the system is an example of mutualism.

There are two principal types of mycorrhizae (figure 31.17). In arbuscular mycorrhizae, the fungal hyphae penetrate the outer cells of the plant root, forming coils, swellings, and minute branches; they also extend out into the surrounding soil. In **ectomycorrhizae**, the hyphae surround but do not penetrate the cell walls of the roots. In both kinds of mycorrhizae, the mycelium extends far out into the soil. A single root may associate with many fungal species, dividing the root at a millimeter-by-millimeter level.

### Arbuscular mycorrhizae

Arbuscular mycorrhizae are by far the more common of the two types, involving roughly 70% of all plant species (figure 31.17*a*). The fungal component in them are glomeromycetes, a monophyletic group that arose within one of the zygomycete lineages. The glomeromycetes are associated with more than 200,000 species of plants.

Unlike mushrooms, none of the glomeromycetes produce aboveground fruiting structures, and as a result, it is difficult to arrive at an accurate count of the number of extant species. Arbuscular mycorrhizal fungi are being studied intensively because they are potentially capable of increasing crop yields with lower phosphate and energy inputs.

The earliest fossil plants often show arbuscular mycorrhizal roots. Such associations may have played an important role in allowing plants to colonize land. The soils available at such times would have been sterile and lacking in organic matter. Plants that form mycorrhizal associations are particularly successful in infertile soils; considering the fossil evidence, it seems reasonable that mycorrhizal associations helped the earliest plants succeed on such soils. In addition, the closest living relatives of early vascular plants surviving today continue to depend strongly on mycorrhizae.

Some nonphotosynthetic plants also have mycorrhizal associations, but the symbiosis is one-way because the plant has no photosynthetic resources to offer. Instead of a two-partner symbiosis, a tripartite symbiosis is established. The fungal mycelium extends between a photosynthetic plant and a nonphotosynthetic, parasitic plant. This third, nonphotosynthetic member of the symbiosis is called an *epiparasite*. Not only does it obtain phosphate from the fungus, but it uses the fungus to channel carbohydrates from the photosynthetic plant to itself. Epiparasitism also occurs in ectomycorrhizal symbiosis.

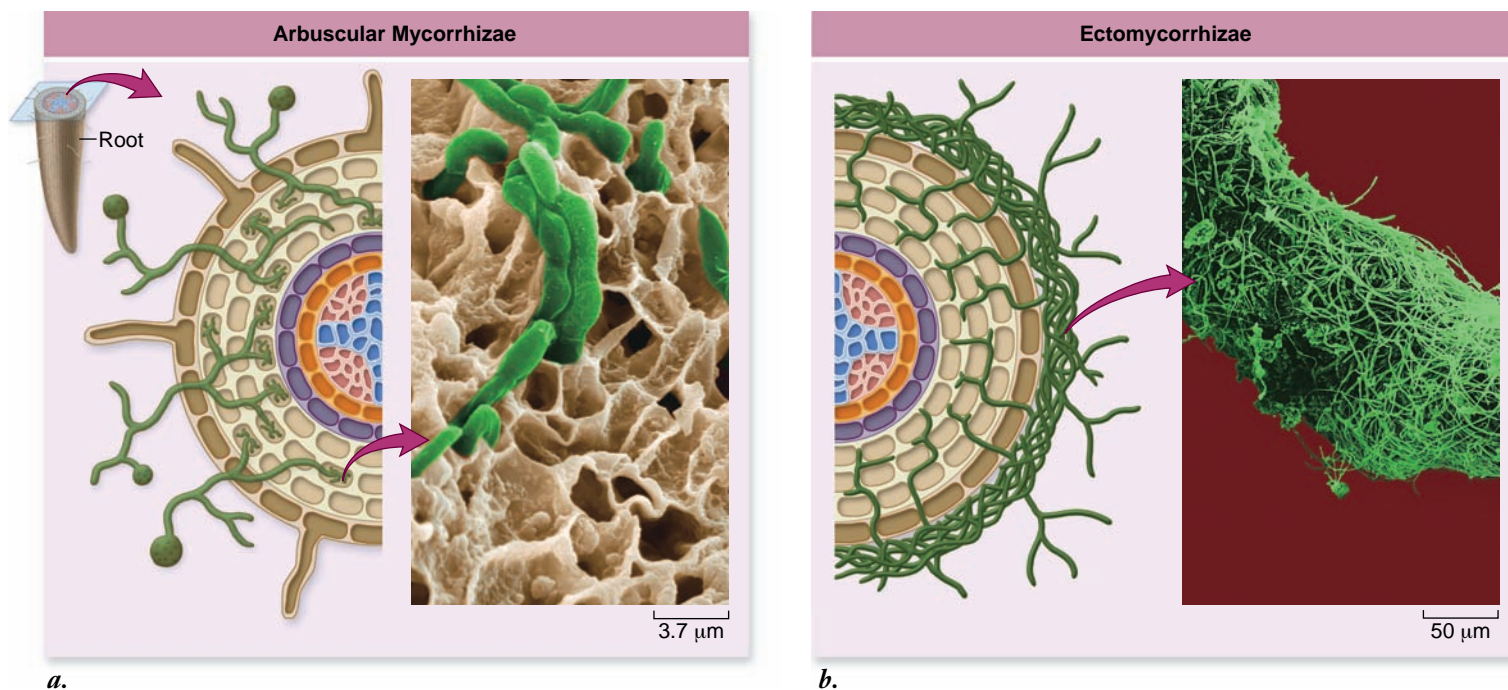

### Ectomycorrhizae

Ectomycorrhizae (see figure 31.17*b*) involve far fewer kinds of plants than do arbuscular mycorrhizae—perhaps a few thousand. Most ectomycorrhizal hosts are forest trees, such as pines, oaks, birches, willows, eucalyptus, and many others. The fungal components in most ectomycorrhizae are basidiomycetes, but some are ascomycetes.

Most ectomycorrhizal fungi are not restricted to a single species of plant, and most ectomycorrhizal plants form associations with many ectomycorrhizal fungi. Different combinations have different effects on the physiological characteristics of the plant and its ability to survive under different environmental conditions. At least 5000 species of fungi are involved in ectomycorrhizal relationships.

### Fungi also form mutual symbioses with animals

A range of mutualistic fungal–animal symbioses has been identified. Ruminant animals host neocallimastigomycete fungi in

**Figure 31.17 Arbuscular mycorrhizae and ectomycorrhizae.** *a.* In arbuscular mycorrhizae, fungal hyphae penetrate the root cell wall of plants but not the plant membranes. *b.* Ectomycorrhizae on the roots of a *Eucalyptus* tree do not penetrate root cells, but grow around and extend between the cells.

**Figure 31.18** Ant–fungal symbiosis. Ants farming their fungal garden.

their gut. The fungus gains a nutrient-rich environment in exchange for releasing nutrients from grasses with high cellulose and lignin content.

One tripartite symbiosis involves ants, plants, and fungi. Leaf-cutter ants are the dominant herbivore in the New World tropics. These ants, members of the phylogenetic tribe Attini, have an obligate symbiosis with specific fungi that they have domesticated and maintain in an underground garden. The ants provide fungi with leaves to eat and protection from pathogens and other predators (figure 31.18). The fungi are the ants' food source.

Depending on the species of ant, the ant nest can be as small as a golf ball or as large as 50 cm in diameter and many feet deep. Some nests are inhabited by millions of leaf-cutter ants that maintain fungal gardens. These social insects have a caste system, and different ants have specific roles. Traveling on trails as long as 200 m, leaf-cutter ants search for foliage for their fungi. A colony of ants can defoliate an entire tree in a day. This ant farmer–fungi symbiosis has evolved multiple times and may have occurred as early as 50 MYA.

*a.*

www.ravenbiology.com

### Learning Outcomes Review 31.8

Fungi are the primary decomposers in ecosystems. A range of symbiotic relationships have evolved between fungi and plants. Endophytes live inside tissues of a plant and may protect it from parasites. Lichens are a complex symbiosis between fungal species and cyanobacteria or green algae. Mycorrhizal associations between fungi and plant roots are mutually beneficial and in some cases are obligate symbioses. Fungi have also coevolved with animals in mutualistic relationships.

- How might the symbiosis between fungi and ants have evolved?

## 31.9 Fungal Parasites and Pathogens

### Learning Outcomes

1. Review the pathogenic effects of fungi and the targets they affect.
2. Explain why treating fungal disease in animals is particularly difficult.

Fungi can destroy a crop of plants and create significant problems for human health. A major problem in treatment and prevention is that fungi are eukaryotes, as are plants and animals. Understanding how fungi are distinct from these other two eukaryotic kingdoms may lead to safer and more efficient means of treating diseases caused by fungal parasites and pathogens.

### Fungal infestation can harm plants and those who eat them

Fungal species cause many diseases in plants (figure 31.19), and they are responsible for billions of dollars in agricultural losses

*b.*

*c.*

### Figure 31.19 World's largest organism?

*a.* *Armillaria*, a pathogenic fungus shown here afflicting three discrete regions of coniferous forest in Montana, grows out from a central focus as a single, circular clone. The large patch at the bottom of the picture is almost 8 hectares. *b.* Closeup of tree destroyed by *Armillaria*. *c.* *Armillaria* growing on a tree.

every year. Not only are fungi among the most harmful pests of living plants, but they also spoil food products that have been harvested and stored. In addition, fungi often secrete substances into the foods they are infesting that make these foods unpalatable, carcinogenic, or poisonous.

Pathogenic fungal–plant symbioses are numerous, and fungal pathogens of plants can also harm the animals that consume the plants. *Fusarium* species growing on spoiled food produce highly toxic substances, including vomitoxin, which has been implicated in brain damage in humans and animals in the southwestern United States.

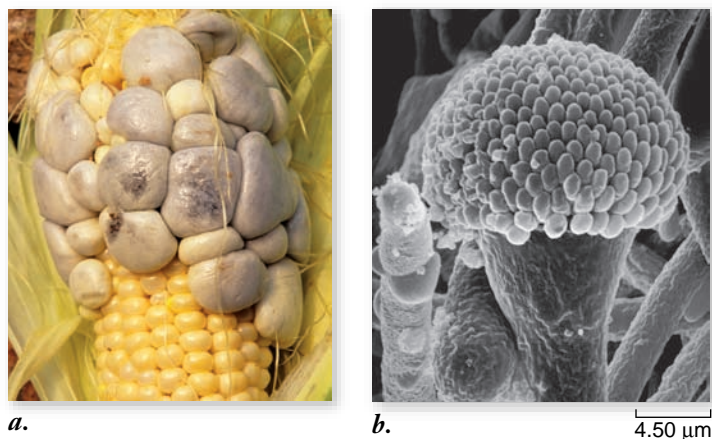

Aflatoxins, which are among the most carcinogenic compounds known, are produced by some *Aspergillus flavus* strains growing on corn, peanuts, and cotton seed (figure 31.20). Aflatoxins can also damage the kidneys and the nervous system of animals, including humans. Most developed countries have legal limits on the concentration of aflatoxin permitted in different foods. More recently, aflatoxins have been considered as possible bioterrorism agents.

In contrast, corn smut is a maize fungal disease that is harmful to the plant, but not animals that consume it (figure 31.20). Corn smut is caused by the basidiomycete *Ustilago maydi* and is edible.

## Fungal infections are difficult to treat in humans and other animals

Human and animal diseases can also be fungal in origin. Some common diseases, such as ringworm (which is not a worm but a fungus), athlete’s foot, and nail fungus, can be treated with topical antifungal ointments and in some cases with oral medication.

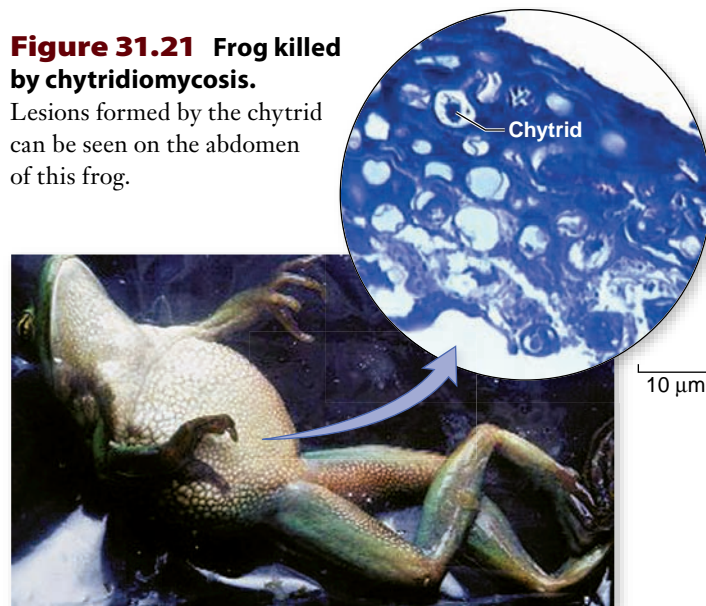

Fungi can create devastating human diseases that are often difficult to treat because of the close phylogenetic relationship between fungi and animals. Yeast ascomycetes are important pathogens that cause diseases such as thrush, an infection of the mouth; the yeast *Candida* causes common oral or vaginal infections. *Pneumocystis jiroveci* (formerly *P. carinii*) invades the lungs, disrupting breathing, and can spread to other organs. In immune-suppressed AIDS patients, this infection can lead to death.

**Figure 31.20** Maize (corn) fungal infections. *a.* *Ustilago maydis* infections of maize are a delicacy in Hispanic cuisine. *b.* A photomicrograph of *Aspergillus flavus* conidia. *Aspergillus flavus* infects maize and can produce aflatoxins that are harmful to animals.

## Figure 31.21 Frog killed by chytridiomycosis.

Lesions formed by the chytrid can be seen on the abdomen of this frog.

Mold allergies are common, and mold-infested “sick” buildings pose concerns for inhabitants. Individuals with suppressed immune systems and people undergoing steroid treatments for inflammatory disorders are particularly at risk for fungal disease.

An example of a parasitic fungal–animal symbiosis is **chytridiomycosis**, first identified in 1998 as an emerging infectious disease of amphibians. Amphibian populations have been declining worldwide for over three decades. The many possible causes for the decline in amphibian numbers are covered in chapter 60. In this chapter, a primary causative agent, fungal infection, is explored. The decline correlates with the presence of the chytrid *Batrachochytrium dendrobatidis* encased in the skin (figure 31.21), identified after extensive studies of frog carcasses. Sick and dead frogs were more likely than healthy frogs to have flasklike structures encased in their skin, which proved to be associated with chytrid spore production (see figure 31.21).

The connection with *B. dendrobatidis* has been supported by DNA sequence data, by isolating and culturing the chytrid, and by infecting healthy frogs with the organism and replicating disease symptoms. The *B. dendrobatidis* genome has now been sequenced. The infection reduces sodium and potassium transport across the skin, altering electrolyte balance which leads to cardiac arrest. Bathing frogs in antifungal drugs can halt the disease or even eliminate the chytrids.

How the disease emerged simultaneously on different continents is a yet unsolved mystery. Both environmental change and carriers are being considered.

### Learning Outcomes Review 31.9

Fungi can severely harm or kill both plants and animals, either by direct infection or by secretion of toxins and carcinogens. Treatment of fungal disease and parasitism in animals is made difficult by the close relationship between fungi and animals; what is damaging to the fungus may also have ill effects on the host.

- What is likely to be the most common mechanism for the spread of fungal disease?

## Chapter Review

### 31.1 Defining Fungi

Fungi are more closely related to animals than to plants and form seven monophyletic phyla (see figure 31.1).

Fungi are heterotrophic and have hyphal cells; their cell walls contain chitin. They may have a dikaryon stage and undergo nuclear mitosis.

**The body of a fungus is a mass of connected hyphae.**

A mass of connected hyphae is termed a mycelium. Hyphae can be continuous and multinucleate, or they may be divided into long chains of cells separated by cross-walls called septa.

The chitin found in fungi cell walls is the same material found in the exoskeletons of arthropods.

**Fungal cells may have more than one nucleus.**

A hypha with only one nucleus is monokaryotic; a hypha with two nuclei is dikaryotic. The two haploid nuclei exist independently, but both genomes are transcribed so that some properties of diploids may be observed.

**Mitosis is not followed by cell division.**

Because cells are linked, the cell is not the relevant unit of reproduction, but rather the nucleus is. The spindle forms inside the nuclear envelope, which does not break down and re-form.

**Fungi can reproduce both sexually and asexually.**

Fungi can reproduce sexually by fusion of hyphae from two compatible mating types or hyphae from the same fungus. Spores can form either by asexual or sexual reproduction and are usually dispersed by the wind.

**Fungi are heterotrophs that absorb nutrients.**

Fungi obtain their nutrients through excreting enzymes for external digestion and then absorbing the products.

### 31.2 Microsporidia: Unicellular Parasites

Microsporidia are obligate cellular parasites that lack mitochondria but may have had them at one time; they were previously classed with the protists.

### 31.3 Chytridiomycota and Relatives: Fungi with Flagellated Zoospores

Chytrids form symbiotic relationships; they have been implicated in the decline of amphibian species.

**Blastocladiomycota have single flagella.**

*Allomyces*, a blastocladiomycete, is an example of a fungus with a haplodiplontic life cycle.

**Neocallimastigomycota digest cellulose in ruminant herbivores.**

Neocallimastigomycetes have enzymes that can digest cellulose and lignin; they may have uses in production of biofuels.

### 31.4 Zygomycota: Fungi That Produce Zygotes

**In sexual reproduction, zygotes form inside a zygosporangium.**

Zygomycetes all produce a diploid zygote. In sexual reproduction, fusion (karyogamy) of the haploid nuclei of gametangia produces diploid zygote nuclei. These become zygosporangia.

**Asexual reproduction is more common.**

Sporangia produce haploid spores that are airborne; bread mold is a common example of a zygomycete.

### 31.5 Glomeromycota: Asexual Plant Symbionts

Glomeromycete hyphae form intracellular associations with plant roots and are called arbuscular mycorrhizae.

The glomeromycetes show no evidence of sexual reproduction.

### 31.6 Basidiomycota: The Club (Basidium) Fungi

The basidiocarp is the visible reproductive structure of this group, which includes mushrooms, toadstools, puffballs, and others.

**Basidiomycetes sexually reproduce within basidia (see figure 31.11).**

Karyogamy occurs within the basidia, giving rise to a diploid cell. Meiosis then ultimately results in four haploid basidiospores.

**The secondary mycelium of basidiomycetes is heterokaryotic.**

Primary mycelium is monokaryotic, but different mating types may fuse to form the secondary mycelium. Maintenance of two haploid genomes allows greater genetic plasticity.

### 31.7 Ascomycota: The Sac (Ascus) Fungi

**Sexual reproduction occurs within the ascus (see figure 31.12).**

Karyogamy occurs only in the ascus and results in a diploid nucleus. Meiosis and mitosis then result in eight haploid nuclei in walled ascospores.

**Asexual reproduction occurs within conidiophores.**

Asexual reproduction is very common and occurs by means of conidia formed at the end of modified hyphae called conidiophores.

**Some ascomycetes have yeast morphology.**

Yeasts usually reproduce by cell fission or budding.

**Ascomycete genetics and genomics have practical applications.**

### 31.8 Ecology of Fungi

Fungi are organisms capable of breaking down cellulose and lignin.

**Fungi have a range of symbioses.**

Fungi can be pathogenic or parasitic, commensal or mutualistic.

**Endophytes live inside plants and may protect plants from parasites.**

**Lichens are an example of symbiosis between different kingdoms.**

A lichen is composed of a fungus, usually an ascomycete, along with cyanobacteria, green algae, or both.

**Mycorrhizae are fungi associated with roots of plants.**

Arbuscular mycorrhizae are common and involve glomeromycetes; ectomycorrhizae are primarily found in forest trees and involve basidiomycetes and a few ascomycetes.

**Fungi also form mutual symbioses with animals.**

Some ants grow “farms” of fungi by providing plant material.

### 31.9 Fungal Parasites and Pathogens

**Fungal infestation can harm plants and those who eat them.**

Fungi spread via spores and can secrete chemicals that make food unpalatable, carcinogenic, or poisonous.

**Fungal infections are difficult to treat in humans and other animals.**

Treatment of fungal diseases in animals is difficult because of the similarities between the two kingdoms.

## Review Questions

### UNDERSTAND

- Which of the following is not a characteristic of a fungus?
  - Cell walls made of chitin
  - A form of mitosis different from plants and animals
  - Ability to conduct photosynthesis
  - Filamentous structure
- A fungal cell that contains two genetically different nuclei would be classified as
  - monokaryotic.
  - bikaryotic.
  - homokaryotic.
  - heterokaryotic.
- Which of the following groups of fungi is *not* monophyletic?
  - Zygomycota
  - Basidiomycota
  - Glomeromycota
  - Ascomycota
- Based on physical characteristics, the \_\_\_\_\_ represent the most ancient phylum of fungi.
  - Basidiomycota
  - Zygomycota
  - Ascomycota
  - Chytridiomycota
- The early evolution of terrestrial plants was made possible by mycorrhizal relationships with the
  - Zygomycetes.
  - Glomeromycota.
  - Ascomycota.
  - Basidiomycota.
- Symbiotic relationships occur between the fungi and
  - plants.
  - bacteria.
  - animals.
  - all of the above.
- Which of the following species of fungi is not associated with diseases in humans?
  - Pneumocystis jiroveci*
  - Aspergillus flavus*
  - Candida albicans*
  - Batrachochytrium dendrobatidis*

### APPLY

- In a culture of hyphae of unknown origin you notice that the hyphae lack septa and that the fungi reproduce asexually by using clumps of erect stalks. However, at times sexual reproduction can be observed. To what group of fungi would you assign it?
  - Chytridiomycota
  - Basidiomycota
  - Ascomycota
  - Zygomycota
- Examine the life cycle of a typical basidiomycetes and determine where you would expect to find a dikaryotic cell.
  - Primary mycelium
  - Secondary mycelium
  - In the basidiospores
  - In the zygote

- Determine which of the following is correct regarding the yeast *Saccharomyces cerevisiae*.
  - It reproduces asexually by a process called budding.
  - It produces an ascocarp during reproduction.
  - It belongs in the group Zygomycota.
  - All of the above are correct.
- Appraise the fungal relationship between a forest tree and a basidiomycetes and determine the most suitable classification for the symbiosis.
  - Parasitism only
  - An arbuscular mycorrhizae
  - Ectomycorrhizae
  - A lichen
- Choose which of the following best reflects the symbiotic relationships between animals and fungi.
  - Protection from bacteria
  - Colonization of land
  - Protection from desiccation
  - Exchange of nutrients

### SYNTHESIZE

- Historically fungi have been classified as being more plantlike despite their lack of photosynthetic ability. Although we now know that fungi are more closely related to the animals than the plants, review characteristics that initially led scientists to place them closer to the plants.
- The importance of fungi in the evolution of terrestrial life is typically understated. Evaluate the importance of fungi in the colonization of land.
- Based on your understanding of fungi, hypothesize why antibiotics won't work in the treatment of a fungal infection.

Chapter **32**

# Overview of Animal Diversity

## Chapter Outline

---

- 32.1** Some General Features of Animals
- 32.2** Evolution of the Animal Body Plan
- 32.3** The Classification of Animals
- 32.4** The Roots of the Animal Tree of Life

## Introduction

---

*We now explore the great diversity of modern animals, the result of a long evolutionary history. Animals are among the most abundant living organisms. Found in almost every habitat, they bewilder us with their diversity in form, habitat, behavior, and lifestyle. About a million and a half species have been described, and several million more are thought to await discovery. Despite their great diversity, animals have much in common. For example, locomotion is a distinctive characteristic, although not all animals can move about. Early naturalists thought that sponges and corals were plants because the adults are attached to the surface on which they live.*

## 32.1 Some General Features of Animals

### Learning Outcome

1. Identify three features that characterize all animals and three that characterize only some types of animals.

Animals are so diverse that few criteria fit them all. But some, such as animals being eaters, or consumers, apply to all. Others, such as their being mobile (they can move about) have excep-

tions. Taken together, the universal characteristics and other features of major importance that have exceptions are convincing evidence that animals are monophyletic—that they descended from a common ancestor. Table 32.1 describes the general features of animals.

### Learning Outcome Review 32.1

All animals are multicellular and heterotrophic, and their cells lack cell walls. Most animals can move from place to place, can reproduce sexually, and possess unique tissues. Animals can be found in almost all habitats.

- What evidence is there that animals could not have been the first type of life to have evolved?

**TABLE 32.1** General Features of Animals

**Heterotrophy.** All animals are heterotrophs—that is, they obtain energy and organic molecules by ingesting other organisms. Unlike autotrophic plants and algae, animals cannot construct organic molecules from inorganic chemicals. Some animals (herbivores) consume autotrophs; other animals (carnivores) consume heterotrophs; some animals (omnivores) consume both autotrophs and heterotrophs; and still others (detritivores) consume decomposing organisms.

**Multicellularity.** All animals are multicellular; many have complex bodies like that of this jellyfish (phylum Cnidaria). The unicellular heterotrophic organisms called Protozoa, which were at one time regarded as simple animals, are now considered members of the large and diverse kingdom Protista, discussed in chapter 29.

**No Cell Walls.** Animal cells differ from those of other multicellular organisms: they lack rigid cell walls and are usually quite flexible. The many cells of animal bodies are held together by extracellular frames of structural proteins such as collagen. Other proteins form unique intercellular junctions between animal cells.

**Active Movement.** Animals move more rapidly and in more complex ways than members of other kingdoms—this ability is perhaps their most striking characteristic, one directly related to the flexibility of their cells and the evolution of nerve and muscle tissues. A remarkable form of movement unique to animals is flying, a capability that is well developed among vertebrates and insects such as this butterfly (phylum Arthropoda). Many animals cannot move from place to place (they are sessile) or do so rarely or slowly (they are sedentary) although they have muscles or muscle fibers that allow parts of their bodies to move. Sponges, however, have little capacity for movement.

**TABLE 32.1** General Features of Animals, *continued*

**Diversity in Form.** Animals vary greatly in form, ranging in size from organisms too small to see with the unaided eye to enormous whales and giant squids. Almost all animals, like this millipede (phylum Arthropoda), lack a backbone—they are therefore called invertebrates. Of the million known living animal species, only 42,500 have a backbone—they are therefore referred to as **vertebrates**. Probably most of the many millions of animal species awaiting discovery are invertebrates.

**Diversity in Habitat.** The animal kingdom is divided into 35–40 phyla, most of which have members that occur only in the sea like this brittlestar (phylum Echinodermata). Members of fewer phyla occur in fresh water, and members of fewer still occur on land. Members of three phyla that are successful in the marine environment—Arthropoda, Mollusca, and Chordata—also dominate animal life on land. Only one animal phylum, Onychophora (velvet worms) is entirely terrestrial.

**Sexual Reproduction.** Most animals reproduce sexually; these tortoises (phylum Chordata) are engaging in the first step of that process. Animal eggs, which are nonmobile, are much larger than the small, usually flagellated sperm. In animals, cells formed in meiosis function as gametes. These haploid cells do not divide by mitosis first, as they do in plants and fungi, but rather fuse directly with each other to form the zygote. Consequently, there is no counterpart among animals to the alternation of haploid (gametophyte) and diploid (sporophyte) generations characteristic of plants. Some individuals of some species and all individuals of a very few animal species are incapable of sexual reproduction.

**Embryonic Development.** An animal zygote first undergoes a series of mitotic divisions, called *cleavage*, and like this dividing frog's egg, that produces a ball of cells, the **blastula**. In most animals, the blastula folds inward at one point to form a hollow sac with an opening at one end called the **blastopore**. An embryo at this stage is called a **gastrula**. The subsequent growth and movement of the cells of the gastrula differ from one group of animals to another, reflecting the evolutionary history of the group. Embryos of most kinds of animals develop into a larva, which looks unlike the adult of the species, lives in a different habitat, and eats different sorts of food; in most groups, it is very small. A larva undergoes metamorphosis, a radical reorganization, to transform into the adult body form.

**Tissues.** The cells of all animals except sponges are organized into structural and functional units called **tissues**, collections of cells that together are specialized to perform specific tasks. Animals are unique in having two tissues associated with movement: (1) muscle tissue, which contracts, and (2) nervous tissue, which conducts signals among cells. Neuromuscular junctions, where nerves connect with muscle tissue, are shown here.

## 32.2 Evolution of the Animal Body Plan

### Learning Outcomes

1. Differentiate between a pseudocoelom and a coelom.
2. Explain the difference between protostomes and deuterostomes.
3. Describe the advantages of segmentation.

The features described in the preceding section evolved over the course of millions of years. We can understand how the history of life has proceeded by examining the types of animal bodies and body plans present in fossils and in existence today.

Five key innovations can be noted in animal evolution:

1. The evolution of symmetry
2. The evolution of tissues, allowing specialized structures and functions
3. The evolution of a body cavity
4. The evolution of various patterns of embryonic development
5. The evolution of segmentation, or repeated body units

These innovations are explained in the sections that follow. Some innovations appear to have evolved only once, some twice or more. Scientists use an innovation that evolved once as evidence that all the animals possessing it are more closely related to one another than they are to any animal lacking the innovation. The animals with the innovation and their ancestor in which the innovation arose are said to constitute a clade—an evolutionarily coherent group (see chapter 23). On the other hand, some innovations evolve more than once in different clades. This is the phenomenon of convergent evolution (see chapter 23). Although not indicative of close evolutionary relationship, convergently evolved innovations may be important to how species have adapted to their environments.

### Most animals exhibit radial or bilateral symmetry

A typical sponge lacks definite symmetry, growing as an irregular mass. Virtually all other animals have a definite shape and symmetry that can be defined along an imaginary axis drawn through the animal's body. The two main types of symmetry are radial and bilateral.

#### Radial symmetry

The body of a member of phylum Cnidaria (jellyfish, sea anemones, and corals: the C of Cnidaria is silent; see chapter 34) exhibits **radial symmetry**. Its parts are arranged in such a way that any longitudinal plane passing through the central axis divides the organism into halves that are approximate mirror images (figure 32.1*a*). A pie, for example, is radially symmetrical. In cnidarians such as corals and sea anemones, the mouth is not circular, but oval, because it opens into a sort of throat that is like a flattened sleeve. Thus there are two planes that divide the body into mirror-

*a.*

*b.*

**Figure 32.1** A comparison of radial and bilateral symmetry. *a.* Radially symmetrical animals, such as this sea anemone (phylum Cnidaria), can be bisected into equal halves by any longitudinal plane that passes through the central axis. *b.* Bilaterally symmetrical animals, such as this turtle (phylum Chordata), can only be bisected into equal halves in one plane (the sagittal plane).

image halves, one along the mouth and one perpendicular to it; these animals are actually biradially symmetrical (figure 32.1*b*).

#### Bilateral symmetry

The bodies of most animals other than sponges and cnidarians exhibit **bilateral symmetry**, in which the body has right and left halves that are mirror images of each other. Animals with this body plan are collectively termed the Bilateria. The sagittal plane defines these halves. A bilaterally symmetrical body has, in addition to left and right halves, dorsal and ventral portions, which are divided by the frontal plane, and anterior (front) and posterior (rear) ends, which are divided by the transverse plane (in an animal that walks on all fours, dorsal is the top side). In echinoderms (sea stars and their relatives), adults are radially symmetrical (actually pentaradially symmetrical, because the body has five clear sections), but the larvae are bilaterally symmetrical.

Bilateral symmetry constitutes a major evolutionary advance in the animal body plan. Bilaterally symmetrical animals have the ability to move through the environment in a consistent direction (typically with the anterior end leading)—a feat that is difficult for radially symmetrical animals. Associated with directional movement is the grouping of nerve cells into a brain, and sensory structures, such as eyes and ears, at the anterior end of the body. This concentration of nervous tissue at the anterior end, which appears to have occurred early in evolution, is called **cephalization**. Much of the layout of the nervous system in bilaterally symmetrical animals is centered on one or more major longitudinal nerve cords that transmit information from the anterior sense organs and brain to the rest of the body. Cephalization is often considered a consequence of the development of bilateral symmetry.

## The evolution of tissues allowed for specialized structures and functions

The zygote (a fertilized egg), has the capability to give rise to all the kinds of cells in an animal's body. That is, it is totipotent (all powerful). During embryonic development, cells specialize to carry out particular functions. In all animals except sponges, the process is irreversible: once a cell differentiates to serve a function, it and its descendants can never serve any other.

A sponge cell that had specialized to serve one function (such as lining the cavity where feeding occurs) can lose the special attributes that serve that function and change to serve another function (such as being a gamete). Thus a sponge cell can dedifferentiate and redifferentiate. Cells of all other animals are organized into tissues, each of which is characterized by cells of particular morphology and capability. But their competence to dedifferentiate prevents sponge cells from forming clearly defined tissues (and therefore, of course, organs, which are composed of tissues).

Because cells differentiate irreversibly in all animals except sponges, scientists infer that bodies containing cells specialized to serve particular functions have an advantage compared to those with cells that potentially have multiple functions. Judging by the relative diversity of animals with specialized tissues and those lacking them, tissues are a favorable adaptation. Presumably the advantage to the animal is embodied in the old adage “Jack of all trades, master of none.”

## A body cavity made possible the development of advanced organ systems

In the process of embryonic development, the cells of animals of most groups organize into three layers (called germ layers): an outer **ectoderm**, an inner **endoderm**, and an intermediate **mesoderm**. Animals with three embryonic cell layers are said to be triploblastic. Part of the maturation from the embryo is that certain organs and organ systems develop from each germ layer. The ectoderm gives rise to the outer covering of the body and the nervous system; the endoderm gives rise to the digestive system, including the intestine; and the skeleton and muscles develop from the mesoderm. Cnidarians have only two layers (thus they are diploblastic), the endoderm and the ectoderm, and lack organs. Sponges lack germ layers altogether; they, of course, have no tissues or organs. All triploblastic animals are members of the Bilateria.

A key innovation in the body plan of some bilaterians was a body cavity isolated from the exterior of the animal. This is different from the digestive cavity, which is open to the exterior at least through the mouth, and in most animals at the opposite end as well, via the anus. The evolution of efficient organ systems within the animal body was not possible until a body cavity evolved for accommodating and supporting organs (such as our heart and lungs), distributing materials, and fostering complex developmental interactions. The cavity is filled with fluid: in most animals, the fluid is liquid, but in vertebrates, it is gas—the body cavity of humans filling with liquid is a life-threatening condition. A very few types of bilaterians have no body cavity, the space between tissues that develop from the mesoderm and those that develop from the endoderm being filled with cells and connective tissue. These are the so-called acoelomate animals (figure 32.2).

**Figure 32.2 Three body plans for bilaterally symmetrical animals.** Acoelomates, such as flatworms, have no body cavity between the digestive tract (derived from the endoderm) and the musculature layer (derived from the mesoderm). Pseudocoelomates have a body cavity, the pseudocoelom, between tissues derived from the endoderm and those derived from the mesoderm. Coelomates have a body cavity, the coelom, that develops entirely within tissues derived from the mesoderm, and so is lined on both sides by tissue derived from the mesoderm.

## Body cavities

Body cavities appear to have evolved multiple times in the Bilateria (see figure 32.2). A body cavity called the **pseudocoelom** develops embryologically between mesoderm and endoderm, so occurs in the adult between tissues derived from the mesoderm and those derived from endoderm; animals with this type of body cavity are termed pseudocoelomates. Although the word *pseudocoelom* means “false coelom,” this is a true body space and characterizes many successful groups of animals. A **coelom** is a cavity that develops entirely within the mesoderm. The coelom is surrounded by a layer of epithelial cells derived from the mesoderm and termed the peritoneum.

Zoologists previously inferred that the first animals were acoelomate, that some of their descendants evolved a pseudocoelom, and that some pseudocoelomate descendants evolved the coelom. However, as you saw in chapter 21, evolution rarely occurs in such a linear and directional way. Rather, pseudocoeloms seem to have evolved several times, and some animals have lost the body space, becoming acoelomate secondarily. However, a coelom appears to have evolved just once. Thus, species possessing a coelom form a clade, but those with a pseudocoelom do not.

## The circulatory system

In many small animals, nutrients and oxygen are distributed and wastes are removed by fluid in the body cavity. Most larger animals, in contrast, have a **circulatory system**, a network of vessels that carry fluids to and from the parts of the body distant from the sites of digestion (gut) and gas exchange (gills or lungs). The circulating fluid carries nutrients and oxygen to the tissues and removes wastes, including carbon dioxide, by diffusion between the circulatory fluid and the other cells of the body.

In an **open circulatory system**, the blood passes from vessels into sinuses, mixes with body fluid that bathes the cells of tissues, then reenters vessels in another location. In a **closed circulatory system**, the blood is entirely confined to blood vessels, so is physically separated from other body fluids. Blood moves through a closed circulatory system faster and more efficiently than it does through an open system; open systems are typical of animals that are relatively inactive and so do not have a high demand for oxygen. In small animals, blood can be pushed through a closed circulatory system by movement of the animal. In larger animals, the body musculature does not provide enough force, so the blood must be propelled by contraction of one or more hearts, which are specialized, muscular parts of the blood vessels.

## Bilaterians have two main types of development

The processes of embryonic development in animals is discussed fully in chapter 54. Briefly, development of a bilaterally symmetrical animal begins with mitotic cell divisions (called cleavages) of the egg that lead to the formation of a hollow ball of cells, which subsequently indents to form a two-layered ball. The internal space that is created through such indentation (figure 54.11) is the **archenteron** (literally

the “primitive gut”); it communicates with the outside by a **blastopore**.

In a protostome, the mouth of the adult animal develops from the blastopore or from an opening near the blastopore (protostome means “first mouth”—the first opening becomes the mouth). **Protostomes** include most bilaterians, including flatworms, nematodes, mollusks, annelids, and arthropods. In some protostomes, both mouth and anus form from the embryonic blastopore; in other protostomes, the anus forms later in another region of the embryo. Two outwardly dissimilar groups, the echinoderms and the chordates, together with a few other small phyla, constitute the **deuterostomes**, in which the mouth of the adult animal does not develop from the blastopore. The deuterostome blastopore gives rise to the organism’s anus, and the mouth develops from a second pore that arises later in development (deuterostome means “second mouth”). Protostomes and deuterostomes differ in several other aspects of embryology too, as discussed later.

## Cleavage patterns

The cleavage pattern relative to the embryo’s polar axis determines how the resulting cells lie with respect to one another. In some protostomes, each new cell cleaves off at an angle oblique to the polar axis. As a result, a new cell nestles into the space between the older ones in a closely packed array. This pattern is called **spiral cleavage** because a line drawn through a sequence of dividing cells spirals outward from the polar axis (figure 32.3 top). Spiral cleavage is characteristic of annelids, mollusks, nemertean, and related phyla; the clade of animals with this cleavage pattern is therefore known as the Spiralia.

In all deuterostomes, by contrast, the cells divide parallel to and at right angles to the polar axis. As a result, the pairs of cells from each division are positioned directly above and below one another, a process that gives rise to a loosely packed ball. This pattern is called **radial cleavage** because a line drawn through a sequence of dividing cells describes a radius outward from the polar axis (figure 32.3 bottom).

## Determinate versus indeterminate development

Many protostomes exhibit **determinate development**, in which the type of tissue each embryonic cell will form in the adult is determined early, in many lineages even before cleavage begins, when the molecules that act as developmental signals are localized in different regions of the egg. Consequently, the cell divisions that occur after fertilization segregate molecular signals into different daughter cells, specifying the fate of even the very earliest embryonic cells. Each embryonic cell is destined to occur only in particular parts of the adult body, so if the cells are separated, development cannot proceed.

Deuterostomes, on the other hand, display **indeterminate development**. The first few cell divisions of the zygote produce identical daughter cells. If the cells are separated, any one can develop into a complete organism because the molecules that signal the embryonic cells to develop differently are not segregated in different cells until later in the embryo’s development. (This is how identical twins are formed.) Thus, each cell remains totipotent and its fate is not determined for several cleavages.

**Figure 32.3 Embryonic development in protostomes and deuterostomes.** In spiralian protostomes, embryonic cells cleave in a spiral pattern and exhibit determinate development; the blastopore becomes the animal's mouth, and the coelom originates from a split among endodermal cells. In deuterostomes, embryonic cells cleave radially and exhibit indeterminate development; the blastopore becomes the animal's anus, and the coelom originates from an invagination of the archenteron.

### Formation of the coelom

The coelom arises within the mesoderm. In protostomes, cells simply move apart from one another to create an expanding coelomic cavity within the mass of mesodermal cells. In deuterostomes, groups of cells pouch off the end of the archenteron, which you will recall is the primitive gut—the hollow in the center of the developing embryo that is lined with endoderm.

The consistency of deuterostome development and its distinctiveness from that of the protostomes suggest that it evolved once, in the ancestor of the deuterostome phyla. The mode of development in protostomes is more diverse, but because of the distinctiveness of spiral development, scientists infer it also evolved once, in the common ancestor to all spiralian phyla.

### Segmentation allowed for redundant systems and improved locomotion

Segmented animals consist of a series of linearly arrayed compartments that typically look alike (see figure 34.14), at least

early in development, but that may have specialized functions. Development of segmentation is mediated at the molecular level by *Hox* genes (see chapters 19 and 25, and in section 32.4). During early development, segments first are obvious in the mesoderm but later are reflected in the ectoderm and endoderm. Two advantages result from early embryonic segmentation:

1. In highly segmental animals, such as earthworms (phylum Annelida), each segment may develop a more or less complete set of adult organ systems. Because these are redundant systems, damage to any one segment need not be fatal because other segments duplicate the damaged segment's functions.
2. Locomotion is more efficient when individual segments can move semi-independently. Because partitions isolate the segments, each can contract or expand autonomously. Therefore, a long body can move in ways that are often quite complex.

**Segmentation** underlies the organization of body plans of the most morphologically complex animals. In some adult

arthropods, the segments are fused, but segmentation is usually apparent in embryological development. In vertebrates, the backbone and muscle blocks are segmented, although segmentation is often disguised in the adult form.

Previously, zoologists considered that true segmentation was found only in annelids, arthropods, and chordates, but segmentation is now recognized to be more widespread. Animals such as onychophorans (velvet worms), tardigrades (water bears), and kinorhynchans (mud dragons) are also segmented.

### Learning Outcomes Review 32.2

Animals are distinguished on the basis of symmetry, tissues, type of body cavity, sequence of embryonic development, and segmentation. A pseudocoelom is a space that develops between the mesoderm and endoderm; a coelom develops entirely within mesoderm. In bilaterians, protostomes develop the mouth prior to the anus; deuterostomes develop the mouth after the anus has formed. Segmentation allows redundant systems and more efficient locomotion.

- How is cephalization related to body symmetry?

## 32.3 The Classification of Animals

### Learning Outcomes

1. List the major criteria scientists have used to distinguish animal phyla.
2. Distinguish between spiralian and ecdysozoan organisms.
3. Identify the placement of humans among the animal phyla.

Multicellular animals, or metazoans, are traditionally divided into 35 to 40 phyla (singular, *phylum*). There is little disagreement among biologists about the placement of most animals in phyla, although zoologists disagree on the status of some, particularly those with few members or recently discovered ones. The diversity of animals is obvious in tables 32.2 and 32.3, which describe key characteristics of 20 of the phyla.

Traditionally, the phylogeny of animals has been inferred using features of anatomy and aspects of embryological development, as discussed earlier, from which a broad consensus emerged over the last century concerning the main branches of the animal tree of life. In the past 30 years, data derived from molecular features have been added, leading to some rethinking of classification schemes. Depending on the features compared, biologists may draw quite different family trees—although, of course, there is only one way that evolution actually occurred, and the goal of phylogeny is to detect that history.

Whether morphological or molecular characters (or both) are used, the underlying principle is the same: systematists use features they assume to have evolved only once, so the animals sharing such a feature are inferred to be more closely

related to one another than they are to animals not sharing the feature. The shared derived characters unique to a group and its ancestors define a monophyletic assemblage termed a clade (see chapter 23). The animal phylogenetic tree viewed in these terms is a hierarchy of clades nested within larger clades, and containing smaller clades.

### Tissues and symmetry separate the Parazoa and Eumetazoa

Systematists traditionally divided the kingdom Animalia (also termed Metazoa) into two main branches. Parazoa (“near animals”) comprises animals that, for the most part, lack definite symmetry, and that do not possess tissues. These are the sponges, phylum Porifera. Because they are so different in so many ways from other animals, some scientists inferred that sponges were not closely related to other animals, which would mean that what we consider animals had two separate origins. Eumetazoa (“true animals”) are animals that have a definite shape and symmetry. All have tissues, and most have organs and organ systems. Now most systematists agree that Parazoa and Eumetazoa are descended from a common ancestor, so animal life had a single origin. And although most trees constructed including molecular data consider Parazoa to be at the base of the animal tree of life, some do not.

Further divisions are based on other key features, as discussed previously. Bilaterally symmetrical animals (which are also triploblastic) are divided into the groups Protostomia and Deuterostomia depending on whether the embryonic blastopore (see figure 32.3) becomes the mouth or the anus (or both), respectively, in the adult animal.

Animals are traditionally classified into 35 to 40 phyla. The evolutionary relationships among the animal phyla are based on the inference that phyla sharing certain fundamental morphological and molecular characters are more closely related to one another than they are to phyla not sharing those characters. Phylogenetically informative characters are inferred to have arisen only once.

### Molecular data help reveal evolutionary relationships

Gene sequence data are accumulating at an accelerating pace for all animal groups. Phylogenies developed from different molecules sometimes suggest quite different evolutionary relationships among the same groups of animals. However, combining data from multiple genes has resolved the relationships of most phyla. Current studies are using sequences from hundreds of genes to try to fully resolve the animal tree of life.

Molecular data are helping to resolve some problems with the traditional phylogeny, such as puzzling groups that did not fit well into the widely accepted phylogeny. These data may be especially helpful in clarifying relationships that conventional data cannot, as, for example, in animals such as parasites. Through dependence on their host, the anatomy, physiology, and behavior of parasites tends to be greatly altered, so features that may reveal the phylogenetic affinities of free-living animals can be highly modified or lost.

**TABLE 32.2** Animal Phyla with the Most Species

Phylum	Typical Examples		Key Characteristics	Approximate Number of Named Species
<b>Arthropoda</b> (arthropods)	Beetles, other insects, crabs, spiders, krill, scorpions, centipedes, millipedes		Chitinous exoskeleton covers segmented, coelomate body. With paired, jointed appendages; many types of insects have wings. Occupy marine, terrestrial, and freshwater habitats. Most arthropods are insects (as are most animals!).	1,000,000
<b>Mollusca</b> (mollusks)	Snails, oysters, clams, octopuses, slugs		Coelomate body of many mollusks is covered by one or more shells secreted by a part of the body termed the mantle. Many kinds possess a unique rasping tongue, a radula. Members occupy marine, terrestrial, and freshwater habitats (35,000 species are terrestrial).	110,000
<b>Chordata</b> (chordates)	Mammals, fish, reptiles, amphibians		Each coelomate individual possesses a notochord, a dorsal nerve cord, pharyngeal slits, and a postanal tail at some stage of life. In vertebrates, the notochord is replaced during development by the spinal column. Members occupy marine, terrestrial, and freshwater habitats (20,000 species are terrestrial).	56,000
<b>Platyhelminthes</b> (flatworms)	Planarians, tapeworms, liver and blood flukes		Unsegmented, acoelomate, bilaterally symmetrical worms. Digestive cavity has only one opening; tapeworms lack a gut. Many species are parasites of medical and veterinary importance. Members occupy marine, terrestrial, and freshwater habitats (as well as the bodies of other animals)	20,000
<b>Nematoda</b> (roundworms)	<i>Ascaris</i> , pinworms, hookworms, filarial worms		Pseudocoelomate, unsegmented, bilaterally symmetrical worms; tubular digestive tract has mouth and anus. Members occupy marine, terrestrial, and freshwater habitats; some are important parasites of plants and animals, including humans.	25,000 (but it is thought by some that the number of nematode species may be much greater)
<b>Annelida</b> (segmented worms)	Earthworms, polychaetes, tube worms, leeches		Segmented, bilaterally symmetrical, coelomate worms with a complete digestive tract; most have bristles (chaetae) on each segment that anchor them in tubes or aid in crawling. Occupy marine, terrestrial, and freshwater habitats.	16,000
<b>Cnidaria</b> (cnidarians)	Jellyfish, <i>Hydra</i> , corals, sea anemones, sea fans		Radially symmetrical, acoelomate body has tissues but no organs. Mouth opens into a simple digestive sac and is surrounded by tentacles armed with stinging capsules (nematocysts). In some groups, individuals are joined into colonies; some can secrete a hard exoskeleton. The very few nonmarine species live in fresh water.	10,000
<b>Echinodermata</b> (echinoderms)	Sea stars, sea urchins, sand dollars, sea cucumbers		Adult body pentaradial (fivefold) in symmetry. Water-vascular system is a coelomic space; endoskeleton of calcium carbonate plates. Many can regenerate lost body parts. Fossils are more diverse in body plan than extant species. Exclusively marine.	7000
<b>Porifera</b> (sponges)	Barrel sponges, boring sponges, basket sponges, bath sponges		Bodies of most asymmetrical: defining “an individual” is difficult. Body lacks tissues or organs, being a meshwork of cells surrounding channels that open to the outside through pores, and that expand into internal cavities lined with food-filtering flagellated cells (choanocytes). Most species are marine (150 species live in fresh water).	7000
<b>Bryozoa</b> (moss animals) (also called Polyzoa and Ectoprocta)	Sea mats, sea moss		The only exclusively colonial phylum; each colony comprises small, coelomate individuals (zooids) connected by an exoskeleton (calcareous in marine species, organic in most freshwater ones). A ring of ciliated tentacles (lophophore) surrounds the mouth of each zooid; the anus lies beyond the lophophore.	4500

**TABLE 32.3**
**Some Important Animal Phyla with Fewer Species—and Three Recently Discovered Ones**

Phylum	Typical Examples		Key Characteristics	Approximate Number of Named Species
<b>Rotifera</b> (wheel animals)	Rotifers		Small pseudocoelomates with a complete digestive tract including a set of complex jaws. Cilia at the anterior end beat so they resemble a revolving wheel. Some are very important in marine and freshwater habitats as food for predators such as fishes.	2000
<b>Nemertea</b> (ribbon worms) (also called Rhynchozoela)	<i>Lineus</i>		Protostome worms notable for their fragility—when disturbed, they fragment in pieces. Long, extensible proboscis occupies a coelomic space; that of some tipped by a spearlike stylet. Most marine, but some live in fresh water, and a few are terrestrial.	900
<b>Tardigrada</b> (water bears)	<i>Hypsibius</i>		Microscopic protostomes with five body segments and four pairs of clawed legs. An individual lives a week or less but can enter a state of suspended animation (“cryptobiosis”) in which it can survive for many decades. Occupy marine, freshwater, and terrestrial habitats.	800
<b>Brachiopoda</b> (lamp shells)	<i>Lingula</i>		Protostomous animals encased in two shells that are oriented with respect to the body differently than in bivalved mollusks. A ring of ciliated tentacles (lophophore) surrounds the mouth. More than 30,000 fossil species are known.	300
<b>Onychophora</b> (velvet worms)	<i>Peripatus</i>		Segmented protostomous worms resembling tardigrades; with a chitinous soft exoskeleton and unsegmented appendages. Related to arthropods. The only exclusively terrestrial phylum, but what are interpreted as their Cambrian ancestors were marine.	110
<b>Ctenophora</b> (sea walnuts)	Comb jellies, sea walnuts		Gelatinous, almost transparent, often bioluminescent marine animals; eight bands of cilia; largest animals that use cilia for locomotion; complete digestive tract with anal pore.	100
<b>Chaetognatha</b> (arrow worms)	<i>Sagitta</i>		Small, bilaterally symmetrical, transparent marine worms with a fin along each side, powerful bristly jaws, and lateral nerve cords. Some inject toxin into prey and some have large eyes. It is uncertain if they are coelomates, and, if so, whether protostomes or deuterostomes.	100
<b>Loricifera</b> (loriciferans)	<i>Nanaloricus mysticus</i>		Tiny marine pseudocoelomates that live in spaces between grains of sand. The mouth is borne on the tip of a flexible tube. Discovered in 1983.	10
<b>Cycliophora</b> (cycliophorans)	<i>Symbion</i>		Microscopic animals that live on mouthparts of claw lobsters. Discovered in 1995.	3
<b>Micrognathozoa</b> (micrognathozoans)	<i>Limnognathia</i>		Microscopic animals with complicated jaws. Discovered in 2000 in Greenland.	1

## Morphology- and molecule-based phylogenies agree on many major groupings

Although they differ from one another in some respects, phylogenies incorporating molecular data or based entirely on them share some deep structure with the traditional animal tree of life. Figure 32.4 is a summary of animal phylogeny developed from morphological, molecular, life-history, and other types of relevant data. Some aspects of this view have been contradicted by studies based on particular characters or using particular analytical methods. It is an exciting time to be a systematist, but shifts in understanding of relationships among groups of animals can be frustrating to some! Like any scientific idea, a phylogeny is a hypothesis, open to challenge and to being revised in light of additional data.

One consistent result is that Porifera (sponges) constitutes a monophyletic group that shares a common ancestor with other animals. Some systematists had considered sponges to comprise two (or three) groups that are not particularly closely related, but molecular data support what had been the majority view, that phylum Porifera is monophyletic. And, as mentioned earlier, all animals are found to be monophyletic.

Among eumetazoans, molecular data are in accord with the traditional view that cnidarians (hydras, sea jellies, and corals) branch off the tree before the origin of animals with bilateral symmetry. Our understanding of the phylogeny of the deuterostome branch of Bilateria (discussed in chapter 34) has not changed much, but our understanding of the phylogeny of protostomes has been altered by molecular data.

Most revolutionary is that annelids and arthropods, which had been considered closely related based on the occurrence of segmentation in both, belong to separate clades. Now arthropods are grouped with protostomes that molt their cuticles at least once during their life. These are termed ecdysozoans, which means “molting animals” (see chapter 34). Molecular sequence data can help test our ideas of which morphological features reveal evolutionary relationships best; in this case, molecular data allowed us to see that, contrary to our hypothesis, segmentation seems to have evolved convergently, but molting did not.

But not all features are easy to diagnose, and molecular data do not resolve all uncertainties. The enigmatic phylum Ctenophora (comb jellies)—pronounced with a silent C—has been considered both diploblastic and triploblastic and has been thought to have both a complete gut and a blind gut. Likewise the enigmatic phylum Chaetognatha (arrow worms) has been considered both coelomate and pseudocoelomate, and if coelomate, both protostome and deuterostome (as reflected in figure 32.4). Their placement in phylogenies varies, seeming to depend on the features and methods used to construct the tree. Further research is needed to resolve these uncertainties.

Molecular data are contributing to our understanding of relationships among animal phyla. Animals are monophyletic, as are sponges—relationships that were uncertain using only morphological data. Molecular data confirm that cnidarians branched off from the rest of animals before bilateral symmetry evolved. Although the position of ctenophores has not been

resolved, molecular data have significantly altered some ideas of protostome evolution.

## Morphology-based phylogeny focused on the state of the coelom

In the morphology-based animal family tree, bilaterally symmetrical animals comprised three major branches. If the body has no cavity (other than the gut), the animal is said to be acoelomate; members of phylum Platyhelminthes are acoelomates.

A body cavity not lined with tissue derived from mesoderm is a pseudocoelom; members of the phylum Nematoda are pseudocoelomate. A body cavity lined with tissue derived from mesoderm is a coelom; we and members of the phylum Annelida are coelomate. All acoelomates and pseudocoelomates are protostomes; some coelomates are protostomes and some are deuterostomes.

## Protostomes consist of spiralian and ecdysozoans

Two major clades of protostomes are recognized as having evolved independently since ancient times: the spiralian and the ecdysozoans (see figure 32.4).

### *Spiralia*

Spiralian animals grow by gradual addition of mass to the body. Most live in water, and propel themselves through it using cilia or contractions of the body musculature. Spiralian undergo spiral cleavage (see figure 32.3).

There are two main groups of spiralian: Lophotrochozoa and Platyzoa. Lophotrochozoa includes most coelomate protostome phyla; those animals move by muscular contractions. Most platyzoans are acoelomates; these animals are tiny or flat, and move by ciliary action. Some platyzoans (such as rotifers, gnathostomulids, and the recently discovered phylum Micrognathozoa have a set of complicated jaws. The most prominent group is phylum Platyhelminthes; a flatworm has a simple body with no circulatory or respiratory system but a complex reproductive system. This group includes marine and freshwater planarians as well as the parasitic flukes and tapeworms.

Lophotrochozoa consists of two major phyla and several smaller ones. Many of the animals have a type of free-living larva known as a **trochophore**, and some have a feeding structure termed a **lophophore**, a horseshoe-shaped crown of ciliated tentacles around the mouth used in filter-feeding. The phyla characterized by a lophophore are Bryozoa and Brachiopoda. Lophophorate animals are sessile (anchored in place).

Among the lophotrochozoans with a trochophore are phyla Mollusca and Annelida. Mollusks are unsegmented, and their coelom is reduced to a hemocoel (open circulatory space) and some other small body spaces. This phylum includes animals as diverse as octopuses, snails, and clams. Annelids are segmented coelomate worms, the most familiar of which is the earthworm, but also includes leeches and the largely marine polychaetes.

**Figure 32.4 Proposed revision of the animal tree of life.** A phylogeny of many of the 35–40 phyla reflects the consensus as of 2005 based on interpretation of anatomical and developmental data as well as results derived from molecular phylogenetic studies. Whether Chaetognatha is a protostome or a deuterostome is unclear.

### Ecdysozoa

The other major clade of protosomes is the Ecdysozoa. Ecdysozoans are animals that molt, a phenomenon that seems to have evolved only once in the animal kingdom. When an animal grows large enough that it completely fills its hard external skeleton, it must lose that skeleton (by molting, a process also called ecdysis). While the animal grows, it forms a new exoskeleton underneath the existing one. The first step in molting is for the body to swell until the existing exoskeleton cracks open and is shed (figure 32.5). Upon molting that skeleton, the animal inflates the soft, new one, expanding it using body fluids (and, in many insects and spiders, air as well). When the new one hardens, it is larger than the molted one had been and has room for growth. Thus, rather than being continuous, as in other animals, the growth of ecdysozoans is step-wise.

Of the numerous phyla of protosomes assigned to the Ecdysozoa, Arthropoda contains the largest number of described species of any phylum. Each phylum contains one of the model organisms used in laboratory studies that have informed much of our current understanding of genetics and development: the fruit fly *Drosophila melanogaster* and the roundworm *Caenorhabditis elegans*.

Arthropods are coelomate animals with jointed appendages and segmented external skeletons composed of chitin. Ar-

thropods include insects, spiders, crustaceans, and centipedes, among many others. Arthropods have colonized almost all habitats, being found from the ocean floor to the air and in all terrestrial and freshwater environments.

Roundworms are pseudocoelomate worms that lack circulatory or gas exchange structures, and their bodies have only longitudinal muscles. Nematodes inhabit marine, freshwater, and terrestrial environments, and many species are parasitic in

### Figure 32.5 Blue crab undergoing ecdysis (molting).

Members of Ecdysozoa grow step-wise because their external skeleton is rigid.

## 32.4 The Roots of the Animal Tree of Life

### Learning Outcomes

1. Explain the colonial flagellate hypothesis of metazoan origin and why it is now favored.
2. Describe the possible role of Hox genes in the Cambrian explosion.

Some of the most exciting contributions of molecular systematics are being made to our understanding of the base of the animal family tree—the origins of the major clades of animals.

### Metazoans appear to have evolved from colonial protists

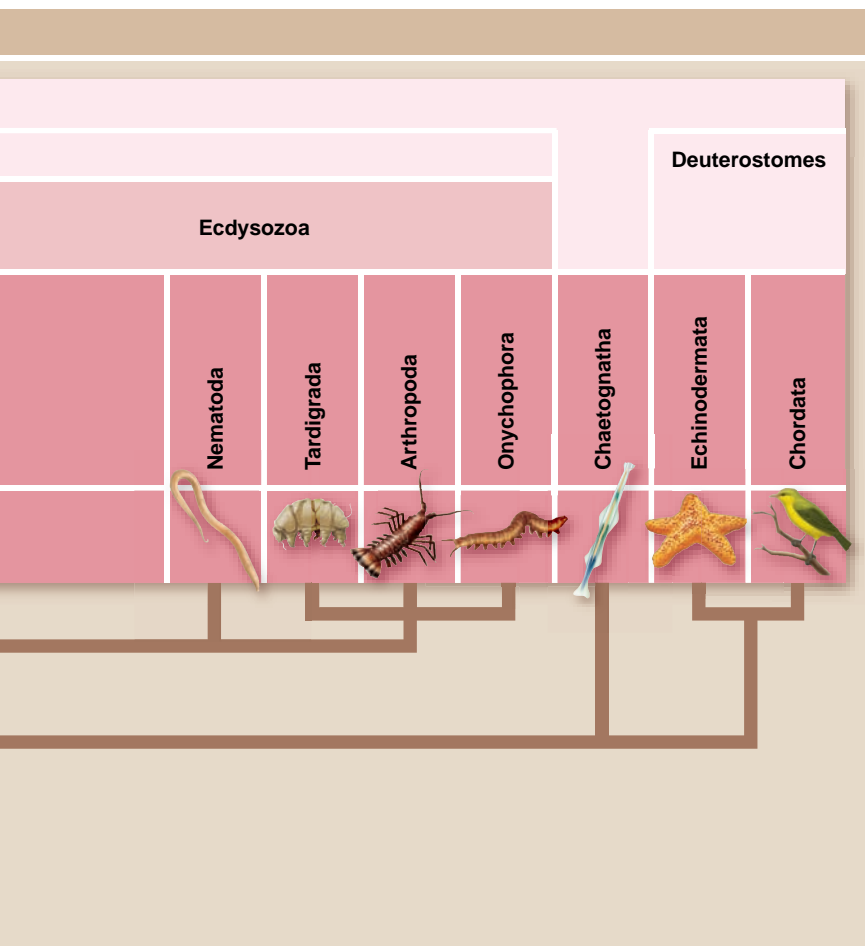

The ancestor to all animals was presumably a protist (see chapter 29), but it is not clear from which line of protists animals evolved. Evidence is available to support two major hypotheses.

- The multinucleate hypothesis is that metazoans arose from a multinuclear protist similar to today's ciliates. Each nucleus became compartmentalized into a cell, resulting in the multicellular condition.
- The **colonial flagellate hypothesis**, first proposed by Ernst Haeckel in 1874, is that metazoans descended from colonial protists. Each colony is a hollow sphere composed of flagellated cells. Some of the cells of sponges are strikingly like those of choanoflagellate protists.

Molecular data based on ribosomal RNA sequences favor the colonial flagellate hypothesis, and reject the multinucleate ciliate hypothesis based on evidence that metazoans are more closely related to eukaryotic algae than to ciliates.

### Molecular analysis may explain the Cambrian explosion

Most major animal body plans can be seen in fossils of Cambrian age, dating from 543 to 525 MYA. Although fossil cnidarians are found in rocks from the Ediacaran period, as old as 565 million years, along with what appear to be fossil mollusks and the burrows of worms, the great diversity of animals evolved quite rapidly in geological terms around the beginning of the Cambrian period—an event known as the **Cambrian explosion**. Biologists have long debated what caused this enormous expansion of animal diversity (figure 32.6). Many have argued that the emergence of new body plans was biological—the consequence of the evolution of predation, which encouraged an arms race between defenses, such as armor, and innovations that improved mobility and hunting success. Others have attributed the rapid diversification in body plans to physical factors—such as the build-up of dissolved oxygen and minerals in the oceans.

plants or animals. It is said that if everything in the world except nematodes were to disappear, an outline of what had been there would be visible in the remaining nematodes!

### Deuterostomes include chordates and echinoderms

Deuterostomes consist of fewer phyla and species than protostomes, and are more uniform in many ways, despite great differences in appearance. Echinoderms such as sea stars, and chordates such as humans, share a mode of development that is evidence of their evolution from a common ancestor, and separates them clearly from other animals.

#### Learning Outcomes Review 32.3

Scientists have defined phyla based on tissues, symmetry, characteristics such as presence or absence of a coelom or pseudocoelom, protostome versus deuterostome development, growth pattern and larval stages, and molecular data. Among protostomes, spiralian organisms have a growth pattern in which their body size simply increases; ecdysozoans must molt in order to grow larger. Among the deuterostome phyla are Echinodermata and Chordata, which includes humans.

- **Why do systematists attempt to characterize each group of animals by one or more features that have evolved only once?**

**Figure 32.6** Diversity of animals that evolved during the Cambrian explosion. The Cambrian saw an astonishing variety of body plans, many of which gave rise to the animals we find today. The natural history of these species is open to speculation.

Whether these causes or others are at the heart of the Cambrian explosion, molecular studies in the field of evolutionary developmental biology may provide a mechanism for the emergence of so many body plans. Much of the variation in animal body plans is associated with changes in the location or time of expression of *homeobox* genes (*Hox* genes) in embryos (see chapters 19 and 25). *Hox* genes specify the identity of developing body parts, such as the legs, thorax, and antennae. Perhaps the Cambrian explosion reflects the evolution of the *Hox* developmental gene complex, which provides a mechanism for producing rapid changes in body plan.

### Learning Outcomes Review 32.4

The hypothesis of evolution of metazoans from colonial flagellates is favored because of the similarity between flagellate colonies and metazoan sponges, and because of molecular data based on ribosomal RNA sequences. Animal fossils become highly abundant in the Cambrian period in what is known as the Cambrian explosion. *Hox* genes, which control development of body shape and parts, may be responsible for the diversity found in this period.

- *What alternative interpretations are there for the fossils that have led to the idea of the Cambrian explosion?*

## Chapter Review

### 32.1 Some General Features of Animals

Features common to all animals are multicellularity, heterotrophic lifestyle, and lack of a cell wall. Other features include specialized tissues, ability to move, and sexual reproduction.

### 32.2 Evolution of the Animal Body Plan

**Most animals exhibit radial or bilateral symmetry.**

Most sponges are asymmetrical, but other animals are bilaterally or radially symmetrical at some time during their life. The body parts of radially symmetrical animals are arranged around a central axis. The body of a bilaterally symmetrical animal has left and right halves. Most bilaterally symmetrical organisms are cephalized and can move directionally.

**The evolution of tissues allowed for specialized structures and functions.**

Each tissue consists of differentiated cells that have characteristic forms and functions.

**A body cavity made possible the development of advanced organ systems.**

Most bilaterian animals possess a body cavity other than the gut. A coelom is a cavity that lies within tissues derived from mesoderm. A pseudocoelom lies between tissues derived from mesoderm and the gut (which develops from endoderm). The acoelomate condition and the pseudocoelom appear to have evolved more than once, but the coelom evolved only once.

A circulatory system is an example of a specialized organ system that assists with distribution of nutrients and removal of wastes.

**Bilaterians have two main types of development.**

In a protostome, the mouth develops from or near the blastopore. A protostome has determinate development, and many have spiral cleavage.

In a deuterostome, the anus develops from the blastopore. A deuterostome has indeterminate development and radial cleavage.

**Segmentation allowed for redundant systems and improved locomotion.**

Segmentation, which evolved multiple times, allows for efficient and flexible movement because each segment can move somewhat independently. Another advantage to segmentation is redundant organ systems.

### 32.3 The Classification of Animals

Animals are classified into 35 to 40 phyla based on shared characteristics. Systematists attempt to use features assumed to have evolved only once.

**Tissues and symmetry separate the Parazoa and Eumetazoa.**

With the exception of sponges, animals exhibit embryonic germ layers and differentiated cells that form tissues. These characteristics lead to most animals being termed collectively the Eumetazoa; other animals, including the sponges, are Parazoa.

### **Molecular data help reveal evolutionary relationships.**

By incorporating molecular data into phylogenetic analyses, major alterations have been made to the traditional view of how members of these phyla are related.

### **Morphology- and molecule-based phylogenies agree on many major groupings.**

Porifera (sponges) constitutes a monophyletic group that shares a common ancestor with other animals. Cnidarians (hydras, sea jellies, and corals) evolved before the origin of bilaterally symmetrical animals.

Annelids and arthropods had been considered closely related based on segmentation, but now arthropods are grouped with protostomes that molt their cuticles at least once during their life.

### **Morphology-based phylogeny focused on the state of the coelom.**

The two groups of bilaterally symmetrical animals (the Bilateria)—protostomes and deuterostomes—differ in embryology. All acoelomates and pseudocoelomates are protostomes; some coelomates are protostomes and some are deuterostomes.

### **Protostomes consist of spiralian and ecdysozoans.**

Spiralia comprises the clades Lophotrochozoa and Platyzoa. Spiralian animals grow by gradual addition of mass to the body

and undergo spiral cleavage. Examples of Lophotrochozoa include annelids and mollusks. Examples of Platyzoa are rotifers and platyhelminthine worms.

Ecdysozoans grow by molting the external skeleton; Ecdysozoa includes many varied species, ranging from the pseudocoelomate, unsegmented Nematoda to the coelomate, segmented Arthropoda.

### **Deuterostomes include chordates and echinoderms.**

The major groups of deuterostomes are the echinoderms, which include animals such as sea stars and sea urchins, and the chordates, which include vertebrates.

Deuterostome development indicates that echinoderms and chordates evolved from a common ancestor, distinguishing them clearly from other animals.

## **32.4 The Roots of the Animal Tree of Life**

### **Metazoans appear to have evolved from colonial protists.**

Systematics based on ribosomal RNA supports the hypothesis that the Eumetazoa are monophyletic and arose from colonial flagellates.

### **Molecular analysis may explain the Cambrian explosion.**

Molecular analysis suggests that the rapid diversification during the Cambrian explosion may have been due to evolution of the *Hox* genes.

## **Review Questions**

### **UNDERSTAND**

- Which of the following characteristics is unique to all members of the animal kingdom?
  - Sexual reproduction
  - Multicellularity
  - Lack of cell walls
  - Heterotrophy
- Animals are unique in the fact that they possess \_\_\_\_\_ for movement and \_\_\_\_\_ for conducting signals between cells.
  - brains; muscles
  - muscle tissue; nervous tissue
  - limbs; spinal cords
  - flagella; nerves
- In animal sexual reproduction the gametes are formed by the process of
  - meiosis.
  - mitosis.
  - fusion.
  - binary fission.
- The evolution of bilateral symmetry was a necessary precursor for the evolution of
  - tissues.
  - segmentation.
  - a body cavity.
  - cephalization.
- A fluid-filled cavity that develops completely within mesodermal tissue is a characteristic of a
  - coelomate.
  - pseudocoelomate.
  - acoelomate.
  - all of the above
- Which of the following statements is not true regarding segmentation?
  - Segmentation allows the evolution of redundant systems.
  - Segmentation is a requirement for a closed circulatory system.
  - Segmentation enhances locomotion.
  - Segmentation represents an example of convergent evolution.
- Which of the following characteristics is used to distinguish between a parazoan and a eumetazoan?
  - Presence of a true coelom
  - Segmentation
  - Cephalization
  - Tissues
- With regard to classification in the animals, the study of which of the following is changing our understanding of the organization of the kingdom?
  - Molecular systematics
  - Origin of tissues
  - Patterns of segmentation
  - Evolution of morphological characteristics
- The \_\_\_\_\_ contain the greatest number of known species.
  - Chordata
  - Arthropoda
  - Porifera
  - Mollusca
- The evolution of which of the following occurred after the Cambrian explosion?
  - Cephalization
  - Coelom
  - Segmentation
  - None of the above
- A coelomate organism may have which of the following characteristics?
  - Circulatory system
  - Internal skeleton
  - Larger size than a pseudocoelomate
  - All of the above

## APPLY

- The following diagram is of the blastopore stage of embryonic development. Based on the information in the diagram, which of the following statements is correct?
  - It is a diagram of a protostome.
  - It would have formed by radial cleavage.
  - It would exhibit determinate development.
  - All of the above are correct.

- Which of the following characteristics would not apply to a species in the Ecdysozoa?
  - Bilateral
  - Indeterminate cleavage
  - Molt at least once in their life cycle
  - Metazoan
- In the rain forest you discover a new species that is terrestrial, has determinate development, molts during its lifetime, and

possesses jointed appendages. To which phylum of animals should it be assigned?

## SYNTHESIZE

- Worm evolution represents an excellent means of understanding the evolution of a body cavity. Using the phyla of worms Nematoda, Annelida, Platyhelminthes, and Nemetera, construct a phylogenetic tree based only on the form of body cavity (refer to figure 32.2 and table 32.2 for assistance). How does this relate to the material in figure 32.4? Should body cavity be used as the sole characteristic for classifying a worm?
- Most students find it hard to believe that Echinodermata and Chordata are closely related phyla. If it were not for how their members form a body cavity, where would you place Echinodermata in the animal kingdom? Defend your answer.

# Chapter 33

## Noncoelomate Invertebrates

### Chapter Outline

---

- 33.1** Parazoa: Animals That Lack Specialized Tissues
- 33.2** Eumetazoa: Animals with True Tissues
- 33.3** The Bilaterian Acoelomates
- 33.4** The Pseudocoelomates

### Introduction

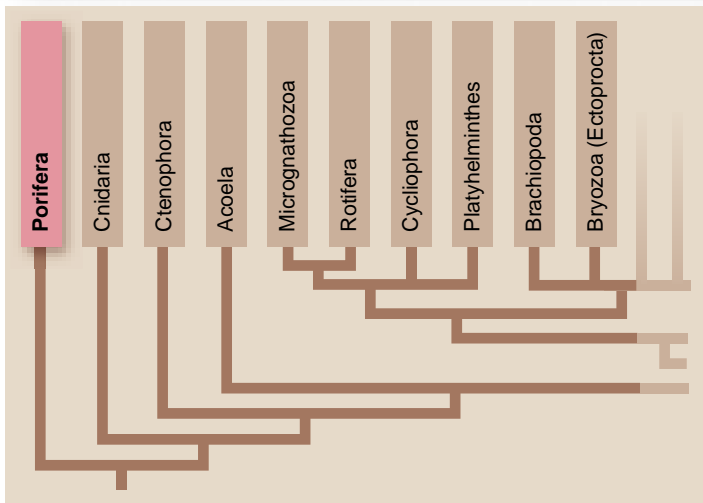

---

*Our exploration of the great diversity of animals starts with the morphologically simplest members of the animal kingdom—sponges, jellyfish, and some of the worms (fully a third of animal phyla are based on a “wormy” body plan!). Despite their simplicity, these animals can carry out all the essential functions of life, just as do more morphologically complex animals—eating, respiring, reproducing, and protecting themselves. These animals lack a coelom, so we refer to them as noncoelomates, but many have a body space called a pseudocoelom. The major organization of the animal body first evolved in these animals, the basic body plan from which that of all the rest of animals evolved. In chapter 34, we consider the invertebrate animals that have a coelom, and in chapter 35 the vertebrates. You will see that all animals, despite their great variation, have much in common.*

## 33.1 Parazoa: Animals That Lack Specialized Tissues

### Learning Outcomes

1. Describe the different types of cells in the sponge body.
2. Explain the function of choanocytes.

Parazoans are animals lacking tissues (and therefore organs) and a definite symmetry. The major group of parazoans is phylum **Porifera**, the sponges. Despite their morphological simplicity, like all animals, sponges are truly multicellular.

### The sponges, phylum Porifera, have a loose body organization

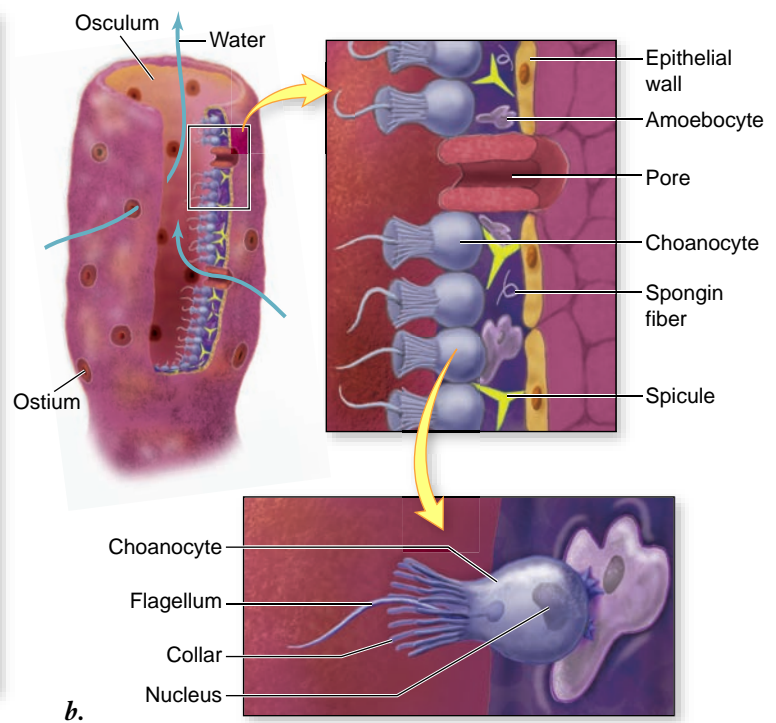

Nearly 7000 species of sponges live in the sea, and perhaps 150 species live in fresh water. Marine sponges occur at all depths, and may be among the most abundant animals in the deepest part of the oceans. Although some sponges are small (no more than a few millimeters across), some may reach 2 m or more in diameter.

A few small sponges are radially symmetrical, but most members of this phylum lack symmetry. Some have a low and encrusting form and grow covering various sorts of surfaces; others are erect and lobed, some in complex patterns (figure 33.1*a*).

As is true of many marine invertebrate animals, larval sponges are free-swimming. After a sponge larva attaches to an appropriate surface, it metamorphoses into an adult and remains attached to that surface for the rest of its life. Thus adult sponges are sessile; that is, they are anchored, immobile, on rocks or other submerged objects. Sponges defend themselves by producing chemicals that repel potential predators and organisms that might overgrow them.

*a.*

*b.*

**Figure 33.1 Phylum Porifera: Sponges.** *a.* *Aplysina longissima*. This beautiful, bright orange and purple elongated sponge is found on deep coral reefs. *b.* Diagrammatic drawing of the simplest type of sponge. Sponges are composed of several distinct cell types, the activities of which are coordinated. The sponge body has no organized tissues, and most are not symmetrical.

As a result, pharmaceutical companies are interested in possibly using these chemicals for human applications.

## The sponge body is composed of several cell types

Lacking head or appendages, mouth or anus, and the organized internal structure characteristic of all other animals, at first sight a sponge seems to be little more than a mass of cells embedded in a gelatinous matrix. In fact, a sponge contains several cell types (figure 33.1*b*), each with specialized functions. If a sponge is put through a fine sieve or coarse cloth so that the cells are separated, they will seek one another out and reassemble the entire sponge—a phenomenon that does not occur in any other animal.

As mentioned in chapter 32, a unique feature of sponge cells is their ability to differentiate from one type to another, and to dedifferentiate from a specialized state to an unspecialized one. Activities of the cells are loosely coordinated to perform functions such as synchronizing reproduction and building the complex skeletal meshwork. This distinguishes sponges as truly multicellular, by contrast with colonial protists, which may form aggregates of cells, but all are functionally identical (except for the reproductive cells).

A small, anatomically simple sponge has a vase-like shape. The walls of the “vase” have three functional layers. Facing the internal cavity are flagellated cells called **choanocytes**, or collar cells (see figure 33.1*b*). A larger and more complex sponge has many small chambers connected by channels rather than a single chamber. Once water has passed through a flagellated chamber, it travels through channels that converge at a large opening called an **osculum** (plural, *oscula*), through which water is expelled from the sponge.

The body of a sponge is bounded by an outer epithelium consisting of flattened cells somewhat like those that make up the outer layers of animals in other phyla. Pores on the sponge allow water to enter the channels that course through its body, leading to and from the flagellated chambers. The name of the phylum, Porifera, refers to these pores, the ostia (singular, ostium); a large sponge has multiple oscula, but they are far fewer than the number of ostia.

Some epithelial cells are specialized to surround the ostia; they can contract when touched or exposed to appropriate stimuli, causing the ostia to close and thereby protecting the delicate inner cells from the entry of potentially harmful substances such as sand and noxious chemicals. Cells surrounding individual ostia operate independently of one another; because a sponge has no nervous system, actions cannot be coordinated across large distances.

Between the outer and inner layers of cells, sponges consist mainly of a gelatinous, protein-rich matrix called the **mesohyl**, which contains various types of amoeboid cells (and eggs). In many kinds of sponges, some of these cells secrete needles of calcium carbonate or silica known as **spicules**, or fibers of a tough protein called **spongin**. Spicules and spongin form the skeleton of the sponge, strengthening its body. The siliceous spicules of some deep-sea sponges can reach a meter in length! A genuine bath sponge is the spongin skeleton of a marine sponge; artificial sponges made of cellulose or plastic are modeled on the body design of this animal, with a porous body

adapted to contain large amounts of water. The three classes of sponges—Hexactinellida, Demospongiae, and Calcarea—are distinguished in part by the mineral form of their spicules.

## Choanocytes help circulate water through the sponge

Each choanocyte resembles a protist with a single flagellum (plural, flagella) (see figure 33.1*b*), a similarity that may reflect its evolutionary derivation. The pressure created by the beating flagella in the cavity contributes to circulating the water that brings in food and oxygen and carries out wastes. In large sponges, the inner wall of the body interior is convoluted, increasing the surface area and, therefore, the number of flagella. In such a sponge, 1 cm<sup>3</sup> of sponge can propel more than 20 L of water per day. Choanocytes also capture food particles from the passing water, engulfing and digesting them. Obviously, this arrangement restricts a sponge to feeding on particles considerably smaller than choanocytes—largely bacteria.

## Sponges reproduce both asexually and sexually

Some sponges can reproduce asexually simply by breaking into fragments. Each fragment is able to continue growing as a new individual. Whether a sponge should be considered colonial is an illustration of the limitations of human language. A colony of invertebrate animals, such as coral, is generally defined as a group of individuals that are physically connected (and may be physiologically connected as well), all having been produced by asexual reproduction (such as budding or dividing) from a single progenitor that arose by sexual reproduction. Nearly all sponges grow by multiplying the number of flagellated chambers connected to a single osculum, but whether these units can be considered “individuals” is debatable.

Sponge sperm are created by the transformation of choanocytes, which are then released into the water where they may be carried into another sponge of the same species. When a sperm is captured by a choanocyte, it is carried to an egg cell, which is in the mesohyl (and in some sponges is also a transformed choanocyte). In many sponges, development of the externally ciliated larva occurs within the mother. In sponges of other species, the fertilized egg is released into the water, where development occurs. Whether a fertilized egg or a ciliated larva is released, after a short planktonic (drifting) stage, the larva settles on a suitable substrate where it transforms into an adult.

### Learning Outcomes Review 33.1

Sponges possess multicellularity but have neither tissue-level development nor body symmetry. Cells that compose a sponge include a layer of choanocytes, a layer of epithelial cells, and amoeboid cells in the mesohyl between the two layers. Choanocytes have flagella that beat to circulate water through the sponge body.

- *What features of a sponge make it seem to be a colony, and what features make it seem to be a single organism?*

## 33.2 Eumetazoa: Animals with True Tissues

### Learning Outcomes

1. Explain the defining feature of cnidarians.
2. Differentiate between cnidarians and ctenophores.
3. Discuss the question of symmetry of ctenophores.

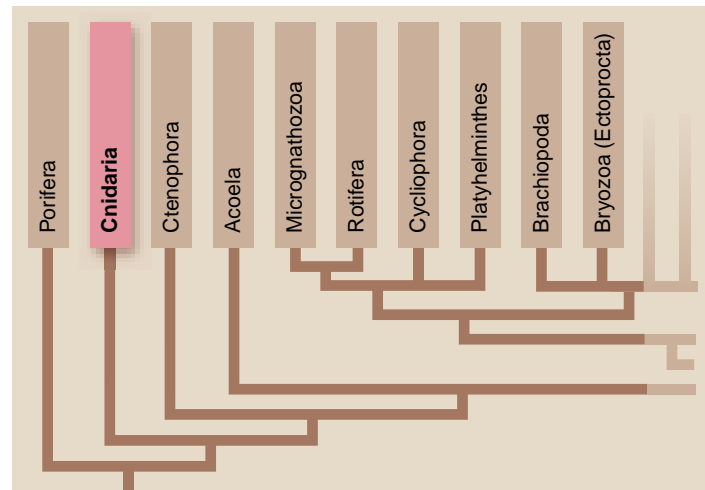

The Eumetazoa contains animals that evolved the first key transition in the animal body plan: distinct tissues. The embryonic cell layers differentiate into the tissues of the adult body, giving rise to the body plan characteristic of each group of animals.

Recall that the outer covering of the body (the epidermis) and the nervous system develop from the embryonic ectoderm, and the digestive tissue (called the **gastrodermis**) develops from the embryonic endoderm. In the Bilateria, the embryonic mesoderm, which lies between endoderm and ectoderm, forms the muscles.

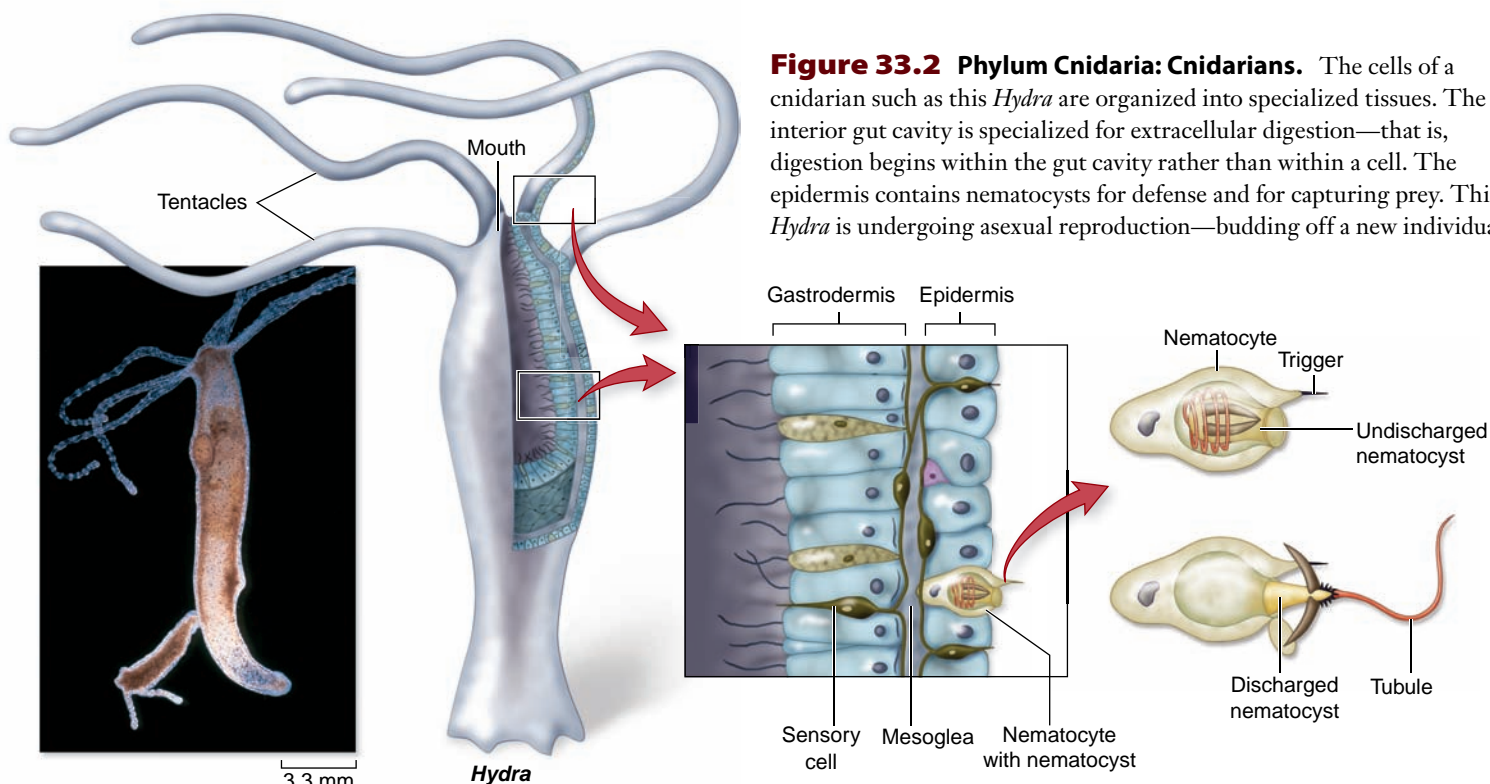

Eumetazoans also evolved body symmetry. Metazoans living sessile on the ocean floor or free-living in the water may be radially symmetrical. One phylum consisting of pentaradially symmetrical animals (those with fivefold symmetry), the Echinodermata, are dealt with in chapter 34. Some animals of the phylum Cnidaria, comprising hydroids, jellyfish, sea anemones, and corals, are clearly radially symmetrical and some are biradially symmetrical (see chapter 32). Members of the phylum Ctenophora, the comb jellies, are considered by some people to be radially symmetrical but by others to be bilaterally symmetrical.

### All cnidarians, phylum Cnidaria, are carnivores

Most of the 10,000 species of cnidarians are marine; a very few live in fresh water. The bodies of these fascinating and simply constructed diploblastic animals are made of distinct tissues, although they do not have organs. Despite having no reproductive, circulatory, digestive, or excretory systems, cnidarians reproduce, exchange gas, capture and digest prey, and distribute the resulting organic molecules to all their cells. A cnidarian has no concentration of nervous tissue that could be considered a brain or even a ganglion. Rather, its nervous system is a latticework, the cells having junctions like those of bilaterians. All cnidarians have nervous receptors sensitive to touch, and some have gravity and light receptors, which include, in a few species, image-forming eyes.

Cnidarians capture their prey (which includes fishes, crustaceans, and many other kinds of animals) with nematocysts (figure 33.2), microscopic intracellular structures unique

**Figure 33.2 Phylum Cnidaria: Cnidarians.** The cells of a cnidarian such as this *Hydra* are organized into specialized tissues. The interior gut cavity is specialized for extracellular digestion—that is, digestion begins within the gut cavity rather than within a cell. The epidermis contains nematocysts for defense and for capturing prey. This *Hydra* is undergoing asexual reproduction—budding off a new individual.

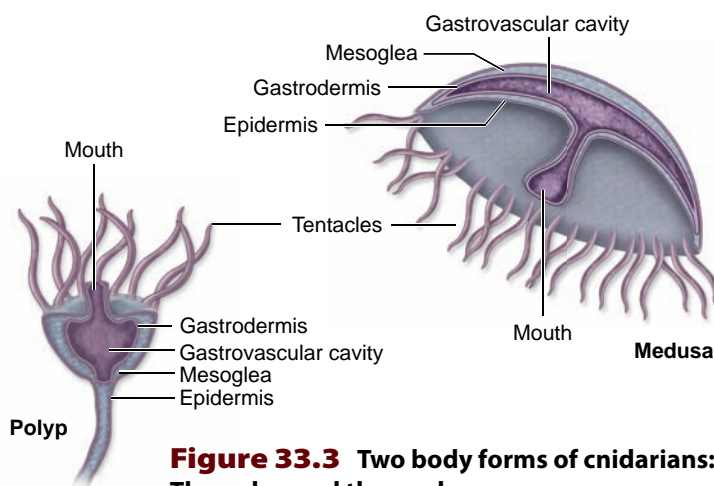

to the phylum. Food captured by a cnidarian is brought to the mouth by the tentacles that ring the mouth.

### Basic body plans

A cnidarian exhibits one of two body forms: the polyp and the medusa (figure 33.3). A **polyp** is cylindrical, with a mouth surrounded by tentacles at the end of the cylinder opposite where it is attached. Attachment in most solitary polyps is to a firm substratum, but in those that are part of a colony, it is to the mass of common colonial tissue. A **medusa** is discoidal or umbrella-shaped, with a mouth surrounded by tentacles on one side; most live free in the water. These two seemingly quite different body forms share the same morphology—the mouth opens into a sac-like gastrovascular cavity and is surrounded by tentacles.

The cnidarian body plan has a single opening leading to the gastrovascular space, which is the site of digestion, most gas exchange, waste discharge, and, in many cnidarians, formation of gametes. The body wall is composed of two layers: the epidermis, which covers the surfaces in contact with the outside environment, and the gastrodermis, which covers the gastrovascular cavity. Between these two layers is the **mesoglea**, which varies from acellular, being no more than a glue holding gastrodermis to epidermis in *Hydra*, to thick and rubbery with many cells in large medusae called jellyfish (see figures 33.2, 33.3).

The gastrovascular space also serves as a hydrostatic skeleton (see chapter 47). A hydrostatic skeleton serves two of the roles that a skeleton made of bone or shells does: it provides a rigid structure against which muscles can operate, and it gives the animal shape. For muscles to operate against it, the fluid-filled space must be closed sufficiently tightly so the fluid is under pressure and does not escape when muscles contract around the space. Think of the gastrovascular space of a cnidarian full of water like an inflated, elongated, air-filled balloon. Because it is firm, muscles that shorten it cause it to broaden, and muscles that decrease its diameter lengthen it. However, if you inflate the balloon with air, but then do not hold the opening closed, the air will escape and the balloon will become flaccid. Similarly, when a cnidarian contracts greatly, it must open its mouth so water can escape. However, the mouth can close sufficiently tightly to retain water in the gastrovascular cavity, so the animal is turgid and can bend and extend its tentacles.

**Figure 33.3** Two body forms of cnidarians: The polyp and the medusa.

In addition to the hydrostatic skeleton of all polyps, those of many species build an exoskeleton of chitin or calcium carbonate around themselves; in many colonial species, the skeleton links the members of the colony. The polyps of a smaller number of species secrete internal skeletal elements. Polyps of some groups of cnidarians, such as sea anemones, have no skeleton at all. All medusae are solitary (that is, they do not form colonies) and form no skeleton.

### The cnidarian life cycle

Some cnidarians occur only as polyps, and others exist only as medusae, but many alternate between these two phases (see figure 33.3); both phases consist of diploid individuals. In general, in species having both polyp and medusa in the life cycle, the medusa forms gametes. The sexes are separate; this condition, known as gonochorism, means an individual is either male or female. An egg and a sperm unite to form a zygote, which develops into a planktonic ciliated **planula** larva that metamorphoses into a polyp. The polyp produces medusae asexually. Dispersal occurs in both medusa and larvae. In most species with such a life cycle, a polyp may also produce other polyps asexually; if they remain attached to one other, the resulting group is referred to as a colony.

In a small number of species, the planula produced by medusae may develop directly or indirectly into another medusa without passing through the polyp stage. More commonly, there is a polyp but no medusa in the life cycle. In such cnidarians, the polyp can form gametes, and the resulting planula will develop into another polyp. In some, but by no means all, of these species, the polyp can also produce other polyps asexually, by dividing, budding, or breaking off bits of itself that regenerate (grow the missing parts).

### Digestion

A major evolutionary innovation in cnidarians is extracellular digestion of food inside the animal. Recall that in a sponge, digestion occurs within choanocytes, so food particles must be small enough to be engulfed by a choanocyte. In a cnidarian, digestion takes place partly in the gastrovascular cavity. Digestive enzymes, released from cells lining the cavity, partially break down food. Other cells lining the space engulf those food fragments by phagocytosis. This allows a cnidarian to feed on prey larger than a sponge can handle.

### Nematocysts

Cnidarians capture food with the aid of **nematocysts**, microscopic stinging capsules unique to the phylum (see figure 33.2). Although often referred to as “stinging cells,” they are capsules, each secreted within a cell called a nematocyte. Cnidarians may be morphologically simple, but nematocysts are the most complex structures secreted by single animal cells. When appropriately stimulated, the closure at the end of the capsule springs open, and a tubule is emitted. Nematocyst discharge is one of the fastest cellular processes in nature. The mechanism of discharge of a nematocyst is unknown—several hypotheses for it have been proposed. Although the action of a nematocyst is often described as harpoon-like, the tubule actually everts (turns inside-out). It may penetrate or wrap around an object; the tubules of some nematocysts are barbed and some carry

venom. In a very few species, the venoms are strong enough to kill a human.

Many thousand nematocytes typically are part of the epidermis of each tentacle. Each one can be used only once. In some types of cnidarians, nematocysts occur in parts of the body other than the tentacles, including in the gastrovascular cavity, where they may aid in digestion. In addition to being used offensively, nematocysts are the only defense of cnidarians—they are the reason jellyfish and fire coral sting. Some cnidarians have stinging capsules of types other than nematocysts, which are termed cnidae—hence the name of the phylum, Cnidaria.

## Cnidarians are grouped into four—or five—classes

Traditionally, three classes of Cnidaria were recognized: Anthozoa (sea anemones, corals, sea fans), Hydrozoa (hydroids, Hydra, Portuguese man-of-war), and Scyphozoa (jellyfish). Now nearly all biologists accept that some scyphozoans are sufficiently distinct in life cycle and morphology that they constitute their own class, Cubozoa (box jellies), some of which have a sting sufficiently toxic to kill humans. Less widely accepted is the separation of some other scyphozoans into their own class, Staurozoa (star jellies).

### **Class Anthozoa: Sea anemones and corals**

The largest class of Cnidaria is **Anthozoa**, consisting of approximately 6200 species of solitary and colonial polyps. They include stony corals (figure 33.4), soft-bodied sea anemones (figure 33.5), and other groups known by such fanciful names as sea pens, sea pansies, sea fans, and sea whips. Many of these names reflect the plantlike appearance of the individual polyps or colonies.

**Figure 33.4** **Stony corals.** *Tubastraea aurea*, a non-reef building species from Malaysia.

**Figure 33.5**  
**Class Anthozoa.**  
Crimson anemone,  
*Cribrinopsis*  
*fernaldi*.

An anthozoan polyp differs from a polyp of the other classes in its gastrovascular cavity being compartmentalized by radially arrayed, longitudinal sheets of tissue called mesenteries. The way they are arranged imparts the biradial symmetry to these animals mentioned in chapter 32. The gametes of an anthozoan develop in the mesenteries. The tentacles of an anthozoan are hollow, whereas those of many other cnidarians are solid.

Sea anemones (see figure 33.5) constitute a group of just over 1000 species of highly muscular and relatively complex soft-bodied anthozoans. Living in waters of all depths throughout the world, they range from a few millimeters to over a meter in diameter, and many are equally long.

Most corals are anthozoans, and most hard corals (about 1400 species, see figure 33.4) are closely related to sea anemones. The polyp of a coral secretes an exoskeleton of calcium carbonate around and under itself (this is the same material of which chalk is composed); as the individual or colony grows upward, dead skeleton accumulates below it. In shallow water of the tropics, these accumulations form coral reefs. Most waters in which coral reefs develop are nutrient-poor, but the corals are able to grow well because they contain within their cells symbiotic dinoflagellates (zooxanthellae) that photosynthesize and provide energy for the animals. Obviously coral reefs are restricted to water sufficiently shallow for sunlight to reach the living animals (typically no more than 100 m), but corals that do not form reefs can grow deeper—to about 5000 m. Only about half the species of hard corals participate in forming reefs.

Coral reefs are economically important, serving as refuges for the young of many species of crustaceans and fishes that are eaten by humans, as well as protecting coasts of many tropical islands. But they are threatened by global climate change. Water warmer than usual can cause the symbiosis with zooxanthellae to break down, a phenomenon known as “coral bleaching” because the underlying white skeleton of the animal becomes visible through its body in the absence of the symbionts. Bleaching does not always kill a coral, but it is stressful. As carbon dioxide in the atmosphere rises, it dissolves in water, forming carbonic acid, which lowers the pH of the water. This makes calcium carbonate less available; some species of calcifying marine plants and animals, including corals, have been shown to form less robust skeletons, and to form them more slowly, as pH drops.

Some “soft corals” secrete needles of calcium carbonate much like sponge spicules; these sclerites form a case around the polyp or are embedded in their tissues, presumably providing protection against predation. Some of these animals also secrete a horny rod that provides flexible support to the members of the colony growing around it (sea fans are such colonies).

**Figure 33.6**  
**Class Cubozoa.**  
*Chironex fleckeri*,  
a box jelly.

### **Class Cubozoa: The box jellies**

As their name implies, medusae of class **Cubozoa** are box-shaped, with a tentacle or group of tentacles hanging from each corner of the box (figure 33.6). Most of the 40 or so species are only a few centimeters in height, although some reach 25 cm. Box jellies are strong swimmers and voracious predators of fish in tropical and subtropical waters; both of these facts are related to some cubozoans having image-forming eyes! The stings of some species can be fatal to humans. The polyp stage is inconspicuous and in many cases unknown.

### **Class Hydrozoa: The hydroids**

Most of the approximately 2700 species of class **Hydrozoa** have both polyp and medusa stages in their life cycle (see figure 33.3). The polyp stage of most species is colonial. The polyps of a colony may not be identical in structure or function: some may be specialized to feed but be unable to reproduce, whereas the opposite may be true of others (they are nourished by material transported from feeding polyps through the gastrovascular space connecting members of the colony). The Portuguese man-of-war (figure 33.7) is not a jellyfish, but is a floating colony of highly integrated polypoid and medusoid individuals! Some marine hydroids and medusae are bioluminescent.

Hydrozoa is the only class of Cnidaria with freshwater members. A well-known hydroid is the freshwater *Hydra*, which is exceptional not only in its habitat, but in having no medusa stage and being solitary (see figure 33.2). Each polyp attaches by a basal disk, on which it can glide, aided by mucous

**Figure 33.7**  
**Portuguese man-of-war**  
**(*Physalia physalis*).** This species has a very painful sting.

**Figure 33.8**  
**Class Scyphozoa.**  
*Aurelia aurita*, a  
jellyfish.

secretions. It can also somersault—by bending over and attaching to the substrate by its tentacles, then looping over to a new location. If the polyp detaches from the substrate, it can float to the surface.

### **Class Scyphozoa: The jellyfish**

In the approximately 200 species of class **Scyphozoa**, the medusa is much more conspicuous and complex than the polyp. Although many scyphomedusae are essentially colorless (figure 33.8), some are a striking orange, blue, or pink. The polyp is small, inconspicuous, simple in structure, and typically white in color, but is entirely lacking in a few scyphozoans that live in the open ocean.

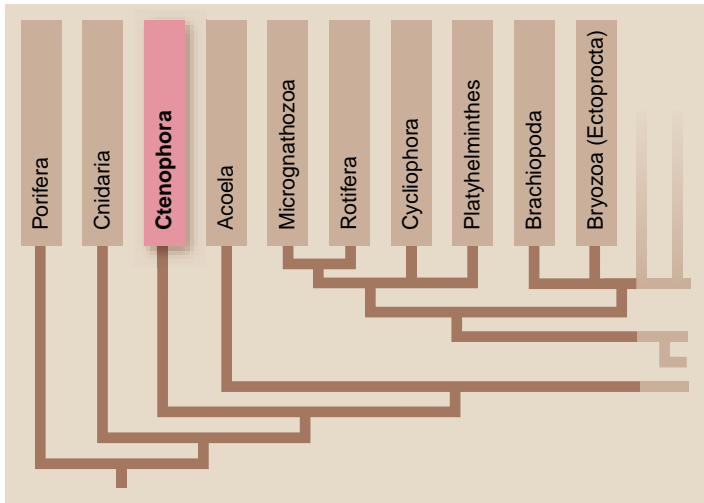

The epithelium around the margin of a jellyfish contains a ring of muscle cells that can contract rhythmically to propel the animal through the water by jetting water from the gastrovascular cavity or space beneath it; by contracting those on just one side, the animal can steer. A scyphomedusa (*Cyanea capillata*) was the killer in the Sherlock Holmes tale “The Lion’s Mane,” but, although some can inflict pain on humans, they are unlikely to be capable of killing.

### **Class Staurozoa: The star jellies**

Among the reasons the 50 species of this group were separated from the Scyphozoa and placed in their own class (Staurozoa) is that the animal resembles a medusa in most ways but is attached to the substratum by a sort of stalk that emerges from the side opposite the mouth (figure 33.9). In addition, in all staurozoans known, the planula larva creeps rather than swims or drifts.

**Figure 33.9**  
**Star jelly.** Stalked  
jellyfish (*Halicystus auricula*).

### The comb jellies, phylum Ctenophora, use cilia for movement

Pelagic members of the small marine phylum **Ctenophora** range from spherical to ribbon-like and are known as comb jellies, sea walnuts, or sea gooseberries. Abundant in the open ocean, most of these animals are transparent and only a few centimeters long, but rare ones are deeply pigmented and reach 1 m in length. They propel themselves through the water with eight rows of comblike plates of fused cilia that beat in a coordinated fashion, scattering light so they appear like rainbows (figure 33.10). Ctenophores are the largest animals that use cilia for locomotion. Many ctenophores are bioluminescent, giving off bright flashes of light that are particularly evident in the deep sea or on the surface of the ocean at night. Most ctenophores have two long, retractable tentacles used in prey capture. The epithelium of the tentacles contains **colloblasts**, a type of cell that bursts to discharge a strong adhesive material on contact with animal prey.

**Figure 33.10**  
A comb jelly (phylum Ctenophora). Note the iridescent rows of comblike plates of fused cilia.

The phylogenetic position of Ctenophora is unclear. It was formerly considered closely related to Cnidaria because of the gelatinous, medusa-like form of most species. However, ctenophores lack nematocysts and are structurally more complex than cnidarians. They have anal pores through which water and other substances can exit the body. Although ctenophores have been considered diploblasts with radial symmetry, recent developmental studies have demonstrated them to have muscle cells derived from mesoderm, which means they should be considered triploblasts, like bilaterians. The two tentacles placed on opposite sides of a ctenophore's body impart some bilaterality to them, but whether their symmetry should be considered biradial, like that of sea anemones, is unclear. A recent molecular phylogeny places ctenophores at the base of the animal tree of life, as the sister group to all other metazoans. If this is borne out, it implies that the ancestral animal was triploblastic and bilaterally symmetrical.

#### Learning Outcomes Review 33.2

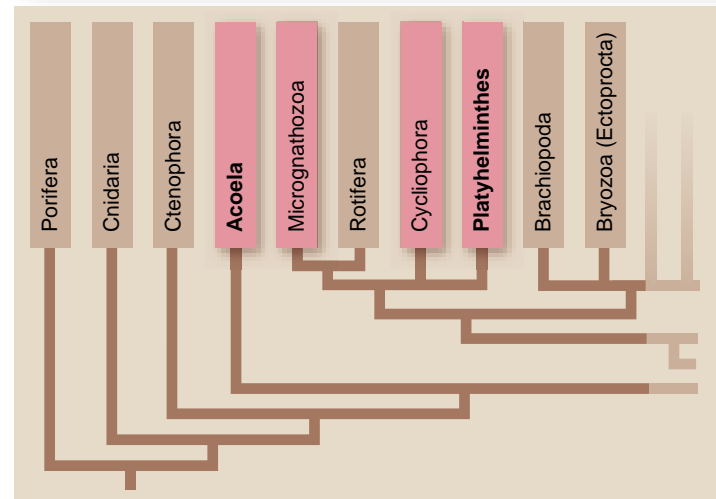

Members of phylum Cnidaria have nematocysts, capsules used in defense and prey capture, and are radially symmetrical. Members of phylum Ctenophora lack nematocysts; they propel themselves by means of eight rows of comblike plates of fused cilia. Ctenophores have cells called colloblasts that assist in prey capture. The symmetry of ctenophores is a subject of debate.

- Why would triploblasty be important to phylogeny?

## 33.3 The Bilaterian Acoelomates

#### Learning Outcomes

1. List the distinguishing features of bilaterian flatworms.
2. Explain why the scolex of a tapeworm is not a head.

The Bilateria is characterized by a key transition in the animal body plan—bilateral symmetry—which allowed animals to achieve high levels of specialization within parts of their bodies,

such as the concentration of sensory structures at the anterior. (Even if ctenophores are truly bilateral as just mentioned, they lack these other specializations.)

As discussed in chapter 32, bilaterians are traditionally divided into acoelomates, pseudocoelomates, and coelomates. The acoelomate and pseudocoelomate conditions appear to have evolved multiple times; thus these conditions are convergent and not homologous and do not necessarily indicate close evolutionary relationship among the animals sharing that anatomy. Nonetheless, the state of the internal part of the animal's body does provide information about how the animals are constructed and how they live. In this chapter, we cover acoelomates and pseudocoelomates; in the next chapter we cover coelomates, which are probably monophyletic.

Structurally, the simplest bilaterians are the acoelomates, which lack an internal cavity other than the digestive tract. The largest phylum of the group is the Platyhelminthes.

## The flatworms, phylum Platyhelminthes, have an incomplete gut

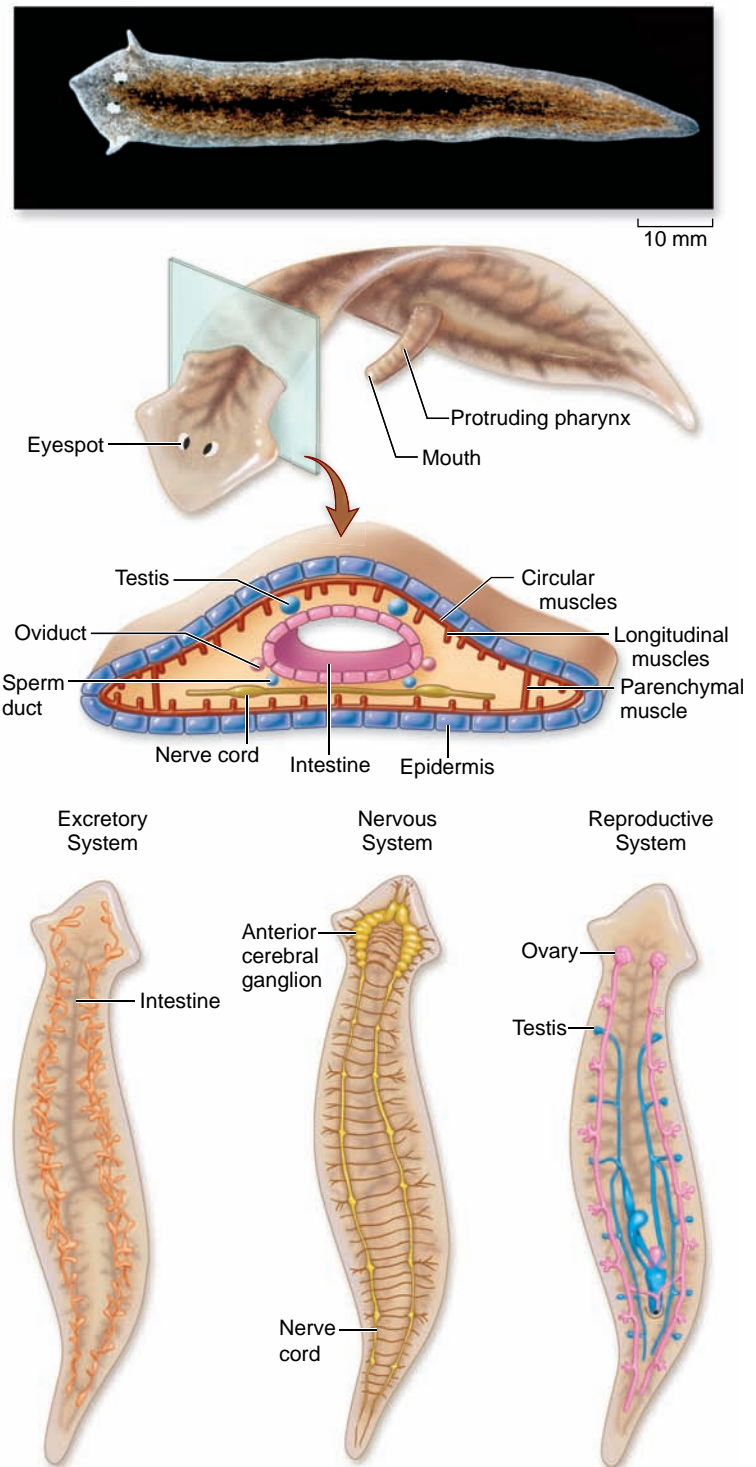

The phylum Platyhelminthes consists of some 20,000 species. These ciliated, soft-bodied animals are flattened dorsoventrally, the anatomy that gives them the name flatworms. Flatworm bodies are solid aside from an incomplete digestive cavity (figure 33.11). Although among the morphologically simplest of bilaterally symmetrical animals, they have some complex structures, like their reproductive apparatus, and they have the most complex life cycles among animals.

Free-living flatworms occur in a wide variety of marine, freshwater, and even moist terrestrial habitats. They are carnivores and scavengers, eating small animals and bits of organic debris. They move around by means of ciliated epithelial cells, which are particularly concentrated on their ventral surfaces, but they also have well-developed musculature. By contrast, many species of flatworms are parasitic, living inside the bodies of other animals. Flatworms range in length from 1 mm or less to many meters (some tapeworms).

### Digestion in flatworms

Most flatworms have only a single opening for their digestive cavity, a mouth located on the bottom side of the animal at midbody. A flatworm ingests its food and tears it into small bits using muscular contractions in the upper end of the gut, the pharynx.

Like sponges, cnidarians, and ctenophores, a flatworm lacks a circulatory system for the transport of oxygen and food molecules. The thin body of a flatworm allows gas to diffuse between its cells and the air (oxygen diffuses in and carbon dioxide diffuses out). Branches of the gut extend throughout the body, so the gut functions in both digestion and distribution of food. Cells that line the gut engulf most of the food particles by phagocytosis and digest them; but, as in cnidarians and most bilaterians, some particles are partly digested extracellularly. Tapeworms, which are parasitic, have a mouth at the front of their body and no digestive cavity at all; they absorb food directly through the body wall.

**Figure 33.11 Architecture of a flatworm.** A photo and an idealized diagram of the genus *Dugesia*, the familiar freshwater planarian of ponds and rivers. Upper schematic shows a whole animal and a transverse section through the anterior part of the body. Schematics below show the digestive, central nervous, and reproductive systems.

### Excretion and osmoregulation

Unlike cnidarians and ctenophores, flatworms have an excretory system, which consists of a network of fine tubules that run throughout the body. Bulblike **flame cells**, so named

because of the flickering movements of the flagella beating inside them, are located on the side branches of the tubules. Flagella in the flame cells move water and excretory substances into the tubules and then to pores located between the epidermal cells through which the liquid is expelled. Flame cells primarily regulate water balance of the organism; the excretory function appears to be secondary, and much of the metabolic waste of a flatworm diffuses into the gut and is eliminated through the mouth.

### **Nervous system and sensory organs**

The flatworm nervous system comprises an anterior cerebral ganglion and nerve cords that run down the body, with cross-connections that give it a ladder-like shape (see figure 33.11). Free-living flatworms are poorly cephalized, with eyespots on their heads (see figure 33.11). These inverted, pigmented cups, which contain light-sensitive cells connected to the nervous system, enable a worm to distinguish light from dark: most flatworms tend to move away from strong light.

### **Flatworm reproduction**

The reproductive systems of flatworms are complex. Most are **hermaphroditic**, each individual containing both male and female sexual structures (see figure 33.11). In many of members of Platyhelminthes, copulation is required between two individuals, and fertilization is internal, each partner depositing sperm in the copulatory sac of the other. The sperm travel along special tubes to reach the eggs.

In most freshwater flatworms, fertilized eggs are laid in cocoons strung in ribbons and hatch into miniature adults. In contrast, some marine species develop indirectly, the fertilized egg undergoing spiral cleavage, and the embryo giving rise to a larva that swims or drifts until metamorphosing, when it settles in an appropriate habitat.

Flatworms are known for their regenerative capacity: when a single individual of some species is divided into two or more parts, an entirely new flatworm can regrow what is missing from each bit.

## **Flatworms comprise two major groups**

Most flatworms are parasitic; those that are not are referred to as free-living. There is strong morphological and molecular evidence that the parasitic lifestyle evolved only once in platyhelminths, from free-living ancestors.

### **Turbellaria: Free-living flatworms**

Flatworm phylogeny is in a state of flux. The group of free-living flatworms, Turbellaria, has been considered a class, but recent studies show it is not monophyletic so it is likely to be divided into several classes. One of the most familiar members of this group are freshwater members of the genus *Dugesia*, the common planarian used in biology laboratories.

### **Neodermata: Parasitic flatworms**

All parasitic flatworms are placed in the subphylum Neodermata. That name means “new skin” and refers to the animal’s

outer surface. All neodermatans live as ectoparasites or endoparasites on or in the bodies of other animals for some period of their lives. The neodermis is resistant to the digestive enzymes and immune defenses produced by the animals parasitized by these flatworms. These animals also lack other features of free-living flatworms such as eyespots, which are of no adaptive value to an organism living inside the body of another animal. Neodermata contains two subgroups: Trematoda, the flukes, and Cercomeromorpha, the tapeworms and their relatives.

### **Trematoda: The flukes**

There are more than 10,000 named species of flukes, ranging in length from less than 1 mm to more than 8 cm. Flukes attach themselves within the bodies of their hosts by means of suckers, anchors, or hooks. A fluke takes in food (cells or fluids of the host) through its mouth, like its free-living relatives. The life cycle of some species involves only one host, usually a fish, but the life cycle of most flukes involves two or more hosts. The first intermediate host is almost always a snail, and the final host (in which the adult fluke lives and reproduces sexually) is almost always a vertebrate; in between there may be other intermediate hosts. Although the life of a parasite is secure within a host, which provides food and shelter, getting from one host to another is extremely risky, and most individuals die in the transition.

### **Flukes that cause disease in humans**

The oriental liver fluke, *Clonorchis sinensis*, is an example of a flatworm that parasitizes humans, living in the bile duct of the liver (as well as that of cats, dogs, and pigs) (figure 33.12). It is especially common in Asia. Each worm is 1 to 2 cm long and, like all flukes, has a complex life cycle. A fertilized egg containing a ciliated first-stage larva, the **miracidium**, is passed in the feces. If the larva reaches water, it may be ingested by an aquatic snail (but most do not reach water and most that do are not ingested. The prodigious number of eggs a parasitic flatworm produces is an adaptation to this life-cycle full of risks). Within the snail, the ciliated larva transforms into a **sporocyst**, a bag-like structure containing embryonic germ cells, each of which develops into a **redia** (plural, *rediae*), an elongated, nonciliated larva. Each of these larvae grows within the snail, then gives rise to several individuals of the next larval stage, the tadpole-like **cercaria** (plural, *cercariae*).

Cercariae escape into the water, where they swim about freely. When one encounters a fish of the family Cyprinidae—the family that includes carp and goldfish—it bores into the muscles, loses its tail, and encysts, transforming into a metacercaria. If a human or other mammal eats raw fish containing metacercariae, the cyst dissolves in the intestine, and the young fluke migrates to the bile duct, where it matures, thereby completing the cycle. Even if infected fish is cooked, the parasite can be transmitted if metacercariae stuck to cutting boards or the hands of a person handling the raw fish flesh are ingested. An individual fluke may live for 15 to 30 years in the liver; a heavy infection of liver flukes may cause cirrhosis of the liver and death in humans.

Perhaps the most important trematodes to human health are blood flukes of the genus *Schistosoma*. They afflict about 5%

**Figure 33.12** Life cycle of the oriental liver fluke, *Clonorchis sinensis*.

of the world's population, or more than 200 million people, in tropical Asia, Africa, Latin America, and the Middle East. About 800,000 people die each year from the disease called **schistosomiasis**, or bilharzia.

Schistosomes live in blood vessels associated with the intestine or the urinary bladder, depending on the species (figure 33.13). Thus if the worm is killed, it cannot be washed out of the host, unlike parasites that live in the gut or associated organs such as the liver. Nor do its fertilized eggs have that easy route out of the body. Instead, a fertilized egg must break through the wall of the blood vessel to get into either the intestine or the urinary bladder (depending on the species). The damage done to the blood vessels and gut or bladder wall is considerable, especially considering that an individual worm may release 300 to 3000 eggs per day and live for many years.

Great effort is being made to control schistosomiasis. The worms protect themselves from the body's immune system in part by coating themselves with some of the host's own antigens that effectively render the worm immunologically invisible (see chapter 52). The search is on for a vaccine that would cause the host to develop antibodies to one of the antigens of young worms before they can protect themselves.

### **Cercaromorpha: The tapeworms and their relatives**

An adult tapeworm hangs onto the inner wall of its host's intestine by means of a terminal attachment structure. It lacks a digestive cavity as well as digestive enzymes, absorbing food from the host's gut through its outer surface. Most species of tape-

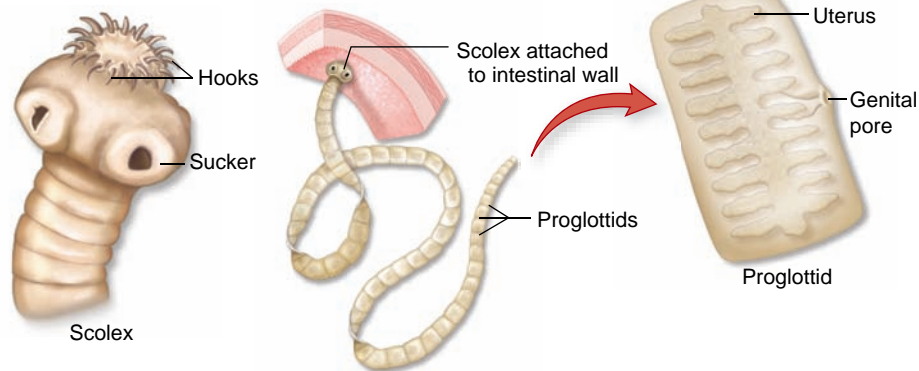

worm occur in the intestines of vertebrates; about a dozen of them regularly occur in humans.

The long, flat body of a tapeworm is divided into three zones: the **scolex**, or attachment structure; the neck; and a series of repetitive sections, the **proglottids** (figure 33.14). The scolex of many species bears four suckers and may also have hooks. The scolex is not a head: it has neither concentrated nervous tissue nor a mouth. Each proglottid is a complete hermaphroditic unit, containing both male and female

**Figure 33.13** Schistosomes. The male lies within the groove on the female's ventral side, with its front and hind ends protruding.

**Figure 33.14 Tapeworms.**

Flatworms such as this beef tapeworm, *Taenia saginata*, live parasitically in the intestine of mammals.

reproductive organs. Proglottids are formed continuously in a growth zone at the base of the neck, with maturing ones being pushed posteriorly as new ones are formed. The gonads in the proglottids progressively mature away from the neck, fertilization occurs, and the embryos form, the proglottids nearer the end of the body being more mature. The most terminal proglottid, filled with embryonated eggs, breaks off; either it ruptures and the embryos, each surrounded by a shell, are carried out with the host's feces, or the entire proglottid is carried out, where the embryos emerge from it through a pore or the ruptured body wall. Embryos are scattered in the environment, on leaves, in water, or in other places where they may be picked up by another animal.

The beef tapeworm, *Taenia saginata*, occurs as a juvenile in the intermuscular tissue of cattle; as an adult, it inhabits the intestines of human beings, where a mature worm may reach a length of 10 m or more. A worm attaches itself to the intestinal wall of the host by a scolex with four suckers. Shed proglottids pass from the human in the feces and may crawl onto vegetation, a favorable place to be picked up by cattle; they may remain viable for up to five months. If one is ingested by cattle, the larva burrows through the wall of the intestine and ultimately reaches muscle tissues through the blood or lymph vessels. About 1% of cattle in the United States are infected, and because some 20% of the beef consumed is not federally inspected, when humans eat infected beef that is cooked "rare," infection by these tapeworms can occur. As a result, the beef tapeworm is a frequent parasite of humans.

### Acoel flatworms appear to be distinct from Platyhelminthes: A case study

An acoel flatworm (figure 33.15) has a nervous system that consists of a simple network of nerves with a minor concentration of neurons in the anterior body end. It lacks a permanent digestive cavity, so the mouth leads to a solid digestive syncytium (a mass of cells that have no cell membranes separating them).

These characteristics had been used to place the acoels at the base of phylum Platyhelminthes and that phylum at the base of the Bilateria. However, based on molecular evidence, scientists have concluded that acoels are not closely related to members of phylum Platyhelminthes—similarities between the two groups are convergent. They belong in their own phylum, Acoela, or are members of the phylum Acoelomorpha, which

includes another group of simple bilaterians once considered to be flatworms. Their precise position in the phylogenetic tree differs depending on the features used to construct it; one hypothesis is they evolved before the phylogenetic split between protostomes and deuterostomes.

### Phylum Cycliophora was discovered relatively recently

In December 1995, Danish biologists Peter Funch and Reinhardt Kristensen reported the discovery of a strange new kind of acoelomate creature about the size of a period on a printed page. The tiny organism has a striking circular mouth surrounded by a ring of cilia, and its anatomy and life cycle are so unusual that their discoverers assigned it to an entirely new phylum, Cycliophora (figure 33.16).

The newest phylum to be named before Cycliophora, the Loricifera, was discovered also by Reinhardt Kristensen in 1983, and he and Peter Funch discovered yet another new phylum in 2000, the Micrognathozoa.

Cycliophorans live on the mouthparts of claw lobsters on both sides of the North Atlantic. When the lobster to which they are attached starts to molt, the tiny cycliophoran undergoes sexual reproduction. Each male, which consists of nothing but brains and reproductive organs, seeks out a female on the molting lobster and fertilizes her eggs, generating free-swimming larvae that can seek out another lobster and continue the life cycle.

**Figure 33.15 Phylum Acoela.** An acoel flatworm of the genus *Waminoa*. These flatworms, long thought to be relatives of the Platyhelminthes, have a primitive nervous system and lack a permanent digestive cavity.

### Figure 33.16 Phylum Cyclophora.

About the size of the period at the end of this sentence, these acoelomates live on the mouthparts of claw lobsters. One feeding stage (and part of a second one) of *Symbion pandora* are shown attached to the mouthpart of a lobster.

#### Learning Outcomes Review 33.3

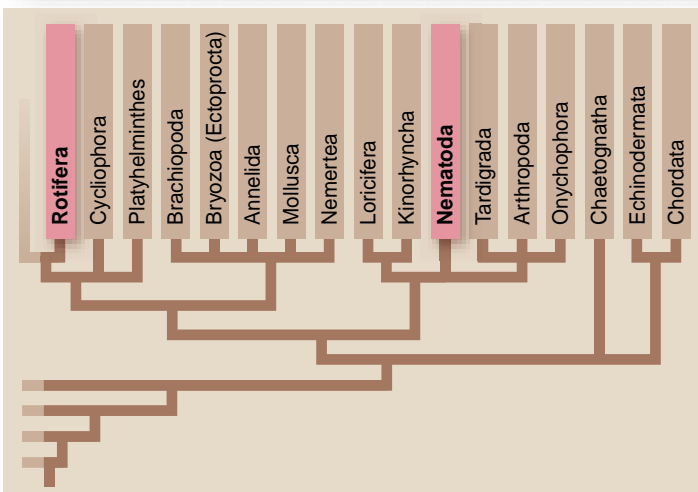

The acoelomates, typified by flatworms, are compact, bilaterally symmetrical animals. Most have a blind digestive cavity with only one opening; they also have an excretory system consisting of flame cells within tubules that run throughout the body. Many are free-living, but some cause human diseases. The scolex of a tapeworm is not a head, but simply an anchoring device to hold the animal in the intestine where it acts as a parasite.

- How does the anatomy of a tapeworm relate to its way of life?

## 33.4 The Pseudocoelomates

#### Learning Outcomes

1. Describe the distinguishing features of pseudocoelomates.
2. Describe the musculature of a nematode that allows it to wriggle in a highly characteristic manner.
3. Explain why rotifers are referred to as “wheel animals.”

All bilaterians except acoelomates possess an internal body cavity. One type of cavity is a pseudocoelom, which, you will

recall, lies between tissues derived from the mesoderm and those derived from the endoderm (chapter 32; see figure 32.2). The pseudocoelomic fluid performs the functions carried out by a circulatory system in most coelomate animals. The pseudocoelom also serves as a hydrostatic skeleton. The hydrostatic skeleton of both pseudocoelomates and coelomates is an improvement on the one supporting cnidarian polyps and medusae because, not being the digestive cavity, it is entirely isolated from the environment. The movement of these animals with a hydrostatic skeleton is more efficient than that of the solid acoelomates.

Recall that pseudocoelomates are not monophyletic. Most belong to the Ecdysozoa, which includes phyla Nematoda, Kinorhyncha, and Loricifera. Other pseudocoelomates, such as the rotifers, belong to the Platyzoa. In this section, we focus on two significant pseudocoelomate phyla.

### The roundworms, phylum Nematoda, are ecdysozoans comprising many species

Vinegar eels, eelworms, and other roundworms constitute a large phylum, **Nematoda**, with some 20,000 recognized species; scientists estimate that the actual number might approach 100 times that many. Nematodes are abundant and diverse in marine and freshwater habitats, and many members of this phylum are parasites of animals (figure 33.17) and plants. Many nematodes are microscopic and live in soil. A spadeful of fertile soil may contain, on the average, a million nematodes.

#### Nematode structure

Nematodes are bilaterally symmetrical, unsegmented worms covered by a flexible, thick cuticle that is molted as they grow—parasitic nematodes molt four times. Lacking specialized respiratory organs, nematodes exchange oxygen and carbon dioxide through their cuticles. Muscles beneath the epidermis, which underlies the cuticle, extend longitudinally, from anterior to posterior. Nematodes are unusual among worms in that they lack circular musculature, so they can shorten but not change

### Figure 33.17 *Trichinella* nematode encysted in pork.

The serious disease trichinosis can result from eating undercooked pork or bear meat containing such cysts.

diameter. The pulling of these longitudinal muscles against both the cuticle and the pseudocoelom produces the characteristic wriggling motion of nematodes.

Nematodes possess a well-developed digestive system and feed on a diversity of food sources. Near the mouth, at the anterior end, are hairlike sensory structures. The mouth may be equipped with piercing organs called **stylets**. Food passes into the mouth as a result of the sucking action produced by the rhythmic contraction of a muscular pharynx and continues through the intestine; waste is eliminated through the anus (figure 33.18).

### Reproduction and development

Reproduction in nematodes is sexual; most nematodes are gonochoric. Nematode males and females differ in form, a state known as **sexual dimorphism** (meaning “two bodies”): the tail end of the smaller male is hooked (see figure 33.18), whereas that of a female is straight. Fertilization is internal, the male using its hooked end and associated structure to help inseminate the female. Development is indirect, meaning that an egg hatches into a larva, which does not grow directly into an adult, but must pass through several molts and, in parasitic species, transfer from one host to another.

The adults of some species consist of a fixed number of cells, a phenomenon known as eutely. For this reason, nematodes have become extremely important subjects for genetic and developmental studies (see chapter 19). The 1 mm long *Caenorhabditis elegans* matures in three days; its body is transparent, and it has precisely 959 cells. It is the only animal whose complete developmental cellular anatomy is known.

### Nematode lifestyles

Many nematodes are active hunters, preying on protists and other small animals. Many are parasites of plants or live within the bodies of larger animals. Almost every species of plant and animal that has been studied has been found to have at least one parasitic species of nematode. The largest known nematode, which can attain a length of 9 m, parasitizes the placenta of sperm whales.

### Nematode-caused human diseases

About 50 species of nematodes, including several that are rather common in the United States, regularly parasitize human beings. Hookworms, most of the genus *Necator*, can be common in southern states. By sucking blood through the intestinal wall, they can produce anemia.

The most serious and common nematode-caused disease in temperate regions is trichinosis. Worms of the genus *Trichinella* (see figure 33.17) live in the small intestine of some mammals, especially pigs and bears, where fertilized females burrow through the intestinal wall and release live young (as many as 1500 per female). The young enter the lymph channels, which transport them to muscles throughout the body. There they mature and form highly resistant, calcified cysts. Eating undercooked or raw pork or bear in which cysts are present transmits the worm. Fatal infections, which can occur if the worms are abundant, are rare: in the United States, only about 20 deaths have been attributed to trichinosis during the past decade.

It is estimated that pinworms, *Enterobius vermicularis*, infect about 30% of children and 16% of adults in the United States. Adult pinworms live in the human rectum where they

**Figure 33.18 Phylum Nematoda: Roundworms.** Roundworms such as this male nematode possess a body cavity between the gut and the body wall called the pseudocoelom. It allows nutrients to circulate throughout the body and prevents organs from being deformed by muscle movements.

usually cause nothing more serious than itching of the anus; large numbers, however, can lead to prolapse of the rectum. The worms can easily be killed by drugs.

The intestinal roundworm *Ascaris lumbricoides* infects approximately one of six people worldwide, but is rare in areas with modern plumbing. An adult female, which can be as much as 30 cm long, can release as many as 20,000 fertilized eggs each day into the gut of its host. The eggs, are carried from the body in the host's feces, and can remain viable for years in the soil; dust may carry them onto food, eating implements, or lips. Because the embryo has developed in each egg before it is shed, once it is ingested, it hatches. The larva follows a circuitous path through the body, and metamorphoses into an adult, which lives in the human intestine.

Some nematode-caused diseases are extremely serious in the tropics. Filariasis is caused by several species of nematodes that infect at least 250 million people worldwide. Filarial worms of some species live in the circulatory system. Infection by *Wuchereria bancrofti* may produce the condition known as elephantiasis, in which the lower extremities may swell to disfiguring proportions. This occurs because worms clog the lymph nodes, causing severe inflammation and resulting in swelling by preventing the lymph from circulating. The larval filarial worms are transmitted by an intermediate host, typically a blood-sucking insect such as a mosquito.

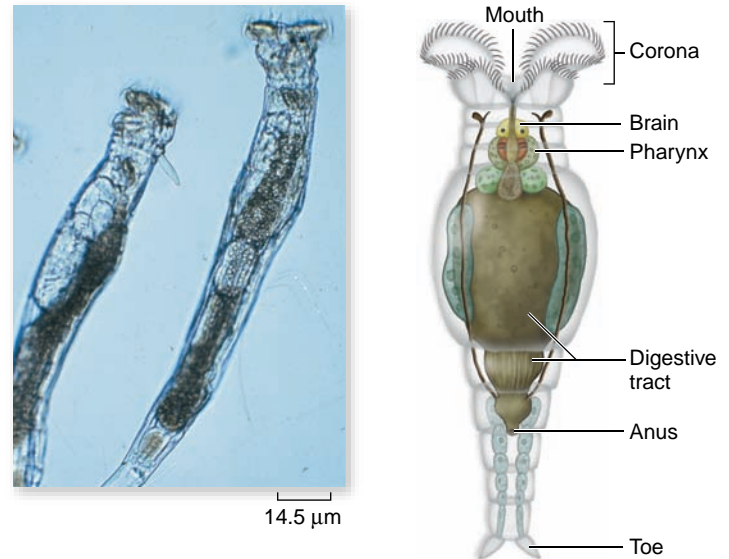

### The rotifers, phylum Rotifera, are tiny

Rotifers (phylum **Rotifera**) are bilaterally symmetrical, unsegmented pseudocoelomates (figure 33.19) that look nothing like nematodes. Several features suggest their ancestors may have resembled flatworms, with which they are classified in the spiralian Platyzoa.

At 50 to 500  $\mu\text{m}$  long, rotifers are smaller than some ciliate protists. But they have complex bodies with three cell layers, highly developed internal organs, and a complete gut. An extensive pseudocoelom acts as a hydrostatic skeleton; the cytoskeleton provides rigidity. A rotifer has a rigid external covering, but its body can lengthen and shorten greatly because the posterior part is tapered so it can fold up like a telescope. Many have adhesive toes used for clinging to vegetation and other such objects.

#### Diversity and distribution

About 1800 species are known, most of which occur in fresh water; a few rotifers live in soil, the capillary water in cushions of mosses, and the ocean. The lifespan of a rotifer is typically no longer than 1 or 2 weeks, but some species can survive in a des-

**Figure 33.19 Phylum Rotifera.** Microscopic in size, rotifers are smaller than some ciliate protists, and yet have complex internal organs.

iccated, inactive state on the leaves of plants; when rain falls, the rotifers become active and feed in the film of water that temporarily covers the leaf.

#### Food gathering

The corona, a conspicuous ring of cilia at the anterior end (see figure 33.19), is the source of the common name “wheel animals” for rotifers because its beating cilia make it appear that a wheel is rotating around the head of the animal. The corona is used for locomotion, but its cilia also sweep food into the rotifer’s mouth. Once food is swallowed, it is crushed with a complex jaw in the pharynx.

#### Learning Outcomes Review 33.4

Pseudocoelomates have fluid-filled body cavities lined by endoderm and mesoderm. Nematodes are bilaterally symmetrical, unsegmented worms that have longitudinal muscle, but not muscle in a circle around the body. Aside from the many free-living species, some nematodes are parasites of animals and plants. Rotifers are extremely small but with highly complex body structure; the name “wheel animals” comes from the apparent motion of their beating cilia.

- **What modern development is most effective in combating the spread of intestinal roundworms?**

### 33.1 Parazoa: Animals That Lack Specialized Tissues

**The sponges, phylum Porifera, have a loose body organization.**

Sponges lack tissues and organs and a definite symmetry, but they do have a complex multicellularity. Larval sponges are free-swimming, and the adults are anchored onto submerged objects.

**The sponge body is composed of several cell types.**

Sponges are composed of three layers: an external protective epithelial layer; a central protein-rich matrix called mesohyl with amoeboid cells; and an inner layer of choanocytes that circulate water and capture food particles (see figure 33.1*b*).

**Choanocytes help circulate water through the sponge.**

The mesohyl may contain spicules and/or fibers of a tough protein called spongin that strengthen the body of the sponge.

**Sponges reproduce both asexually and sexually.**

Fragments of a sponge are able to grow into complete individuals. Sperm and eggs may be produced by mature individuals; these undergo fertilization to form zygotes that develop into free-swimming larvae that eventually become sessile adults.

### 33.2 Eumetazoa: Animals with True Tissues

**All cnidarians, phylum Cnidaria, are carnivores.**

Members of the carnivorous and radially (or biradially) symmetrical Cnidaria have distinct tissues but no organs. They are diploblastic and have two body forms: a sessile, cylindrical polyp and a free-floating medusa (see figure 33.3).

Cnidarians are distinguished by capsules called nematocysts that are used in offense and defense.

Cnidarians have no circulatory, excretory, or respiratory systems. They have a latticework of nerve cells and are sensitive to touch; some have gravity receptors and light receptors.

**Cnidarians are grouped into four—or five—classes.**

The five classes of Cnidaria are the Anthozoa (sea anemones, corals, seafans); Cubozoa (box jellies); Hydrozoa (hydroids, Hydra), Scyphozoa (jellyfish); and Staurozoa (star jellies). The Staurozoa class is not accepted by all scientists.

**The comb jellies, phylum Ctenophora, use cilia for movement.**

Ctenophora (comb jellies) is a small phylum of medusa-like animals that propel themselves with bands of fused cilia. They may be triploblastic. They capture prey with colloblasts, cells that release an adhesive.

### 33.3 The Bilaterian Acoelomates

The Bilateria are characterized by bilateral symmetry, which allows for functional specialization such as having nerve receptors at the anterior end of the body.

**The flatworms, phylum Platyhelminthes, have an incomplete gut.**

Free-living flatworms, phylum Platyhelminthes, move by muscles and ciliated epithelial cells. They also exhibit a head and an incomplete gut (see figure 33.11).

Flatworms have an excretory system containing a fine network of tubules with flame cells. The primary function of this system is water balance.

Flatworms reproduce sexually and are hermaphroditic. They also have the capacity for asexual regeneration.

**Flatworms comprise two major groups.**

Free-living flatworms belong to the groups Turbellaria, which is likely not to be monophyletic.

Parasitic flatworms belong to the group Neodermata, of which there are two groups: the flukes (Trematoda), and the tapeworms and their relatives (Cercaromorphs). Flukes and tapeworms can cause disease in humans.

**Acoel flatworms appear to be distinct from Platyhelminthes: A case study.**

Acoel flatworms, phylum Acoela, were once considered basal to the phylum Platyhelminthes, but they may have evolved before the split between protostomes and deuterostomes.

**Phylum Cycliophora was discovered relatively recently.**

Cycliophorans are tiny organisms that live on the mouthparts of claw lobsters. They undergo sexual reproduction that coincides with the lobsters' molts.

### 33.4 The Pseudocoelomates

A pseudocoelom is a cavity between tissues derived from mesoderm and tissues derived from endoderm. The pseudocoelomate animals do not represent a clade.

**The roundworms, phylum Nematoda, are ecdysozoans comprising many species.**

Nematodes, which are ecdysozoans, reproduce sexually and exhibit sexual dimorphism. More species of nematodes may exist than species of arthropods.

Some important human, veterinary, and plant diseases are caused by nematodes, including hookworm, pinworm, trichinosis, intestinal roundworm, and filariasis.

**The rotifers, phylum Rotifera, are tiny.**

The tiny rotiferans are spiralian, and belong to the Platyzoa.

Rotifers propel themselves and gather food with cilia and break down food with a complex jaw located in the pharynx. They are either free-swimming or sessile.

## Review Questions

### UNDERSTAND

- In modern phylogenetic analysis of the animals, the protostomes are divided into two major groups based on what characteristic?
  - Their symmetry
  - Having a head
  - Their ability to molt
  - The presence or absence of vertebrae
- Which of the following cell types of a sponge possesses a flagellum?
  - Choanocyte
  - Amoebocyte
  - Epithelial
  - Spicules
- Spicules and spongin are found \_\_\_\_\_ of a sponge.
  - within the osculum
  - within the mesohyl
  - within the choanocytes
  - outside of the epithelial cells
- The larval stage of a cnidarian is known as a
  - medusa.
  - planula.
  - polyp.
  - cnidocyte.
- In the flatworm, flame cells are involved in what metabolic process?
  - Reproduction
  - Digestion
  - Locomotion
  - Osmoregulation
- Which of the following nematodes cause disease?
  - Filarial worms
  - Pinworms
  - Trichina worms
  - All of the above
- Which of the following have a complete gut?
  - Tapeworms
  - Medusae
  - Nematodes
  - None of the above

### APPLY

- All animals have which of the following characteristics?
  - Body symmetry
  - Tissues
  - Multicellularity
  - Body cavity
- Which of the following cell layers is not necessary to be considered a eumetazoan?
  - Ectoderm
  - Endoderm
  - Mesoderm
  - All of the above are found in all eumetazoans.
- Which of the following would be considered a neodermatan?
  - Earthworm
  - Fluke
  - Tapeworm
  - Both b and c

### SYNTHESIZE

- What do the phyla Acoela and Cycliophora tell you about our understanding of noncoelomate invertebrates? Do you think that the phylogeny presented in section 33.2 is complete? Explain your answer.
- What benefit would being a hermaphrodite confer on a parasitic species?
- Does the lack of a digestive system in tapeworms indicate that it is a primitive, ancestral form of platyhelminthes? Explain your answer.

# Coelomate Invertebrates

## Chapter Outline

- 34.1 Phylum Mollusca: The Mollusks
- 34.2 Phylum Nemertea: The Ribbon Worms
- 34.3 Phylum Annelida: The Annelids
- 34.4 The Lophophorates: Bryozoa and Brachiopoda
- 34.5 Phylum Arthropoda: The Arthropods
- 34.6 Phylum Echinodermata: The Echinoderms

## Introduction

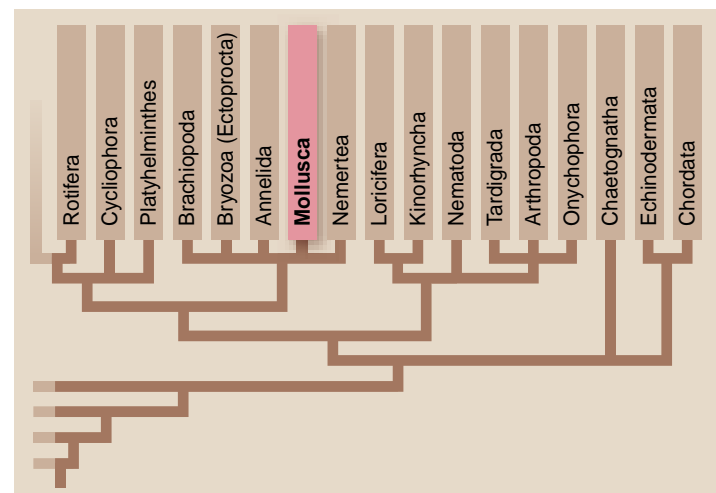

The body cavity of some animals is a coelom. As described in chapter 32, a coelom is an internal space lined with tissue derived from mesoderm. Clades of coelomate animals can be recognized by details of how the coelom develops and other features such as whether the body is segmented or the skeleton is internal or external. Some animals with a coelom are protostomes; all deuterostomes have a coelom. Among coelomate protostomes are mollusks, annelids, and arthropods. Deuterostomes include echinoderms, which are exclusively marine animals, and chordates (the subject of chapter 35).

## 34.1 Phylum Mollusca: The Mollusks

### Learning Outcomes

1. List the defining features of phylum Mollusca.
2. Describe representatives of the four best-known groups of mollusks.
3. Explain the distinguishing features of cephalopods.

Mollusks (phylum Mollusca) are diverse morphologically and live in many types of environments. With more than 110,000 described species, the phylum is second only to arthropods. Mollusks include snails, slugs, clams, scallops,

**Figure 34.1 Mollusk diversity.** Mollusks exhibit a broad range of variation. *a.* The flame scallop, *Lima scabra*, is a filter feeder. *b.* The blue-ringed octopus, *Hapalochlaena maculosa*, is one of the few mollusks dangerous to humans. Strikingly beautiful, it is equipped with a sharp beak that can deliver a poisonous bite! *c.* Nautilus, such as this chambered nautilus, *Nautilus pompilius*, have been around since before the age of the dinosaurs. *d.* The banana slug, *Ariolimax columbianus*, native to the Pacific Northwest, is the second largest slug in the world, attaining a length of 25 cm.

oysters, cuttlefish, octopuses, and many other familiar animals (figures 34.1 and 34.2). The shells of many mollusks are beautiful and elegant; they have long been collected, preserved, and studied by professional scientists and amateurs. Some mollusks, however, lack a shell.

### Mollusks are extremely diverse— and important to humans

Mollusks range in size from almost microscopic to huge. Although most measure a few millimeters to centimeters in their largest dimension, the giant squid may grow to more than 15 m

**Figure 34.2 Giant clam.** Second only to the arthropods in number of described species, members of the phylum Mollusca occupy almost every habitat on Earth. This giant clam, *Tridacna maxima*, contains symbiotic dinoflagellates (zooxanthellae) as do reef-forming corals. Through photosynthesis, the dinoflagellates probably contribute to the food of the clam, although it is a filter feeder like most bivalves. Some individual giant clams may be nearly 1.5 m long and weigh as much as 270 kg.

long and weigh as much as 250 kg. It is therefore one of the heaviest invertebrates (although nemerteans can be longer, as discussed later). Other large mollusks are the giant clams of the genus *Tridacna*, which may be as long as 1.5 m and may weigh as much as 270 kg (see figure 34.2).

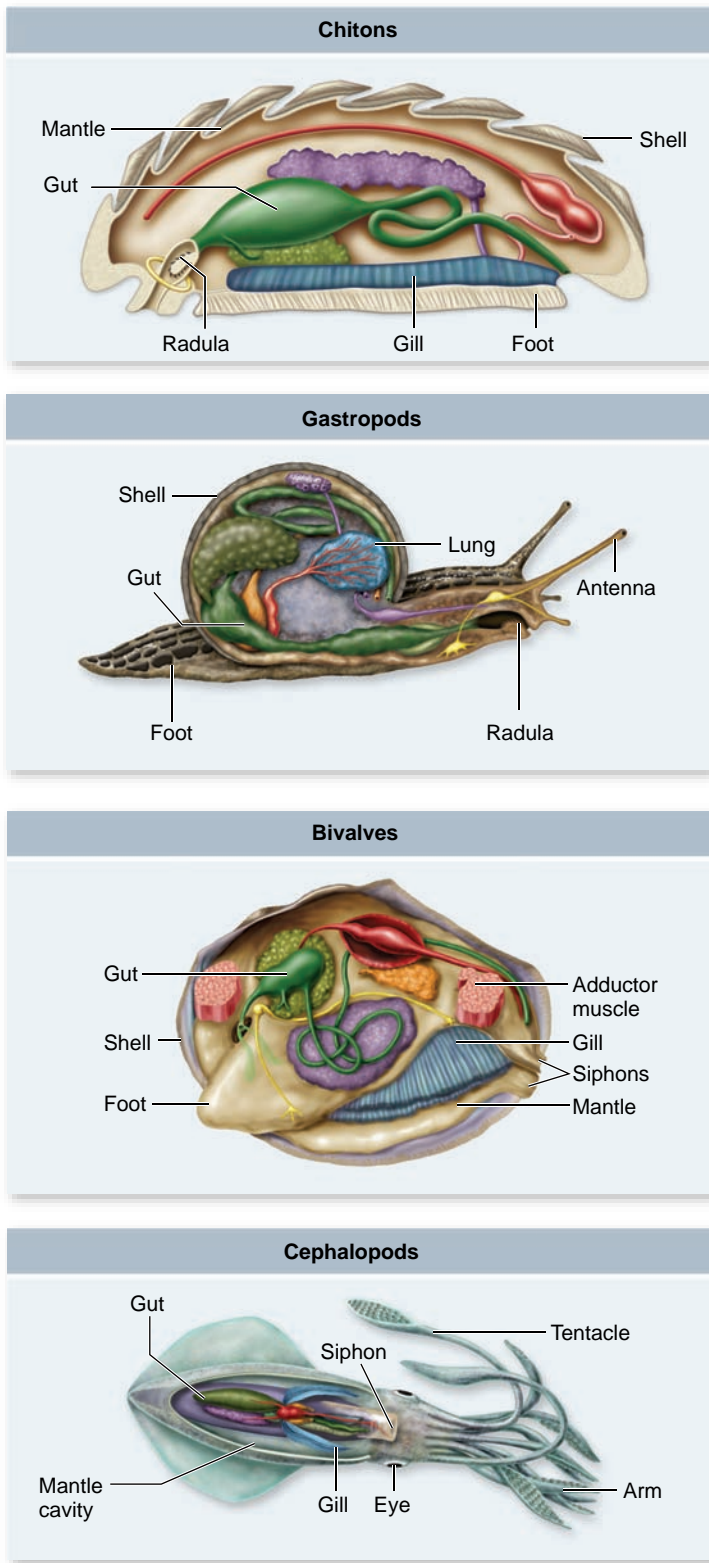

Like all major animal groups, mollusks evolved in the oceans, and most groups have remained there. Marine mollusks are widespread and many are abundant. Snails and slugs have invaded freshwater and terrestrial habitats, and freshwater mussels live in lakes and streams (the flat foot of a snail or slug allows it to crawl, but the foot of clams, mussels, and other bivalved mollusks is adapted to digging, so they cannot move about on land). Some places where terrestrial mollusks live, such as crevices of desert rocks, may appear dry, but if mollusks live there, the habitat has at least a temporary supply of water.

Mollusks—including oysters, clams, scallops, mussels, octopuses, and squids—are an important source of food for humans. They are also economically significant in other ways. For example, the material called mother-of-pearl (nacre), which is used for jewelry and other decorative objects, and formerly for buttons, comes from mollusk shells, most notably that of the abalone. Mollusks can also be pests. Bivalves called ship-worms burrow through wood exposed to the sea, damaging boats, docks, and pilings. The zebra mussel (*Dreissena polymorpha*) (see figure 60.16) has recently invaded many North American freshwater ecosystems. Many slugs and snails damage flowers, vegetable gardens, and crops. Other mollusks serve as hosts to the larval stages of many serious parasites, as discussed in chapter 33.

### The mollusk body plan is complex and varied

Some mollusk body plans are illustrated in figure 34.3. The **mantle**, a thick epidermal sheet, covers the dorsal side of the body, and bounds the mantle cavity. The mantle secretes the calcium carbonate of the shell in those mollusks with a shell. The muscular foot is the primary means of locomotion in mollusks other than cephalopods (octopuses, squid, and

**Figure 34.3** Body plans of some mollusks.

chambered nautilus). The head may be well developed or not. Like all coelomates, mollusks are bilaterally symmetrical, but this symmetry is modified during development of many gastropods (snails and their relatives), which undergo torsion (a twisting of the body discussed in detail later on).

The muscular foot is variously adapted for locomotion, attachment, food capture, digging, or combinations of these

functions. The foot of slugs and snails secretes mucus, forming a path that it glides along. In cephalopods, the foot is divided into tentacles and, in some cephalopods, arms. Clams burrow into mud and sand using their hatchet-shaped foot. In some mollusks that live in the open ocean, the foot is modified into winglike projections, the large surface area of which serves to slow its sinking. The feet of these mollusks can beat like wings.

### Internal organs

In all mollusks, the coelom is highly reduced, being limited to small spaces around the excretory organs, heart, and part of the intestine. An important role of the coelom in some other invertebrates (that is, forming the hydrostatic skeleton) is served in mollusks by the shell. The digestive, excretory, and reproductive organs are concentrated in a **visceral mass**.

In aquatic mollusks, the **ctenidia** (or gills, the respiratory structures) project into the mantle cavity (see figure 34.3). They consist of filaments rich in blood vessels that greatly increase the surface area and capacity for gas exchange. The continuous stream of water that passes through the mantle cavity, propelled by cilia on the gills of all mollusks except cephalopods, carries oxygen in and carbon dioxide away. Mollusk ctenidia are so efficient that they can extract 50% or more of the dissolved oxygen from the water that passes through the mantle cavity. In addition to extracting oxygen from incoming water, the gills of most bivalves filter out food. Because the outlets from the excretory, reproductive, and digestive organs open into the mantle cavity, wastes and gametes are carried away from a mollusk's body with the exiting water stream.

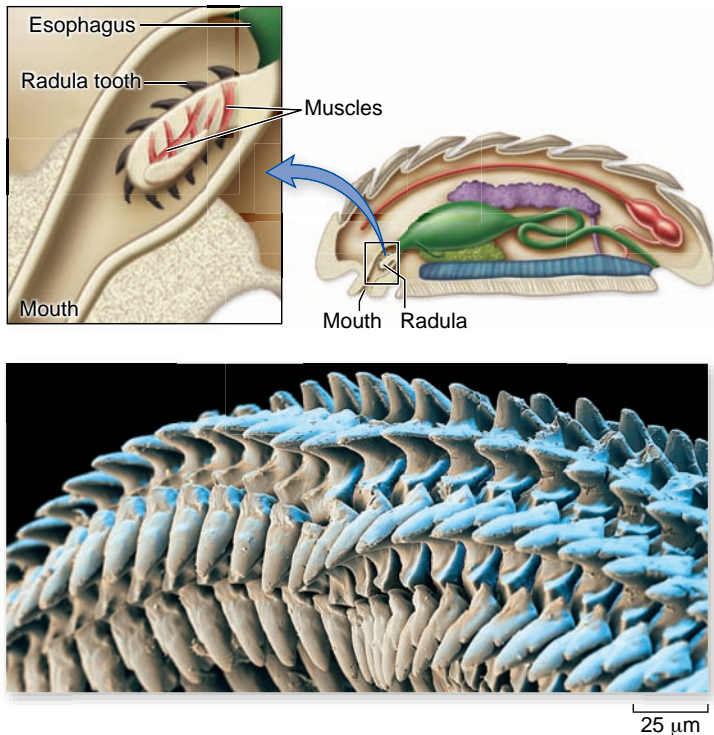

### Shells

One of the best known characters of the phylum is the shell. A mollusk shell, which is secreted by the outer surface of the mantle, protects against predators and adverse environmental conditions. However, a shell is clearly not essential: reduction, internalization, and loss of the shell have evolved repeatedly. Examples of shell-less mollusks are cuttlefish, squids, and octopuses (cephalopods) as well as slugs (gastropods).

A typical mollusk shell consists of two layers of calcium carbonate, which is precipitated extracellularly. The outer layer consists of densely packed crystals. In some species, the inner layer is pearly in appearance, and is called mother-of-pearl or nacre. Particularly in freshwater mollusks, the mineralic layers are covered by a thin organic coating rich in the protein conchiolin that protects the shell from dissolving. Pearls are formed when a foreign object, such as a grain of sand, becomes lodged between the mantle and the inner shell layer. The mantle coats the object with layer upon layer of nacre to reduce the irritation caused by the object. The most beautiful and highly valued pearls are produced by oysters.

### Feeding and prey capture: Radula

A characteristic feature of most mollusks is the **radula** (plural, *radulae*), a rasping, tonguelike structure used in feeding. It consists of dozens to hundreds of microscopic, chitinous teeth arranged in rows on an underlying membrane and lies in a chamber at the anterior end of the gut (figure 34.4). The

**Figure 34.4** Structure of the radular apparatus in a chiton. The radula consists of rows of teeth made of chitin. As the animal feeds, its mouth opens, and the radula is thrust out to scrape food off surfaces.

membrane wraps around a muscular support structure so the radula can be protruded through the mouth and move something like a sanding belt over what is being rasped. Benthic mollusks use their radulae to scrape up algae and other food materials.

In some predatory gastropods (such as moon snails), the radula is modified to drill through clam shells so the snail can eat the clams. In snails of the genus *Conus*, the radula has been transformed into a harpoon that is associated with a venom gland; cone snails use this harpoon to capture prey such as fish, and some cone snails can harm—or even kill—humans.

Bivalves are the only mollusks that have no radula. The gills of most bivalves are adapted to filter food particles from the water, although primitive bivalves pick up bits of food from soft sediments (this is, they are deposit feeders) using appendages around the mouth.

### Removal of wastes

Nitrogenous wastes are removed from the mollusk body by the **nephridium** (plural, *nephridia*), a sort of kidney. A typical nephridium has an open funnel, the **nephrostome**, which is lined with cilia. A coiled tubule runs from the **nephrostome** into a bladder, which in turn connects to an excretory pore. Wastes are gathered by the nephridia from the coelomic cavity and discharged into the mantle cavity. Sugars, salts, water, and other materials are reabsorbed by the walls of the nephridia and returned to the animal's body as needed to maintain osmotic balance.

### The circulatory system

The main coelomic cavity of a mollusk is a hemocoel, which comprises several sinuses and a network of vessels in the gills, where gas exchange takes place. Except for cephalopods, all mollusks have such an open circulatory system; blood (technically termed “hemolymph”) is propelled by a heart through the aorta vessel that empties to the hemocoel. The blood moves through the hemocoel being recaptured by other venous vessels before re-entering the heart (see chapter 50). The heart of most, but not all mollusks has three chambers, two that collect aerated blood from the gills, and a third that pumps it into the hemocoel. The blood of the closed circulatory system of cephalopods is contained in a continuous system of vessels, so it does not contact other tissues directly.

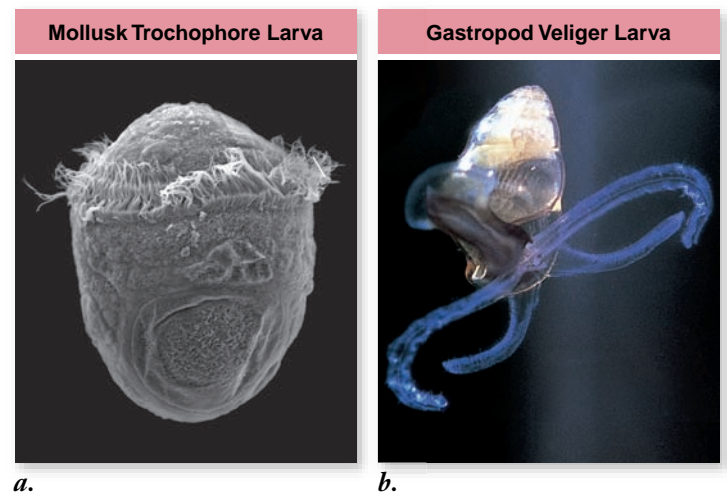

### Reproduction

Most mollusks have separate sexes although a few bivalves and many freshwater and terrestrial gastropods are hermaphroditic. Most hermaphroditic mollusks engage in cross-fertilization. Some oysters are able to change sex.

As is typical of animals living in the sea, many marine mollusks have external fertilization: gametes are released by males and females into the water where fertilization occurs. Most gastropods, however, have internal fertilization, with the male inserting sperm directly into the female's body (not, that is, into a preformed channel). Internal fertilization, a foot, and an efficient excretory system that prevents desiccation are some of the key adaptations that allowed gastropods to colonize the land.

A mollusk zygote undergoes spiral cleavage (thus Mollusca is part of the Spiralia; see chapter 32). The embryo develops into a free-swimming larva called a trochophore (figure 34.5a) that closely resembles the larval stage of many marine annelids and other lophotrochozoans. A trochophore swims by means of cilia that encircle the middle of its body.

In most marine snails and in bivalves, the trochophore develops into a second free-swimming stage, the **veliger**. The veliger forms the beginnings of a foot, shell, and mantle (figure 35.5b). Trochophores and veligers drift widely in the ocean, dispersing these otherwise sedentary mollusks.

**Figure 34.5** Stages in the molluscan life cycle. *a.* The trochophore larva. Similar larvae are characteristic of some annelid worms as well as a few other phyla. *b.* The veliger stage of a gastropod.

## Four classes of mollusks show the diversity of the phylum

We examine four of the seven or eight recognized classes of mollusks: (1) Polyplacophora—chitons; (2) Gastropoda—limpets, snails, slugs, and their relatives; (3) Bivalvia—clams, oysters, scallops, and their relatives; and (4) Cephalopoda—squids, octopuses, cuttlefishes, and the chambered nautilus.

By studying living mollusks and the fossil record, some scientists have deduced that the ancestral mollusk was probably a bilateral, dorsoventrally flattened, unsegmented, wormlike animal that glided on its ventral surface. This animal may have had a chitinous cuticle that secreted calcareous spicules. Other scientists infer that mollusks arose from segmented ancestors and became unsegmented secondarily.

### Class Polyplacophora: Chitons

Chitons are exclusively marine; there are perhaps 1000 species. The oval body is covered dorsally with eight overlapping dorsal calcareous plates (figure 34.6). The body is not segmented, but chitons do have eight sets of dorsoventral pedal retractor muscles and serially repeated gills. The broad, flat ventral foot, on which the animal creeps, is surrounded by a groove, the mantle cavity, in which the gills are suspended. Most chitons are grazing herbivores, and live in shallow marine habitats, but chitons occur to depths of more than 7000 m.

### Class Gastropoda: Snails and slugs

The 40,000 or so species of limpets, snails and slugs belong to this class, which is primarily marine. However, this group contains many freshwater species and the only terrestrial mollusks (figure 34.7). Most gastropods have a single shell, but some, such as slugs and nudibranchs (or sea slugs), have lost the shell through the course of evolution. Most gastropods creep on a foot, but in some it is modified for swimming.

The head of most gastropods has a pair of tentacles, which serve as chemo- or mechanoreceptors, with eyes at the base. A typical garden snail may have two sets of tentacles, one of them bearing eyes at the ends (see figure 34.7).

Uniquely among animals, gastropods undergo torsion during larval life. **Torsion** involves twisting of the body so the

**Figure 34.6** The noble chiton, *Eudoxochiton nobilis*, from New Zealand. The foot of the chiton can grip the substrate very strongly, making chitons hard to dislodge by waves or predators.

**Figure 34.7** A Gastropod mollusk. The terrestrial Oregon forest snail *Allogona townsendiana*.

mantle cavity and anus are moved from a posterior location to the front of the body. Torsion may lead to the reduction or disappearance of the nephridium, gonad, or other internal organs on one side. Most adult gastropods are therefore not bilaterally symmetrical. Torsion should not be confused with coiling, the spiral winding of the shell. Coiling also occurs in cephalopods. The fossil record suggests that the first gastropods were coiled but did not undergo torsion.

Like many gastropods, nudibranchs (sea slugs) are active predators. Nudibranchs get their name from their gills, which, instead of being enclosed within the mantle cavity, are exposed along the dorsal surface (figure 34.8). Nudibranchs would seem vulnerable to predation, but many secrete distasteful chemicals. They prey on animals that are avoided by other predators. Some are specialist feeders on sponges, most species of which form spicules and noxious chemicals. Other nudibranchs specialize in feeding on cnidarians, which are protected from most predators by their nematocysts. Some of these nudibranchs have the extraordinary ability to extract the

**Figure 34.8** A nudibranch (or sea slug). The bright colors of many nudibranchs such as this alert predators to their repulsive taste.

nematocysts undischarged, transfer them through their digestive tract to the surface of their bodies, and use them for their own protection.

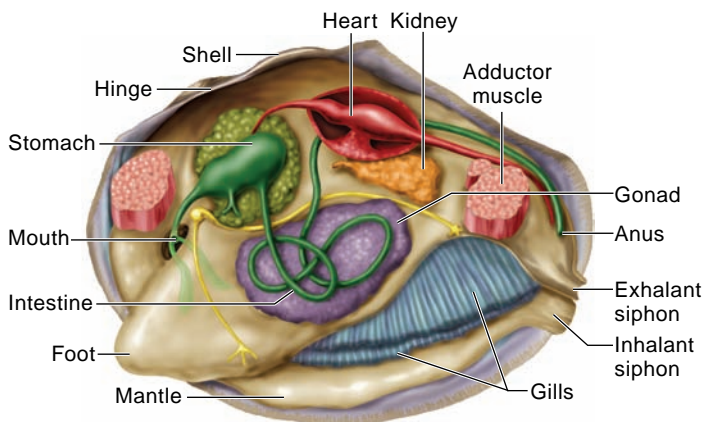

In terrestrial gastropods, the mantle cavity, which is occupied by gills in aquatic snails, is extremely rich in blood vessels and serves as a lung. This lung absorbs oxygen from the air much more effectively than a gill could; however, a snail will drown if its lung fills with water; for this reason, terrestrial gastropods can close the opening of the lung to the outside.

### **Class Bivalvia: Clams, mussels, and cockles**

Most of the 10,000 species of bivalves are marine, but some live in fresh water. More than 500 species of pearly freshwater mussels, or naiads, occur in the rivers and lakes of North America.

Unlike other mollusks, a bivalve does not have a radula or distinct head (figure 34.9). The foot of most is wedge-shaped, adapted for burrowing or anchoring the animal in its burrow. Some species of clams can dig into sand or mud very rapidly by means of muscular contractions of their foot. Some species of scallops and file clams can move swiftly by clapping their shells rapidly together (although they cannot control the direction of their movement); the adductor muscle that allows this clapping is the part of a scallop eaten by humans. Projecting from the edge of a scallop's mantle are tentacle-like projections having complex eyes between them.

Bivalves, as their name implies, have two shells (valves) that are hinged dorsally so the shells are oriented laterally (left and right). A ligament lying along the hinge is structured so it causes the shells to gape open. One or two large adductor muscles link the shells internally (see figure 34.9), and when they contract, they counteract the hinge ligament to draw the shells together. The mantle covers the internal surface of the shells, enveloping the visceral mass on its inner side and secreting the shells on its outer side. As is typical of mollusks, the respiratory structures, a set of complexly folded gills on each side of the visceral mass, lie in the mantle cavity.

**Figure 34.9** **Diagram of a clam.** The left shell and mantle are removed to show the internal organs and the foot. Bivalves such as this clam circulate water across their gills and filter out food particles.

The edges of the mantle may be partly fused. In bivalves in which this is the case, typically two areas are not fused, and may be drawn out to form tubes called siphons (see figure 34.9). Water enters the mantle chamber through the **inhalant siphon** bringing oxygen and food, and water exits through the **exhalant siphon**, taking wastes and gametes with it. In bivalves that live buried deeply in mud or burrow into rock, the siphons allow the animals to eat and breathe, functioning essentially as snorkels.

### **Class Cephalopoda: Octopuses, squids, and nautilus**

The more than 600 species of cephalopods are strictly marine. They are active predators that swim, often swiftly, and they are the only mollusks with a closed circulatory system. The foot has evolved into a series of arms equipped with suction cups, adhesive structures, or hooks that seize prey. Octopuses, as their name suggests, have eight arms; squids have eight arms and two tentacles; and the chambered nautilus has 80 to 90 tentacles (which lack suckers). After snaring prey with its arms, a cephalopod bites the prey with its strong, beak-like jaws, then pulls it into its mouth by the action of the radula. The salivary gland of many cephalopods secretes a toxin that can be injected into prey; the tiny blue-ringed octopus of Australia (see figure 34.1b) can kill a human with its deadly bite.

Cephalopods have the largest relative brain sizes among invertebrates and highly developed nervous systems. Many exhibit complex patterns of behavior and are highly intelligent (figure 34.10); octopuses can be easily trained to distinguish

**Figure 34.10** **Problem-solving by an octopus.** This two-month-old common octopus (*Octopus vulgaris*) was presented with a crab in a jar. It tried to unscrew the lid to get to the crab. Although it failed in this attempt, in some cases it was successful.

among classes of objects and are capable of leaving one tank to seize prey in another, then returning to their original one. Cephalopod eyes are much like those of vertebrates, although they evolved independently (see chapter 45).

Aside from the chambered nautilus, living cephalopods lack an external shell. Shelled cephalopods were formerly far more diverse, as evidenced by the many fossil cephalopods such as ammonites and belemnites. These cephalopods were extraordinarily successful because they could move in open water instead of on the sea bottom like other mollusks. However, once the more maneuverable fishes evolved, shelled mollusks declined, some dying out, others experiencing evolutionary reduction and eventual loss of their heavy shells. The cuttlebone of cuttlefish and the pen of squids are internal shells that support these animals and give them some buoyancy. Even the internal shell has disappeared in the lineage that gave rise to octopuses.

As in other mollusks, water passes through the mantle cavity. In a cephalopod, it is pumped in by muscles and exits through a siphon, which allows the animal to move by jet propulsion, and which can be directed to steer. The ink sac of cephalopods, which typically contains a purplish fluid, can eject its contents through the siphon as a cloud that may hide the cephalopod and confuse predators (figure 34.11).

Most octopuses and squids are capable of changing skin color and texture to match their background or to communicate with one another. They do so using chromatophores, epithelial cells that contain pigments. Some deep-sea squids harbor symbiotic luminescent bacteria. These may be emitted with the ink to produce a glimmering cloud (ink would not be seen at depths where sunlight cannot penetrate) or they may inhabit cells like chromatophores so they can light up the surface of the animal.

Another difference with many other mollusks is that cephalopods have direct development, that is, they lack a larval stage, hatching as miniature adults.

**Figure 34.11** Ink defense by a giant Pacific octopus (*Octopus dofleini*). When threatened, octopuses and squids expel a dark cloudy liquid.

### Learning Outcomes Review 34.1

Mollusks are coelomates with a coelom surrounding the heart. Most have efficient excretory systems, ctenidia for respiration, and a rasping structure, the radula, for gathering food. The mantle of mollusks not only secretes their protective shell but also forms structures essential to body functions. Chitons, gastropods, bivalves, and cephalopods are the four best-known groups. Cephalopods lack cilia on their ctenidia and have a closed circulatory system.

- Why might a closed circulatory system be necessary in a cephalopod?

## 34.2 Phylum Nemertea: The Ribbon Worms

### Learning Outcome

1. Describe the two characteristics that place nemerteans with mollusks in the lophotrochozoa.

Nemerteans (phylum Nemertea) consist of about 900 species of cylindrical to flattened very long worms (figure 34.12). Most nemerteans are marine; a few species live in fresh water and humid terrestrial habitats. An individual may reach 10 to 20 cm in length, although the animals are difficult to measure because they can stretch, and many species break into pieces when disturbed or handled. The species *Lineus longissimus* has been reported to measure 60 m in length—the longest animal known!

The nemertean body plan resembles that of a flatworm (see chapter 33), with networks of fine tubules constituting the excretory system, and with internal organs not lying in a body cavity. A bit of cephalization is present, with two lateral nerve cords extending posteriorly from an anterior ganglion; some animals have eyespots on the head. But, by contrast with a platyhelminth, a nemertean has a complete gut, with both mouth and anus, connected by a straight tube. Nemerteans also possess a fluid-filled cavity called a rhynchocoel. This sac serves

**Figure 34.12** Phylum Nemertea: A ribbon worm of the genus *Lineus*. Some nemerteans can stretch to several meters in length.

as a hydraulic power source for the proboscis, a long muscular tube that can be thrust out quickly from a sheath to capture animal prey.

Nemerteans are gonochoric, and all reproduce sexually. Some are capable of asexual reproduction by fragmentation. However, in most species, most fragments resulting from disturbance die, so nemertean regenerative powers may not be as great as is sometimes stated.

Blood of nemerteans flows entirely in vessels that are derived from the coelom. That and the rynchocoel are good evidence that nemerteans are not related to flatworms, which they resemble superficially, but belong to the Lophotrochozoa, along with mollusks.

### Learning Outcome Review 34.2

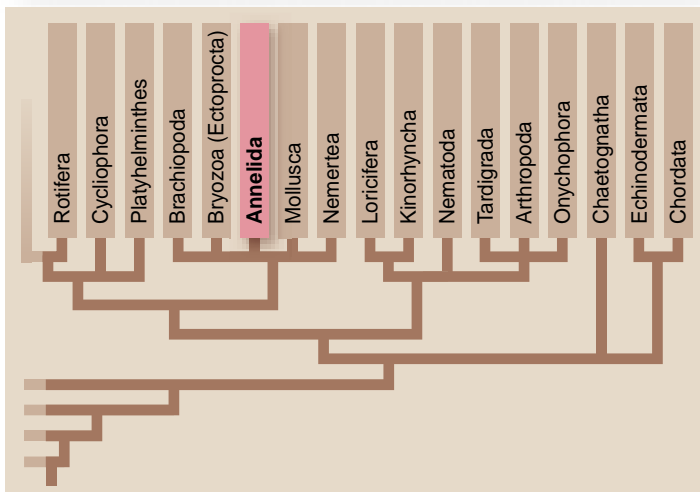

Nemerteans are very long worms that have a coelomic cavity and blood vessels derived from the coelom. They capture prey with a muscular proboscis. Unlike the acoelomate flatworms, nemerteans have a complete gut with mouth and anus.

- What would be some advantages of a flow-through digestive tract?

## 34.3 Phylum Annelida: The Annelids

### Learning Outcomes

1. Explain how circular and longitudinal muscles in a segmented body facilitate movement.
2. Distinguish between the classes Polychaeta and Clitellata.
3. Describe adaptations in leeches for feeding on the blood of animals.

An important innovation in the animal body plan was segmentation, the building of a body from a series of repeated units (see chapter 32), which has evolved multiple times. Worms of the phylum Annelida (figure 34.13) are segmented. One advan-

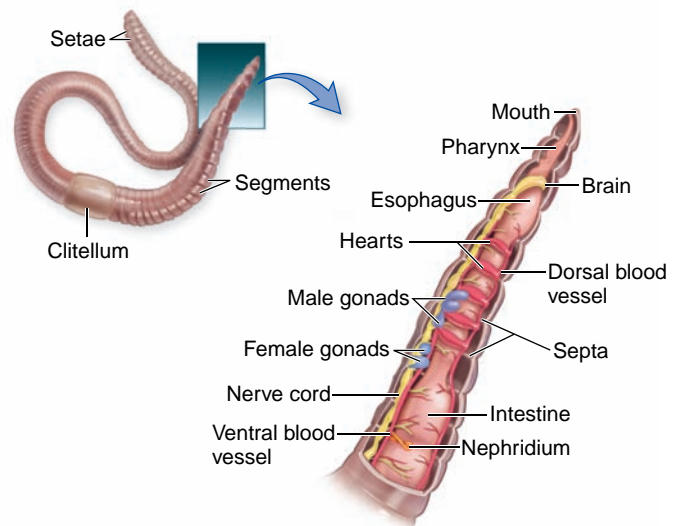

**Figure 34.13** A polychaete annelid. *Nereis virens* is a wide-ranging, predatory, marine polychaete worm equipped with feathery parapodia for movement and respiration, as well as jaws for hunting. You may have purchased *Nereis* as fishing bait!

tage of a segmented body is that the development and function of individual segments or groups of segments can differ. For example, some segments may be specialized for reproduction, whereas others are adapted for locomotion or excretion.

All animals that have been regarded as annelids are segmented, so the animals were considered to constitute a natural group, but the monophyly of Annelida is being reconsidered because some unsegmented worms may belong to this clade.

### The annelid body is composed of ringlike segments

The head, which contains a well-developed cerebral ganglion, or brain, and sensory organs occurs at the anterior end (front) of a series of ringlike segments that resemble a stack of coins (figure 34.14). Many species have eyes, which in some species have lenses and retinas. Technically the head is not a segment,

**Figure 34.14** Phylum Annelida: An oligochaete. The earthworm body plan is based on repeated body segments. Segments are separated internally from each other by septa.

nor is the posterior end of the worm, the pygidium. In embryonic development, the head and tail form first, and then segments form between them; if a worm is cut in pieces, generally only those parts containing either head or tail can regenerate the missing parts and the middle bits just die.

Internally, the segments are divided from one another by partitions called septa, just as bulkheads separate the compartments of a submarine. Each segment has a pair of excretory organs, a ganglion, and locomotory structure; in most marine annelids, each also has a set of reproductive organs.

Although septa separate the segments, materials and biological signals do pass between segments. A closed circulatory system carries blood the length of the animal, anteriorly in the dorsal vessel and posteriorly in the ventral one. Connections from ventral to dorsal vessel in each segment bring the blood near enough to each cell so oxygen and food molecules diffuse from the blood into the cells of the body wall, and carbon dioxide and other wastes diffuse from the cells into the blood. A ventral nerve cord connects the ganglia in each segment with one another and with the brain. These neural connections allow the worm to function as a unified and coordinated organism.

## Annelids move by contracting their segments

The basic annelid body plan is a tube within a tube, the digestive tract—extending from mouth to anus—passing through the septa, and suspended within the spacious coelom, which is surrounded by the body wall. Each portion of the digestive tract—pharynx, esophagus, crop, gizzard, and intestine—is specialized for a different function.

The coelomic fluid creates a hydrostatic skeleton that gives each segment rigidity, like an inflated balloon (see chapter 47). Annelid locomotion is effected by contraction of the circular and longitudinal muscles against the hydrostatic skeleton. When circular muscles are contracted around a segment, the segment decreases in diameter, so the coelomic fluid causes the segment to elongate. When longitudinal muscles are contracted, the segment shortens, so the coelomic fluid causes the segment to increase in diameter. Alternating these contractions and confining them to only some segments allows the worms to move in complex ways.

In most annelid groups, each segment possesses bristles of chitin called **chaetae** (or setae—singular, seta or chaeta). By extending the chaetae in some segments so that they protrude into the substrate and retracting them in other segments, the worm can extend its body, but not slip (see figure 47.1).

## Annelids have a common, closed circulatory system but a segmented excretory system

Unlike arthropods and mollusks, except for cephalopods, annelids have a closed circulatory system. Annelids exchange oxygen and carbon dioxide with the environment through their body surfaces, although some nonterrestrial ones have gills along the sides of the body or at the anterior end. Gases (and food molecules) are distributed throughout the body in blood vessels. Some of the vessels at the anterior end of the body are

enlarged and heavily muscular, serving as hearts that pump the blood. An earthworm has five pulsating blood vessels on each side that help to move blood from the main dorsal vessel, the major pumping structure, to the ventral vessel.

The excretory system of annelids consists of ciliated, funnel-shaped nephridia like those of mollusks. Each segment has a pair of nephridia that collect wastes and transport them out of the body by way of excretory tubes. Some polychaetes have protonephridia like the flame cells of planarians.

## Annelida comprises two—or three—classes

The roughly 12,000 described species of annelids occur in many habitats. They range in length from as little as 0.5 mm to giant Australian earthworms more than 3 m long. Although traditionally annelids have been classified into classes Polychaeta (mostly marine worms), Oligochaeta (mostly terrestrial worms, including earthworms), and Hirudinea (leeches), the monophyly of polychaetes is not well established. The classification of annelids may change in the near future, but we adopt the current two-class system of Polychaeta and Clitellata (which combines Oligochaeta and Hirudinea).

### Class Polychaeta: Polychaetes

Polychaetes include clamworms, scaleworms, lugworms, sea mice, tubeworms, and many others. Polychaetes are a crucial part of many marine food chains, and are extremely abundant in particular habitats. Some of these worms are beautiful, with unusual forms and iridescent colors (figure 34.15).

On most segments, a polychaete has paired, fleshy, paddle-like lateral projections called **parapodia** (see figures 34.13, 34.15). The parapodia bear chaetae; the word *polychaeta* means “many chaetae.” Parapodia are used in swimming, burrowing, or crawling, and those of polychaetes that live in burrows or tubes may have chaetae with hooks that help anchor the worm. Parapodia can also play an important role in gas exchange because they greatly increase the surface area of the body, and in some species they bear or are even transformed into gill-like structures.

**Figure 34.15** A polychaete. The shiny bristleworm *Oenone fulgida*. Notice chaetae extending from the iridescent parapodia.

**Figure 34.16** Giant tubeworms (*Riftia pachyptila*) living in deep-sea hydrothermal vents near the Galápagos. These tubeworms and associated animals (notice the small white crab) are an example of a community dependent on hydrogen sulfide, rather than the Sun, as an energy source.

Polychaetes can swim or crawl, and some are active predators with powerful jaws. Other polychaetes live in tubes or burrows of hardened mud, sand, mucuslike secretions, or calcium carbonate. Sedentary polychaetes may project feathery tentacles that sweep the water for food, filter feeding; the tentacles may also serve as gills, exchanging gas. Some deep-sea tubeworms such as *Riftia* (figure 34.16) are gutless as adults. Projections from the body of these worms house sulfur-oxidizing bacteria that synthesize organic compounds used by the worm. These worms aggregate near hydrothermal vents where sulfur is plentiful and can grow to more than a meter in length.

Most polychaetes are gonochoric. Gametes typically are released into the water, where fertilization occurs externally. Many polychaetes have gonads in most segments, but in some groups, gonads are confined to certain segments. In palolo worms and their relatives, these segments are at the end of the body; spawning involves the end of the worm breaking off and swimming to the surface of the sea, where it ruptures, releasing the gametes. The gamete-filled terminal parts of palolo worms are considered delicacies by some people in the South Pacific.

Fertilization results in spiral cleavage followed by the production of ciliated, mobile trochophore larvae similar to that of mollusks. Metamorphosis of a trochophore involves differentiation of a head and tail end, with development of segments in between, from a posterior growth zone.

### **Class Clitellata: Earthworms and leeches**

Some authorities still consider earthworms to belong to class Oligochaeta and leeches to class Hirudinea, but most now put earthworms and leeches into a single class, although, confusingly, it sometimes may be called Oligochaeta. More often it is called Clitellata, because of the feature that unites these seemingly quite different animals, the clitellum—a thickened band on the body, which is the familiar “saddle” of an earthworm (see figure 34.14).

**Earthworms.** The body of a typical earthworm consists of 100 to 175 similar segments. The head is not well differentiated. An earthworm has no parapodia, and its chaetae (which are fewer than in polychaetes—the word *oligochaeta* means “few chaetae”) project directly from the body wall.

Earthworms eat their way through the soil, ingesting it by muscular action of their strong pharynx; organic material is ground in the gizzard. What passes through an earthworm is deposited outside the opening of its burrow as castings that form irregular mounds. In this way, earthworms contribute to loosening, aeration, and enrichment of the soil. In view of their underground lifestyle, it is not surprising that earthworms have no eyes. But they do have light-, chemo-, and touch-sensitive cells, most concentrated in segments near each end of the body—those regions most likely to encounter light or other stimuli.

Earthworms are hermaphroditic, another way in which they differ from most polychaetes, but they cross-fertilize through mating (figure 34.17). The clitellum secretes mucus that holds the worms together during copulation, their anterior ends pointing in opposite directions, their ventral surfaces touching. Sperm cells are released from pores in specialized segments of one partner into the sperm receptacles of the other, the process going in both directions simultaneously. Several days after the worms separate, the clitellum of each worm secretes a mucus cocoon, surrounded by a protective layer of chitin. As the worm moves, this sheath passes over the female pores of the body, receiving eggs and incorporating the deposited sperm so that fertilization takes place within the cocoon. When the cocoon passes over the end of the worm, its edges pinch together. Within the cocoon, the fertilized eggs develop directly into young worms similar to adults.

**Leeches.** Most leeches live in fresh water, although a few are marine and some tropical leeches occupy terrestrial habitats. Dorsoventrally flattened, most leeches are 2 to 6 cm long, but one tropical species reaches 30 cm. Like earthworms, leeches are hermaphroditic, but the clitellum develops only during the breeding season. Leeches also cross-fertilize.

Unlike that of earthworms and polychaetes, the coelom of a leech is reduced and not divided into segments. The suckers at one or both ends of a leech’s body are used for locomotion and to attach to prey. A leech with suckers at both ends moves by attaching first one and then the other end to the substrate, looping along. Many species are also capable of swimming. Except for one species, leeches have no chaetae.

**Figure 34.17** Earthworms mating. The anterior ends are pointing in opposite directions.

**Figure 34.18 A leech.** *Hirudo medicinalis*, the medicinal leech, feeding on a human arm. Leeches use chitinous, bladelike jaws to make an incision to access blood; they secrete an anticoagulant to keep the blood from clotting. Both the anticoagulant and the leech itself have made important contributions to modern medicine.

About half the known species of leeches eat detritus or devour small animals. The others suck blood or other fluids from their hosts (figure 34.18). Such a leech secretes an anticoagulant into the wound to prevent the blood from clotting, and vasodilators to keep the blood flowing; the leech's powerful pharynx pumps the blood out quickly once a hole has been opened. Anesthetics injected into the prey prevent the leech from being noticed while piercing the skin; they are usually detected only after detaching, when blood starts to flow from the wound. Freshwater parasitic leeches may remain on their hosts for long periods, sucking the host's blood from time to time. Leeches detect prey by sensing gradients of carbon dioxide in the environment. In some tropical forests, a few seconds after you stop on a trail, you can see dozens of leeches approaching you from all directions!

One of the best-known species, the medicinal leech *Hirudo medicinalis* (see figure 34.18), reaches 10 to 12 cm long, and has bladelike, chitinous jaws that can rasp through an animal's skin. Leeches were used in medicine for hundreds of years to treat patients whose diseases were mistakenly believed to be caused by an excess of blood. Today, leeches are used to remove excess blood after surgery or to keep blood from coagulating in severed appendages that have been reattached. Accumulations of blood can cause the tissue to die; when leeches remove such blood, new capillaries form in about a week, and the tissues remain healthy. The anticoagulant and anesthetic properties of the leech are also being investigated by pharmaceutical companies.

### Learning Outcomes Review 34.3

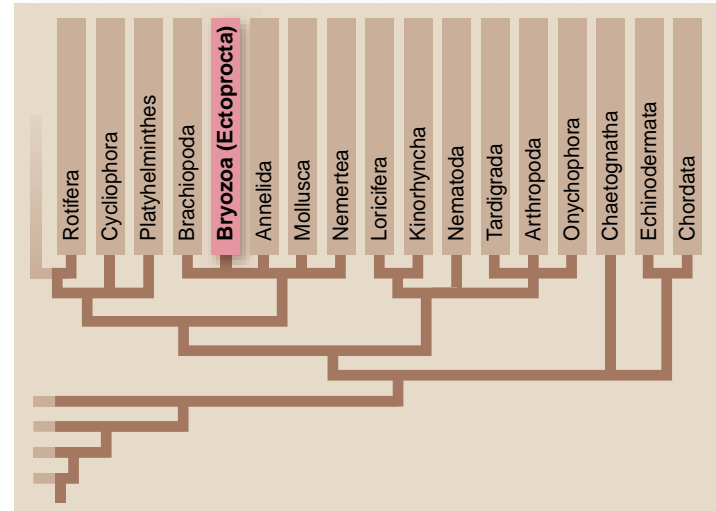

Annelids generally exhibit segmentation. Each segment has its own excretory and locomotor elements; circular and longitudinal muscles in segments cause the body to extend and contract, respectively. Worms of class Polychaeta, which are mostly marine, have parapodia on their segments. Leeches and earthworms were formerly in separate classes, but a major morphological similarity, the clitellum, has been used to group them into a single class, Clitellata.

- **What would be the advantages of having nervous and circulatory systems that serve the entire body instead of segmented systems?**

## 34.4 The Lophophorates: Bryozoa and Brachiopoda

### Learning Outcomes

1. Describe the lophophore and its function.
2. Distinguish between bryozoans and brachiopods.

Two phyla of mostly marine animals—Bryozoa and Brachiopoda—are characterized by a lophophore, a circular or U-shaped ridge around the mouth bearing one or two rows of ciliated tentacles into which the coelom extends. The lophophore functions as a surface for gas exchange, and the cilia of the lophophore serve to guide organic detritus and plankton on which the animal feeds to the mouth. Because of the lophophore, bryozoans and brachiopods have been considered related to one another, but some recent data indicate that the structures may have evolved convergently.

Brachiopods share some features with protostomes and others with deuterostomes. Cleavage in both brachiopods and bryozoans is mostly radial, as in deuterostomes. The formation of the coelom varies. In phoronids (once considered a phylum on their own but now considered part of Brachiopoda), the mouth forms from the blastopore (a feature of protostomes), whereas in the rest of brachiopods and in the bryozoans, it forms from the end of the embryo opposite the blastopore (a feature of deuterostomes). Molecular evidence allies lophophorates with protostomes. Because of the discrepancies between anatomical and developmental characters and molecular characters, the phylogeny of these animals continues to be a fascinating puzzle.

### The bryozoans, phylum Bryozoa, are the only exclusively colonial animals

Bryozoans (phylum Bryozoa or Ectoprocta) are small—usually less than 0.5 mm long—and live in colonies that look like patches of moss on the surfaces of submerged objects (figure 34.19).

a.

b.

**Figure 34.19 Bryozoans (phylum Bryozoa).** a. This drawing depicts a small portion of a colony of the freshwater bryozoan genus *Plumatella*, which grows on rocks. The individual at the left has a fully extended lophophore. The tiny individuals disappear into the zoecium when disturbed. b. *Plumatella repens*, another freshwater bryozoan.

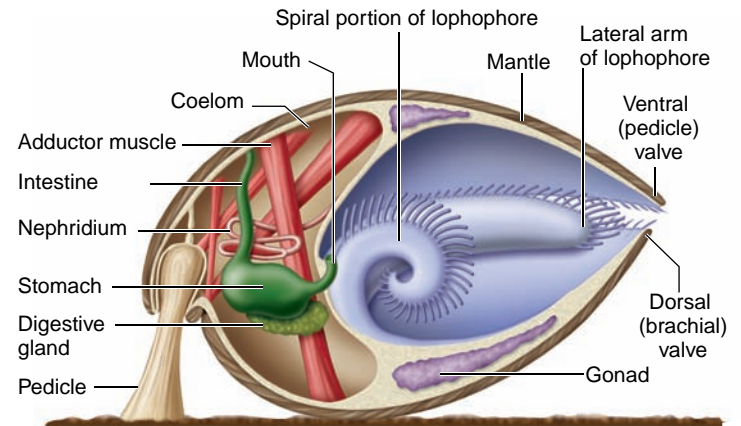

Their common name, “moss-animals,” is a direct translation of the Latin word *bryozoa*. The digestive system is U-shaped, with the anus opening near the mouth, as in many sessile animals. The alternative name Ectoprocta refers to the location of the anus (proct) outside the ring of the lophophore.

The 4000 species of bryozoans include both marine and freshwater forms. Each individual bryozoan—a zooid—secretes a tiny chitinous chamber called a zoecium (plural, *zoecia*) that is attached to rocks or other substrates such as the leaves of marine plants and algae. Calcium carbonate is deposited in the wall of a zoecium in many marine bryozoans, and in early geological times, bryozoans formed reefs just as corals do today. A zooid can divide or bud to create asexually another zooid beside the existing one so one wall of the new zooid’s zoecium is shared with that of the existing one; this expanding group of zoecia constitutes a colony. Individuals in the colony communicate chemically through pores between the zoecia. Not all zoecia of a colony may be identical; some are specialized for functions such as feeding, reproduction, or defense.

### The brachiopods and phoronids, phylum Brachiopoda, are solitary lophophorates

Brachiopods, or lamp shells, superficially resemble clams because they have two calcified valves (figure 34.20). Recall that the shells of bivalves are lateral, but in brachiopods, the valves are dorsal and ventral. Many species attach to rocks or sand by the pedicle (a stalk) that protrudes through an opening in one shell, whereas in others one valve is cemented to the substrate and the animal lacks a pedicle. The lophophore lies on the body, between the shells. The gut in some brachiopods is U-shaped, as in bryozoans, whereas in others there is no anus at all.

Slightly more than 300 species of brachiopods exist today, but more than 30,000 fossil species are known. Because brachiopods were common in the Earth’s oceans for millions of years and because their shells fossilize readily, many are used as index fossils, defining a particular geological period or sediment type.

a.

b.

**Figure 34.20 Brachiopods (phylum Brachiopoda).** a. All the body structures except the pedicle lay within two calcified shells, or valves. b. The brachiopod *Terebratulina septentrionalis* is slightly opened so the lophophore is visible.

**Figure 34.21 Phoronids.** A phoronid lives in a chitinous tube that the animal secretes. The lophophore consists of two horseshoe-shaped ridges of tentacles and can be withdrawn into the tube when the animal is disturbed.

Each **phoronid** (figure 34.21) secretes a chitinous tube around itself from which it can extend its lophophore to feed. The animal quickly withdraws into the tube when disturbed, as some polychaete worms do. Only about 10 phoronid species are known, ranging in length from a few millimeters to 30 cm. Individuals of some species lie buried in sand; others are attached to rocks, either singly or in groups, forming loose colonies.

### Learning Outcomes Review 34.4

The two phyla of lophophorates probably share a common ancestor, and they show a mixture of protostome and deuterostome characteristics. The lophophore is a characteristic feeding and exchange structure with ciliated tentacles. Bryozoans are exclusively colonial, whereas brachiopods and phoronids are solitary. Brachiopods have two shells with dorsal and ventral valves, not lateral.

- How is a U-shaped digestive tract an advantage to bryozoans and brachiopods?

## 34.5 Phylum Arthropoda: The Arthropods

### Learning Outcomes

1. Name the key features of arthropods.
2. List the four extant classes of arthropods and a characteristic that distinguishes them from one another.
3. Describe the advantages and drawbacks of an exoskeleton.

Arthropods are by far the most successful of all animals (table 34.1). Well over 1,000,000 species—about two-thirds of all the named species on Earth—are members of the phylum Arthropoda (figure 34.22). One scientist recently estimated that insects alone may comprise as many as 30 million species. About 200 million individual insects are alive at any time for each human! Insects (see figure 34.22) and other arthropods abound in every habitat on the planet, but there are few marine insects. Members of the phylum are small, generally a few millimeters in length, but adults range in size from about 80  $\mu\text{m}$  long (some parasitic mites) to 3 m across (Japanese spider crabs).

Arthropods are of enormous economic importance, affecting all aspects of human life. They pollinate crops and are valuable as food for humans and other animals, but they also compete with humans for food and damage crops. Diseases spread by insects and ticks strike every kind of plant and animal, including human beings. Insects are by far the most important herbivores in terrestrial ecosystems: virtually every kind of plant is eaten by one or more species.

Although our understanding of the phylogenetic relationships among the groups of arthropods and their relationships to other animals may shift with new findings, taxonomists currently recognize four extant classes (a fifth, the trilobites, is extinct): chelicerates, crustaceans, hexapods, and myriapods. Mouthparts of chelicerates are chelicerae (pincers), whereas those of the other three classes are **mandibles** (biting jaws). Mandibles are inferred to have arisen (probably from a pair of limbs) in the common ancestor of crustaceans, hexapods, and

**TABLE 34.1**

**Major Groups of the Phylum Arthropoda**

Class		Characteristics	Members
Chelicerata		Mouthparts are chelicerae (pincers or fangs).	Spiders, mites, ticks, scorpions, daddy long-legs, horseshoe crabs
Crustacea		Mouthparts are mandibles; appendages are biramous ("two-branched"); the head has two pairs of antennae.	Lobsters, crabs, shrimps, isopods, barnacles
Hexapoda		Mouthparts are mandibles; the body consists of three regions: a head with one pair of antennae, a thorax, and an abdomen; appendages are uniramous ("single-branched").	Insects (beetles, bees, flies, fleas, true bugs, grasshoppers, butterflies, termites), springtails
Myriapoda		Mouthparts are mandibles; the body consists of a head with one pair of antennae, and numerous segments, each bearing paired uniramous appendages.	Centipedes, millipedes

myriapods, which means that these groups are more closely related to one another than any of them is to chelicerates.

**Arthropods exhibit key features and organ systems**

Part of arthropod success is explained by the modularity of the segmented body, the **exoskeleton**, and the jointed appendages. The advantages of segmentation were discussed in the section on annelids. A hard exoskeleton confers protection against predators, but it acts something like a straight-jacket, restricting motion. Joints in the appendages maintain protection while providing some flexibility. With this system, arthropods have developed many efficient modes of locomotion, both in the oceans, where they originated, and on land, which they colonized early in the Devonian period.

**Segmentation**

In members of some classes of arthropods, many body segments look alike. In others, the segments are specialized into functional groups, or **tagmata** (singular, *tagma*), such as the head, thorax, and abdomen of an insect (figure 34.23). The fusion of segments, known as tagmatization, is of central importance in

the evolution of arthropods. Typically, the segments can be distinguished during larval development, but fusion in development obliterates them. All arthropods have a distinct head; in many crustaceans and chelicerates, head and thorax fuse to form the cephalothorax, or **prosoma**.

**An exoskeleton**

The rigid external skeleton, or exoskeleton, is made of chitin and protein. In any animal, the skeleton provides antagonism for muscles (and in many animals, a surface for muscle attachment), support for the body, and protection against physical forces. The arthropod exoskeleton protects against water loss,

**Figure 34.22 Arthropods are a successful group.** About two-thirds of all named species are arthropods. About 80% of all arthropods are insects, and about half of the named species of insects are beetles.

**Figure 34.23 Phylum Arthropoda.** This bee, like all insects and other arthropods, has a segmented body and jointed appendages. An insect body is composed of three tagmata: head, thorax, and abdomen. All arthropods have an exoskeleton made of chitin. Some insects evolved wings that permit them to fly.

which was a powerful advantage in insects colonizing land. As you learned in chapter 3, chitin is chemically similar to cellulose, the dominant structural component of plants, and shares with it properties of toughness and flexibility. The chitin and protein of an arthropod exoskeleton provide a covering that is very strong while being capable of flexing in response to the contraction of muscles attached to it.

An exoskeleton has inherent limitations. As arthropods increase in size, their exoskeletons must get disproportionately thick to bear the pull of the muscles. If beetles were as large as eagles, or crabs the size of cows, the exoskeleton would be so thick that the animal would be unable to move its great weight. Few terrestrial arthropods weigh more than a few grams, but aquatic ones can be heavier because water, being denser than air, provides more support. Another limitation is that, because the body is encased in a rigid skeleton, arthropods periodically must undergo **ecdysis**, or molting. Controlled by ecdysteroid hormones (chapter 46), molting was explained in chapter 32. The anterior and posterior regions of the digestive tract as well as the **compound eyes** are covered with cuticle and therefore are also shed at ecdysis. The animal is especially vulnerable during molting while the exoskeleton is soft, and it may hide from predators until the new exoskeleton hardens.

### Jointed appendages

The name *arthropod* means “jointed feet”; all arthropods have jointed appendages. Appendages may be modified into antennae, mouthparts of various kinds, or legs.

One advantage of jointed appendages is that they can be extended and retracted by bending. Imagine how difficult life would be if your arms and legs could not bend! In addition, joints serve as a fulcrum, or stable point, for appendage movement, so leverage is possible. A small muscle force on a lever can produce a large movement; for example, extending your lower arm takes advantage of the fulcrum of the elbow. A small contraction distance in your muscles moves your hand through a large arc.

### Circulatory system

The circulatory system of arthropods is open. The principal component of an insect’s circulatory system is a longitudinal muscular vessel called the heart, which is near the dorsal surface of the thorax and abdomen (figure 34.24). When the heart contracts, blood is pumped anteriorly. From there it gradually flows through the spaces between the tissues toward the posterior end. When the heart relaxes, blood returns to it from those spaces through one-way valves in the posterior region of the heart.

### Nervous system

The central feature of the arthropod nervous system is a double chain of segmented ganglia along the animal’s ventral surface (see figure 34.24). At the anterior end of the animal are three fused pairs of dorsal ganglia, which constitute the brain; however, ventral ganglia (generally a pair per segment) control much of the animal’s activities. Therefore, an arthropod can carry out functions such as eating, moving, and copulating even if the brain has been removed. The brain seems to be a control

a.

a. External anatomy. b. Internal anatomy.

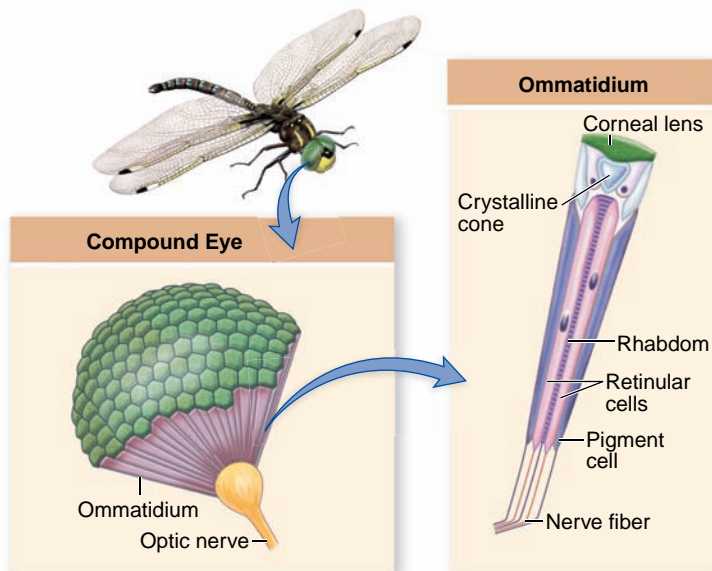

point, or inhibitor, for various actions, rather than a stimulator, as it is in vertebrates.

Compound eyes (figure 34.25) occur in many insects, crustaceans, centipedes, and the extinct trilobites. They are composed of hundreds or more independent visual units called **ommatidia** (singular, *ommatidium*), each covered with a lens and including a complex of eight reticular cells and a light-sensitive central core, the rhabdom. Simple eyes, or **ocelli** (singular, *ocellus*) with single lenses, occur in some arthropods including those with compound eyes. Ocelli distinguish light from darkness. The ocelli of locusts and dragonflies function as horizon detectors to help the insect visually stabilize flight.

### Respiratory system

Marine arthropods such as crustaceans have gills, and marine chelicerates (such as horseshoe crabs) have book gills, flaps under the prosoma that appear to have evolved from legs. Some tiny arthropods lack any structures for exchanging oxygen, and their outer epithelium or gut have a respiratory function.

The respiratory system of most terrestrial arthropods consists of small, branched, cuticle-lined ducts called **tracheae** (singular, *trachea*) (figure 34.26) (the lining of which is shed at ecdysis). Tracheae ultimately branch into very small **tracheoles**, which are in direct contact with individual cells,

**Figure 34.25 The compound eye.** The compound eyes in insects are complex structures composed of many independent visual units called ommatidia.

allowing oxygen and carbon dioxide to diffuse across the plasma membranes. Because insects depend on the respiratory system rather than the circulatory system to carry oxygen to their tissues, all parts of the body must be near a respiratory passage. Along with the weight of the exoskeleton, this places severe limitations on arthropod size.

Air passes into the tracheae through openings in the exoskeleton called **spiracles** (see figures 34.23, 34.24, and 34.26), which, in most insects, can be opened and closed by valves. The ability to prevent water loss by closing the spiracles was a key adaptation that facilitated the arthropod invasion of land.

Many spiders have book lungs instead of or in addition to tracheae. A **book lung** is a series of leaflike plates within a chamber into which air is drawn and from which it is expelled by muscular contraction.

**Figure 34.26 Tracheae and tracheoles.** Tracheae and tracheoles are connected to the exterior by openings called spiracles and carry oxygen to all parts of a terrestrial insect's body.

## Excretory system

Various kinds of excretory systems occur in arthropods. In aquatic arthropods, much of the waste may diffuse from the blood in the gills.

**Malpighian tubules**, which occur in terrestrial insects, myriapods, and chelicerates, are slender projections from the digestive tract attached at the junction of the midgut and hindgut (see figures 34.23, 34.24). Fluid passes through the walls of the Malpighian tubules to and from the blood in which the tubules are bathed. Nitrogenous wastes are precipitated as concentrated uric acid or guanine, emptied into the hindgut, and eliminated. Most of the water and salts in the fluid are reabsorbed by the hindgut and rectum to be returned to the arthropod's body. This efficient conservation of water by Malpighian tubules was another key adaptation facilitating invasion of the land by arthropods.

## Class Chelicerata includes spiders, mites, ticks, and horseshoe crabs

In the class Chelicerata, with some 57,000 species, the most anterior appendages, called **chelicerae** (singular, *chelicera*), may function as fangs or pincers. The body of a chelicerate is divided into two tagmata: the anterior **prosoma**, which bears all the appendages, and the posterior **opisthosoma**, which contains the reproductive organs. Chelicerates include familiar largely terrestrial arthropods such as spiders, ticks, mites, scorpions, and daddy long-legs. However, 4000 known species of mites and one species of spider live in freshwater habitats, and a few mites live in the sea. Exclusively marine groups of chelicerates are horseshoe crabs and sea spiders.

In addition to a pair of chelicerae, a chelicerate has a pair of **pedipalps**, and four pairs of walking legs on its prosoma. The pedipalps (often simply called palps) resemble legs but have one fewer segment and are not used for locomotion. In male spiders, the pedipalps are copulatory organs; in scorpions, they are large pincers; and in most other chelicerates, they are sensorial, acting like the antennae of other arthropods.

Most chelicerates are carnivorous, but mites are largely herbivorous. Aside from the daddy long-legs, which can ingest small particles, most cannot consume solid food. They subsist on liquids, including solid food that they liquefy by injecting with digestive enzymes and then suck up with the muscular pharynx.

Horseshoe crabs comprise four species that live off the North American Atlantic coast and in Southeast Asia. Sea spiders are such strange marine animals that some authorities exclude them from the Chelicerata. Most are small, but some can reach 150 mm or so across; many live in association with other marine animals, such as hydroids.

## Order Araneae: Spiders

The 35,000 named species of spiders (order Araneae) play a major role in virtually all terrestrial ecosystems. They are particularly important as predators of insects and other small animals. Spiders hunt their prey or catch it in silk webs of remarkable diversity. Silk is formed from a fluid protein that is forced out of **spinnerets** on the posterior portion of the spider's abdomen. Trap-door spiders construct silk-lined burrows with lids, seizing

their prey as it passes by. Spiders such as the familiar wolf spiders and tarantulas hunt rather than spin webs.

All spiders have poison glands with channels through their chelicerae, which are pointed and are used to bite and paralyze prey. The bites of some, such as the western black widow (*Latrodectus hesperus*) and brown recluse (*Loxosceles reclusa*) (figure 34.27), can be fatal to humans and other large mammals.

### Order Acari: Mites and ticks

The order Acari is the most diverse of the chelicerates. About 30,000 species of mites and ticks have been named, but scientists estimate that more than a million members of this order may exist. Acarines are found in virtually every habitat; they feed on a variety of organisms as predators and parasites.

Most mites are less than 1 mm long, but adults range from 100 nm to 2 cm. In most mites, the cephalothorax and abdomen are fused into an unsegmented, ovoid body. Respiration is by means of tracheae or directly through the body surface. Many mites pass through several stages during their life cycle. In most, an inactive eight-legged prelarva gives rise to an active six-legged larva, which, in turn, produces a succession of three eight-legged stages, and, finally, the adult.

Ticks are parasites that attach to the surface of humans and other animals, causing discomfort by sucking blood. Ticks, which are larger than most other members of the order, can carry disease-causing agents. For example, Rocky Mountain spotted fever is caused by bacteria; Lyme disease is caused by spirochaetes; and red-water fever, or Texas fever, is an important tick-borne protozoan disease of cattle, horses, sheep, and dogs.

## Class Crustacea includes crabs, shrimps, lobsters, and pill bugs

The crustaceans (class Crustacea) comprise some 35,000 species of largely marine organisms, such as crabs, shrimps, lobsters, and barnacles. However, some groups, such as crayfish, occur in freshwater, and some crabs and copepods (order Co-

pepoda; figure 34.28) are among the most abundant multicellular organisms on Earth. A small number are terrestrial, including about half the estimated 4500 species of order Isopoda, the pillbugs; and some sand fleas or beach fleas (order Amphipoda) are semiterrestrial.

Some crustaceans (such as lobsters and crayfish) are valued as food for humans; planktonic crustaceans (such as krill) and larval crustaceans, which are abundant in the plankton, are the primary food of baleen whales and many smaller marine animals.

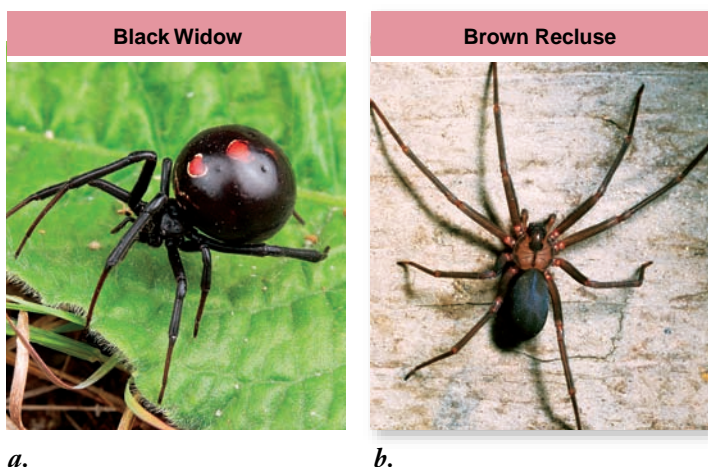

### Crustacean body plans

A typical crustacean has three tagmata; the anteriormost two—the cephalon and thorax—may fuse to form the cephalothorax (figure 34.29). Most crustaceans have two pairs of antennae, three pairs of appendages for chewing and manipulating food, and various pairs of legs. Crustacean appendages, with the possible exception of the first pair of antennae, are biramous (“two-branched”). Crustaceans differ from hexapods, but resemble myriopods, in having appendages on their abdomen as well as their thorax. They are the only arthropods with two pairs of antennae.

Large crustaceans have feathery gills for respiration near the bases of their legs (see figure 34.29). Oxygen extracted from the gills is distributed through the circulatory system. In smaller crustaceans, gas exchange takes place directly through the thinner areas of the cuticle or the entire body.

### Crustacean reproduction

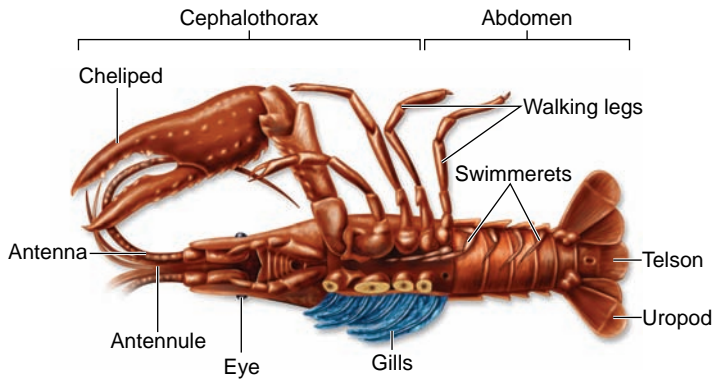

Nearly all crustaceans except barnacles are gonochoric. Many kinds of copulation occur, and the members of some groups carry their eggs, either singly or in egg pouches, until they hatch. Crustaceans develop through a **nauplius** (plural, *nauplii*) stage (figure 34.30). The nauplius hatches with three pairs of appendages and undergoes metamorphosis through several stages before reaching maturity. In many groups, this nauplius stage is passed in the egg, and the hatchling resembles a miniature adult.

**Figure 34.27** Two common poisonous spiders. *a.* The southern black widow, *Latrodectus mactans*. *b.* The brown recluse spider, *Loxosceles reclusa*. Both species are common throughout temperate and subtropical North America.

**Figure 34.28** Freshwater crustacean. A copepod with attached eggs. Members of the marine and freshwater order Copepoda are important components of the plankton. Most are a few millimeters long.

**Figure 34.29 Decapod crustacean.** Ventral view of a lobster, *Homarus americanus*, with some of its principal features labeled.

The nauplius larva is characteristic of Crustacea, providing evidence that all members of this diverse group descended from a common ancestor that had a nauplius in its life cycle. The sessile barnacles, with their shell-like exoskeleton, had been thought to be related to mollusks until they were discovered to have a nauplius larva. More recently, the wormy pentastomids, which parasitize the respiratory tracts of vertebrates, were determined to be crustaceans in part through their nauplii (recall from chapter 32 that parasites may become morphologically simplified and so can be difficult to place phylogenetically).

### **Decapod crustaceans: Shrimps, lobsters, crabs, and crayfish**

Large, primarily marine crustaceans such as shrimps, lobsters, and crabs, along with their freshwater relatives, the crayfish, belong to order Decapoda (see figure 34.29), which means “ten-footed” because of their five pairs of thoracic appendages. The exoskeleton of most is reinforced with calcium carbonate. The cephalothorax is covered by a dorsal shield, or carapace, which arises from the head. The pincers of many decapod crustaceans are used in obtaining food—for example, by crushing mollusk shells.

In lobsters and crayfish, appendages called **swimmerets** that occur along the ventral surface of the abdomen are used in reproduction and swimming. At the posterior end of the abdomen, paired flattened appendages known as **uropods** form a kind of paddle between which is a **telson**, a tail spine (see

**Figure 34.30 The nauplius larva.**

The nauplius of a crustacean is an important unifying feature found in members of this group.

**Figure 34.31 Cephalothorax.** The cephalothorax of a Chesapeake Bay blue crab (*Callinectes sapidus*).

figure 34.29). When a lobster or crayfish contracts its abdominal muscle, the uropods and telson push water anteriorly, propelling the animal posteriorly through the water rapidly and forcefully. It is this very large muscle that constitutes the “lobster tail” so valued by human diners!

One difference between crabs and lobsters is that the crab carapace is relatively much broader and the abdomen is just a small vestige tucked under the cephalothorax. The abdomen of a male crab is much narrower than that of a female of the same species and size (figure 34.31): the female carries her eggs attached to appendages of the abdomen between it and the thorax. A female with eggs is said to be “in berry.”

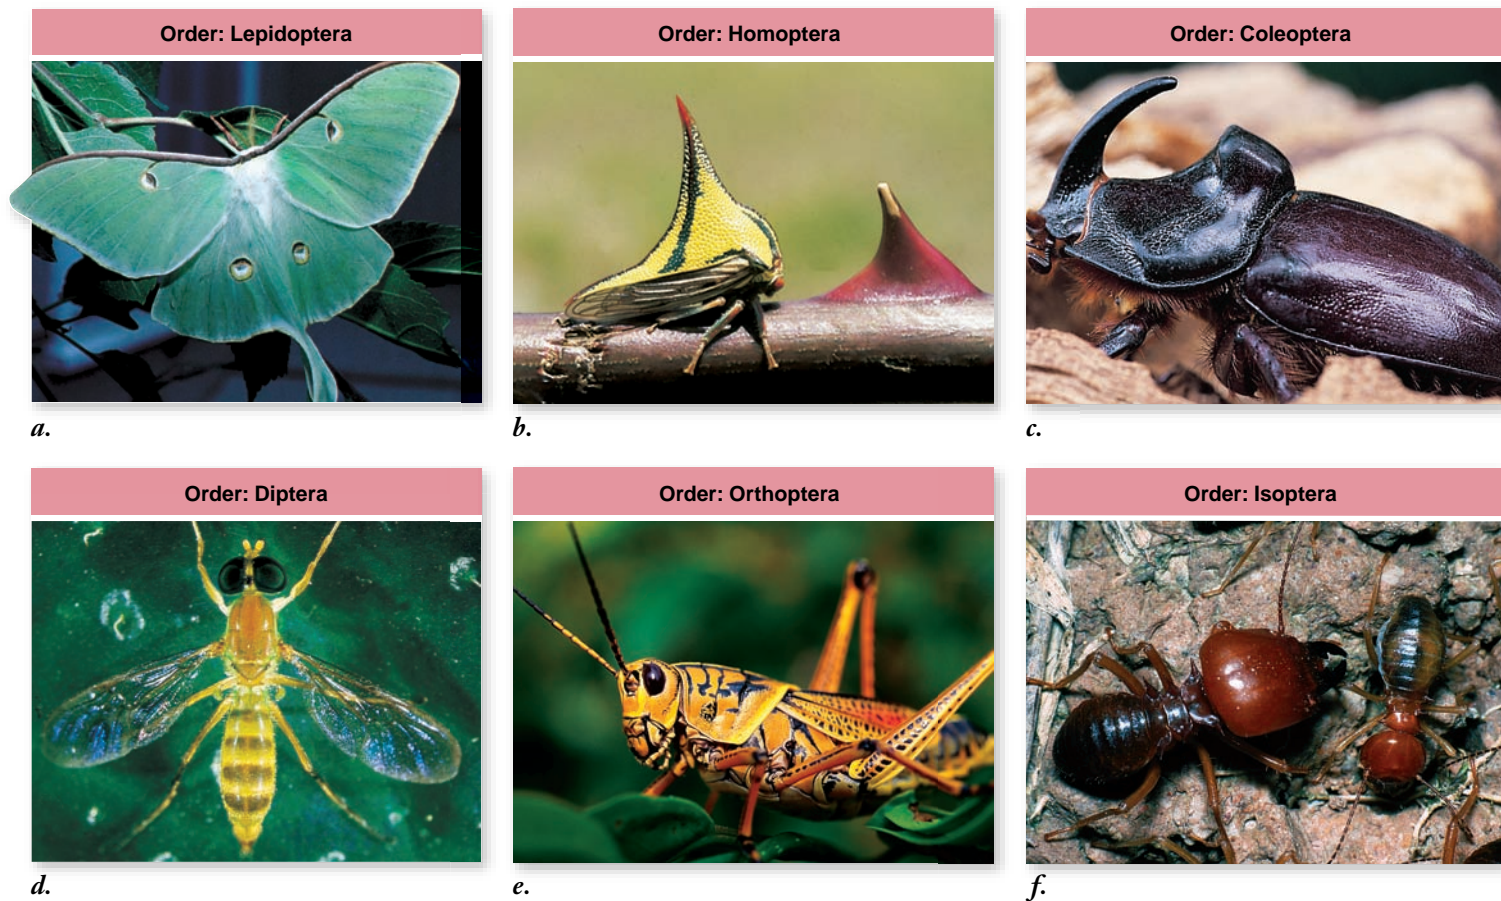

### **Sessile crustaceans: Barnacles**

Barnacles (order Cirripedia; figure 34.32) are sessile as adults. At the end of its larval life, a barnacle nauplius attaches by its

**Figure 34.32 Gooseneck barnacles, *Lepas anatifera*.** These barnacles are filter feeding, which they do by sweeping their jointed legs through the water, gathering small particles of food. These are stalked barnacles; others lack a stalk.

**Figure 34.33 Insect diversity.** *a.* Luna moth, *Actias luna*. Luna moths and their relatives are among the most spectacular insects (order Lepidoptera). *b.* A thorn-shaped treehopper, *Umbonia crassicornis* (order Homoptera). *c.* Boll weevil, *Anthonomus grandis*. Weevils are one of the largest groups of beetles (order Coleoptera). *d.* Soldier fly, *Ptecticus trivittatus* (order Diptera). *e.* Lubber grasshopper, *Romalea guttata* (order Orthoptera). *f.* Termites, like ants, have several castes with individuals specialized for different tasks. The individual on the left is a soldier; its large jaws aid in defending the colony.

head to a piling, rock, or other submerged object, metamorphoses, grows calcareous plates around it, and spends the rest of its life capturing food with its jointed, feathery legs. The hermaphroditic state of barnacles is thought to be related to their sessility. Barnacles have the longest penis in the animal kingdom, relative to their size, which enables these sessile animals to cross-fertilize.

### Class Hexapoda comprises the insects

The insects, members of class Hexapoda, are by far the largest group of animals on Earth, in terms of number of species and number of individuals. Insects live in every habitat on land and in fresh water, but very few have invaded the sea. More than half of named animal species are insects, and the actual proportion may be higher because millions of forms await detection, classification, and naming.

Approximately 90,000 described species occur in the United States and Canada; the actual number probably approaches 125,000. A hectare of lowland tropical forest is estimated to be inhabited by as many as 41,000 species of insects, and many suburban gardens may have 1500 or more species. It has been estimated that approximately a billion billion ( $10^{18}$ )

individual insects are alive at any one time. A glimpse into the enormous diversity of insects is presented in figure 34.33 and table 34.2.

#### External features

Insects are primarily terrestrial, and aquatic insects probably had terrestrial ancestors. Most are small, ranging from 0.1 mm to about 30 cm in length or wingspan. Insect mouthparts all have the same basic structure; modifications reflect feeding habits (figure 34.34). Most insects have compound eyes, and many also have ocelli.

An insect body has three regions: the head, thorax, and abdomen (see figures 34.23, 34.24). The thorax consists of three segments, each with a pair of legs, which accounts for the name of the group, hexa (six) and poda (legs). Legs are absent in the larvae of certain groups—for example, most flies (order Diptera) and mosquitoes (figure 34.35). In addition, an insect may have one or two pairs of wings, which are not homologous to the other appendages, and which attach to the middle and posterior segments of the thorax (see figure 34.23). The wings, which consist of chitin and protein, arise as saclike outgrowths of the body wall; wings of moths and butterflies are covered with detachable scales that provide most of their bright colors

**TABLE 34.2 Major Orders of Insects**

Order	Typical Examples	Key Characteristics	Approximate Number of Named Species
Coleoptera	Beetles 	Two pairs of wings, the front one hard, protecting the rear one; heavily armored exoskeleton; biting and chewing mouthparts. Complete metamorphosis. The most diverse animal order.	350,000
Diptera	Flies 	Front flying wings transparent; hindwings reduced to knobby balancing organs called halteres. Sucking, piercing, or lapping mouthparts; some bite people and other mammals. Complete metamorphosis.	120,000
Lepidoptera	Butterflies, moths 	Two pairs of broad, scaly, flying wings, often brightly colored. Hairy body; tubelike, sucking mouthparts. Complete metamorphosis.	120,000
Hymenoptera	Bees, wasps, ants 	Two pairs of transparent flying wings; mobile head and well-developed compound eyes; often possess stingers; chewing and sucking mouthparts. Many social. Complete metamorphosis.	100,000
Hemiptera and Homoptera	True bugs, bedbugs, leafhoppers, aphids, cicadas 	Wingless or with two pairs of wings; piercing, sucking mouthparts, with which some draw blood, some feed on plants. Simple metamorphosis.	60,000
Orthoptera	Grasshoppers, crickets 	Wingless or with two pairs of wings; among the largest insects; biting and chewing mouthparts in adults. Third pair of legs modified for jumping. Simple metamorphosis.	20,000
Odonata	Dragonflies 	Two pairs of transparent flying wings that cannot fold back; large, long, and slender body; chewing mouthparts. Simple metamorphosis.	5000
Isoptera	Termites 	Two pairs of wings, but some stages wingless; chewing mouthparts; simple metamorphosis. Social organization: labor divided among several body types. Some are among the few types of animals able to digest wood. Complete metamorphosis.	2000
Siphonaptera	Fleas 	Wingless; flattened body with jumping legs; piercing and sucking mouthparts. Small; known for irritating bites. Complete metamorphosis.	1200

b.

c.

**Figure 34.34 Mouthparts in three kinds of insects.** Mouthparts are modified for (a) piercing in this mosquito of the genus *Culex*; (b) sucking nectar from flowers in the alfalfa butterfly of the genus *Colias*; and (c) sipping up liquids in the housefly, *Musca domestica*.

**Figure 34.35** Larva of a mosquito, *Culex pipiens*.

The aquatic larvae of mosquitoes are quite active. They breathe through tubes at the surface of the water, as shown here. Covering the water with a thin film of oil suffocates them.

(figure 34.36). Veins strengthen wings. An insect's thorax is almost entirely filled with muscles that operate the legs and wings. Fleas and lice are considered secondarily wingless, having descended from ancestors with wings. However, the ancestors of springtails and silverfish evolved before wings did, so those hexapods are considered primarily wingless.

**Internal organization**

The internal features of insects resemble those of other arthropods in many ways. The digestive tract is a tube about the same length as the body in some groups. However, in insects that feed on juices and so have sucking mouthparts, such as leafhoppers, cicadas, and many flies, the greatly coiled digestive tube may be several times longer than the body. Digestion takes place primarily in the stomach, or midgut, and excretion takes place through Malpighian tubules. Digestive enzymes are mainly secreted from the cells that line the midgut, although some are contributed by the salivary glands near the mouth.

**Figure 34.36** Scales on the wing of *Parnassius imperator*, a butterfly from China. Scales of this sort account for most of the colored patterns on the wings of butterflies and moths.

In many winged insects, tracheae are dilated in various parts of the body, forming air sacs, which are surrounded by muscles to form a kind of bellows system that forces air deep into the body. The spiracles through which air enters the tracheal system are located on or between the segments along the sides of the thorax and abdomen. In most insects, the spiracles can be opened by muscular action. In some parasitic and aquatic groups of insects, the spiracles are permanently closed. In these groups, the tracheae are just below the surface of the insect, and gas exchange takes place by diffusion.

**Sensory receptors**

In addition to eyes, insects have several characteristic kinds of sense receptors. **Sensory setae** are hairlike structures that are widely distributed over the body. They are sensitive to mechanical and chemical stimulation and are linked to nerve cells. They are particularly abundant on the antennae and legs, the parts of the insect most likely to come into contact with other objects.

Sound, which may be of vital importance to insects such as grasshoppers, crickets, cicadas, and some moths, is detected by a thin membrane, each called a **tympanum** (see figure 34.24), associated with the tracheal air sacs. In other groups of insects, sound waves are detected by sensory hairs. Male mosquitoes use thousands of sensory hairs on their antennae to detect sounds made by the vibrating wings of female mosquitoes.

In addition to sound, nearly all insects communicate by means of chemicals known as pheromones. These extremely diverse compounds are sent forth into the environment, where they convey a variety of messages, including mating signals and trail markers.

**Insect life histories**

During the course of their development, many insects undergo metamorphosis. For those such as grasshoppers, in which immature individuals are quite similar to adults, a series of molts results in an individual gradually getting bigger and more developed; this is termed simple metamorphosis. Those such as moths and butterflies have a life history involving a wormlike larval stage, a resting stage called a **pupa** or **chrysalis**, during which metamorphosis occurs, and then a final molt into the adult form or imago; this is termed complete metamorphosis.

**Myriapoda includes centipedes and millipedes**

The body of a centipede (subclass Chilopoda) and millipede (subclass Diplopoda) consists of a head region posterior to which are numerous, more or less similar segments. Nearly all segments of a centipede have one pair of appendages (figure 34.37a), and nearly all segments of a millipede have two pairs of appendages (figure 34.37b). Each segment of a millipede is a simple tagma derived evolutionarily from two ancestral segments, which explains why millipedes have twice as many legs per segment as centipedes. Although the name *centipede* would imply an animal with 100 legs and the name *millipede* one with 1000, an adult centipede usually has fewer than 100 legs (most have 15, 21, or 23 pairs of legs); an adult millipede never reaches 1000 legs, most having 100 or fewer.

Both centipedes and millipedes are gonochoric; fertilization is internal, and all lay eggs. Young millipedes usually hatch with three pairs of legs; they add segments and legs as they pass

a.

b.

**Figure 34.37 Myriapods.** *a.* Centipedes, such as this member of the genus *Scolopendra*, are active predators. *b.* Millipedes, such as this member of the genus *Sigmoria*, are important herbivores and detritivores. Centipedes have one pair of legs per body segment, millipedes have two pairs per segment.

through growth stages, but they do not change in general appearance. Centipedes have several types of development, young of some species hatching with their final number of legs and others adding legs after hatching. Centipedes that do not add legs as they grow tend to take care of their young, a behavior rather uncommon among invertebrates.

Centipedes, of which some 3000 species are known, are carnivorous, feeding mainly on insects. The appendages of the first trunk segment are modified into a pair of poison fangs. The poison may be toxic to humans, and although extremely painful, centipede bites are never fatal. In contrast, most millipedes are herbivores, feeding mainly on decaying vegetation such as leaf litter and rotting logs (which are typical habitats for the animals). Many millipedes can roll their bodies into a flat coil or sphere to defend themselves. More than 12,000 species of millipedes have been named, but this is estimated to be no more than one-sixth of the number of species that exists.

In each segment of their body, many millipedes have a pair of complex glands that produce a bad-smelling fluid, which they exude for defense through openings along the sides of the body. The chemistry of this material interests biologists because of the diversity of the compounds involved and their effectiveness in protecting millipedes from attack. Some species produce cyanide gas from segments near their head.

### Learning Outcomes Review 34.5

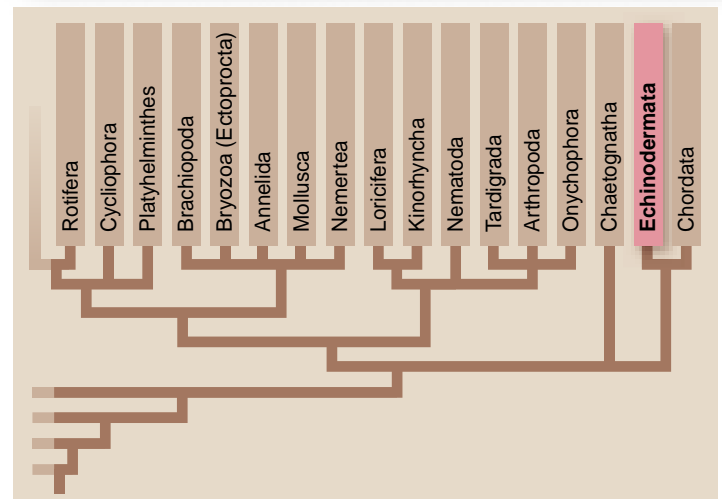

Arthropods are segmented animals with exoskeletons and jointed appendages. The four living classes of arthropods are Chelicerata, with mouthparts (chelicerae) that function as fangs or pincers; Crustacea, in which all members have a nauplius developmental stage; Hexapoda, the insects, having three pairs of legs attached to fused segments of the thorax as adults; and Myriopoda, with one or two pairs of appendages on every body segment. An exoskeleton provides protection and muscle attachment, but growth requires molting. In some cases, larvae undergo metamorphosis into an adult with very different appearance.

- What would explain why the largest arthropods are found in marine environments?

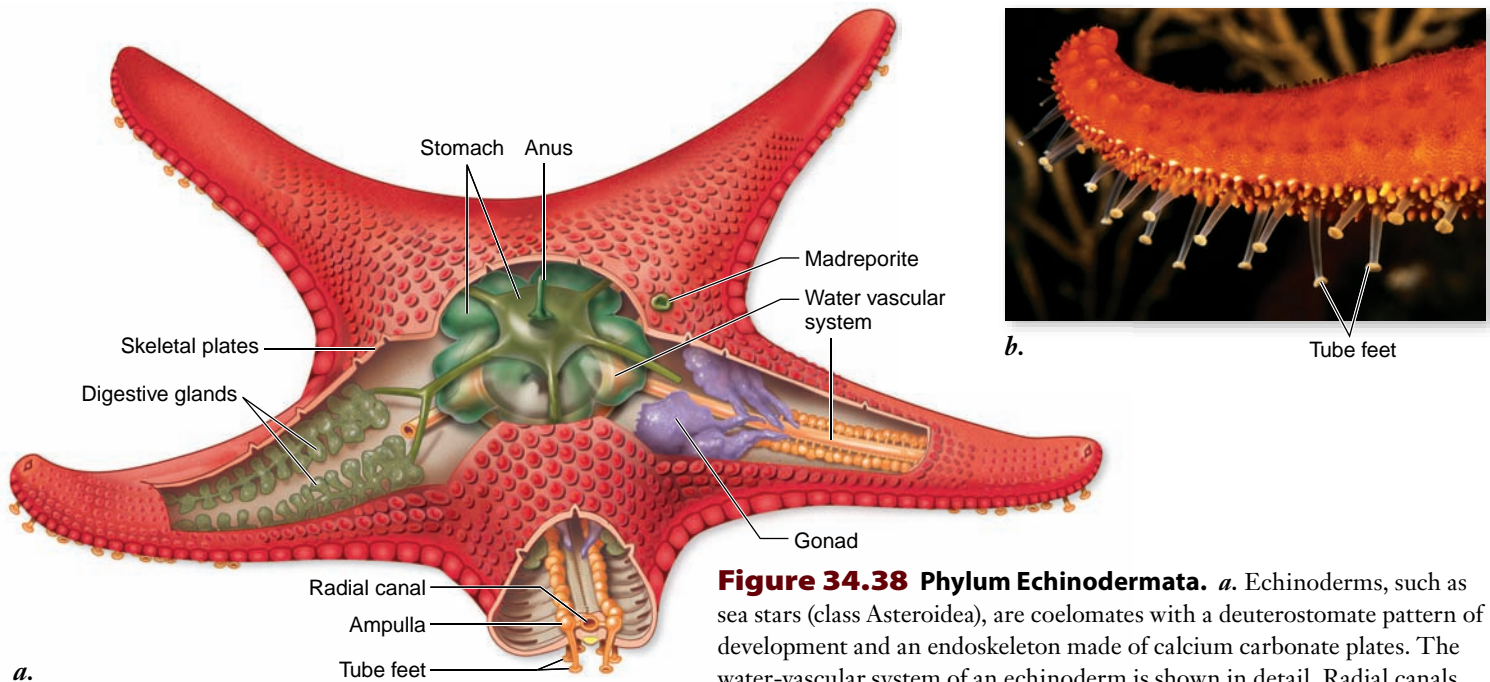

## 34.6 Phylum Echinodermata: The Echinoderms

### Learning Outcomes

1. Explain what is meant by pentaradial symmetry.
2. Describe the five extant classes of echinoderms.

Members of the exclusively marine phylum Echinodermata are characterized by deuterostome development (see chapter 32) and an endoskeleton. The endoskeleton is composed of hard, calcium carbonate plates that lie just beneath the delicate skin. The term *echinoderm*, which means “spiny skin,” refers to the spines or bumps that occur on these plates in many species. Echinoderms, including sea stars (figure 34.38), brittle stars, sea urchins, sand dollars, and sea cucumbers are some of the most familiar animals on the seashore. All have five axes of symmetry (that is, you could draw lines through their body in five different places that produced mirror images on each side) and thus are said to be **pentaradially symmetrical**.

**Figure 34.38 Phylum Echinodermata.** *a.* Echinoderms, such as sea stars (class Asterozoa), are coelomates with a deuterostomate pattern of development and an endoskeleton made of calcium carbonate plates. The water-vascular system of an echinoderm is shown in detail. Radial canals transport liquid to the tube feet. As the ampulla in each tube foot contracts, the tube foot extends and can attach to the substrate. When the muscles in the tube feet contract, the tube foot bends, pulling the animal forward. *b.* Extended nonsuckered tube feet of the sea star *Luidia magnifica*.

## Echinoderms are ancient and unmistakable

Echinodermata is an ancient group of marine animals that appeared nearly 600 MYA and that comprise about 6000 living species. As with other deuterostomes, the mouth does not form from the embryonic blastopore.

Because the skeletal elements of echinoderms are covered by living tissue, they constitute an endoskeleton. A unique feature of echinoderms is the hydraulic system that aids in movement or feeding called a **water-vascular system**. This fluid-filled system, which is a modification of one of several coelomic spaces, is composed of a central ring canal from which **radial canals** extend.

Although an excellent fossil record extends back into the Cambrian period, the origin of echinoderms remains unclear. They are thought to have evolved from bilaterally symmetrical ancestors because echinoderm larvae are bilaterally symmetrical (figure 34.39).

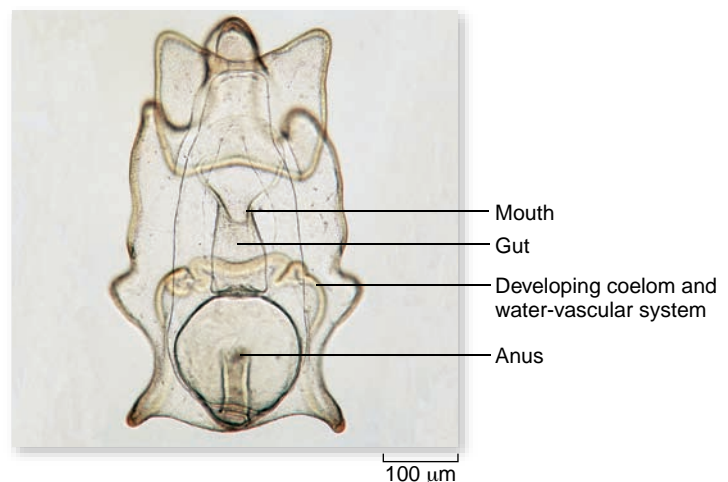

## Echinoderm symmetry is bilateral in larvae but pentaradial in adults

The body of echinoderms undergoes a fundamental shift during development, from bilaterally symmetrical larvae (see figure 34.39) to pentaradially symmetrical adults (see figure 34.38). Dorsal, ventral, anterior, and posterior have no meaning without a head or tail for orientation. Thus, orientation of the body of an adult echinoderm is described in reference to the mouth, which defines the **oral surface**. All systems of an adult echinoderm are organized with branches radiating from a center. For example, the nervous system consists of a central nerve ring from which branches arise; although the animals are capable of complex behavior patterns, there is no centralization of function.

In many echinoderms, the oral surface faces the substratum, although in sea cucumbers, the animal's axis is horizontal, so the animal crawls oral surface foremost, and in crinoids (sea lilies and feather stars), the oral surface is located opposite to the substratum.

### The endoskeleton

Echinoderms have a delicate epidermis that stretches over an endoskeleton composed of calcium carbonate (calcite) plates called **ossicles**. In echinoderms such as asteroids (sea stars), the individual skeletal elements are loosely joined to

**Figure 34.39 The free-swimming larva of the common sea star, *Asterias rubens*.** Such bilaterally symmetrical larvae suggest that the ancestors of the echinoderms may not have been radially symmetrical.

one another. In others, especially echinoids (sea urchins and sand dollars), the ossicles abut one another tightly, forming a rigid shell (called a test). In sea cucumbers, by contrast, the ossicles are widely scattered, so the body wall is flexible. The ossicles in certain portions of the body of some echinoderms are perforated by pores. Through these pores extend tube feet, part of the water-vascular system that is a unique feature of this phylum.

Members of this phylum have mutable collagenous tissue, which can change in texture from tough and rubbery to weak and fluid. This amazing tissue accounts for attributes of echinoderms such as the ability to autotomize (cast off) parts. This tissue is also responsible for a sea cucumber being able to change from almost rigid to flaccid in a matter of seconds.

### The water-vascular system

The water-vascular system is radially organized. From the ring canal, which encircles the animal's esophagus, a radial canal extends into each branch of the body (see figure 34.38). Water enters the water-vascular system through a **madreporite**, a sieve-like plate that, in most echinoderms, is on the animal's surface, and flows to the ring canal through a stone canal, so named because it is reinforced by calcium carbonate. Each radial canal, in turn, extends through short side branches into the hollow tube feet (see figure 34.38b). In some echinoderms, each tube foot has a sucker at its end; in others, suckers are absent. At the base of each tube foot in most types of echinoderms is a muscular sac, the ampulla. When the ampulla contracts, the fluid, prevented from entering the radial canal by a one-way valve, is forced into the tube foot, thus extending it. Contraction of longitudinal muscles on one side of the tube foot wall causes the tube foot to bend; relaxation of the muscles in the ampulla and contraction of all the longitudinal muscles in the tube foot forces the fluid back into the ampulla.

In asteroids and echinoids, concerted action of a very large number of small, individually weak tube feet causes the animal to move across the sea floor. The tube feet around the mouth of a holothurian are used in feeding. In crinoids, tube feet that arise from the branches of the arms, which extend from the margins of an upward-directed cup, are used in capturing food from the surrounding water. Ophiuroid tube feet are pointed and specialized for feeding.

Gas exchange in most echinoderms is through the body surface and tube feet. In addition, a holothurian has paired respiratory trees, which branch off the hindgut. Water is drawn into them and exits from them through the anus. In an asteroid, one of the coelomic spaces other than the water-vascular system has branches into protrusions from the epidermis called papulae through which gas exchange also occurs.

### Regeneration and reproduction

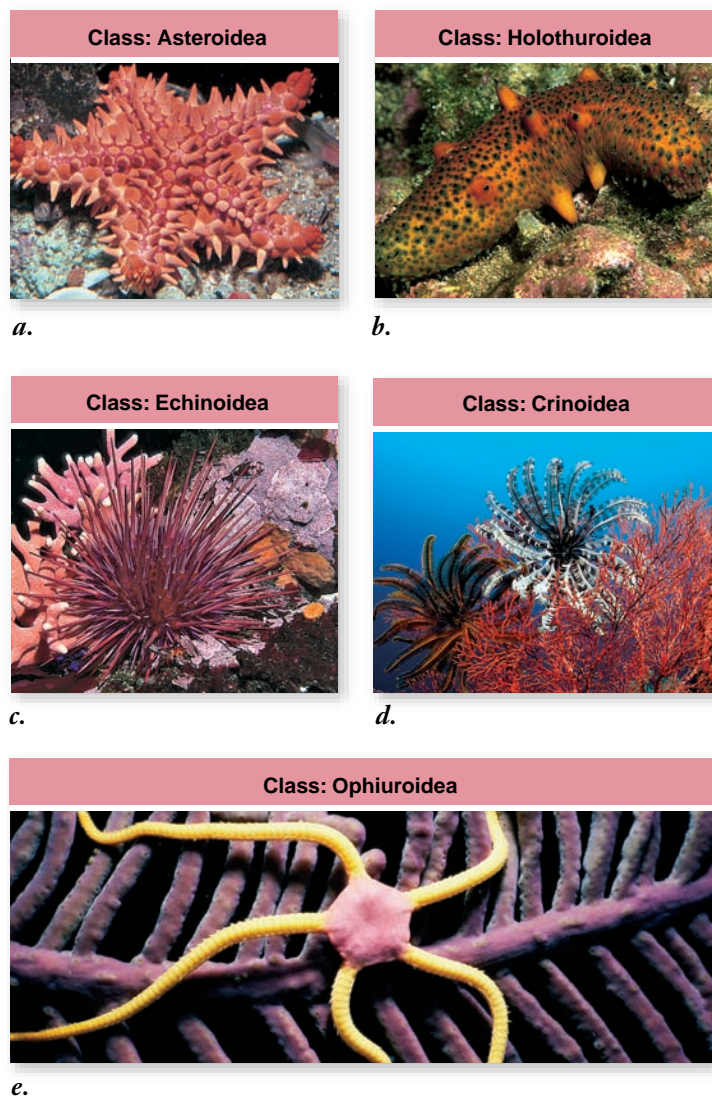

Many echinoderms are able to regenerate lost parts. Some asteroids and especially ophiuroids can autotomize an arm. When a holothurian of some species is disturbed, it can cast out its entire digestive system. Some echinoderms can reproduce asexually by splitting.

However, most reproduction in echinoderms is sexual. As a rule, echinoderms are gonochoric. Gametes are generally released into the water, where fertilization occurs, and free-swimming

bilaterally symmetrical larvae develop (see figure 34.39). Each class of echinoderms has a characteristic type of larva. These larvae develop in the plankton until they metamorphose into the sedentary adults.

## Echinodermata comprises five extant classes

There are five classes of living echinoderms, but more than 20 others have gone extinct. Living ones are: (1) Asterozoa, sea stars, or starfish, and sea daisies; (2) Crinozoa, sea lilies and feather stars; (3) Echinozoa, sea urchins and sand dollars; (4) Holothurozoa, sea cucumbers; and (5) Ophiurozoa, brittle stars (figure 34.40).

**Figure 34.40 Diversity in echinoderms.** *a.* Sea star, *Oreaster occidentalis* (class Asterozoa), in the Gulf of California, Mexico. *b.* Warty sea cucumber, *Parastichopus parvimensis* (class Holothurozoa), Philippines. *c.* Sea urchin of the genus *Echinometra* (class Echinozoa). *d.* Feather star (class Crinozoa) of the genus *Comatheria*, from Indonesia. *e.* Gaudy brittle star, *Ophioderma ensiferum* (class Ophiurozoa).

Adults of all classes exhibit a five-part body plan. Even sea cucumbers, which are shaped like their fruit namesake, have five longitudinal grooves along their bodies. Here we discuss three of the living classes.

### **Class Asteroidea: Sea stars**

Sea stars are perhaps the most familiar echinoderms. Important predators in many marine ecosystems, they range in size from a centimeter to a meter across. They are abundant in the intertidal zone, but also occur at the greatest depths of the ocean—10,000 m. Around 1500 species of sea stars are known.

A sea star consists of tapering arms that gradually merge into a central disk. Most sea stars have five arms, but some have many more, typically in multiples of five. The digestive space and gonads extend into the arms. The body is somewhat flattened, flexible, and covered with a pigmented epidermis. Asteroidea includes sea daisies, which were discovered in 1986 and were once considered to constitute their own class.

### **Class Ophiuroidea: Brittle stars**

Brittle stars constitute the largest class of echinoderms, with about 2000 species, and are probably the most abundant also. They resemble asteroids, but differ morphologically in several ways. The arms, which are of nearly equal diameter their entire length, tapering only slightly from base to tip, merge abruptly into the central disk. They are nearly solid and can easily be autotomized (the source of the name “brittle”). The tube feet lack ampullae and suckers, being used for feeding, not locomotion. The animal has no anus.

The most mobile of echinoderms, brittle stars move by pulling themselves along by “rowing” over the substrate by moving their slender arms, often in pairs or groups, from side

to side. Some brittle stars use their arms to swim, an unusual habit among echinoderms. A brittle star has five arms, but in some larger ones (the basket stars), each arm may bifurcate several times. Brittle stars avoid light and are more active at night.

### **Class Echinoidea: Sea urchins and sand dollars**

Sand dollars and sea urchins lack arms. Five double rows of tube feet protrude through the plates of the calcareous skeleton. The protective, moveable spines that are attached to the skeleton by muscles and connective tissue, are also arrayed pentamerally.

About 950 living species constitute the class Echinoidea. Their calcareous plates preserve well, so sea urchins and sand dollars are well represented in the fossil record, with more than 5000 extinct species described. Sand dollars are essentially flattened sea urchins; heart urchins are intermediate between the two.

Like holothurians, sea urchins are eaten by humans. The gonads, known as *uni* in Japan, are the part considered edible.

### **Learning Outcomes Review 34.6**

Echinoderms are marine deuterostomes with endoskeletons. They are characterized by pentaradial symmetry in the adult, in which a line drawn in five directions produces mirror images. The water-vascular system and tube feet that act as suction cups aid in movement and feeding. The five living classes of echinoderms are Asteroidea (sea stars), Crinoidea (sea lilies), Echinoidea (sea urchins and sand dollars), Holothuroidea (sea cucumbers), and Ophiuroidea (brittle stars).

- **What is the significance of the bilateral larval form of echinoderms?**

## **Chapter Review**

### **34.1 Phylum Mollusca: The Mollusks**

**Mollusks are extremely diverse—and important to humans.**

Mollusks range from microscopic to huge and exhibit many different forms. They all have a coelom surrounding the heart.

**The mollusk body plan is complex and varied.**

Mollusks are generally bilaterally symmetrical, at least at some point in their lives (see figure 34.3). They use a muscular foot (podium) for locomotion, attachment, food capture, or a combination.

The mantle is a thick epidermal sheet that forms the mantle cavity. It houses the respiratory structures (ctenidia or gills), and digestive, excretory, and reproductive products are discharged into it.

The outer mantle secretes a protective calcium carbonate shell. Some mollusks have internal or reduced shells, or none at all.

All mollusks except bivalves have a radula, a rasplike structure used in feeding (see figure 34.4). Most have an open circulatory system, but cephalopods have a closed circulatory system.

In many mollusks, an embryo develops into a free-swimming trochophore larva (see figure 34.5*a*). In some bivalves and gastropods, the embryo becomes a free-swimming veliger larva (see figure 34.5*b*).

**Four classes of mollusks show the diversity of the phylum.**

The four best-known classes are Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams, mussels, and cockles), and Cephalopoda (octopuses and squids).

### **34.2 Phylum Nemertea: The Ribbon Worms**

Nemerteans superficially resemble acoelomate flatworms, but they have a closed circulatory system and a complete digestive tract.

### **34.3 Phylum Annelida: The Annelids**

**The annelid body is composed of ringlike segments.**

The segments of the annelid body are separated by septa. Each segment contains a pair of excretory organs, a ganglion, and, in most

marine annelids, a set of reproductive organs. Anterior and posterior segments contain light-, chemo-, and touch receptors.

Segments are connected by a ventral nerve cord that includes an anterior brain region, and by a closed circulatory system.

**Annelids move by contracting their segments.**

The fluid-filled coelom acts as a hydrostatic skeleton. Each segment typically possesses chaetae, chitin bristles that help anchor the worm.

**Annelids have a common, closed circulatory system but a segmented excretory system.**

Annelids have a closed circulatory system; the dorsal vessel is connected to the ventral vessel by smaller vessels in the body wall.

Each segment contains a pair of nephridia that excrete wastes out of the body via the coelom and excretory tubes.

**Annelids comprise two—or three—classes.**

Annelids have been grouped into three classes, but the currently accepted classification recognizes two: the Polychaeta, which exhibit parapodia and are mostly marine; and the Clitellata, which includes earthworms and leeches.

### 34.4 The Lophophorates: Bryozoa and Brachiopoda

Bryozoa and Brachiopoda are characterized by a lophophore, a U-shaped ridge around the mouth bearing ciliated tentacles.

**The bryozoans, phylum Bryozoa, are the only exclusively colonial animals.**

Each individual zooid produces a chitinous chamber called a zoecium that attaches to substrates and other colony members. They have deuterostome development.

**The brachiopods and phoronids, phylum Brachiopoda, are solitary lophophorates.**

The body of brachiopods is enclosed between two calcified shells that are dorsal and ventral, not lateral as in bivalves (see figure 34.20). They also are deuterostomes.

The phoronids, tube worms, are included with bryozoans because they are solitary lophophorates; however, they are protostomes.

### 34.5 Phylum Arthropoda: The Arthropods

**Arthropods exhibit key features and organ systems.**

Arthropods are segmented and exhibit an exoskeleton with muscles attached to the inside. The exoskeleton is molted during ecdysis, allowing the arthropod to grow. In some species, segments are fused into units called tagmata.

Arthropods' jointed appendages may be modified into mouth parts, antennae, or legs.

An open circulatory system includes a muscular heart. The respiratory system in terrestrial arthropods comprises spiracles, tracheae, and tracheoles (see figure 34.26). The main components of the nervous system are an inhibitory brain and a ventral nerve cord.

Many arthropods have compound eyes composed of ommatidia (figure 34.25); others have simple eyes (ocelli).

The excretory system of terrestrial hexapods, myriapods, and chelicerates consists of Malpighian tubules that eliminate uric acid or guanine.

**Class Chelicerata includes spiders, mites, and horseshoe crabs.**

Chelicerates have specialized anterior appendages, the chelicerae, that function as fangs or pincers.

**Class Crustacea includes crabs, shrimps, lobsters, and pill bugs.**

Crustaceans have three tagmata, and the two anterior ones fused to form a cephalothorax (see figure 34.29). Crustacea is characterized by a nauplius larva (see figure 34.30).

**Class Hexapoda comprises the insects.**

The hexapods are extraordinarily diverse. Insects have three pairs of legs attached to the thorax and may have wings. They have highly developed sensory systems.

**Myriapoda includes centipedes and millipedes.**

Centipedes have one pair of appendages per segment, whereas millipedes have two pairs.

### 34.6 Phylum Echinodermata: The Echinoderms

**Echinoderms are ancient and unmistakable.**

Echinoderms are characterized by deuterostome development, pentamerous symmetry, an endoskeleton covered by a delicate epidermis, and a water-vascular system.

**Echinoderm symmetry is bilateral in larvae but pentaradial in adults.**

The larvae of echinoderms are bilateral, but the adult is pentaradial.

The water-vascular system, which is one of several coelomic compartments, aids in movement, feeding, circulation, respiration, and excretion.

**Echinodermata comprises five extant classes.**

The five classes of echinoderms are Asterozoa (sea stars), Crinozoa (sea lilies), Echinozoa (sea urchins and sand dollars), Holothurozoa (sea cucumbers), and Ophiurozoa (brittle stars).

## Review Questions

### UNDERSTAND

- The \_\_\_\_\_ of a mollusk is a highly efficient respiratory structure.
  - nephridium
  - radula
  - ctenidium
  - veliger
- Torsion is a unique characteristic of the
  - bivalves.
  - gastropods.
  - chitons.
  - cephalopods.
- Intelligence and complex behaviors are characteristics of the
  - cephalopods.
  - polychaetes.
  - brachiopods.
  - echinoderms.
- Serial segmentation is a key characteristic of which of the following phyla?
  - Mollusca
  - Brachiopoda
  - Bryozoa
  - Annelida

- The distinguishing feature of the Bryozoa and Brachiopoda is
  - coelom.
  - segmentation.
  - chaetae.
  - a lophophore.
- In terms of numbers of species, the most successful phylum on the planet is the
  - Mollusca.
  - Arthropoda.
  - Echinodermata.
  - Annelida.
- Which of the following characteristics is not found in the arthropods?
  - Jointed appendages
  - Segmentation
  - Closed circulatory system
  - Segmented ganglia
- Which of the following classes of arthropod possess chelicerae?
  - Chilopoda
  - Crustacea
  - Hexapoda
  - Chelicerata
- Examples of decapods are
  - centipedes and millipedes.
  - barnacles.
  - ticks and mites.
  - lobsters and crayfish.
- What characteristic separates the Diptera, Lepidoptera, and Hymenoptera?
  - Type of wings
  - Type of mouthparts
  - Type of legs
  - Method of reproduction
- Which of the following structures is not a component of the water-vascular system of an echinoderm?
  - Ossicles
  - Ampullae
  - Radial canals
  - Madreporites

## APPLY

- The fact that Arthropods molt means that they are considered
  - spiralian.
  - ectodermates.
  - deuterostomes.
  - parazoans.

- Based on embryonic development, which of the following phyla is the closest to the chordates?
  - Annelida
  - Arthropoda
  - Echinodermata
  - Mollusca
- To which of the following groups would a species that does not molt, possesses a coelom, and has a trochophore larva belong?
  - Ecdysozoa
  - Parazoa
  - Platyzoa
  - Lophotrochozoa
- Nematodes once were thought to be closely related to rotifers due to the presence of a pseudocoelom, but are now considered closer to the arthropods due to
  - molting.
  - jointed appendages.
  - wings.
  - a coelom.

## SYNTHESIZE

- Scientists studying the Chesapeake Bay have discovered that the decline in populations of clams and scallops has led to a drastic increase in the levels of pollution. What characteristic of this group could be attributed to this observation?
- Chitin is present in a number of invertebrate coelomates, as well as the fungi. What does this tell you about the origin and importance of this substance?

# Chapter 35

## Vertebrates

### Chapter Outline

---

- 35.1 The Chordates
- 35.2 The Nonvertebrate Chordates
- 35.3 The Vertebrate Chordates
- 35.4 Fishes
- 35.5 Amphibians
- 35.6 Reptiles
- 35.7 Birds
- 35.8 Mammals
- 35.9 Evolution of the Primates

### Introduction

---

*Members of the phylum Chordata exhibit great changes in the endoskeleton from what is seen in echinoderms. As you saw in chapter 34, the endoskeleton of echinoderms is functionally similar to the exoskeleton of arthropods—a hard shell with muscles attached to its inner surface. Chordates employ a very different kind of endoskeleton, one that is truly internal. Members of the phylum Chordata are characterized by a flexible rod that develops along the back of the embryo. Muscles attached to this rod allowed early chordates to swing their bodies from side to side, swimming through the water. This key evolutionary advance, attaching muscles to an internal element, started chordates along an evolutionary path that led to the vertebrates—and, for the first time, to truly large animals.*

## 35.1 The Chordates

### Learning Outcomes

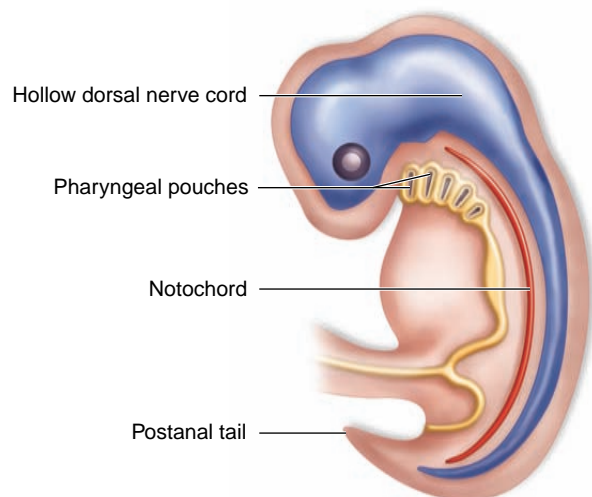

1. List the defining characteristics of chordates.
2. Describe the evolutionary relationships of chordates to other taxa.

**Chordates** (phylum Chordata) are deuterostome coelomates; their nearest relatives in the animal kingdom are the echinoderms, the only other major phylum of deuterostomes. There are some 56,000 species of chordates, a phylum that includes fishes, amphibians, reptiles, birds, and mammals.

Four features characterize the chordates and have played an important role in the evolution of the phylum (figure 35.1):

1. A single, hollow **nerve cord** runs just beneath the dorsal surface of the animal. In vertebrates, the dorsal nerve cord differentiates into the brain and spinal cord.
2. A flexible rod, the **notochord**, forms on the dorsal side of the primitive gut in the early embryo and is present at some developmental stage in all chordates. The notochord is located just below the nerve cord. The notochord may persist in some chordates; in others it is replaced during embryonic development by the vertebral column that forms around the nerve cord.

**Figure 35.1** The four principal features of the chordates, as shown in a generalized embryo.

3. **Pharyngeal slits** connect the **pharynx**, a muscular tube that links the mouth cavity and the esophagus, with the external environment. In terrestrial vertebrates, the slits do not actually connect to the outside and are better termed **pharyngeal pouches**. Pharyngeal pouches are present in the embryos of all vertebrates. They become slits, open to the outside in animals with gills, but leave no external trace in those lacking gills. The presence of these structures in all vertebrate embryos provides evidence of their aquatic ancestry.
4. Chordates have a **postanal tail** that extends beyond the anus, at least during their embryonic development. Nearly all other animals have a terminal anus.

All chordates have all four of these characteristics at some time in their lives. For example, humans as embryos have pharyngeal pouches, a dorsal nerve cord, a postanal tail, and a notochord. As adults, the nerve cord remains, and the notochord is replaced by the vertebral column. All but one pair of pharyngeal pouches are lost; this remaining pair forms the Eustachian tubes that connect the throat to the middle ear. The postanal tail regresses, forming the tail bone (coccyx).

A number of other characteristics also fundamentally distinguish the chordates from other animals. Chordate muscles are arranged in segmented blocks that affect the basic organization of the chordate body and can often be clearly seen in embryos of this phylum (figure 35.2). Most chordates have an internal skeleton against which the muscles work. Either this internal skeleton or the notochord (figure 35.3) makes possible the extraordinary powers of locomotion characteristic of this group.

### Learning Outcomes Review 35.1

Chordates are characterized by a hollow dorsal nerve cord, a notochord, pharyngeal pouches, and a postanal tail at some point in their development. The flexible notochord anchors internal muscles and allows rapid, versatile movement. Chordates are deuterostomes; their nearest relatives are the echinoderms.

- What distinguishes a chordate from an echinoderm?

**Figure 35.2** A mouse embryo.

At 11.5 days of development, the mesoderm is already divided into segments called somites (stained dark in this photo), reflecting the fundamentally segmented nature of all chordates.

**Figure 35.3 Phylum Chordata: Chordates.** Vertebrates, tunicates, and lancelets are chordates (phylum Chordata), coelomate animals with a flexible rod, the notochord, that provides resistance to muscle contraction and permits rapid lateral body movements. Chordates also possess pharyngeal pouches or slits (reflecting their aquatic ancestry and present habitat in some) and a hollow dorsal nerve cord. In nearly all vertebrates, the notochord is replaced during embryonic development by the vertebral column.

## 35.2 The Nonvertebrate Chordates

**Learning Outcome**

1. Describe the nonvertebrate chordates and their characteristics.

Phylum Chordata can be divided into three subphyla. Two of these, Urochordata and Cephalochordata, are nonvertebrate; the third subphylum is Vertebrata. The nonvertebrate chordates do not form vertebrae or other bones, and in the case of the urochordates, their adult form is greatly different from what we expect chordates to look like.

### Tunicates have chordate larval forms

The tunicates and salps (subphylum Urochordata) are a group of about 1250 species of marine animals. Most of them are immobile as adults, with only the larvae having a notochord and nerve cord. As adults, they exhibit neither a major body cavity nor visible signs of segmentation (figure 35.4a, b). Most species occur in shallow waters, but some are found at great depths. In some tunicates, adults are colonial, living in masses on the ocean floor. The pharynx is lined with numerous cilia; beating of the cilia draws a stream of water into the pharynx, where microscopic food particles become trapped in a mucous sheet secreted from a structure called an *endostyle*.

The tadpolelike larvae of tunicates plainly exhibit all of the basic characteristics of chordates and mark the tunicates as having the most primitive combination of features found in any chordate (figure 35.4c). The larvae do not feed and have a poorly developed gut. They remain free-swimming for only a few days before settling to the bottom and attaching themselves to a suitable substrate by means of a sucker.

Tunicates change so much as they mature and adjust developmentally to an immobile, filter-feeding existence that it would be difficult to discern their evolutionary relationships solely by examining an adult. Many adult tunicates secrete a tunic, a tough sac composed mainly of cellulose, a substance frequently found in the cell walls of plants and algae but rarely found in animals. The tunic surrounds the animal and gives the subphylum its name. Colonial tunicates may have a common sac and a common opening to the outside.

**Figure 35.4 Tunicates (phylum Chordata, subphylum Urochordata).** a. The sea peach, *Halocynthia aurantiiformis*, like other tunicates, does not move as an adult, but rather is firmly attached to the sea floor. b. Diagram of the structure of an adult tunicate. c. Diagram of the structure of a larval tunicate, showing the characteristic tadpolelike form. Larval tunicates resemble the postulated common ancestor of the chordates.

**Figure 35.5**  
**Lancelets.** Two lancelets, *Branchiostoma lanceolatum* (phylum Chordata, subphylum Cephalochordata), partly buried in shell gravel, with their anterior ends protruding. The muscle segments are clearly visible.

One group of Urochordates, the Larvacea, retains the tail and notochord into adulthood. One theory of vertebrate origins involves a larval form, perhaps that of a tunicate, which acquired the ability to reproduce.

### Lancelets are small marine chordates

Lancelets (subphylum Cephalochordata) were given their English name because they resemble a lancet—a small, two-edged surgical knife. These scaleless chordates, a few centimeters long, occur widely in shallow water throughout the oceans of the world. There are about 23 species of this subphylum. Most of them belong to the genus *Branchiostoma*, formerly called *Amphioxus*, a name still used widely. In lancelets, the notochord runs the entire length of the dorsal nerve cord and persists throughout the animal's life.

Lancelets spend most of their time partly buried in sandy or muddy substrates, with only their anterior ends protruding (figure 35.5). They can swim, although they rarely do so. Their muscles can easily be seen through their thin, transparent skin as a series of discrete blocks, called myomeres. Lancelets have many more pharyngeal gill slits than fishes do. They lack pigment in their skin, which has only a single layer of cells, unlike the multilayered skin of vertebrates. The lancelet body is pointed at both ends. There is no distinguishable head or sensory structure other than pigmented light receptors.

Lancelets feed on microscopic plankton, using a current created by beating cilia that line the oral hood, pharynx, and gill slits. The gill slits provide an exit for the water and are an adaptation for filter feeding. The oral hood projects beyond the mouth and bears sensory tentacles, which also ring the mouth.

The recent discovery of fossil forms similar to living lancelets in rocks 550 million years old argues for the antiquity of this group. Recent studies by molecular systematists further support the hypothesis that lancelets are the closest relatives of vertebrates.

#### Learning Outcome Review 35.2

Nonvertebrate chordates have notochords but no vertebrae or bones. Urochordates, such as tunicates, have obviously chordate larval forms but drastically different adult forms. Cephalochordates, such as lancelets, do not change body form as adults.

- How do lancelets and tunicates differ from each other, and from vertebrates?

## 35.3 The Vertebrate Chordates

### Learning Outcomes

1. Distinguish vertebrates from other chordates.
2. Explain how cartilage and bone contributed to increased size in vertebrates.

Vertebrates (subphylum Vertebrata) are chordates with a spinal column. The name *vertebrate* comes from the individual bony or cartilaginous segments called vertebrae that make up the spine.

### Vertebrates have vertebrae, a distinct head, and other features

Vertebrates differ from the tunicates and lancelets in two important respects:

**Vertebral column.** In all vertebrates except the earliest diverging fishes, the notochord is replaced during embryonic development by a vertebral column (figure 35.6). The column is a series of bony or cartilaginous vertebrae that enclose and protect the dorsal nerve cord like a sleeve.

**Head.** Vertebrates have a distinct and well-differentiated head with three pairs of well-developed sensory organs; the brain is encased within a protective box, the skull, or cranium, made of bone or cartilage.

In addition to these two key characteristics, vertebrates differ from other chordates in other important respects (figure 35.7):

**Neural crest.** A unique group of embryonic cells called the **neural crest** contributes to the development of many vertebrate structures. These cells develop on the crest of the neural tube as it forms by invagination and pinching together of the neural plate (see chapter 54 for a detailed account). Neural crest cells then migrate to various locations in the developing embryo, where they participate in the development of many different structures.

**Internal organs.** Internal organs characteristic of vertebrates include a liver, kidneys, and endocrine glands. The ductless endocrine glands secrete hormones that help regulate many of the body's functions. All vertebrates have a heart and a closed circulatory system. In both their circulatory and their excretory functions, vertebrates differ markedly from other animals.

**Endoskeleton.** The endoskeleton of most vertebrates is made of cartilage or bone. Cartilage and bone are specialized tissues containing fibers of the protein collagen compacted together (see chapter 47). Bone also contains crystals of a calcium phosphate salt. The great advantage of bone over chitin as a structural material is that bone is a dynamic, living tissue that is strong without being brittle. The vertebrate endoskeleton makes possible the great size and extraordinary powers of movement that characterize this group.

**Figure 35.6 Embryonic development of a vertebra.** During the evolution of animal development, the flexible notochord is surrounded and eventually replaced by a cartilaginous or bony covering, the centrum. The neural tube is protected by an arch above the centrum. The vertebral column functions as a strong, flexible rod that the muscles pull against when the animal swims or moves.

## Vertebrates evolved half a billion years ago: An overview

The first vertebrates evolved in the oceans about 545 MYA, during the Cambrian period. Many of them looked like a flattened hot dog, with a mouth at one end and a fin at the other. The appearance of a hinged jaw was a major advance, opening up new food-gathering options, and jawed fishes became the dominant creatures in the sea. Their descendants, the amphibians, invaded the land. Amphibians, in turn, gave rise to the first reptiles about 300 MYA. Within 50 million years, reptiles, better suited to living out of water, replaced amphibians as the dominant land vertebrates.

With the success of reptiles, vertebrates truly came to dominate the surface of the Earth. Many kinds of reptiles evolved, ranging in size from smaller than a chicken to bigger than a truck, and including some that flew and others that swam. Among them evolved reptiles that gave rise to the two remaining great lines of terrestrial vertebrates: birds and mammals.

Dinosaurs and mammals appear at about the same time in the fossil record, 220 MYA. For over 150 million years, dinosaurs dominated the face of the Earth. Over all these million-and-a-half centuries, the largest mammal was no bigger than a medium-sized dog. Then, in the Cretaceous mass extinction, about 65 MYA, the dinosaurs abruptly disappeared. In their absence, mammals and birds quickly took their place, becoming abundant and diverse.

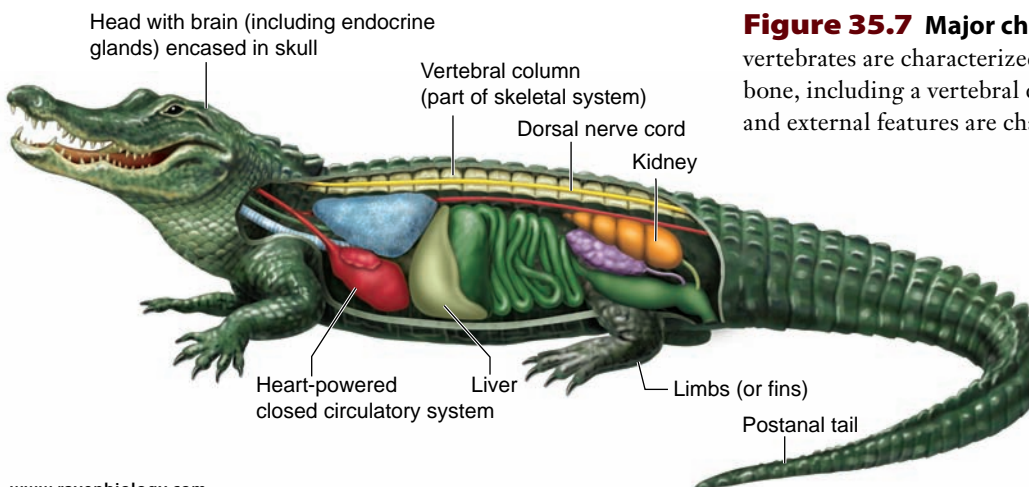

The history of vertebrates has been a series of evolutionary advances that have allowed vertebrates to first invade the land and then the air. In this chapter, we examine the key evolutionary advances that permitted vertebrates to invade the land successfully. As you will see, this invasion was a staggering evolutionary achievement, involving fundamental changes in many body systems.

While considering vertebrate evolution, keep in mind that two vertebrate groups—fish and reptiles—are paraphyletic (figure 35.8). Some fish are more closely related to other vertebrates than they are to some other fish. Similarly, some reptiles are more closely related to birds than they are to other reptiles. Biologists are currently divided about how to handle situations like this, as we discussed in chapter 23 (see figure 23.5). For the time being, we continue to use the traditional classification of vertebrates, bearing in mind the evolutionary implications of the paraphyly of fish and reptiles.

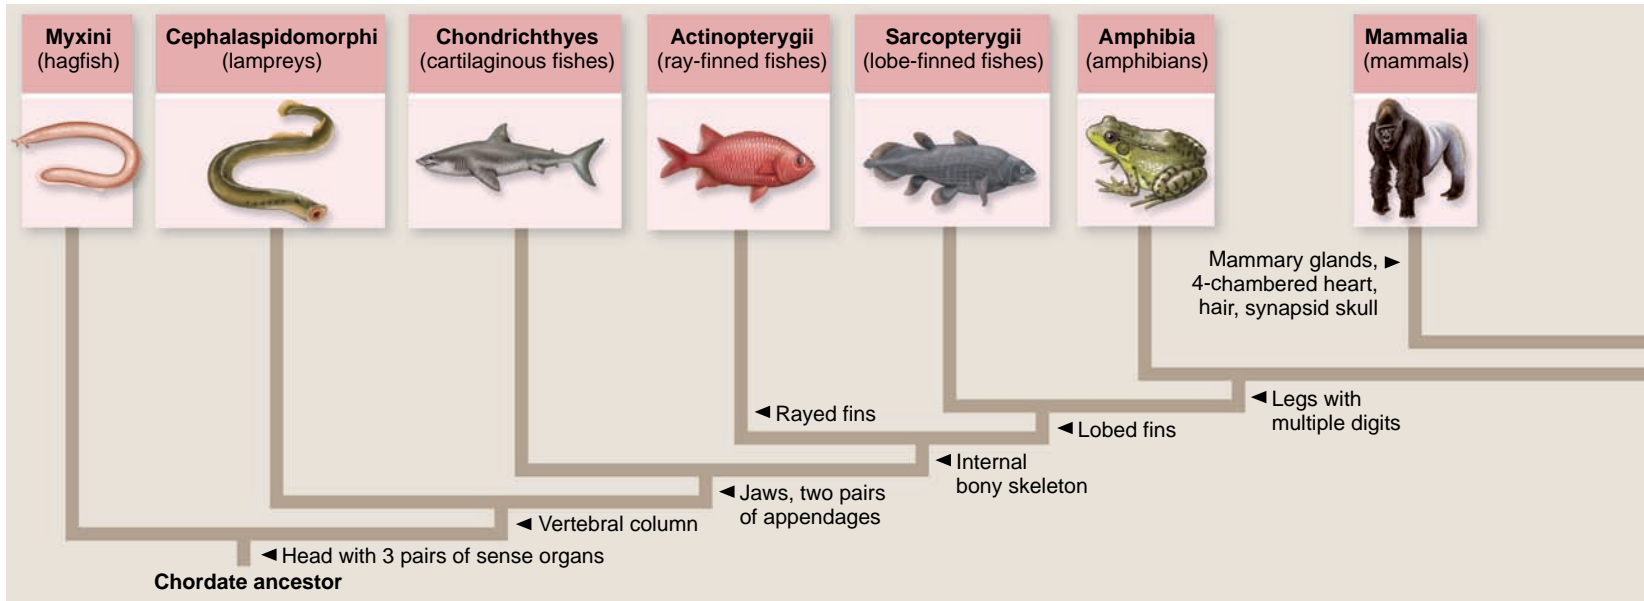

### Learning Outcomes Review 35.3

Vertebrates are characterized by a vertebral column and a distinct head. Other distinguishing features are the development of a neural crest, a closed circulatory system, specialized organs, and a bony or cartilaginous endoskeleton that has the strength to support larger body size and powerful movements.

- *In what ways would an exoskeleton limit the size of an organism?*

**Figure 35.7 Major characteristics of vertebrates.** Adult vertebrates are characterized by an internal skeleton of cartilage or bone, including a vertebral column and a skull. Several other internal and external features are characteristic of vertebrates.

**Figure 35.8 Phylogeny of the living vertebrates.** Some of the key characteristics that evolved among the vertebrate groups are shown in this phylogeny.

## 35.4 Fishes

**Learning Outcomes**

1. Describe the major groups of fishes.
2. List the evolutionary innovations of fishes.

Over half of all vertebrates are fishes. The most diverse vertebrate group, fishes provided the evolutionary base for invasion of land by amphibians. In many ways, amphibians can be viewed as transitional—“fish out of water.”

The story of vertebrate evolution started in the ancient seas of the Cambrian period (545 to 490 MYA). Figure 35.8 shows the key vertebrate characteristics that evolved subsequently. Wriggling through the water, jawless and toothless, the first fishes sucked up small food particles from the ocean floor like miniature vacuum cleaners. Most were less than a foot long, respired with gills, and had no paired fins or vertebrae (although some had rudimentary vertebrae); they did have a head and a primitive tail to push them through the water.

For 50 million years, during the Ordovician period (490 to 438 MYA), these simple fishes were the only vertebrates. By the end of this period, fish had developed primitive fins to help them swim and massive shields of bone for protection. Jawed fishes first appeared during the Silurian period (438 to 408 MYA), and along with them came a new mode of feeding.

### Fishes exhibit five key characteristics

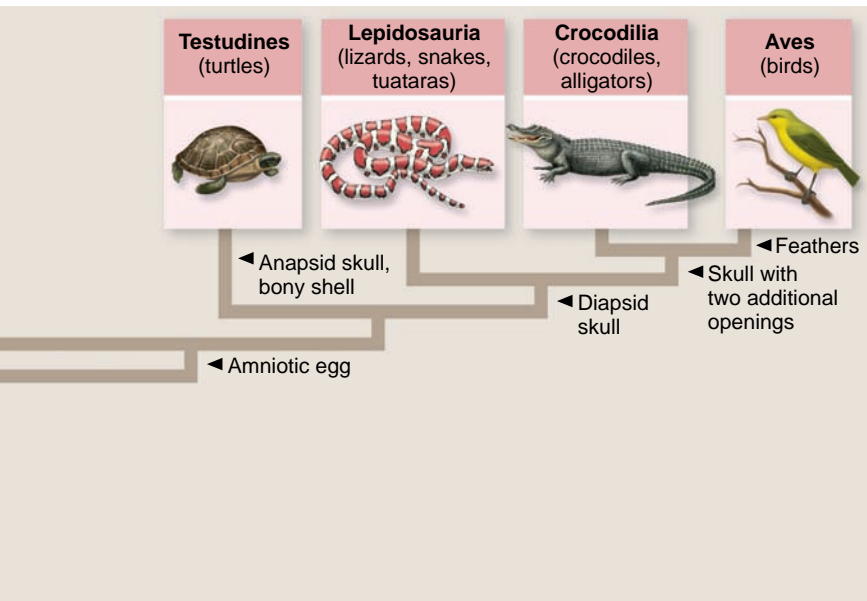

From whale sharks 18 m long to tiny gobies no larger than your fingernail, fishes vary considerably in size, shape, color, and appearance (figure 35.9). Some live in freezing arctic seas, others in warm, freshwater lakes, and still others spend a lot of time

entirely out of water. However varied, all fishes have important characteristics in common:

1. **Vertebral column.** Fish have an internal skeleton with a bony or cartilaginous spine surrounding the dorsal nerve cord, and a bony or cartilaginous skull encasing the brain. Exceptions are the jawless hagfish and lampreys. In hagfish, a cartilaginous skull is present, but vertebrae are not; the notochord persists and provides support. In lampreys, a cartilaginous skeleton and notochord are

**Figure 35.9 Fish.** Fish are the most diverse vertebrates and include more species than all other kinds of vertebrates combined. Top, ribbon eel, *Rhinomuraena quaesita*; bottom left, leafy sea dragon, *Phycodurus eques*; bottom right, yellowfin tuna, *Thunnus albacares*.

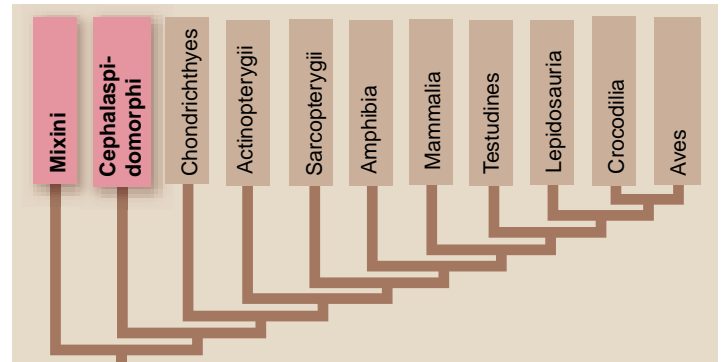

present, but rudimentary cartilaginous vertebrae also surround the notochord in places.

- Jaws and paired appendages.** Fishes other than lampreys and hagfish all have jaws and paired appendages, features that are also seen in tetrapods (see figure 35.8). Jaws allowed these fish to capture larger and more active prey. Most fishes have two pairs of fins: a pair of pectoral fins at the shoulder, and a pair of pelvic fins at the hip. In the lobe-finned fish, these pairs of fins became jointed.
- Internal gills.** Fishes are water-dwelling creatures and must extract oxygen dissolved in the water around them. They do

this by directing a flow of water through their mouths and across their gills (see chapter 49). The gills are composed of fine filaments of tissue that are rich in blood vessels.

- Single-loop blood circulation.** Blood is pumped from the heart to the gills. From the gills, the oxygenated blood passes to the rest of the body, and then returns to the heart. The heart is a muscular tube-pump made of two chambers that contract in sequence.
- Nutritional deficiencies.** Fishes are unable to synthesize the aromatic amino acids (phenylalanine, tryptophan, and tyrosine; see chapter 3), and they must consume them in their foods. This inability has been inherited by all of their vertebrate descendants.

### The first fishes

The first fishes did not have jaws, and instead had only a mouth at the front end of the body that could be opened to take in food. Two groups survive today as hagfish (class Myxini; table 35.1) and lampreys (class Cephalaspidomorphi).

Class	Typical Examples	Key Characteristics	Approximate Number of Living Species
Sarcopterygii	Lobe-finned fishes 	Largely extinct group of bony fishes; ancestral to amphibians; paired lobed fins	8
Actinopterygii	Ray-finned fishes 	Most diverse group of vertebrates; swim bladders and bony skeletons; paired fins supported by bony rays	30,000
Chondrichthyes	Sharks, skates, rays 	Cartilaginous skeletons; no swim bladders; internal fertilization	750
Cephalaspidomorphi	Lampreys 	Largely extinct group of jawless fishes with no paired appendages; parasitic and nonparasitic types; all breed in fresh water	35
Myxini	Hagfishes 	Jawless fishes with no paired appendages; scavengers; mostly blind, but having a well-developed sense of smell	30
Placodermi	Armored fishes 	Jawed fishes with heavily armored heads; many were quite large	Extinct
Acanthodii and Ostracodermi	Spiny fishes 	Fishes with (acanthodians) or without (placoderms) jaws; paired fins supported by sharp spines; head shields made of bone; rest of skeleton cartilaginous	Extinct

Another group were the *ostracoderms* (a word meaning “shell-skinned”). Only their head-shields were made of bone; their elaborate internal skeletons were constructed of cartilage. Many ostracoderms were bottom-dwellers, with a jawless mouth underneath a flat head, and eyes on the upper surface. Ostracoderms thrived in the Ordovician and Silurian periods (490 to 408 MYA), only to become almost completely extinct at the close of the Devonian period (408 to 360 MYA).

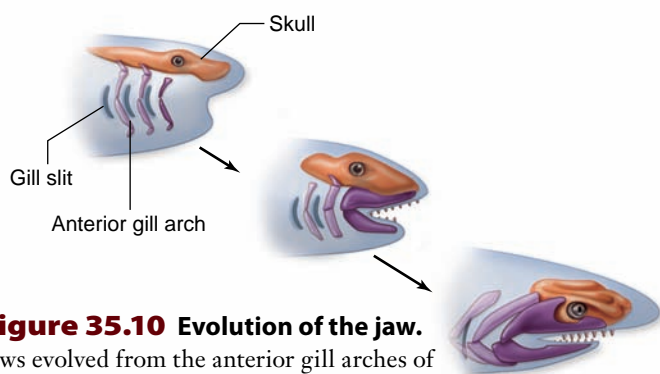

### Evolution of the jaw

A fundamentally important evolutionary advance that occurred in the late Silurian period was the development of jaws. Jaws evolved from the most anterior of a series of arch-supports made of cartilage, which were used to reinforce the tissue between gill slits to hold the slits open (figure 35.10). This transformation was not as radical as it might at first appear.

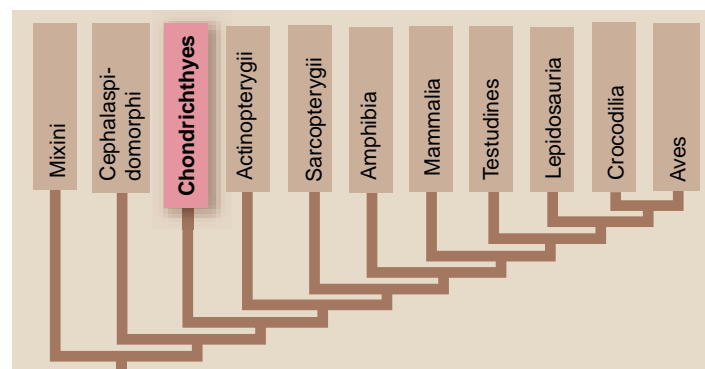

Each gill arch was formed by a series of several cartilages (which later evolved to become bones) arranged somewhat in the shape of a V turned on its side, with the point directed outward. Imagine the fusion of the front pair of arches at top and bottom, with hinges at the points, and you have the primitive vertebrate jaw. The top half of the jaw is not attached to the skull directly except at the rear. Teeth developed on the jaws from modified scales on the skin that lined the mouth (see figure 35.10).

Armored fishes called placoderms and spiny fishes called acanthodians both had jaws. Spiny fishes were very common during the early Devonian period, largely replacing ostracoderms, but they became extinct themselves at the close of the Permian. Like ostracoderms, they had internal skeletons made of cartilage, but their scales contained small plates of bone, foreshadowing the much larger role bone would play in the future of vertebrates. Spiny fishes were jawed predators and far better swimmers than ostracoderms, with as many as seven fins to aid their swimming. All of these fins were reinforced with strong spines, giving these fishes their name.

By the mid-Devonian period, the heavily armored placoderms became common. A very diverse and successful group, seven orders of placoderms dominated the seas of the late Devonian, only to become extinct at the end of that period. The placoderm jaw was much improved over the primitive jaw of spiny fishes, with the upper jaw fused to the skull and the skull hinged on the shoulder. Many of the placoderms grew to enormous sizes, some over 30 feet long, with 2-foot skulls that had an enormous bite.

**Figure 35.10 Evolution of the jaw.** Jaws evolved from the anterior gill arches of ancient, jawless fishes.

### Sharks, with cartilaginous skeletons, became top predators

At the end of the Devonian period, essentially all of these pioneer vertebrates disappeared, replaced by sharks and bony fishes in one of several mass extinctions that occurred during Earth’s history (see chapter 22). Sharks and bony fishes first evolved in the early Devonian, 400 MYA. In these fishes, the jaw was improved even further, with the upper part of the first gill arch behind the jaws being transformed into a supporting strut or prop, joining the rear of the lower jaw to the rear of the skull. This allowed the mouth to open much wider than was previously possible.

During the Carboniferous period (360 to 280 MYA), sharks became the dominant predators in the sea. Sharks, as well as skates and rays (all in the class Chondrichthyes), have a skeleton made of cartilage, like primitive fishes, but it is “calcified,” strengthened by granules of calcium carbonate deposited in the outer layers of cartilage. The result is a very light and strong skeleton.

Streamlined, with paired fins and a light, flexible skeleton, sharks are superior swimmers (figure 35.11). Their pectoral fins are particularly large, jutting out stiffly like airplane wings—and that is how they function, adding lift to compensate for the downward thrust of the tail fin. Sharks are very aggressive predators, and some early sharks reached enormous size.

### The evolution of teeth

Sharks were among the first vertebrates to develop teeth. These teeth evolved from rough scales on the skin and are not set into the jaw as human teeth are, but rather sit atop it. They are not firmly anchored and are easily lost. In a shark’s mouth, the teeth are arrayed in up to 20 rows; the teeth in front do the biting and cutting, and behind them other teeth grow and wait their turn.

**Figure 35.11 Chondrichthyes.** Members of the class Chondrichthyes, such as this blue shark, *Prionace glauca*, are mainly predators or scavengers.

When a tooth breaks or is worn down, a replacement from the next row moves forward. A single shark may eventually use more than 20,000 teeth in its lifetime.

A shark's skin is covered with tiny, toothlike scales, giving it a rough "sandpaper" texture. Like the teeth, these scales are constantly replaced throughout the shark's life.

### The lateral line system

Sharks, as well as bony fishes, possess a fully developed lateral line system. The **lateral line system** consists of a series of sensory organs that project into a canal beneath the surface of the skin. The canal runs the length of the fish's body and is open to the exterior through a series of sunken pits. Movement of water past the fish forces water through the canal. The pits are oriented so that some are stimulated no matter what direction the water moves. Details of the lateral line system's function are described in chapter 45. In a very real sense, the lateral line system is a fish's equivalent of hearing and therefore is an additional means of mechanoreception.

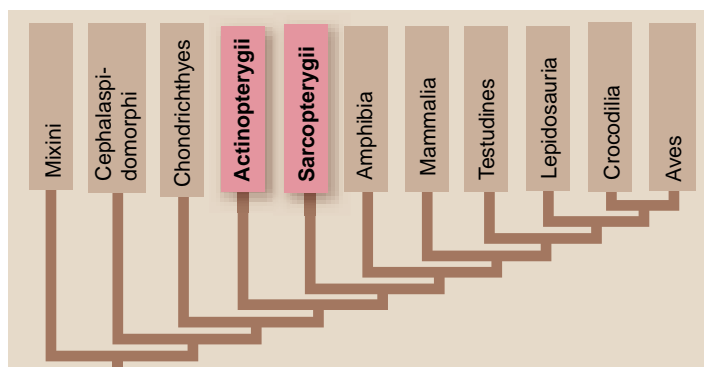

### Reproduction in cartilaginous fishes

Reproduction in the class Chondrichthyes differs from that of most other fishes. Shark eggs are fertilized internally. During mating, the male grasps the female with modified fins called claspers, and sperm run from the male into the female through grooves in the claspers. Although a few species lay fertilized eggs, the eggs of most species develop within the female's body, and the pups are born alive.

In recent times, this reproductive system has worked to the detriment of sharks. Because of their long gestation periods and relatively few offspring, shark populations are not able to recover quickly from population declines. Unfortunately, in recent times sharks have been fished very heavily because shark fin soup has become popular in Asia and elsewhere. As a result, shark populations have declined greatly, and there is concern that many species may soon face extinction.

### Shark evolution

Many of the early evolutionary lines of sharks died out during the great extinction at the end of the Permian period (248 MYA). The survivors thrived and underwent a burst of diversification during the Mesozoic era (248 to 65 MYA), when most of the modern groups of sharks appeared. Skates and rays, which are dorsoventrally flattened relatives of sharks, evolved at this time, some 200 million years after the sharks first appeared.

### Bony fishes dominate the waters

Bony fishes evolved at the same time as sharks, some 400 MYA, but took quite a different evolutionary road. Instead of gaining

speed through lightness, as sharks did, bony fishes adopted a heavy internal skeleton made completely of bone.

Bone is very strong, providing a base against which very strong muscles can pull. Not only is the internal skeleton ossified, but so is the outer covering of plates and scales. Most bony fishes have highly mobile fins, very thin scales, and completely symmetrical tails (which keep the fish on a straight course as it swims through the water). Bony fishes are the most species-rich group of fishes, indeed of all vertebrates. There are several dozen orders containing more than 30,000 living species.

The remarkable success of the bony fishes has resulted from a series of significant adaptations that have enabled them to dominate life in the water. These include the swim bladder and the gill cover (figure 35.12).

### Swim bladder

Although bones are heavier than cartilaginous skeletons, most bony fishes are still buoyant because they possess a **swim bladder**, a gas-filled sac that allows them to regulate their buoyant density and so remain suspended at any depth in the water effortlessly. Sharks, by contrast, must move through the water or sink because, lacking a swim bladder, their bodies are denser than water.

In primitive bony fishes, the swim bladder is a dorsal outpocketing of the pharynx behind the throat, and these species fill the swim bladder by simply gulping air at the surface of the water. In most of today's bony fishes, the swim bladder is an independent organ that is filled and drained of gases, mostly nitrogen and oxygen, internally.

**Figure 35.12 Diagram of a swim bladder.** The bony fishes use this structure, which evolved as a dorsal outpocketing of the pharynx, to control their buoyancy in water. The swim bladder can be filled with or drained of gas to allow the fish to control buoyancy. Gases are taken from the blood, and the gas gland secretes the gases into the swim bladder; gas is released from the bladder by a muscular valve, the oval body.

How do bony fishes manage this remarkable trick? It turns out that the gases are harvested from the blood by a unique gland that discharges the gases into the bladder when more buoyancy is required. To reduce buoyancy, gas is reabsorbed into the bloodstream through a structure called the oval body. A variety of physiological factors control the exchange of gases between the bloodstream and the swim bladder.

### Gill cover

Most bony fishes have a hard plate called the **operculum** that covers the gills on each side of the head. Flexing the operculum permits bony fishes to pump water over their gills. The gills are suspended in the pharyngeal slits that form a passageway between the pharynx and the outside of the fish's body. When the operculum is closed, it seals off the exit.

When the mouth is open, closing the operculum increases the volume of the mouth cavity, so that water is drawn into the mouth. When the mouth is closed, opening the operculum decreases the volume of the mouth cavity, forcing water past the gills to the outside. Using this very efficient bellows, bony fishes can pass water over the gills while remaining stationary in the water. That is what a goldfish is doing when it seems to be gulping in a fish tank.

## The evolutionary path to land ran through the lobe-finned fishes

Two major groups of bony fish are the ray-finned fishes (class Actinopterygii; figure 35.13a) and lobe-finned fishes (class Sarcopterygii). The groups differ in the structure of their fins (figure 35.13b). In ray-finned fishes, the internal skeleton of the fin is composed of parallel bony rays that support and stiffen each fin. There are no muscles within the fins; rather, the fins are moved by muscles within the body.

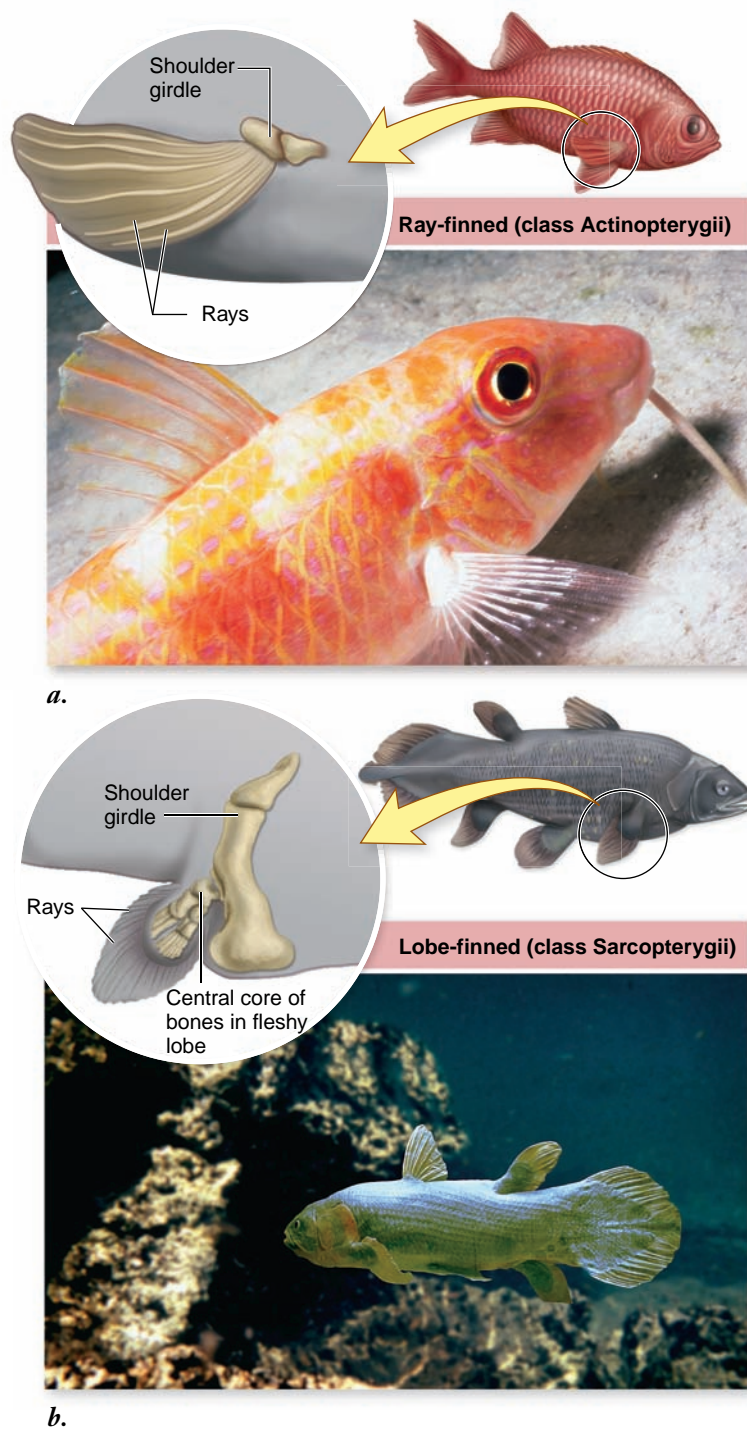

By contrast, lobe-finned fishes have paired fins that consist of a long fleshy muscular lobe (hence their name), supported by a central core of bones that form fully articulated joints with one another. There are bony rays only at the tips of each lobed fin. Muscles within each lobe can move the fin rays independently of one another, a feat no ray-finned fish could match.

Lobe-finned fishes evolved 390 MYA, shortly after the first bony fishes appeared. Only eight species survive today, two species of coelacanth (figure 35.13b) and six species of lungfish. Although rare today, lobe-finned fishes played an important part in the evolutionary story of vertebrates. Amphibians almost certainly evolved from the lobe-finned fishes.

### Learning Outcomes Review 35.4

Fishes are generally characterized by the possession of a vertebral column, jaws, paired appendages, a lateral line system, internal gills, and single-loop circulation. Cartilaginous fishes have lightweight skeletons and were among the first vertebrates to develop teeth. The very successful bony fishes have unique characteristics such as swim bladders and gill covers, as well as ossified skeletons. One type of bony fish, the lobe-finned fish, gave rise to the ancestors of amphibians.

- What advantages do lobed fins have over ray fins?

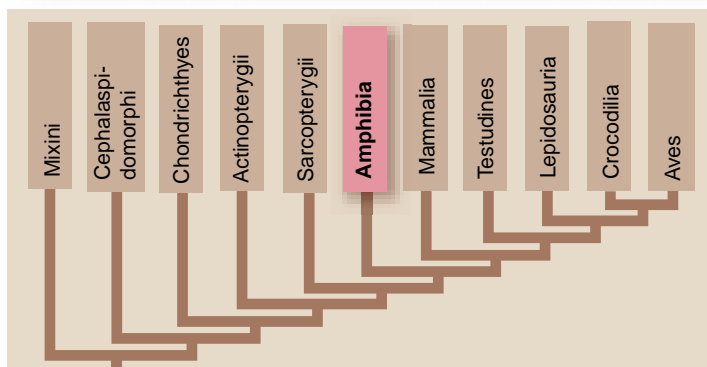

**Figure 35.13** Ray-finned and lobe-finned fishes.

**a.** The ray-finned fishes, such as this Koi carp (*Cyprinus carpio*), are characterized by fins of only parallel bony rays. **b.** By contrast, the fins of lobe-finned fish have a central core of bones as well as rays. The coelacanth, *Latimeria chalumnae*, a lobe-finned fish (class Sarcopterygii), was discovered in the western Indian Ocean in 1938. This coelacanth represents a group of fishes thought to have been extinct for about 70 million years. Scientists who studied living individuals in their natural habitat at depths of 100–200 m observed them drifting in the current and hunting other fishes at night. Some individuals are nearly 3 m long; they have a slender, fat-filled swim bladder.

## 35.5 Amphibians

### Learning Outcomes

1. Describe the characteristics and major groups of amphibians.
2. Explain the challenges of moving from an aquatic to a terrestrial environment.

Frogs, salamanders, and caecilians, the damp-skinned vertebrates, are direct descendants of fishes. They are the sole survivors of a very successful group, the amphibians (class Amphibia), the first vertebrates to walk on land. Most present-day amphibians are small and live largely unnoticed by humans, but they are among the most numerous of terrestrial vertebrates. Throughout the world, amphibians play key roles in terrestrial food chains.

### Living amphibians have five distinguishing features

Biologists have classified living species of amphibians into three orders (table 35.2): 5000 species of frogs and toads in 22 fami-

lies make up the order Anura (“without a tail”); 500 species of salamanders and newts in 9 families make up the order Caudata (“visible tail”); and 170 species (6 families) of wormlike, nearly blind organisms called caecilians that live in the tropics make up the order Apoda (“without legs”). These amphibians have several key characteristics in common:

1. **Legs.** Frogs and most salamanders have four legs and can move about on land quite well. Legs were one of the key adaptations to life on land. Caecilians have lost their legs during the course of adapting to a burrowing existence.
2. **Lungs.** Most amphibians possess a pair of lungs, although the internal surfaces have much less surface area than do reptilian or mammalian lungs. Amphibians breathe by lowering the floor of the mouth to suck in air, and then raising it back to force the air down into the lungs (see chapter 49).
3. **Cutaneous respiration.** Frogs, salamanders, and caecilians all supplement the use of lungs by respiring through their skin, which is kept moist and provides an extensive surface area.
4. **Pulmonary veins.** After blood is pumped through the lungs; two large veins called pulmonary veins return the aerated blood to the heart for repumping. In this way aerated blood is pumped to the tissues at a much higher pressure.
5. **Partially divided heart.** A dividing wall helps prevent aerated blood from the lungs from mixing with nonaerated blood being returned to the heart from the rest of the body. The blood circulation is thus divided into two separate paths: pulmonary and systemic. The separation is imperfect, however, because no dividing wall exists in one chamber of the heart, the ventricle (see chapter 49).

Several other specialized characteristics are shared by all present-day amphibians. In all three orders, there is a zone of weakness between the base and the crown of the teeth. They also have a peculiar type of sensory rod cell in the retina of the eye called a “green rod.” The function of this rod is unknown.

**TABLE 35.2** Orders of Amphibians

Order	Typical Examples	Key Characteristics	Approximate Number of Living Species
Anura	Frogs, toads 	Compact, tailless body; large head fused to the trunk; rear limbs specialized for jumping	5000
Caudata	Salamanders, newts 	Slender body; long tail and limbs set out at right angles to the body	500
Apoda	Caecilians 	Tropical group with a snakelike body; no limbs; little or no tail	170

## Amphibians overcame terrestrial challenges

The word *amphibia* means “double life,” and it nicely describes the essential quality of modern-day amphibians, reflecting their ability to live in two worlds—the aquatic world of their fish ancestors and the terrestrial world they first invaded. Here, we review the checkered history of this group, almost all of whose members have been extinct for the last 200 million years. Then we examine in more detail what the few kinds of surviving amphibians are like.

The successful invasion of land by vertebrates posed a number of major challenges:

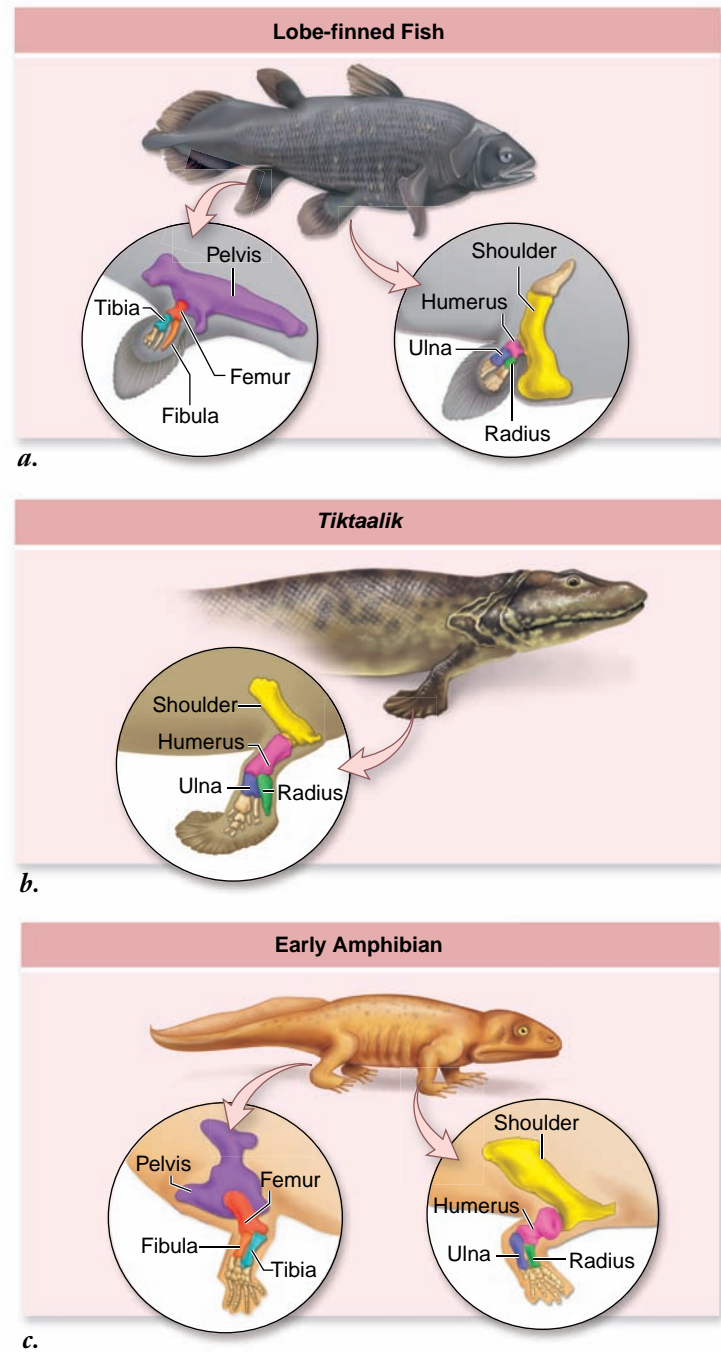

- Because amphibian ancestors had relatively large bodies, supporting the body's weight on land as well as enabling movement from place to place was a challenge (figure 35.14). Legs evolved to meet this need.
- Even though far more oxygen is available to gills in air than in water, the delicate structure of fish gills requires the buoyancy of water to support them, and they will not function in air. Therefore, other methods of obtaining oxygen were required.
- Delivering great amounts of oxygen to the larger muscles needed for movement on land required modifications to the heart and circulatory system.
- Reproduction still had to be carried out in water so that eggs would not dry out.
- Most importantly, the body itself had to be prevented from drying out.

### The first amphibian

Amphibians solved these problems only partially, but their solutions worked well enough that amphibians have survived for 350 million years. Evolution does not insist on perfect solutions, only workable ones.

Paleontologists agree that amphibians evolved from lobe-finned fish. *Ichthyostega*, one of the earliest amphibian fossils (figure 35.15), was found in a 370-million-year-old rock in Greenland. At that time, Greenland was part of what is now the North American continent and lay near the equator. All amphibian fossils from the next 100 million years are found in North America. Only when Asia and the southern continents merged with North America to form the supercontinent Pangaea did amphibians spread throughout the world.

*Ichthyostega* was a strongly built animal, with sturdy forelegs well supported by shoulder bones. Unlike the bone structure of fish, the shoulder bones were no longer attached to the skull, so the limbs could support the animal's weight. Because the hindlimbs were flipper-shaped, *Ichthyostega* probably moved like a seal, with the forelimbs providing the propulsive force for locomotion and the hindlimbs being dragged along with the rest of the body. To strengthen the backbone further, long, broad ribs that overlap each other formed a solid cage for the lungs and heart. The rib cage was so solid that it probably couldn't expand and contract for breathing. Instead, *Ichthyostega* probably obtained oxygen as many amphibians do today, by lowering the floor of the mouth to draw air in, and then raising it to push air down the windpipe into the lungs.

**Figure 35.14** A comparison between the limbs of a lobe-finned fish, *Tiktaalik*, and a primitive amphibian.

**a.** A lobe-finned fish. Some of these animals could probably move on land. **b.** *Tiktaalik*. The shoulder and limb bones are like those of an amphibian, but the fins are like those of a lobe-finned fish. The fossil of *Tiktaalik* did not contain the hindlimbs. **c.** A primitive amphibian. As illustrated by their skeletal structure, the legs of such an animal clearly could function better than those of its ancestors for movement on land.

In 2006, an important transitional fossil between fish and *Ichthyostega* was discovered in northern Canada. *Tiktaalik*, which lived 375 MYA, had gills and scales like a fish, but a neck like an amphibian. Particularly significant, however, was the form of its forelimbs (see figure 35.14): its shoulder, forearm, and wrist bones were like those of amphibians, but at the end of the limb

**Figure 35.15 Amphibians were the first vertebrates to walk on land.** *Ichthyostega*, one of the first amphibians, had efficient limbs for crawling on land, an improved olfactory sense associated with a lengthened snout and a relatively advanced ear structure for picking up airborne sounds. Despite these features, *Ichthyostega*, which lived about 350 MYA, was still quite fishlike in overall appearance and may have spent much of its life in water.

was a lobed fin, rather than the toes of an amphibian. Ecologically, the 3-m long *Tiktaalik* was probably also intermediate between fish and amphibians, spending most of its time in the water, but capable of hauling itself out onto land to capture food or escape predators.

### The rise and fall of amphibians

By moving onto land, amphibians were able to utilize many resources and to access many habitats. Amphibians first became common during the Carboniferous period (360 to 280 MYA). Fourteen families of amphibians are known from the early Carboniferous, nearly all of them aquatic or semiaquatic, like *Ichthyostega* (see figure 35.15). By the late Carboniferous, much of North America was covered by low-lying tropical swamplands, and 34 families of amphibians thrived in this wet terrestrial environment, sharing it with pelycosaurs and other early reptiles.

In the early Permian period that followed (280 to 248 MYA), a remarkable change occurred among amphibians—they began to leave the marshes for dry uplands. Many of these terrestrial amphibians had bony plates and armor covering their bodies and grew to be very large, some as big as a pony. Both their large size and the complete covering of their bodies indicate that these amphibians did not use the skin respiratory system of present-day amphibians, but rather had an impermeable leathery skin to prevent water loss. Consequently, they must have relied entirely on their lungs for respiration. By the mid-Permian period, there were 40 families of amphibians. Only 25% of them were still semiaquatic like *Ichthyostega*; 60% of the amphibians were fully terrestrial, and 15% were semiterrestrial. This was the peak of amphibian success, sometimes called the Age of Amphibians.

By the end of the Permian period, reptiles had evolved from amphibians. One group, therapsids, had become common and ousted the amphibians from their newly acquired niche on land. Following the mass extinction event at the end of the Permian, therapsids were the dominant land vertebrate, and most amphibians were aquatic. This trend continued in the following Triassic period (248 to 213 MYA), which saw the virtual extinction of amphibians from land.

### Modern amphibians belong to three groups

All of today's amphibians descended from the three families of amphibians that survived the Age of the Dinosaurs. During the Tertiary period (65 to 2 MYA), these moist-skinned amphibians accomplished a highly successful invasion of wet habitats all over the world, and today there are over 5600 species of amphibians in 37 different families, comprising the orders Anura, Caudata, and Apoda.

#### Order Anura: Frogs and toads

Frogs and toads, amphibians without tails, live in a variety of environments, from deserts and mountains to ponds and puddles (figure 35.16a). Frogs have smooth, moist skin, a broad body, and long hind legs that make them excellent jumpers.

**Figure 35.16 Class Amphibia.** a. Red-eyed tree frog, *Agalychnis callidryas* (order Anura). b. An adult tiger salamander, *Ambystoma tigrinum* (order Caudata). c. A caecilian, *Caecilia tentaculata* (order Apoda).

## 35.6 Reptiles

### Learning Outcomes

1. Describe the characteristics and major groups of reptiles.
2. Distinguish between synapsids and diapsids.
3. Explain the significance of the evolution of the amniotic egg.

Most frogs live in or near water and go through an aquatic tadpole stage before metamorphosing into frogs; however, some tropical species that don't live near water bypass this stage and hatch out as little froglets.

Unlike frogs, toads have a dry, bumpy skin and short legs, and are well adapted to dry environments. Toads do not form a monophyletic group; that is, all toads are not more closely related to each other than they are to some other frogs. Rather, the term *toad* is applied to those anurans that have adapted to dry environments by evolving a suite of adaptive characteristics; this convergent evolution has occurred many times among distantly related anurans.

Most frogs and toads return to water to reproduce, laying their eggs directly in water. Their eggs lack watertight external membranes and would dry out quickly on land. Eggs are fertilized externally and hatch into swimming larval forms called tadpoles. Tadpoles live in the water, where they generally feed on algae. After considerable growth, the body of the tadpole gradually undergoes metamorphosis into that of an adult frog.

### Order Caudata: Salamanders

Salamanders have elongated bodies, long tails, and smooth, moist skin (figure 35.16*b*). They typically range in length from a few inches to a foot, although giant Asiatic salamanders of the genus *Andrias* are as much as 1.5 m long and weigh up to 33 kg. Most salamanders live in moist places, such as under stones or logs, or among the leaves of tropical plants. Some salamanders live entirely in water.

Salamanders lay their eggs in water or in moist places. Most species practice a type of internal fertilization in which the female picks up sperm packets deposited by the male. Like anurans, many salamanders go through a larval stage before metamorphosing into adults. However, unlike anurans, in which the tadpole is strikingly different from the adult frog, larval salamanders are quite similar to adults, although most live in water and have external gills and gill slits that disappear at metamorphosis.

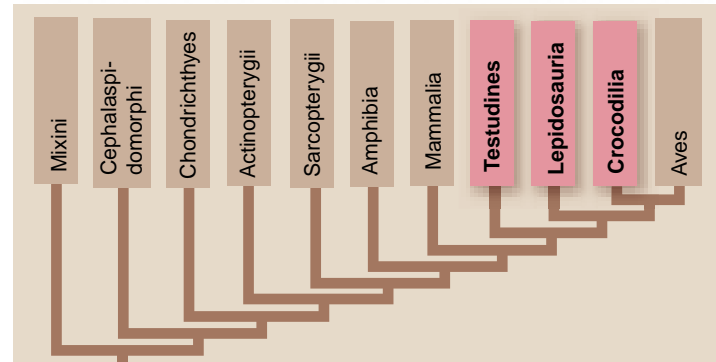

### Order Apoda: Caecilians

Caecilians, members of the order Apoda (also called Gymnophiona), are a highly specialized group of tropical burrowing amphibians (figure 35.16*c*). These legless, wormlike creatures average about 30 cm long, but can be up to 1.3 m long. They have very small eyes and are often blind. They resemble worms but have jaws with teeth. They eat worms and other soil invertebrates. Fertilization is internal.

### Learning Outcomes Review 35.5

Amphibians, which includes frogs and toads, salamanders, and caecilians, are generally characterized by legs, lungs, cutaneous respiration, and a more complex and divided circulatory system. All of these developed as adaptations to life on land. Most species rely on a water habitat for reproduction. Although some early forms reached the size of a pony, modern amphibians are generally quite small.

- What challenges did amphibians overcome to make the transition to living on land?

If we think of amphibians as a first draft of a manuscript about survival on land, then reptiles are the finished book. For each of the five key challenges of living on land, reptiles improved on the innovations of amphibians. The arrangement of legs evolved to support the body's weight more effectively, allowing reptile bodies to be bigger and to run. Lungs and heart became more efficient. The skin was covered with dry plates or scales to minimize water loss, and watertight coverings evolved for eggs.

Over 7000 species of reptiles (class Reptilia) now live on Earth (table 35.3). They are a highly successful group in today's world; there are more living species of snakes and lizards than there are of mammals.

### Reptiles exhibit three key characteristics

All living reptiles share certain fundamental characteristics, features they retain from the time when they replaced amphibians as the dominant terrestrial vertebrates. Among the most important are:

1. **Amniotic eggs.** Amphibians' eggs must be laid in water or a moist setting to avoid drying out. Most reptiles lay watertight eggs that contain a food source (the yolk) and a series of four membranes: the yolk sac, the amnion, the allantois, and the chorion (figure 35.17). Each membrane plays a role in making the egg an independent life-support system. All modern reptiles, as well as birds and mammals, show exactly this same pattern of membranes within the egg. These three classes are called **amniotes**.

The outermost membrane of the egg is the **chorion**, which lies just beneath the porous shell. It allows exchange of respiratory gases but retains water. The **amnion** encases the developing embryo within a fluid-filled cavity. The **yolk sac** provides food from the yolk for the embryo via blood vessels connecting to the embryo's gut. The **allantois** surrounds a cavity into which waste products from the embryo are excreted.

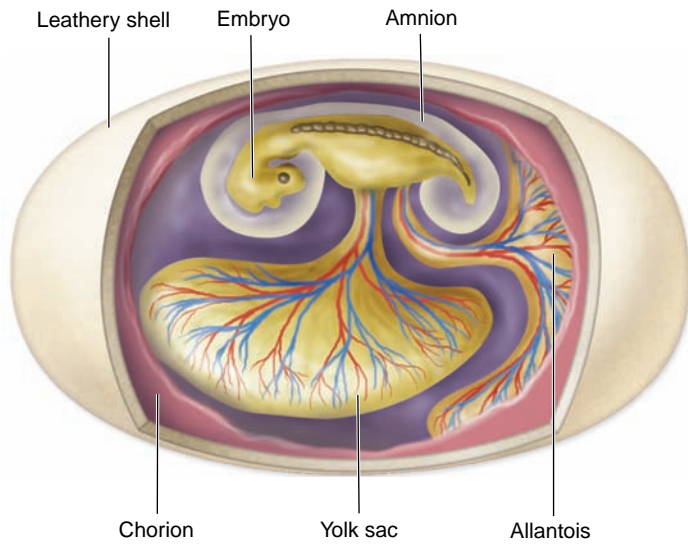

**TABLE 35.3**
**Major Orders of Reptiles**

Order	Typical Examples	Key Characteristics	Approximate Number of Living Species
Squamata, suborder Sauria	Lizards 	Limbs set at right angles to body; anus is in transverse (sideways) slit; most are terrestrial	3800
Squamata, suborder Serpentes	Snakes 	No legs; move by slithering; scaly skin is shed periodically; most are terrestrial	3000
Rhynchocephalia	Tuataras 	Sole survivors of a once successful group that largely disappeared before dinosaurs; fused, wedgelike, socketless teeth; primitive third eye under skin of forehead	2
Chelonia	Turtles, tortoises, sea turtles 	Armored reptiles with shell of bony plates to which vertebrae and ribs are fused; sharp, horny beak without teeth	250
Crocodylia	Crocodiles, alligators 	Advanced reptiles with four-chambered heart and socketed teeth; anus is a longitudinal (lengthwise) slit; closest living relatives to birds	25
Ornithischia	Stegosaur 	Dinosaurs with two pelvic bones facing backward, like a bird's pelvis; herbivores; legs under body	Extinct
Saurischia	Tyrannosaur 	Dinosaurs with one pelvic bone facing forward, the other back, like a lizard's pelvis; both plant- and flesh-eaters; legs under body; birds evolved from Saurischian dinosaurs.	Extinct
Pterosauria	Pterosaur 	Flying reptiles; wings were made of skin stretched between fourth fingers and body; wingspans of early forms typically 60 cm, later forms nearly 8 m	Extinct
Plesiosauro	Plesiosaur 	Barrel-shaped marine reptiles with sharp teeth and large, paddle-shaped fins; some had snakelike necks twice as long as their bodies	Extinct
Ichthyosauria	Ichthyosaur 	Streamlined marine reptiles with many body similarities to sharks and modern fishes	Extinct

2. **Dry skin.** Most living amphibians have moist skin and must remain in moist places to avoid drying out. Reptiles have dry, watertight skin. A layer of scales covers their bodies, preventing water loss. These scales develop as surface cells fill with keratin, the same protein that forms claws, fingernails, hair, and bird feathers.

3. **Thoracic breathing.** Amphibians breathe by squeezing their throat to pump air into their lungs; this limits their breathing capacity to the volume of their mouths. Reptiles developed pulmonary breathing, expanding and contracting the rib cage to suck air into the lungs and then force it out. The capacity of this system is limited only by the volume of the lungs.

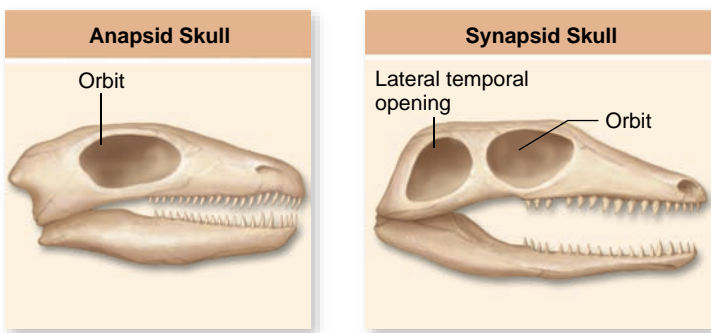

**Figure 35.17 The watertight egg.** The amniotic egg is perhaps the most important feature that allows reptiles to live in a wide variety of terrestrial habitats.

## Reptiles dominated the Earth for 250 million years

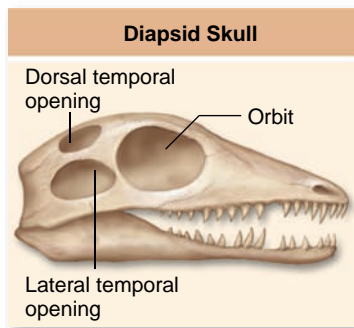

During the 250 million years that reptiles were the dominant large terrestrial vertebrates, a series of different reptile groups appeared and then disappeared.

### Synapsids

An important feature of reptile classification is the presence and number of openings behind the eyes (figure 35.18). Reptiles' jaw muscles were anchored to these holes, which allowed them to bite more powerfully. The first group to rise to dominance were the **synapsids**, whose skulls had a pair of temporal holes behind the openings for the eyes.

**Figure 35.18 Skulls of reptile groups.** Reptile groups are distinguished by the number of holes on the side of the skull behind the eye orbit: 0 (anapsids), 1 (synapsids), or 2 (diapsids). Turtles are the only living anapsids, although several extinct groups also had this condition.

**Figure 35.19 A pelycosaur.** *Dimetrodon*, a carnivorous pelycosaur, had a dorsal sail that is thought to have been used to regulate body temperature by dissipating body heat or gaining it by basking.

Pelycosaur, an important group of early synapsids, were dominant for 50 million years and made up 70% of all land vertebrates; some species weighed as much as 200 kg. With long, sharp, “steak knife” teeth, these pelycosaur were the first land vertebrates to kill beasts their own size (figure 35.19).

About 250 MYA, pelycosaur were replaced by another type of synapsid, the therapsids (figure 35.20). Some evidence indicates that they may have been endotherms, able to produce heat internally, and perhaps even possessed hair. This would have permitted therapsids to be far more active than other vertebrates of that time, when winters were cold and long.

For 20 million years, therapsids (also called “mammal-like reptiles”) were the dominant land vertebrate, until they were largely replaced 230 MYA by another group of reptiles, the diapsids. Most therapsids became extinct 170 MYA, but one group survived and has living descendants today—the mammals.

**Figure 35.20 A therapsid.** This small, weasel-like cynodont therapsid, *Megazostrodon*, may have had fur. Living in the late Triassic period, this therapsid is so similar to modern mammals that some paleontologists consider it the first mammal.

**Figure 35.21** An early archosaur. *Euparkeria* had rows of bony plates along the sides of the backbone, as seen in modern crocodiles and alligators.

### Archosaurs

**Diapsids** have skulls with two pairs of temporal holes, and like amphibians and early reptiles, they were ectotherms. A variety of different diapsids occurred in the Triassic period (213 to 248 MYA), but one group, the archosaurs, were of particular evolutionary significance because they gave rise to crocodiles, pterosaurs, dinosaurs, and birds (figure 35.21).

Among the early archosaurs were the largest animals the world had seen, up to that point, and the first land vertebrates to be bipedal—to stand and walk on two feet. By the end of the Triassic period, however, one archosaur group rose to prominence: the dinosaurs.

Dinosaurs evolved about 220 MYA. Unlike previous bipedal diapsids, their legs were positioned directly underneath their bodies (figure 35.22). This design placed the weight of the body directly over the legs, which allowed dinosaurs to run with great speed and agility. Subsequently, a number of types of dinosaur evolved enormous size and reverted to a four-legged

**Figure 35.22** Mounted skeleton of *Afrosvenator*. This bipedal carnivore was about 30 feet long and lived in Africa about 130 MYA.

**Figure 35.23** A comparison of reptile and fish circulation. *a.* In most reptiles, oxygenated blood (red) is repumped after leaving the lungs, and circulation to the rest of the body remains vigorous. *b.* The blood in fishes flows from the gills directly to the rest of the body, resulting in slower circulation.

posture to support their massive weight. Other types—the theropods—became the most fearsome predators the earth has ever seen, and one theropod line evolved to become birds. Dinosaurs went on to become the most successful of all land vertebrates, dominating for more than 150 million years. All dinosaurs, except their bird descendants, became extinct rather abruptly 65 MYA, apparently as a result of an asteroid's impact.

### Important characteristics of modern reptiles

As you might imagine from the structure of the amniotic egg, reptiles and other amniotes do not practice external fertilization as most amphibians do. Sperm would be unable to penetrate the membrane barriers protecting the egg. Instead, the male places sperm inside the female, where sperm fertilizes the egg before the protective membranes are formed. This is called internal fertilization.

The circulatory system of reptiles is an improvement over that of fish and amphibians, providing oxygen to the body more efficiently (figure 35.23; see chapter 50). The improvement is achieved by extending the septum within the heart from the atrium partway across the ventricle. This septum creates a partial wall that tends to lessen mixing of oxygen-poor blood with oxygen-rich blood within the ventricle. In crocodiles, the septum completely divides the ventricle, creating a four-chambered heart, just as it does in birds and mammals (and probably did in dinosaurs).

### Order Chelonia

a.

### Order Rhynchocephalia

b.

**Figure 35.24 Living orders of reptiles.** **a. Chelonia.** The red-bellied turtle, *Pseudemys rubriventris* (left) is shown basking, an effective means by which many ectotherms can precisely regulate their body temperature. The domed shells of tortoises, such as this Sri Lankan star tortoise, *Geochelone elegans*, provide protection against predators for these entirely terrestrial chelonians. **b. Tuatara (*Sphenodon punctatus*).** The sole living members of the ancient group Rhynchocephalia. Although they look like lizards, the common ancestor of rhynchocephalians and lizards diverged more than 250 MYA. **c. Squamata.** A collared lizard, *Crotaphytus collaris*, is shown left, and a smooth green snake, *Lioclorophis vernalis*, on the right. **d. Crocodylia.** Most crocodylians, such as the crocodile, *Crocodylus acutus*, and the gharial, *Gavialis gangeticus* (right), resemble birds and mammals in having four-chambered hearts; all other living reptiles have three-chambered hearts. Like birds, crocodiles are more closely related to dinosaurs than to any of the other living reptiles.

All living reptiles are **ectothermic**, obtaining their heat from external sources. In contrast, **endothermic** animals are able to generate their heat internally (see chapter 43). Although they are ectothermic, that does not mean that reptiles cannot control their body temperature. Many species are able to precisely regulate their temperature by moving in and out of sunlight. In this way, some desert lizards can keep their bodies at a constant temperature throughout the course of an entire day. Of course, on cloudy days, or for species that live in shaded habitats, such thermoregulation is not possible, and in these cases, body temperature is the same as the temperature of the surrounding environment.

## Modern reptiles belong to four groups

The four surviving orders of reptiles contain about 7000 species. Reptiles occur worldwide except in the coldest regions, where it is impossible for ectotherms to survive. Reptiles are among the most numerous and diverse of terrestrial vertebrates.

### Order Chelonia: Turtles and tortoises

The order Chelonia (figure 35.24a) consists of about 250 species of turtles (most of which are aquatic) and tortoises (which are terrestrial). Turtles and tortoises lack teeth but have sharp beaks. They differ from all other reptiles because their bodies are encased within a protective shell. Many of them can pull their head and legs into the shell as well, for total protection from predators.

The shell consists of two basic parts. The carapace is the dorsal covering, and the plastron is the ventral portion. In a fundamental commitment to this shell architecture, the vertebrae and ribs of most turtle and tortoise species are fused to the inside of the carapace. All of the support for muscle attachment comes from the shell.

Whereas most tortoises have a dome-shaped shell into which they can retract their head and limbs, water-dwelling turtles have a streamlined, disc-shaped shell that permits rapid turning in water. Freshwater turtles have webbed toes; in marine turtles, the forelimbs have evolved into flippers.

Although marine turtles spend their lives at sea, they must return to land to lay their eggs. Many species migrate long distances to do this. Atlantic green turtles (*Chelonia mydas*) migrate from their feeding grounds off the coast of Brazil to Ascension Island in the middle of the South Atlantic—a distance of more than 2000 km—to lay their eggs on the same beaches where they themselves hatched.

### Order Rhynchocephalia: Tuataras

Today, the order Rhynchocephalia contains only two species of tuataras, large, lizard-like animals about half a meter long (figure 35.24b). The only place in the world where these endangered species are found is a cluster of small islands off the coast of New Zealand. The limited diversity of modern rhynchocephalians belies their rich evolutionary past: In the Triassic period, rhynchocephalians experienced a great adaptive radiation, producing many species that differed greatly in size and habitat.

An unusual feature of the tuatara (and some lizards) is the inconspicuous “third eye” on the top of its head, called a parietal eye. Concealed under a thin layer of scales, the eye has a lens and a retina and is connected by nerves to the brain. Why have an eye, if it is covered up? The parietal eye may function to alert the tuatara when it has been exposed to too much sunlight, protecting it against overheating. Unlike most reptiles, tuataras are most active at low temperatures. They burrow during the day and feed at night on insects, worms, and other small animals.

Rhynchocephalians are the closest relatives of snakes and lizards, with whom they form the group Lepidosauria.

### Order Squamata

c.

### Order Crocodylia

d.

#### Order Squamata: Lizards and snakes

The order Squamata (figure 35.24c) includes 3800 species of lizards and about 3000 species of snakes. A distinguishing characteristic of this order is the presence of paired copulatory organs in the male. In addition, changes to the morphology of the head and jaws allow greater strength and mobility. Most lizards and snakes are carnivores, preying on insects and small animals, and these improvements in jaw design have made a major contribution to their evolutionary success.

Snakes, which evolved from a lizard ancestor, are characterized by the lack of limbs, movable eyelids, and external ears, as well as a great number of vertebrae (sometimes more than 300). Limblessness has actually evolved more than a dozen times in lizards; snakes are simply the most extreme case of this evolutionary trend.

Common lizards include iguanas, chameleons, geckos, and anoles. Most are small, measuring less than a foot in length. The largest lizards belong to the monitor family. The largest of all monitor lizards is the Komodo dragon of Indonesia, which reaches 3 m in length and can weigh more than 100 kg. Snakes also vary in length from only a few inches to more than 10 m.

Many lizards and snakes rely on agility and speed to catch prey and elude predators. Only two species of lizard are venomous, the Gila monster of the southwestern United States and the beaded lizard of western Mexico. Similarly, most species of snakes are nonvenomous. Of the 13 families of snakes, only 4 contain venomous species: the elapids (cobras, kraits, and coral snakes); the sea snakes; the vipers (adders, bushmasters, rattlesnakes, water moccasins, and copperheads); and some colubrids (African boomslang and twig snake).

Many lizards, including anoles, skinks, and geckos, have the ability to lose their tails and then regenerate a new one. This ability allows these lizards to escape from predators.

#### Order Crocodylia: Crocodiles and alligators

The order Crocodylia is composed of 25 species of large, primarily aquatic reptiles (figure 35.24d). In addition to crocodiles and alligators, the order includes two less familiar animals: the caimans and the gavials. Although all crocodylians are fairly similar in appearance today, much greater diversity existed in the past, including species that were entirely terrestrial and others that achieved a total length in excess of 50 feet.

Crocodiles are largely nocturnal animals that live in or near water in tropical or subtropical regions of Africa, Asia, and the Americas. The American crocodile (*Crocodylus acutus*) is found in southern Florida, Cuba, and throughout tropical Central America. Nile crocodiles (*Crocodylus niloticus*) and estuarine crocodiles (*Crocodylus porosus*) can grow to enormous size and are responsible for many human fatalities each year.

There are only two species of alligators: one living in the southern United States (*Alligator mississippiensis*) and the other a rare endangered species living in China (*Alligator sinensis*). Caimans, which resemble alligators, are native to Central America. Gharials, or gavials, are a group of fish-eating crocodylians with long, slender snouts that live only in India and Burma.

All crocodylians are carnivores. They generally hunt by stealth, waiting in ambush for prey, and then attacking ferociously. Their bodies are well adapted for this form of hunting with eyes on top of their heads and their nostrils on top of their snouts, so they can see and breathe while lying quietly submerged in water. They have enormous mouths, studded with sharp teeth, and very strong necks. A valve in the back of the mouth prevents water from entering the air passage when a crocodylian feeds underwater.

In many ways, crocodiles resemble birds far more than they do other living reptiles. For example, crocodiles build nests and care for their young (traits they share with at least some dinosaurs), and they have a four-chambered heart, as birds do. Why are crocodiles more similar to birds than to other living reptiles? Most biologists agree that birds are in fact the direct descendants of dinosaurs. Both crocodiles and birds are more closely related to dinosaurs, and to each other, than they are to lizards and snakes.

#### Learning Outcomes Review 35.6

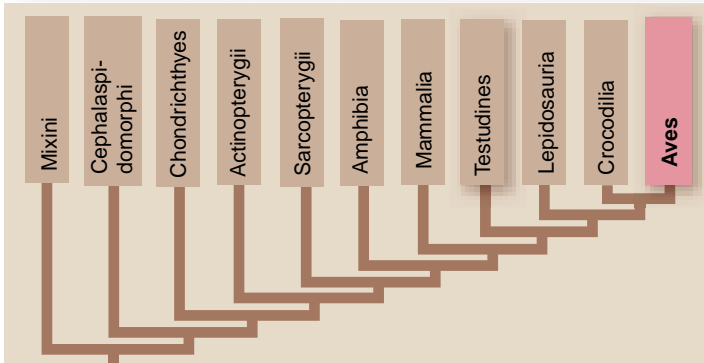

Reptiles have a hard, scaly skin that minimizes water loss, thoracic breathing, and an enclosed, amniotic egg that does not need to be laid in water. Synapsids had a single hole in the skull behind the eyes, and included ancestors of mammals; diapsids had two holes and are ancestors of modern reptiles and birds. The four living orders of reptiles include the turtles and tortoises, tuataras, lizards and snakes, and crocodiles.

- How do reptile eggs differ from those of amphibians?

## 35.7 Birds

### Learning Outcomes

1. Name the key characteristics of birds.
2. Explain why some consider birds to be one type of reptile.

The success of birds lies in the development of a structure unique in the animal world—the feather. Developed from reptilian scales, feathers are the ideal adaptation for flight, serving as lightweight airfoils that are easily replaced if damaged (unlike the vulnerable skin wings of bats and the extinct pterosaurs). Today, birds (class **Aves**) are the most diverse of all terrestrial vertebrates, with 28 orders containing a total of 166 families and about 8600 species (table 35.4).

### Key characteristics of birds are feathers and a lightweight skeleton

Modern birds lack teeth and have only vestigial tails, but they still retain many reptilian characteristics. For instance, birds lay amniotic eggs. Also, reptilian scales are present on the feet and lower legs of birds. Two primary characteristics distinguish birds from living reptiles:

1. **Feathers.** Feathers are modified reptilian scales made of keratin, just like hair and scales. Feathers serve two functions: providing lift for flight and conserving heat. The structure of feathers combines maximum flexibility and strength with minimum weight (figure 35.25).

Feathers develop from tiny pits in the skin called follicles. In a typical flight feather, a shaft emerges from the follicle, and pairs of vanes develop from its opposite sides. At maturity, each vane has many branches called barbs. The barbs, in turn, have many projections called barbules that are equipped with microscopic hooks. These hooks link the barbs to one another, giving the feather a continuous surface and a sturdy but flexible shape.

Like scales, feathers can be replaced. Among living animals, feathers are unique to birds. Recent fossil finds suggest that some dinosaurs may have had feathers.

2. **Flight skeleton.** The bones of birds are thin and hollow. Many of the bones are fused, making the bird skeleton more rigid than a reptilian skeleton. The fused sections of

**Figure 35.25 A feather.** The enlargement shows how the secondary branches and barbs of the vanes are linked together by microscopic barbules.

backbone and of the shoulder and hip girdles form a sturdy frame that anchors muscles during flight. The power for active flight comes from large breast muscles that can make up 30% of a bird's total body weight. They stretch down from the wing and attach to the breastbone, which is greatly enlarged and bears a prominent keel for muscle attachment. Breast muscles also attach to the fused collarbones that form the so-called wishbone. No other living vertebrates have a fused collarbone or a keeled breastbone.

### Birds arose about 150 MYA

A 150-million-year-old fossil of the first known bird, *Archaeopteryx* (see figures 21.11 and 35.26) was found in 1862 in a limestone quarry in Bavaria, the impression of its feathers stamped clearly into the rocks. The skeleton of *Archaeopteryx* shares many features with small theropod dinosaurs. About the size of a crow, *Archaeopteryx* had a skull with teeth, and very few of its bones were fused to one another. Its bones are thought to have been solid, not hollow like a bird's. Also, it had a long, reptilian tail and no enlarged breastbone such as modern birds use to anchor flight muscles. Finally, the skeletal structure of the forelimbs were nearly identical to those of theropods.

Because of its many dinosaur features, several *Archaeopteryx* fossils were originally classified as *Compsognathus*, a small theropod dinosaur of similar size—until feathers were discovered on

**Figure 35.26 Archaeopteryx.** Closely related to its ancestors among the bipedal dinosaurs, the crow-sized *Archaeopteryx* lived in the forests of central Europe 150 MYA. The true feather colors of *Archaeopteryx* are not known.

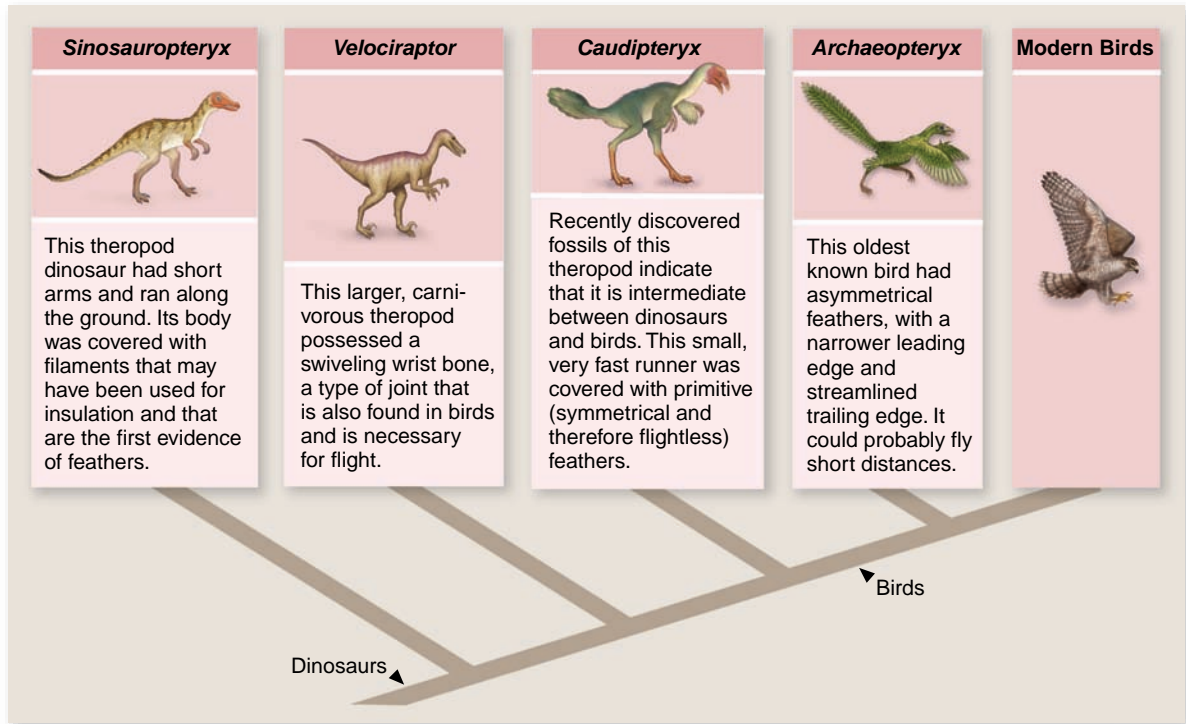

**TABLE 35.4**
**Major Orders of Birds**

Order	Typical Examples	Key Characteristics	Approximate Number of Living Species
Passeriformes	Crows, mockingbirds, robins, sparrows, starlings, warblers 	<i>Songbirds</i> Well-developed vocal organs; perching feet; dependent young	5276 (largest of all bird orders; contains over 60% of all species)
Apodiformes	Hummingbirds, swifts 	<i>Fast fliers</i> Short legs; small bodies; rapid wing beat	428
Piciformes	Honeyguides, toucans, woodpeckers 	<i>Woodpeckers or toucans</i> Grasping feet; chisel-like, sharp bills can break down wood	383
Psittaciformes	Cockatoos, parrots 	<i>Parrots</i> Large, powerful bills for crushing seeds; well-developed vocal organs	340
Charadriiformes	Auks, gulls, plovers, sandpipers, terns 	<i>Shorebirds</i> Long, stiltlike legs; slender, probing bills	331
Columbiformes	Doves, pigeons 	<i>Pigeons</i> Perching feet; rounded, stout bodies	303
Falconiformes	Eagles, falcons, hawks 	<i>Diurnal birds of prey</i> Carnivorous; keen vision; sharp, pointed beaks for tearing flesh; active during the day	288
Galliformes	Chickens, grouse, pheasants, quail 	<i>Gamebirds</i> Often limited flying ability; rounded bodies	268
Gruiformes	Bitterns, coots, cranes, rails 	<i>Marsh birds</i> Long, stiltlike legs; diverse body shapes; marsh-dwellers	209
Anseriformes	Ducks, geese, swans 	<i>Waterfowl</i> Webbed toes; broad bill with filtering ridges	150
Strigiformes	Barn owls, screech owls 	<i>Owls</i> Nocturnal birds of prey; strong beaks; powerful feet	146
Ciconiiformes	Hérons, ibises, storks 	<i>Waders</i> Long-legged; large bodies	114
Procellariiformes	Albatrosses, petrels 	<i>Seabirds</i> Tube-shaped bills; capable of flying for long periods of time	104
Sphenisciformes	Emperor penguins, crested penguins 	<i>Penguins</i> Marine; modified wings for swimming; flightless; found only in southern hemisphere; thick coats of insulating feathers	18
Dinornithiformes	Kiwis 	<i>Kiwis</i> Flightless; small; confined to New Zealand	2
Struthioniformes	Ostriches 	<i>Ostriches</i> Powerful running legs; flightless; only two toes; very large	1

**Figure 35.27**  
**The evolutionary path to the birds.**

Almost all paleontologists now accept the theory that birds are the direct descendants of theropod dinosaurs.

the fossils. What makes *Archaeopteryx* distinctly avian is the presence of feathers on its wings and tail.

The remarkable similarity of *Archaeopteryx* to *Compsognathus* has led almost all paleontologists to conclude that *Archaeopteryx* is the direct descendant of dinosaurs—indeed, that today’s birds are “feathered dinosaurs.” Some even speak flipantly of “carving the dinosaur” at Thanksgiving dinner. The recent discovery of fossils of a feathered dinosaur in China lends strong support to this inference. The dinosaur *Caudipteryx*, for example, is clearly intermediate between *Archaeopteryx* and dinosaurs, having large feathers on its tail and arms but also many features of dinosaurs like *Velociraptor* (figure 35.27). Because the arms of *Caudipteryx* were too short to use as wings, feathers probably didn’t evolve for flight, but instead served as insulation, much as fur does for mammals.

Flight is an ability certain kinds of dinosaurs achieved as they evolved longer arms. We call these dinosaurs birds. Despite their close affinity to dinosaurs, birds exhibit three evolutionary novelties: feathers, hollow bones, and physiological mechanisms such as superefficient lungs that permit sustained, powered flight.

By the early Cretaceous period, only a few million years after *Archaeopteryx* lived, a diverse array of birds had evolved, with many of the features of modern birds. Fossils in Mongolia, Spain, and China discovered within the last few years reveal a diverse collection of toothed birds with the hollow bones and breastbones necessary for sustained flight (figure 35.28). Other fossils reveal highly specialized, flightless diving birds. These diverse birds shared the skies with pterosaurs for 70 million years until the flying reptiles went extinct at the end of the Cretaceous.

Because the impression of feathers is rarely fossilized and modern birds have hollow, delicate bones, the fossil record of birds is incomplete. Relationships among the 166 families of modern birds are mostly inferred from studies of the anatomy and degree of DNA similarity among living birds.

**Figure 35.28** A fossil bird from the early cretaceous. *Confuciusornis* had long tail feathers. Some fossil specimens of this species lack the long tail feathers, suggesting that this trait was present in only one sex, as in some modern birds.

## Modern birds are diverse but share several characteristics

The most ancient living birds appear to be the flightless birds, such as the ostrich. Ducks, geese, and other waterfowl evolved next, in the early Cretaceous, followed by a diverse group of woodpeckers, parrots, swifts, and owls. The largest of the bird orders, Passeriformes, evolved in the mid-Cretaceous and comprise 60% of species alive today. Overall, there are 28 orders of birds, the largest consisting of over 5000 species (figure 35.29).

You can tell a great deal about the habits and food of a bird by examining its beak and feet. For instance, carnivorous birds such as owls have curved talons for seizing prey and sharp beaks for tearing apart their meal. The beaks of ducks are flat for shoveling through mud, and the beaks of finches are short, thick seed-crushers.

Many adaptations enabled birds to cope with the heavy energy demands of flight, including respiratory and circulatory adaptations and endothermy.

### Efficient respiration

Flight muscles consume an enormous amount of oxygen during active flight. The reptilian lung has a limited internal surface area, not nearly enough to absorb all the oxygen needed. Mammalian lungs have a greater surface area, but bird lungs satisfy this challenge with a radical redesign.

When a bird inhales, the air goes past the lungs to a series of air sacs located near and within the hollow bones of the back; from there, the air travels to the lungs and then to a set of anterior air sacs before being exhaled. Because air passes all the way through the lungs in a single direction, gas exchange is highly efficient. Respiration in birds is described in more detail in chapter 49.

### Efficient circulation

The revved-up metabolism needed to power active flight also requires very efficient blood circulation, so that the oxygen cap-

tured by the lungs can be delivered to the flight muscles quickly. In the heart of most living reptiles, oxygen-rich blood coming from the lungs mixes with oxygen-poor blood returning from the body because the wall dividing the ventricle into two chambers is not complete. In birds, the wall dividing the ventricle is complete, and the two blood circulations do not mix—so flight muscles receive fully oxygenated blood (see chapter 50).

In comparison with reptiles and most other vertebrates, birds have a rapid heartbeat. A hummingbird's heart beats about 600 times a minute, and an active chickadee's heart beats 1000 times a minute. In contrast, the heart of the large, flightless ostrich averages 70 beats per minute—the same rate as the human heart.

### Endothermy

Birds, like mammals, are endothermic (an example of convergent evolution). Many paleontologists believe the dinosaurs from which birds evolved were endothermic as well. Birds maintain body temperatures significantly higher than those of most mammals, ranging from 40° to 42°C (human body temperature is 37°C). Feathers provide excellent insulation, helping to conserve body heat.

The high temperatures maintained by endothermy permit metabolism in the bird's flight muscles to proceed at a rapid pace, to provide the ATP necessary to drive rapid muscle contraction.

### Learning Outcomes Review 35.7

Birds have the greatest diversity of species of all terrestrial vertebrates. *Archaeopteryx*, the oldest fossil bird, exhibited many traits shared with theropod dinosaurs. Key features of birds are feathers and a lightweight, hollow skeleton; additional features include auxiliary air sacs and a four-chambered heart.

- What traits do birds share with reptiles?

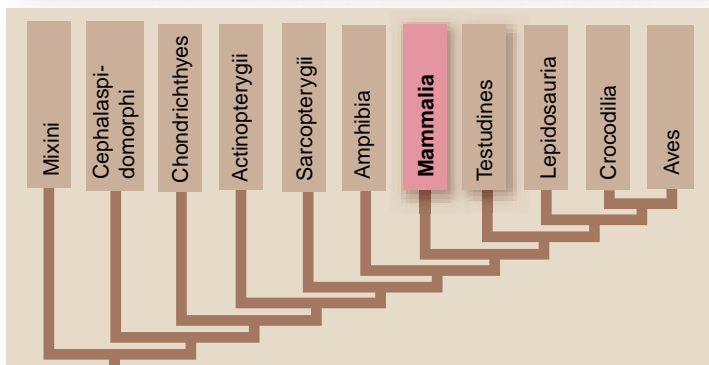

**Figure 35.29** Diversity of Passeriformes, the largest order of birds. *a.* Summer tanager, *Piranga rubra*; *(b)* Indigo bunting, *Passerina cyanea*; *(c)* Stellar's jay, *Cyanositta stelleri*; *(d)* Bobolink, *Dolichonyx oryzivorus*.

## 35.8 Mammals

### Learning Outcomes

1. Describe the characteristics of mammals.
2. Compare the three groups of living mammals.

There are about 4500 living species of mammals (class Mammalia), fewer than the number of fishes, amphibians, reptiles or birds. Most large, land-dwelling vertebrates are mammals. When we look out over an African plain, we see the big mammals—the lions, zebras, gazelles, and antelope. But the typical mammal is not that large. Of the 4500 species of mammals, 3200 are rodents, bats, shrews, or moles.

### Mammals have hair, mammary glands, and other characteristics

Mammals are distinguished from all other classes of vertebrates by two fundamental characteristics—hair and mammary glands—and are marked by several other notable features:

1. **Hair.** All mammals have hair. Even apparently hairless whales and dolphins grow sensitive bristles on their snouts. The evolution of fur and the ability to regulate body temperature enabled mammals to invade colder climates that ectothermic reptiles do not inhabit. Mammals are endothermic animals, and typically maintain body temperatures higher than the temperature of their surroundings. The dense undercoat of many mammals reduces the amount of body heat that escapes. Another function of hair is camouflage. The coloration and pattern of a mammal's coat usually matches its background. A little brown mouse is practically invisible against the brown leaf litter of a forest floor, and the orange and black stripes of a Bengal tiger disappear against the orange-brown color of the tall grass in which it hunts. Hairs also function as sensory structures. The whiskers of cats and dogs are stiff hairs that are very sensitive to touch. Mammals that are active at night or live underground often rely on their whiskers to locate prey or to avoid colliding with objects. Finally, hair can serve as a defensive weapon. Porcupines and hedgehogs protect themselves with long, sharp, stiff hairs called quills.

Unlike feathers, which evolved from modified reptilian scales, mammalian hair is a completely different form of skin structure. An individual mammalian hair is a long, protein-rich filament that extends like a stiff thread from a bulblike foundation beneath the skin known as a hair follicle. The filament is composed mainly of dead cells filled with the fibrous protein keratin.

2. **Mammary glands.** All female mammals possess mammary glands that can secrete milk. Newborn mammals, born without teeth, suckle this milk as their primary food. Even baby whales are nursed by their mother's milk. Milk is a very high-calorie food (human milk has 750 kcal per liter), important because of the high energy needs of a rapidly growing newborn mammal. About 50% of the energy in the milk comes from fat.
3. **Endothermy.** As stated previously, mammals are endothermic, a crucial adaptation that has allowed them to be active at any time of the day or night and to colonize severe environments, from deserts to ice fields. Also, more efficient blood circulation provided by the four-chambered heart (see chapter 50) and more efficient respiration provided by the *diaphragm* (a special sheet of muscles below the rib cage that aids breathing; see chapter 49) make possible the higher metabolic rate on which endothermy depends.
4. **Placenta.** In most mammal species, females carry their developing young internally in a uterus, nourishing them through the placenta, and give birth to live young. The **placenta** is a specialized organ that brings the bloodstream of the fetus into close contact with the bloodstream of the mother (figure 35.30). Food, water, and oxygen can pass across from mother to child, and wastes can pass over to the mother's blood and be carried away.

**Figure 35.30 The placenta.** The placenta is characteristic of the largest group of mammals, the placental mammals. It evolved from membranes in the amniotic egg. The umbilical cord evolved from the allantois. The chorion, or outermost part of the amniotic egg, forms most of the placenta itself. The placenta serves as the provisional lungs, intestine, and kidneys of the fetus, without ever mixing maternal and fetal blood.

In addition to these main characteristics, the mammalian lineage gave rise to several other adaptations in certain groups. These include specialized teeth, the ability of grazing animals to digest plants, hooves and horns made of keratin, and adaptations for flight in the bats.

### Specialized teeth

Mammals have different types of teeth that are highly specialized to match particular eating habits (figure 35.31). It is usually possible to determine a mammal's diet simply by examining its teeth. A dog's long canine teeth, for example, are well suited for biting and holding prey, and some of its premolar and molar teeth are triangular and sharp for ripping off chunks of flesh.

In contrast, large herbivores such as deer lack canine teeth; instead, deer clip off mouthfuls of plants with flat, chisel-like incisors on its lower jaw. The deer's molars are large and covered with ridges to effectively grind and break up tough plant tissues.

### Digestion of plants

Most mammals are herbivores, eating mostly or only plants. Cellulose forms the bulk of a plant's body and is a major source of food for mammalian herbivores. Mammals do not have the

**Figure 35.31 Mammals have different types of specialized teeth.** Carnivores, such as dogs, have canine teeth that are able to rip food; some of the premolars and molars in dogs are also ripping teeth. Herbivores, such as deer, have incisors to chisel off vegetation and molars designed to grind up the plant material. In the beaver, the chiseling incisors dominate. In the elephant, the incisors have become specialized weapons, and molars grind up vegetation. Humans are omnivores; we have all three types: grinding, ripping, and chiseling teeth.

enzymes, however, that break the links between glucose molecules in cellulose. Herbivorous mammals rely on a mutualistic partnership with bacteria in their digestive tracts that have the necessary cellulose-splitting enzymes.

Mammals such as cows, buffalo, antelopes, goats, deer, and giraffes have huge, four-chambered fermentation vats derived from the esophagus and stomach. The first chamber is the largest and holds a dense population of cellulose-digesting bacteria. Chewed plant material passes into this chamber, where the bacteria attack the cellulose. The material is then digested further in the other three chambers.

Rodents, horses, rabbits, and elephants, by contrast, have relatively small stomachs, and instead digest plant material in their large intestine, like a termite. The bacteria that actually carry out the digestion of the cellulose live in a pouch called the cecum that branches from the end of the small intestine.

Even with these complex adaptations for digesting cellulose, a mouthful of plant is less nutritious than a mouthful of meat. Herbivores must consume large amounts of plant material to gain sufficient nutrition. An elephant eats 135 to 150 kg (300 to 330 pounds) of plant foods each day.

### Development of hooves and horns

Keratin, the protein of hair, is also the structural building material in claws, fingernails, and hooves. Hooves are specialized keratin pads on the toes of horses, cows, sheep, and antelopes. The pads are hard and horny, protecting the toe and cushioning it from impact.

The horns of cattle, sheep, and antelope are composed of a core of bone surrounded by a sheath of keratin. The bony core is attached to the skull, and the horn is not shed.

Deer antlers are made not of keratin, but of bone. Male deer grow and shed a set of antlers each year. While growing during the summer, antlers are covered by a thin layer of skin known as velvet.

### Flying mammals: Bats

Bats are the only mammals capable of powered flight (figure 35.32). Like the wings of birds and pterosaurs, bat wings are modified forelimbs. The bat wing is a leathery membrane of skin and muscle stretched over the bones of four fingers. The edges of the membrane attach to the side of the body and to the

**Figure 35.32 Greater horseshoe bat, *Rhinolophus ferrumequinum*.** Bats are the only mammal capable of true flight.

hind leg. When resting, most bats prefer to hang upside down by their toe claws.

After rodents, bats are the second largest order of mammals. They have been a particularly successful group because many species have been able to utilize a food resource that most birds do not use—night-flying insects.

How do bats navigate in the dark? Late in the eighteenth century, the Italian biologist Lazzaro Spallanzani showed that a blinded bat could fly without crashing into things and still capture insects. Clearly another sense other than vision was being used by bats to navigate in the dark. When Spallanzani plugged the ears of a bat, it was unable to navigate and collided with objects. Spallanzani concluded that bats “hear” their way through the night world.

## Mammals diverged about 220 MYA

Mammals have been around since the time of the dinosaurs, about 220 MYA. Tiny, shrewlike creatures that lived in trees eating insects, the earliest mammals were only a minor element in a land that quickly came to be dominated by dinosaurs. Fossils reveal that these early mammals had large eye sockets, evidence that they may have been active at night. Early mammals also had a single lower jawbone. The fossil record shows a change in therapsids (the ancestors of mammals) from the reptile lower jaw, having several bones, to a jaw closer to the mammalian type. Two of the bones forming the therapsid jaw joint moved into the middle ear of mammals, linking with a bone already there to produce a three-bone structure that amplifies sound better than the reptilian ear.

### The age of mammals

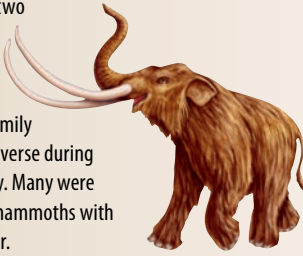

At the end of the Cretaceous period, 65 MYA, the dinosaurs and numerous other land and marine animals became extinct, but mammals survived, possibly because of the insulation their fur provided. In the Tertiary period (lasting from 65 MYA to 2 MYA), mammals rapidly diversified, taking over many of the ecological roles once dominated by dinosaurs.

Mammals reached their maximum diversity late in the Tertiary period, about 15 MYA. At that time, tropical conditions existed over much of the world. During the last 15 million years, world climates have changed, and the area covered by tropical habitats has decreased, causing a decline in the total number of mammalian species (table 35.5).

## Modern mammals are placed into three groups.

For 155 million years, while the dinosaurs flourished, mammals were a minor group of small insectivores and herbivores. The most primitive mammals were members of the subclass Prototheria. Most prototherians were small and resembled modern shrews. All prototherians laid eggs, as did their synapsid ancestors. The only prototherians surviving today are the monotremes.

The other major mammalian group is the subclass **Theria**. Therians are viviparous (that is, their young are born alive). The two living therian groups are marsupials, or pouched mammals (including kangaroos, opossums, and koalas), and the placental mammals (dogs, cats, humans, horses, and most other mammals).

TABLE 35.5		Some Groups of Extinct Mammals	
Group	Description		
Cave bears	Numerous in the ice ages; this enormous bear had a largely vegetarian diet and slept through the winter in large groups.		
Irish elk	Neither Irish nor an elk (it is a kind of deer), <i>Megaloceros</i> was the largest deer that ever lived, with horns spanning 12 feet. Seen in French cave paintings, they became extinct about 2500 years ago.		
Mammoths	Although only two species of elephants survive today, the elephant family was far more diverse during the late Tertiary. Many were cold-adapted mammoths with long, shaggy fur.		
Giant ground sloths	<i>Megatherium</i> was a giant, 20-foot ground sloth that weighed 3 tons and was as large as a modern elephant.		
Sabertooth cats	The jaws of these large, lionlike cats opened an incredible 120° to allow the animal to drive its huge upper pair of saber teeth into prey.		

### Monotremes: Egg-laying mammals

The duck-billed platypus (*Ornithorhynchus anatinus*) and two species of echidna are the only living **monotremes** (figure 35.33a). Among living mammals, only monotremes lay shelled eggs. The structure of their shoulder and pelvis is more similar to that of the early reptiles than to any other living mammal. Also like reptiles, monotremes have a cloaca, a single opening through which feces, urine, and reproductive products leave the body.

### Monotremes

a.

### Marsupials

b.

### Placental Mammals

c.

**Figure 35.33 Today's mammals.** a. Monotremes, the short-nosed echidna, *Tachyglossus aculeatus* (left), and the duck-billed platypus, *Ornithorhynchus anatinus* (right); (b) Marsupials, the red kangaroo, *Macropus rufus* (left) and the opossum, *Didelphis virginiana*, (right); (c) Placental mammals, the lion, *Panthera leo* (left) and the bottle-nosed dolphin, *Tursiops truncatus* (right).

Despite the retention of some reptilian features, monotremes have the diagnostic mammalian characters: a single bone on each side of the lower jaw, fur, and mammary glands. Young monotremes drink their mother's milk after they hatch from eggs. Females lack well-developed nipples; instead, the milk oozes onto the mother's fur, and the babies lap it off with their tongues.

The platypus, found only in Australia, lives much of its life in the water and is a good swimmer. It uses its bill much as a duck does, rooting in the mud for worms and other soft-

bodied animals. Echidnas of Australia (*Tachyglossus aculeatus*, the short-nosed echidna) and New Guinea (*Zaglossus bruijnii*, the long-nosed echidna) have very strong, sharp claws, which they use for burrowing and digging. The echidna probes with its snout for insects, especially ants and termites.

### Marsupials: Pouched mammals

The major difference between **marsupials** (figure 35.33b) and other mammals is their pattern of embryonic development. In marsupials, a fertilized egg is surrounded by chorion and amniotic membranes, but no shell forms around the egg as it does in monotremes. During most of its early development, the marsupial embryo is nourished by an abundant yolk within the egg. Shortly before birth, a short-lived placenta forms from the chorion membrane. Soon after, sometimes within eight days of fertilization, the embryonic marsupial is born. It emerges tiny and hairless, and crawls into the marsupial pouch, where it latches onto a mammary-gland nipple and continues its development.

Marsupials evolved shortly before placental mammals, about 125 MYA. Today, most species of marsupials live in Australia and South America, areas that have undergone long periods of geographic isolation. Marsupials in Australia and New Guinea have diversified to fill ecological positions occupied by placental mammals elsewhere in the world (see figure 21.18). The placental mammals in Australia and New Guinea today arrived relatively recently and include some introduced by humans. The only marsupial found in North America is the Virginia opossum (*Didelphis virginiana*), which has migrated north from Central America within the last three million years.

### Placental mammals

A placenta that nourishes the embryo throughout its entire development forms in the uterus of placental mammals (figure 35.33c). Most species of mammals living today, including humans, are in this group. Of the 19 orders of living mammals, 17 are placental mammals (although some scientists recognize four orders of marsupials, rather than one). Table 35.6 shows some of these orders. They are a very diverse group, ranging in size from 1.5-g pygmy shrews to 100,000-kg whales.

Early in the course of embryonic development, the placenta forms. Both fetal and maternal blood vessels are abundant in the placenta, and substances can be exchanged efficiently between the bloodstreams of mother and offspring (see figure 35.30). The fetal placenta is formed from the membranes of the chorion and allantois. In placental mammals, unlike in marsupials, the young undergo a considerable period of development before they are born.

### Learning Outcomes Review 35.8

Mammals are the only animals with hair and mammary glands. Other mammalian specializations include endothermy, the placenta, a tooth design suited to diet, and specialized sensory systems. Today three subgroups of mammals are recognized: monotremes, which lay eggs; marsupials, which feed embryonic young in a marsupial pouch; and placental mammals, in which the placenta nourishes the embryo throughout its development.

- What features found in both mammals and birds are examples of convergent evolution?

**TABLE 35.6**
**Major Orders of Placental Mammals**

Order	Typical Examples	Key Characteristics	Approximate Number of Living Species
Rodentia	Beavers, mice, porcupines, rats 	<i>Small plant-eaters</i> Chisel-like incisor teeth	1814
Chiroptera	Bats 	<i>Flying mammals</i> Primarily fruit- or insect-eaters; elongated fingers; thin wing membrane; mostly nocturnal; navigate by sonar	986
Insectivora	Moles, shrews 	<i>Small, burrowing mammals</i> Insect-eaters; the most primitive placental mammals; spend most of their time underground	390
Carnivora	Bears, cats, raccoons, weasels, dogs 	<i>Carnivorous predators</i> Teeth adapted for shearing flesh; no native families in Australia	274
Primates	Apes, humans, lemurs, monkeys  	<i>Tree-dwellers</i> Large brain size; binocular vision; opposable thumb; group that evolved from a line that branched off early from other mammals	233
Artiodactyla	Cattle, deer, giraffes, pigs 	<i>Hoofed mammals with two or four toes</i> Most species are herbivorous ruminants	211
Cetacea	Dolphins, porpoises, whales 	<i>Fully marine mammals</i> Streamlined bodies; front limbs modified into flippers; no hindlimbs; blowholes on top of head; no hair except on muzzle	79
Lagomorpha	Rabbits, hares, pika 	<i>Rodentlike jumpers</i> Four upper incisors (rather than the two seen in rodents); hind legs often longer than forelegs, an adaptation for jumping	69
Edentata	Anteaters, armadillos, sloths 	<i>Toothless insect-eaters</i> Many are toothless, but some have degenerate, peglike teeth	30
Perissodactyla	Horses, rhinoceroses, tapirs 	<i>Hoofed mammals with odd number of toes</i> Herbivorous teeth adapted for chewing	17
Proboscidea	Elephants 	<i>Long-trunked herbivores</i> Two upper incisors elongated as tusks; largest living land animal	2

## 35.9 Evolution of the Primates

### Learning Outcomes

1. Describe the characteristics and major groups of primates.
2. List the distinguishing characteristics of hominids.
3. Explain the variations that form the basis for human races and why races do not reflect speciation.

**Primates** are the mammalian group that gave rise to our own species. Primates evolved two distinct features that allowed them to succeed as arboreal (tree-dwelling) insectivores.

1. **Grasping fingers and toes.** Unlike the clawed feet of tree shrews and squirrels, primates have grasping hands and feet that enable them to grip limbs, hang from branches, seize food, and in some primates, use tools. The first digit in many primates, namely the thumb, is opposable, and at least some, if not all, of the digits have nails.
2. **Binocular vision.** Unlike the eyes of shrews and squirrels, which sit on each side of the head, the eyes of primates are shifted forward to the front of the face. This produces overlapping binocular vision that lets the brain judge distance precisely—important to an animal moving through the trees and trying to grab or pick up food items.

Other mammals have binocular vision—for example, carnivorous predators—but only primates have both binocular vision and grasping hands, making them particularly well adapted to their arboreal environment.

### The anthropoid lineage led to the earliest humans

About 40 MYA, the earliest primates split into two groups: the prosimians and the anthropoids. The **prosimians** (“before monkeys”) looked something like a cross between a squirrel and a cat and were common in North America, Europe, Asia, and Africa. Only a few prosimians survive today—lemurs, lorises, and tarsiers (figure 35.34). In addition to grasping digits and binocular

**Figure 35.34** A prosimian. This tarsier, *Tarsius*, a prosimian native to tropical Asia, shows the characteristic features of primates: grasping fingers and toes and binocular vision.

vision, prosimians have large eyes with increased visual acuity. Most prosimians are nocturnal, feeding on fruits, leaves, and flowers, and many lemurs have long tails for balancing.

### Anthropoids

Anthropoids include monkeys, apes, and humans. Anthropoids are almost all diurnal—that is, active during the day—feeding mainly on fruits and leaves. Natural selection favored many changes in eye design, including color vision, that were adaptations to daytime foraging. An expanded brain governs the improved senses, with the braincase forming a larger portion of the head.

Anthropoids, like the relatively few diurnal prosimians, live in groups with complex social interactions. They tend to care for their young for prolonged periods, allowing for a long childhood of learning and brain development.

About 30 MYA, some anthropoids migrated to South America. Their descendants, known as the New World monkeys (figure 35.35a), are easy to identify: All are arboreal; they have flat, spreading noses; and many of them grasp objects with long, prehensile tails.

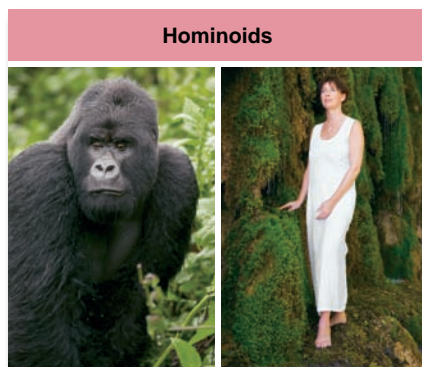

Anthropoids that remained in Africa gave rise to two lineages: the Old World monkeys (figure 35.35b) and the hominoids (apes and humans, figure 35.35c). Old World monkeys include ground-dwelling as well as arboreal species. None of them have prehensile tails, their nostrils are close together, their noses point downward, and some have toughened pads of skin on their rumps for prolonged sitting.

a.

b.

c.

**Figure 35.35** Anthropoids. a. New World Monkey, the squirrel monkey, *Saimiri oerstedii*; (b) Old World Monkey, the mandrill, *Mandrillus sphinx*; (c) hominoids, gorilla, *Gorilla gorilla* (left) and human, *Homo sapiens* (right).

## Hominoids

The **hominoids** include the apes and the **hominids** (humans and their direct ancestors). The living apes consist of the gibbon (genus *Hylobates*), orangutan (*Pongo*), gorilla (*Gorilla*), and chimpanzee (*Pan*). Apes have larger brains than monkeys, and they lack tails. With the exception of the gibbon, which is small, all living apes are larger than any monkey. Apes exhibit the most adaptable behavior of any mammal except human beings. Once widespread in Africa and Asia, apes are rare today, living in relatively small areas. No apes ever occurred in North or South America.

Studies of ape DNA have explained a great deal about how the living apes evolved. The Asian apes evolved first. The line of apes leading to gibbons diverged from other apes about 15 MYA, whereas orangutans split off about 10 MYA (figure 35.36). Neither group is closely related to humans.

The African apes evolved more recently, between 6 and 10 MYA. These apes are the closest living relatives to humans. The taxonomic group “apes” is a paraphyletic group; some apes are more closely related to hominids than they are to other apes. For this reason, some taxonomists have advocated placing humans and the African apes in the same zoological family, the Hominidae.

**Figure 35.36 A primate evolutionary tree.** Prosimians diverged early in primate evolution, whereas hominids diverged much more recently. Apes constitute a paraphyletic group because some apes are more closely related to nonape species (hominids) than they are to other apes.

Fossils of the earliest hominids (humans and their direct ancestors), described later in this section, suggest that the common ancestor of the hominids was more like a chimpanzee than a gorilla. Based on genetic differences, scientists estimate that gorillas diverged from the line leading to chimpanzees and humans some 8 MYA.

Soon after the gorilla lineage diverged, the common ancestor of all hominids split off from the chimpanzee line to begin the evolutionary journey leading to humans. Because this split was so recent, few genetic differences between humans and chimpanzees have had time to evolve. For example, a human hemoglobin molecule differs from its chimpanzee counterpart in only a single amino acid. In general, humans and chimpanzees exhibit a level of genetic similarity normally found between closely related species of the same genus!

## Comparing apes with hominids

The common ancestor of apes and hominids is thought to have been an arboreal climber. Much of the subsequent evolution of the hominoids reflected different approaches to locomotion. Hominids became bipedal, walking upright; in contrast, the apes evolved knuckle-walking, supporting their weight on the dorsal sides of their fingers. (Monkeys, by contrast, walk using the palms of their hands.)

Humans depart from apes in several areas of anatomy related to bipedal locomotion. Because humans walk on two legs, their vertebral column is more curved than an ape's, and the human spinal cord exits from the bottom rather than the back of the skull. The human pelvis has become broader and more bowl-shaped, with the bones curving forward to center the weight of the body over the legs. The hip, knee, and foot have all changed proportions.

Being bipedal, humans carry much of the body's weight on the lower limbs, which comprise 32 to 38% of the body's weight and are longer than the upper limbs; human upper limbs do not bear the body's weight and make up only 7 to 9% of human body weight. African apes walk on all fours, with the upper and lower limbs both bearing the body's weight; in gorillas, the longer upper limbs account for 14 to 16% of body weight, the somewhat shorter lower limbs for about 18%.

## Australopithecines were early hominids

Five to 10 MYA, the world's climate began to get cooler, and the great forests of Africa were largely replaced with savannas and open woodland. In response to these changes, a new kind of hominoid was evolving, one that was bipedal. These new hominoids are classified as hominids—that is, of the human line.

The major groups of hominids include three to seven species of the genus *Homo* (depending how you count them), seven species of the older, smaller-brained genus *Australopithecus*, and several even older lineages (figure 35.37). In every case where the fossils allow a determination to be made, the hominids are bipedal, the hallmark of hominid evolution.

In recent years, anthropologists have found a remarkable series of early hominid fossils extending as far back as 6 to 7 million years. Often displaying a mixture of primitive and modern traits, these fossils have thrown the study of early hominids into turmoil. Although the inclusion of these fossils

**Figure 35.37 Hominid fossil history.** Most, but not all, fossil hominoids are indicated here. New species are regularly being discovered, though great debate sometimes exists about whether a particular specimen represents a new species.

among the hominids seems warranted, only a few specimens have been discovered, and they do not provide enough information to determine with certainty their relationships to australopithecines and humans. The search for additional early hominid fossils continues.

### Early australopithecines

Our knowledge of australopithecines is based on hundreds of fossils, all found in South and East Africa (except for one specimen from Chad in West Africa). Australopithecines may have lived over a much broader area of Africa, but rocks of the proper age that might contain fossils are not exposed elsewhere. The evolution of hominids seems to have begun with an initial radiation of numerous species. The seven species identified so far provide ample evidence that australopithecines were a diverse group.

These early hominids weighed about 18 kg and were about 1 m tall. Their dentition was distinctly hominid, but their brains were no larger than those of apes, generally 500 cubic centimeters (cm<sup>3</sup>) or less. *Homo* brains, by comparison, are usually larger than 600 cm<sup>3</sup>; modern *H. sapiens* brains average 1350 cm<sup>3</sup>.

The structure of australopithecine fossils clearly indicates that they walked upright. Evidence of bipedalism includes a set of some 69 hominid footprints found at Laetoli, East Africa. Two individuals, one larger than the other, walked upright side-by-side for 27 m, their footprints preserved in a layer of

3.7-million-year-old volcanic ash. Importantly, the big toe is not splayed out to the side as in a monkey or ape, indicating that these footprints were clearly made by hominids.

### Bipedalism

The evolution of bipedalism marks the beginning of hominids. Bipedalism seems to have evolved as australopithecines left dense forests for grasslands and open woodland.

Whether larger brains or bipedalism evolved first was a matter of debate for some time. One school of thought proposed that hominid brains enlarged first, and then hominids became bipedal. Another school of thought saw bipedalism as a precursor to larger brains, arguing that bipedalism freed the forelimbs to manufacture and use tools, leading to the evolution of bigger brains. Recently, fossils unearthed in Africa have settled the debate. These fossils demonstrate that bipedalism extended back 4 million years; knee joint, pelvis, and leg bones all exhibit the hallmarks of an upright stance. Substantial brain expansion, on the other hand, did not appear until roughly 2 MYA. In hominid evolution, upright walking clearly preceded large brains.

The reason bipedalism evolved in hominids remains a matter of controversy. No tools appeared until 2.5 MYA, so tool-making seems an unlikely cause. Alternative ideas suggest that walking upright is faster and uses less energy than walking on four legs; that an upright posture permits hominids to pick fruit from trees and see over tall grass; that being upright reduces

the body surface exposed to the Sun's rays; that an upright stance aided the wading of semiaquatic hominids; and that bipedalism frees the forelimbs of males to carry food back to females, encouraging pair-bonding. All of these suggestions have their proponents, and none is universally accepted. The origin of bipedalism, the key event in the evolution of hominids, remains a mystery.

## The genus *Homo* arose roughly 2 MYA

The first humans (genus *Homo*) evolved from australopithecine ancestors about 2 MYA. The exact ancestor has not been clearly identified, but is commonly thought to be *Australopithecus afarensis*. Only within the last 30 years have a significant number of fossils of early *Homo* been uncovered. An explosion of interest has fueled intensive field exploration, and new finds are announced regularly; every year, our picture of the base of the human evolutionary tree grows clearer. The following historical account will undoubtedly be supplanted by future discoveries, but it provides a good example of science at work.

### The first human: *Homo habilis*

In the early 1960s, stone tools were found scattered among hominid bones close to the site where *A. boisei* had been unearthed. Although the fossils were badly crushed, painstaking reconstruction of the many pieces suggested a skull with a brain volume of about 680 cm<sup>3</sup>, larger than the australopithecine range of 400 to 550 cm<sup>3</sup>. Because of its association with tools, this early human was called *Homo habilis*, meaning “handy man.” Partial skeletons discovered in 1986 indicate that *H. habilis* was small in stature, with arms longer than its legs and a skeleton much like that of *Australopithecus*. Because of its general similarity to australopithecines, many researchers at first questioned whether this fossil was human.

### Out of Africa: *Homo erectus*

Our picture of what early *Homo* was like lacks detail because it is based on only a few specimens. We have much more information about the species that replaced it, *Homo erectus* and *H. ergaster*, which are sometimes considered a single species.

These species were a lot larger than *Homo habilis*—about 1.5 m tall. They had a large brain, about 1000 cm<sup>3</sup>, and walked erect. Their skull had prominent brow ridges and, like modern humans, a rounded jaw. Most interesting of all, the shape of the skull interior suggests that *H. erectus* was able to talk.

Far more successful than *H. habilis*, *H. erectus* quickly became widespread and abundant in Africa, and within 1 million years had migrated into Asia and Europe. A social species, *H. erectus* lived in tribes of 20 to 50 people, often dwelling in caves. They successfully hunted large animals, butchered them using flint and bone tools, and cooked them over fires—a site in China contains the remains of horses, bears, elephants, and rhinoceroses.

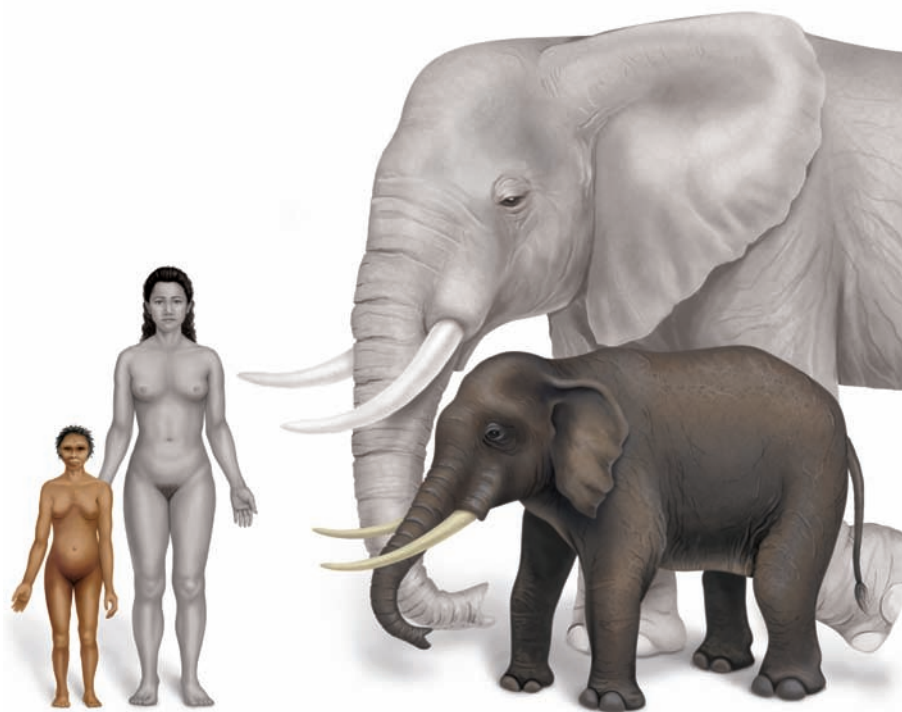

*Homo erectus* survived for over a million years, longer than any other species of human. These very adaptable humans only disappeared in Africa about 500,000 years ago, as modern humans were emerging. Interestingly, they survived even longer in Asia, until 250,000 years ago.

## A new addition to the human family: *Homo floresiensis*

The world was stunned in 2004 with the announcement of the discovery of fossils of a new human species from the tiny Indonesian island of Flores (figure 35.38). *Homo floresiensis* was notable for its diminutive stature; standing only a meter tall, and with a brain size of just 380 cm<sup>3</sup>, the species was quickly nicknamed “the Hobbit” after the characters in J. R. R. Tolkien’s *Lord of the Rings* trilogy. Just as surprising was the age of the fossils, the youngest of which was only 15,000 years old.

Despite its recency, a number of skeletal features suggest to most scientists that *H. floresiensis* is more closely related to *H. erectus* than to *H. sapiens*. If correct (and not all scientists agree), this result would indicate that the *H. erectus* lineage persisted much longer than previously thought—almost to the present day. It also would mean that until very recently, *H. sapiens* was not the only species of human on the planet. We can only speculate about how *H. sapiens* and *H. floresiensis* may have interacted, and how these interactions may have been affected by the great difference in body size.

Why *H. floresiensis* evolved such small size is unknown, although a number of experts have pointed to the phenomenon of “island dwarfism,” in which mammal species evolve to be much smaller on islands. Indeed, *H. floresiensis* coexisted with and preyed on a miniature species of elephant that also lived on Flores, but which also has gone extinct. These findings have rekindled interest in explaining why island dwarfism occurs.

**Figure 35.38** *Homo floresiensis*. This diminutive species (compare the modern human female on the right with the female *H. floresiensis* on the left) occurred on the small island of Flores in what is now Indonesia. *H. floresiensis* preyed upon a dwarf species of elephant, *Stegodon sondaari*, which also occurred on Flores (compare with the larger African elephant, *Loxodonta africana*, in gray).

## Modern humans

The evolutionary journey entered its final phase when modern humans first appeared in Africa about 600,000 years ago. Investigators who focus on human diversity denote three species of modern humans: *Homo heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*. Other investigators lump the three species into one, *H. sapiens* (“wise man”).

The oldest modern human, *Homo heidelbergensis*, is known from a 600,000-year-old fossil from Ethiopia. Although it coexisted with *H. erectus* in Africa, *H. heidelbergensis* has more advanced anatomical features, including a bony keel running along the midline of the skull, a thick ridge over the eye sockets, and a large brain. Also, its forehead and nasal bones are very much like those of *H. sapiens*.

As *H. erectus* was becoming rarer, about 130,000 years ago, a new species of human arrived in Europe from Africa. *Homo neanderthalensis* likely branched off the ancestral line leading to modern humans as long as 500,000 years ago. Compared with modern humans, Neanderthals were short, stocky, and powerfully built; their skulls were massive, with protruding faces, heavy, bony ridges over the brows, and larger braincases.

## Cro-Magnons and Neanderthals

The Neanderthals (classified by many paleontologists as a separate species, *Homo neanderthalensis*) were named after the Neander Valley of Germany where their fossils were first discovered in 1856. Rare at first outside of Africa, they became progressively more abundant in Europe and Asia, and by 70,000 years ago had become common.

The Neanderthals made diverse tools, including scrapers, spearheads, and hand axes. They lived in huts or caves. Neanderthals took care of their injured and sick and commonly buried their dead, often placing food, weapons, and even flowers with the bodies. Such attention to the dead strongly suggests that they believed in a life after death. This is the first evidence of the symbolic thinking characteristic of modern humans.

Fossils of *H. neanderthalensis* abruptly disappear from the fossil record about 34,000 years ago and are replaced by fossils of *H. sapiens* called the Cro-Magnons (named after the valley in France where their fossils were first discovered). We can only speculate why this sudden replacement occurred, but it was complete all over Europe in a short period.

A variety of evidence indicates that Cro-Magnons came from Africa—fossils of essentially modern aspect but as much as 100,000 years old have been found there. Cro-Magnons seem to have replaced the Neanderthals completely in the Middle East by 40,000 years ago, and then spread across Europe, coexisting with the Neanderthals for several thousand years. Recent analyses of Neanderthal DNA reveal it to be quite distinct from Cro-Magnon DNA, indicating the two species did not interbreed, although not all scientists agree on this point. Neanderthals are our cousins, not our ancestors. The Cro-Magnons that replaced the Neanderthals had a complex social organization and are thought to have had full language capabilities. Elaborate and often beautiful cave paintings made by Cro-Magnons can be seen throughout Europe (figure 35.39).

Humans of modern appearance eventually spread across Siberia to North America, where they arrived at least 13,000

**Figure 35.39 Cro-Magnon art.** Rhinoceroses are among the animals depicted in this remarkable cave painting found in 1995 near Vallon-Pont d’Arc, France.

years ago, after the ice had begun to retreat and a land bridge still connected Siberia and Alaska. By 10,000 years ago, about 5 million people inhabited the entire world (compared with more than 6 billion today).

## Our own species: *Homo sapiens*

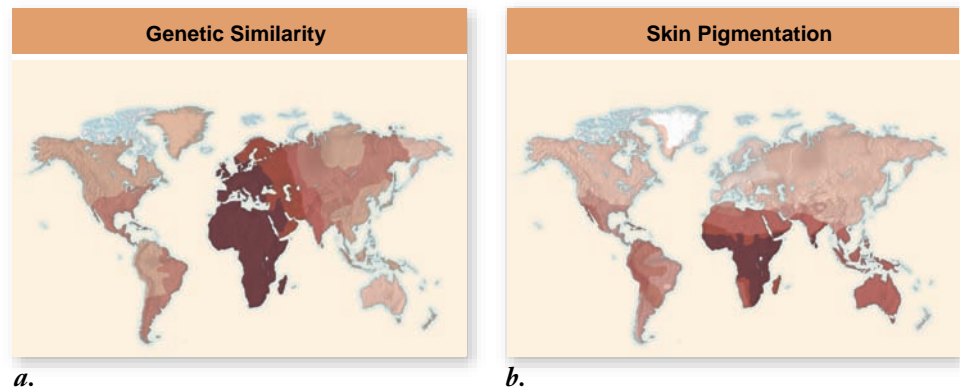

*Homo sapiens* is the only surviving species of the genus *Homo*, and indeed the only surviving hominid. Some of the best fossils of *H. sapiens* are 20 well-preserved skeletons with skulls found in a cave near Nazareth in Israel. Modern dating techniques estimate these humans to be between 90,000 and 100,000 years old. The skulls are modern in appearance and size, with high, short braincases, vertical foreheads with only slight brow ridges, and a cranial capacity of roughly 1550 cm<sup>3</sup>. Our evolution has been marked by a progressive increase in brain size, distinguishing us from other animals in several ways. First, humans are able to make and use tools more effectively than any other animal—a capability that, more than any other factor, has been responsible for our dominant position in the world. Second, although not the only animal capable of conceptual thought, humans have refined and extended this ability until it has become the hallmark of our species. Finally, we use symbolic language and can, with words, shape concepts out of experience and transmit that accumulated experience from one generation to another.

Humans have undergone what no other animal ever has: extensive cultural evolution. Through culture, we have found ways to change and mold our environment, rather than changing evolutionarily in response to the environment’s demands. We control our biological future in a way never before possible—an exciting potential and a frightening responsibility.

**Figure 35.40** Patterns of genetic variation in human populations differ from patterns of skin color variation.

*a.* Genetic variation among *Homo sapiens*. The more similar areas are in color, the more similar they are genetically based on many enzyme and blood group genetic loci.

*b.* Similarity among *Homo sapiens* based on skin color. The color of an area represents the skin pigmentation of the people native to that region.

### Human races

Human beings, like all other species, have differentiated in their characteristics as they have spread throughout the world. Local populations in one area often appear significantly different from those that live elsewhere. For example, northern Europeans often have blond hair, fair skin, and blue eyes, whereas Africans often have black hair, dark skin, and brown eyes. These traits may play a role in adapting the particular populations to their environments. Blood groups may be associated with immunity to diseases more common in certain geographical areas, and dark skin shields the body from the damaging effects of ultraviolet radiation, which is much stronger in the tropics than in temperate regions.

All human beings are capable of mating with one another and producing fertile offspring. The reasons that they do or do not choose to associate with one another are purely psychological and behavioral (cultural).

The number of groups into which the human species might logically be divided has long been a point of contention. Some contemporary anthropologists divide people into as many as 30 “races,” others as few as three: Caucasoid, Negroid, and Oriental. American Indians, Bushmen, and Aborigines are examples of particularly distinctive subunits that are sometimes regarded as distinct groups.

The problem with classifying people or other organisms into races in this fashion is that the characteristics used to define the races are usually not well correlated with one another, and so the determination of race is always somewhat arbitrary. Humans are visually oriented; consequently, we have relied on visual cues—primarily skin color—to define races. However, when other types of characteristics, such as blood groups, are examined, patterns of variation correspond very poorly with visually determined racial classes. Indeed, if one were to break the human species into subunits based on overall genetic similarity, the groupings would be very different from those based on skin color or other visual features (figure 35.40).

In human beings, it is simply not possible to delimit clearly defined races that reflect biologically differentiated and well-defined groupings. The reason is simple: Different groups

of people have constantly intermingled and interbred with one another during the entire course of history. This constant gene flow has prevented the human species from fragmenting into highly differentiated subspecies. Those characteristics that are differentiated among populations, such as skin color, represent classic examples of the antagonism between gene flow and natural selection. As you saw in chapter 20, when selection is strong enough, as it is for dark coloration in tropical regions, populations can differentiate even in the presence of gene flow. However, even in cases such as this, gene flow will still ensure that populations are relatively homogeneous for genetic variation at other loci.

For this reason, relatively little of the variation in the human species represents differences between the described races. Indeed, one study calculated that only 8% of all genetic variation among humans could be accounted for as differences that exist among racial groups; in other words, the human racial categories do a very poor job in describing the vast majority of genetic variation that exists in humans. For this reason, most modern biologists reject human racial classifications as reflecting patterns of biological differentiation in the human species. This is a sound biological basis for dealing with each human being on his or her own merits and not as a member of a particular “race.”

### Learning Outcomes Review 35.9

Primates include prosimians, monkeys, apes, and humans (hominids). Primates have grasping fingers and toes and binocular vision. Hominids diverged from other primates by developing bipedal locomotion that led to a number of additional adaptations, including modification of the spine, pelvis, and limbs. Several species of *Homo* evolved in Africa, and some migrated from there to Europe and Asia. Our own species, *Homo sapiens*, is proficient at conceptual thought and tool use and is the only animal that uses symbolic language. Considerable variation occurs among human populations, but the recognized races, which are based primarily on skin color, do not reflect significant biological differences.

- Which of these groups is monophyletic: prosimians, monkeys, apes, hominids?

## Chapter Review

### 35.1 The Chordates

Chordates share four features at some time during development: a single, hollow nerve cord; a flexible rod, the notochord; pharyngeal slits or pouches; and a postanal tail (see figure 35.1).

### 35.2 The Nonvertebrate Chordates

**Tunicates have chordate larval forms.**

Tunicates have a swimming larval form exhibiting all the features of a chordate, but their adult form is sessile and baglike.

**Lancelets are small marine chordates.**

Lancelets have chordate features throughout life, but as adults they lack bones and have no distinct head (see figure 35.3).

### 35.3 The Vertebrate Chordates

**Vertebrates have vertebrae, a distinct head, and other features.**

In vertebrates, a vertebral column encloses and protects the dorsal nerve cord. The distinct and well-differentiated head carries sensory organs. Vertebrates also have specialized internal organs and a bony or cartilaginous endoskeleton.

**Vertebrates evolved half a billion years ago: An overview.**

In fishes, evolution of a hinged jaw was a major advance. Other changes allowed a move into the terrestrial environment, giving rise to amphibians, reptiles, birds, and mammals (see figure 35.8).

### 35.4 Fishes

**Fishes exhibit five key characteristics.**

The key characteristics of fishes are a vertebral column of bone or cartilage, jaws, paired appendages, internal gills, and a closed circulatory system.

**Sharks, with cartilaginous skeletons, became top predators.**

Sharks, rays, and skates are cartilaginous fishes. Sharks were streamlined for fast swimming, and they evolved teeth that enabled them to readily grab, kill, and devour prey.

The lateral line system of sharks and bony fishes is a sensory system that detects changes in pressure waves.

**Bony fishes dominate the waters.**

Bony fishes belong either to the ray-finned fishes (Actinopterygii), or the lobe-finned fishes (Sarcopterygii). Ray-finned fishes have fins stiffened with bony parallel rays.

**The evolutionary path to land ran through the lobe-finned fishes.**

The lobe-finned fishes have muscular lobes with bones connected by joints (see figure 35.13). These structures could evolve into limbs capable of movement on land.

### 35.5 Amphibians

**Living amphibians have five distinguishing features.**

Amphibian adaptations include legs, lungs, cutaneous respiration, pulmonary veins, and a partially divided heart.

**Amphibians overcame terrestrial challenges.**

Terrestrial adaptations included being able to support large bodies against gravity, to breathe out of water, and to avoid desiccation.

**Modern amphibians belong to three groups.**

The Anura (frogs and toads) lack tails as adults; many have a larval tadpole stage. The Caudata (salamanders) have tails as adults and larvae similar to the adult form. The Apoda (caecilians) are legless.

### 35.6 Reptiles

**Reptiles exhibit three key characteristics.**

Reptiles possess a watertight amniotic egg; dry, watertight skin; and thoracic breathing (see figure 35.17).

Modern reptiles practice internal fertilization and are ectothermic.

**Reptiles dominated the Earth for 250 million years.**

Synapsids gave rise to the therapsids that became the mammalian line. Diapsids gave rise to modern reptiles and the birds.

**Modern reptiles belong to four groups.**

The four groups of reptiles are Chelonia (turtles and tortoises); Rhynchocephalia (tuataras); Squamata (lizards and snakes); and Crocodylia (crocodiles and alligators).

### 35.7 Birds

**Key characteristics of birds are feathers and a lightweight skeleton.**

The feather is a modified reptilian scale. Feathers provide lift in gliding or flight and conserve heat (see figure 35.25).

The lightweight skeleton of birds is an adaptation to flight.

**Birds arose about 150 MYA.**

Birds evolved from theropod dinosaurs. Feathers probably first arose to provide insulation, only later being modified for flight.

**Modern birds are diverse but share several characteristics.**

In addition to the key characteristics, birds have efficient respiration and circulation and are endothermic.

### 35.8 Mammals

**Mammals have hair, mammary glands, and other characteristics.**

Mammals are distinguished by fur and by mammary glands, which provide milk to feed the young. Mammals are also endothermic.

**Mammals diverged about 220 MYA.**

Mammals evolved from therapsids (synapsids) and reached maximum diversity about 15 MYA.

**Modern mammals are placed into three groups.**

The monotremes lay shelled eggs. In marsupials, an embryo completes development in a pouch. Placental mammals produce a placenta in the uterus to nourish the embryo.

### 35.9 Evolution of the Primates (see figure 35.36)

Primates share two innovations: grasping fingers and toes, and binocular vision.

**The anthropoid lineage led to the earliest humans.**

The earliest primates were the prosimians; anthropoids, which include monkeys, apes, and humans, evolved later. Hominoids include the apes and the hominids, or humans.

**Australopithecines were early hominids.**

The distinguishing characteristics of hominids are upright posture and bipedal locomotion.

**The genus *Homo* arose roughly 2 MYA.**

Common features of early *Homo* species include a larger body and brain size. *Homo sapiens* is the only extant species. Humans exhibit conceptual thought, tool use, and symbolic language.

## Review Questions

### UNDERSTAND

- Which of the following statements regarding all species of chordates is false?
  - Chordates are deuterostomes.
  - A notochord is present in the embryo.
  - The notochord is surrounded by bone or cartilage.
  - All possess a postanal tail during embryonic development.
- In the following figure, item A is the \_\_\_\_\_ and item B is the \_\_\_\_\_.
  - complete digestive system; notochord
  - spinal cord; nerve cord
  - notochord; nerve cord
  - pharyngeal slits; notochord

- During embryonic development, a neural crest would be found in all of the following chordates, except
  - cephalochordates.
  - reptiles.
  - birds.
  - mammals.
- The \_\_\_\_\_ of the bony fish evolved to counter the effects of increased bone density.
  - gills
  - jaws
  - swim bladder
  - teeth
- Why was the evolution of the pulmonary veins important for amphibians?
  - To move oxygen to and from the lungs
  - To increase the metabolic rate
  - For increased blood circulation to the brain
  - None of the above
- Which of the following groups lacks a four-chambered heart?
  - Birds
  - Crocodylians
  - Mammals
  - Amphibians

- All of the following are characteristics of reptiles, except
  - cutaneous respiration.
  - amniotic egg.
  - thoracic breathing.
  - dry, watertight skin.
- Which of the following evolutionary adaptations allows the birds to become efficient at flying?
  - Structure of the feather
  - High metabolic temperatures
  - Increased respiratory efficiency
  - All of the above

### APPLY

- The reason that birds and crocodylians both build nests might be because they
  - are both warm-blooded.
  - both eat fish.
  - both inherited the trait from a common ancestor.
  - both lay eggs.
- Which of the following is the closest relative of lungfish?
  - Hagfish
  - Sharks
  - Ray-finned fish
  - Mammals
- The fact that monotremes lay eggs
  - indicates that they are more closely related to some reptiles than they are to some mammals.
  - is a plesiomorphic trait.
  - demonstrates that the amniotic egg evolved multiple times.
  - is a result of ectothermy.

### SYNTHESIZE

- Some scientists believe the feathers did not evolve initially for flight, but rather for insulation. What benefits would this have had for early flightless birds?
- Some people state that the dinosaurs have not “gone extinct,” they are with us today. What evidence can be used to support this statement?
- In what respect is the evolutionary diversification of hominids similar to that of horses discussed in chapter 21?

# Chapter 36

Chapter

## Plant Form

### Chapter Outline

---

- 36.1** Organization of the Plant Body: An Overview
- 36.2** Plant Tissues
- 36.3** Roots: Anchoring and Absorption Structures
- 36.4** Stems: Support for Above-Ground Organs
- 36.5** Leaves: Photosynthetic Organs

### Introduction

---

Although the similarities among a cactus, an orchid, and a hardwood tree might not be obvious at first sight, most plants have a basic unity of structure. This unity is reflected in how the plants are constructed; in how they grow, manufacture, and transport their food; and in how their development is regulated. This chapter addresses the question of how a vascular plant is “built.” We will focus on the cells, tissues, and organs that compose the adult plant body. The roots and shoots that give the adult plant its distinct above- and below-ground architecture are the final product of a basic body plan first established during embryogenesis, a process we will explore in detail in this chapter.

## 36.1 Organization of the Plant Body: An Overview

### Learning Outcomes

1. Distinguish between the functions of roots and shoots.
2. Name the three types of tissues in a plant.
3. Compare primary growth and secondary growth.

As you learned in chapter 30, the plant kingdom has great diversity, not only among its many phyla but even within species. The earliest vascular plants, many of which are extinct, did not have a clear differentiation of the plant body into specialized organs such as roots and leaves.

Among modern vascular plants, the presence of these organs reflects increasing specialization, particularly in relation to the demands of a terrestrial existence. Obtaining water, for example, is a major challenge, and roots are adapted for water absorption from the soil. Leaves, roots, branches, and flowers all exhibit variations in size and number from plant to plant. Development of the form and structure of these parts may be precisely controlled, but some aspects of leaf, stem, and root development are quite flexible. This chapter emphasizes the unifying aspects of plant form, using the flowering plants as a model.

### Vascular plants have roots and shoots

A vascular plant consists of a root system and a shoot system (figure 36.1). Roots and shoots grow at their tips, which are called apices (singular, **apex**).

The **root system** anchors the plant and penetrates the soil, from which it absorbs water and ions crucial for the plant's nutrition. Root systems are often extensive, and growing roots can exert great force to move matter as they elongate and expand. Roots developed later than the shoot system as an adaptation to living on land.

The **shoot system** consists of the stems and their leaves. Stems serve as a scaffold for positioning the leaves, the principal sites of photosynthesis. The arrangement, size, and other features of the leaves are critically important in the plant's production of food. Flowers, other reproductive organs, and ultimately, fruits and seeds are also formed on the shoot (flower morphology and plant reproduction is covered in chapter 42).

The iterative (repeating) unit of the vegetative shoot consists of the internode, node, leaf, and axillary bud, but not reproductive structures. An axillary bud is a lateral shoot apex that allows the plant to branch or replace the main shoot if it is eaten by an herbivore. A vegetative axillary bud has the capacity to reiterate the development of the primary shoot. When the plant has shifted to the reproductive phase of development, these axillary buds may produce flowers or floral shoots.

### Roots and shoots are composed of three types of tissues

Roots, shoots, and leaves all contain three basic types of tissues: dermal, ground, and vascular tissue. Because each of these tissues extend through the root and shoot systems, they are called **tissue systems**.

Plant cell types can be distinguished by the size of their vacuoles, whether they are living or not at maturity, and by the thickness of secretions found in their cellulose cell walls, a distinguishing feature of plant cells (see chapter 4 to review cell structure). Some cells have only a primary cell wall of cellulose, synthesized by the protoplast near the cell membrane. Microtubules align within the cell and determine the orientation of the cellulose fibers (figure 36.2a). Cells that support the plant

**Figure 36.1** Diagram of a plant body. Branching root and shoot systems create the plant's architecture. Each root and shoot has an apex that extends growth. Leaves are initiated at the nodes of the shoot, which also contain axillary buds that can remain dormant, grow to form lateral branches, or make flowers. A leaf can be a simple blade or consist of multiple parts as shown here. Roots, shoots, and leaves are all connected with vascular (conducting) tissue.

**Figure 36.2 Synthesis of a plant cell wall.** *a.* Cellulose is a glucose polymer that is produced at the cellulose-forming rosettes in the cell membrane to form the cell wall. Cellulose fibers are laid down parallel to microtubules inside the cell membrane. Additional substances that strengthen and waterproof the cell wall are added to the cell wall in some cell types. *b.* Some cells extrude additional layers of cellulose, increasing the mechanical strength of the wall. Because new cellulose is produced at the cell, the oldest layers of cellulose are on the outside of the cell wall. All cells have a primary cell wall. Additional layers of cellulose and lignin contribute to the secondary cell wall.

body have more heavily reinforced cell walls with multiple layers of cellulose. Cellulose layers are laid down at angles to adjacent layers like plywood; this enhances the strength of the cell wall (figure 36.2*b*).

Plant cells contribute to three tissue systems. **Dermal tissue**, primarily *epidermis*, is one cell layer thick in most plants, and it forms an outer protective covering for the plant. **Ground tissue** cells function in storage, photosynthesis, and secretion, in addition to forming fibers that support and protect plants. **Vascular tissue** conducts fluids and dissolved substances throughout the plant body. Each of these tissues and their many functions are described in more detail in later sections.

## Meristems elaborate the body plan throughout the plant's life

When a seed sprouts, only a tiny portion of the adult plant exists. Although embryo cells can undergo division and differentiation to form many cell types, the fate of most adult cells is more restricted. Further development of the plant body depends on the activities of *meristems*, specialized cells found in shoot and root apices, as well as other parts of the plant.

### Overview of meristems

Meristems are clumps of small cells with dense cytoplasm and proportionately large nuclei that act as stem cells do in animals. That is, one cell divides to give rise to two cells, of which one remains meristematic, while the other undergoes differentiation and contributes to the plant body (figure 36.3). In this way, the population of meristem cells is continually renewed. Molecular genetic evidence supports the hypothesis that animal stem cells and plant meristem cells may also share some common pathways of gene expression. Extension of both root

and shoot takes place as a result of repeated cell divisions and subsequent elongation of the cells produced by the **apical meristems**. In some vascular plants, including shrubs and most trees, **lateral meristems** produce an increase in root and shoot diameter.

**Figure 36.3 Meristem cell division.** Plant meristems consist of cells that divide to give rise to a differentiating daughter cell and a cell that persists as a meristem cell.

## Apical meristems

Apical meristems are located at the tips of stems and roots (figure 36.4). During periods of growth, the cells of apical meristems divide and continually add more cells at the tips. Tissues derived from apical meristems are called **primary tissues**, and the extension of the root and stem forms what is known as the **primary plant body**. The primary plant body comprises the young, soft shoots and roots of a tree or shrub, or the entire plant body in some plants.

Both root and shoot apical meristems are composed of delicate cells that need protection (see figure 36.4). The root apical meristem is protected by the root cap, the anatomy of which is described later on. Root cap cells are produced by the root meristem and are sloughed off and replaced as the root

**Figure 36.4 Apical meristems.** Shoot and root apical meristems extend the plant body above and below ground. Leaf primordia protect the fragile shoot meristem, while the root meristem produces a protective root cap in addition to new root tissue.

moves through the soil. In contrast, leaf primordia shelter the growing shoot apical meristem, which is particularly susceptible to desiccation because of its exposure to air and sun.

The apical meristem gives rise to the three tissue systems by first initiating **primary meristems**. The three primary meristems are the **protoderm**, which forms the epidermis; the **procambium**, which produces primary vascular tissues (primary xylem for water transport and primary phloem for nutrient transport); and the **ground meristem**, which differentiates further into ground tissue. In some plants, such as horsetails and corn, **intercalary meristems** arise in stem internodes (spaces between leaf attachments), adding to the internode lengths. If you walk through a cornfield on a quiet summer night when the corn is about knee high, you may hear a soft popping sound. This sound is caused by the rapid growth of the intercalary meristems. The amount of stem elongation that occurs in a very short time is quite surprising.

## Lateral meristems

Many herbaceous plants (that is, plants with fleshy, not woody stems) exhibit only primary growth, but others also exhibit **secondary growth**, which may result in a substantial increase of diameter. Secondary growth is accomplished by the lateral meristems—peripheral cylinders of meristematic tissue within the stems and roots that increase the girth (diameter) of gymnosperms and most angiosperms. Lateral meristems form from ground tissue that is derived from apical meristems. Monocots are the major exception (figure 36.5).

Although secondary growth increases girth in many nonwoody plants, its effects are most dramatic in woody plants, which have two lateral meristems. Within the bark of a woody stem is the **cork cambium**—a lateral meristem that contributes to the outer bark of the tree. Just beneath the bark is the **vascular cambium**—a lateral meristem that produces secondary vascular tissue. The vascular cambium forms between the xylem and phloem in vascular bundles, adding secondary vascular tissue to both of its sides.

Secondary xylem is the main component of wood. Secondary phloem is very close to the outer surface of a woody stem. Removing the bark of a tree damages the phloem and may eventually kill the tree. Tissues formed from lateral meristems, which comprise most of the trunk, branches, and older roots of trees and shrubs, are known as **secondary tissues** and are collectively called the **secondary plant body**.

### Learning Outcomes Review 36.1

The root system anchors plants and absorbs water and nutrients, whereas the shoot system, consisting of stems, leaves, and flowers carries out photosynthesis and sexual reproduction. The three general types of tissue in both roots and shoots are dermal, ground, and vascular tissue. Primary growth is produced by apical meristems at the tips of roots and shoots; secondary growth is produced by lateral meristems that are peripheral and increase girth.

- **Why are both primary and secondary growth necessary in a woody plant?**

**Figure 36.5 Apical and lateral meristems.** Apical meristems produce the primary plant body. In some plants, the lateral meristems produce an increase in the girth of a plant. This type of growth is secondary because the lateral meristems were not directly produced by apical meristems. Woody plants have two types of lateral meristems: a vascular cambium that produces xylem and phloem tissues, and a cork cambium that contributes to the bark of a tree.

## 36.2 Plant Tissues

### Learning Outcomes

1. Describe the functions of dermal, ground, and vascular tissues.
2. Name the three cell types found in ground tissue and their functions.
3. Distinguish between xylem and phloem.

Three main categories of tissue can be distinguished in the plant body. These are (1) *dermal tissue* on external surfaces that serves a protective function; (2) *ground tissue* that forms several different internal tissue types and that can participate in photosynthesis, serve a storage function, or provide structural support; and (3) *vascular tissue* that conducts water and nutrients.

### Dermal tissue forms a protective interface with the environment

Dermal tissue derived from an embryo or apical meristem forms **epidermis**. This tissue is one cell layer thick in most

**a.** 4 μm

**b.** 71 μm

**c.** 200 μm

**Figure 36.6 Stomata.** *a.* A stoma is the space between two guard cells that regulate the size of the opening. Stomata are evenly distributed within the epidermis of monocots and eudicots, but the patterning is quite different. *b.* A pea (eudicot) leaf with a random arrangement of stomata. *c.* A maize (corn, a monocot) leaf with stomata evenly spaced in rows. These photomicrographs also show the variety of cell shapes in plants. Some plant cells are boxlike, as seen in maize (*c*), and others are irregularly shaped, as seen in the jigsaw puzzle shapes of the pea epidermal cells, (*b*).

plants and forms the outer protective covering of the plant. In young, exposed parts of the plant, the epidermis is covered with a fatty **cutin** layer constituting the **cuticle**; in plants such as desert succulents, several layers of wax may be added to the cuticle to limit water loss and protect against ultraviolet damage. In some cases, the dermal tissue forms the bark of trees.

**Epidermal cells**, which originate from the protoderm, cover all parts of the primary plant body. A number of types of specialized cells occur in the epidermis, including *guard cells*, *trichomes*, and *root hairs*.

### Guard cells

**Guard cells** are paired, sausage-shaped cells flanking a stoma (plural, stomata), a mouth-shaped epidermal opening. Guard cells, unlike other epidermal cells, contain chloroplasts.

Stomata occur in the epidermis of leaves (figure 36.6*a*) and sometimes on other parts of the plant, such as stems or fruits. The passage of oxygen and carbon dioxide, as well as the diffusion of water in vapor form, takes place almost exclusively through the stomata. There are from 1000 to more than 1 million stomata per square centimeter of leaf surface. In many plants, stomata are more numerous on the lower epidermis of the leaf than on the upper—a factor that helps minimize water loss. Some plants have stomata only on the lower epidermis, and a few, such as water lilies, have them only on the upper epidermis to maximize gas exchange.

Guard cell formation is the result of an asymmetrical cell division producing a guard cell and a subsidiary cell that aids in the opening and closing of the stoma. The patterning of these asymmetrical divisions that results in stomatal distribution has intrigued developmental biologists (figure 36.6*b, c*).

Research on mutants that get “confused” about where to position stomata is providing information on the timing of stomatal initiation and the kind of intercellular communication that triggers guard cell formation. For example, the *too many mouths* (*tmm*) mutation that occurs in *Arabidopsis* disrupts the normal pattern of cell division that spatially separates stomata

(figure 36.7). Investigations of this and other stomatal patterning genes revealed a coordinated network of cell–cell communication (see chapter 9) that informs cells of their position relative to other cells and determines cell fate. The *TMM* gene encodes a membrane-bound receptor that is part of a signaling pathway controlling asymmetrical cell division.

### Trichomes

**Trichomes** are cellular or multicellular hairlike outgrowths of the epidermis (figure 36.8). They occur frequently on stems, leaves, and reproductive organs. A “fuzzy” or “woolly” leaf is covered with trichomes that can be seen clearly with a microscope under low magnification. Trichomes keep leaf surfaces cool and reduce evaporation by covering stomatal openings. They also protect leaves from high light intensities and ultraviolet radiation and can buffer against temperature fluctuations. Trichomes can vary greatly in form; some consist of a single cell; others are multicellular. Some are glandular, often secreting sticky or toxic substances to deter herbivory.

**Figure 36.7 The too many mouths stomatal mutant.** This *Arabidopsis* mutant plant lacks an essential signal for spacing stomata. Usually a differentiating guard cell pair inhibits differentiation of a nearby cell into a guard cell.

272 μm

**Figure 36.8 Trichomes.** The trichomes with tan, bulbous tips on this tomato plant are glandular trichomes. These trichomes secrete substances that can literally glue insects to the trichome.

**Figure 36.10 Root hairs.** Root hair cells are a type of epidermal cell that increase the surface area of the root to enhance water and mineral uptake.

Genes that regulate trichome development have been identified, including *GLABROUS3* (*GL3*) (figure 36.9). When trichome-initiating proteins, like *GL3*, reach a threshold level compared with trichome-inhibiting proteins, an epidermal cell becomes a trichome. Signals from this trichome cell now prevent neighbor cells from expressing trichome-promoting genes (see figure 36.9).

### Root hairs

**Root hairs**, which are tubular extensions of individual epidermal cells, occur in a zone just behind the tips of young, growing roots (figure 36.10). Because a root hair is simply an extension of an epidermal cell and not a separate cell, no cross-wall isolates the hair from the rest of the cell. Root hairs keep the root in intimate contact with the surrounding soil particles and greatly increase the root's surface area and efficiency of absorption.

As a root grows, the extent of the root hair zone remains roughly constant as root hairs at the older end slough off while new ones are produced at the apex. Most of the absorption of water and minerals occurs through root hairs, especially in herbaceous plants. Root hairs should not be confused with lateral roots, which are multicellular structures and originate deep within the root. Root hairs are not found when the dermal tissue system is extended by the cork cambium, which contributes to the periderm (outer bark) of a tree trunk or root. The epidermis gets stretched and broken with the radial expansion of the axis by the vascular cambium

The first land plants lacked roots, which later evolved from shoots. Given this common ancestry, it is not surprising that some of the genes needed for trichome and stomatal

**Figure 36.9 Trichome patterning.** Mutants have revealed genes involved in regulating the spacing and development of trichomes in *Arabidopsis*. **a.** Wild type. **b.** *glabrous3* mutant, which fails to initiate trichome development. **c.** When there is sufficient *GL3* in a cell and the levels of trichome-inhibiting proteins are sufficiently low, that cell will develop a trichome. Once a cell begins trichome initiation, it signals neighboring cells and inhibits their ability to develop trichomes.

differentiation in shoot epidermal cells also play a role in root hair development.

### Inquiry question

? Identify three dermal tissue traits that are adaptive for a terrestrial lifestyle and explain why these traits are advantageous.

## Ground tissue cells perform many functions, including storage, photosynthesis, and support

Ground tissue consists primarily of thin-walled *parenchyma cells* that function in storage, photosynthesis, and secretion. Other ground tissue, composed of *collenchyma cells* and *sclerenchyma cells*, provide support and protection.

### Parenchyma

**Parenchyma cells** are the most common type of plant cell. They have large vacuoles, thin walls, and are initially (but briefly) more or less spherical. These cells, which have living protoplasts, push up against each other shortly after they are produced, however, and assume other shapes, often ending up with 11 to 17 sides.

Parenchyma cells may live for many years; they function in storage of food and water, photosynthesis, and secretion. They are the most abundant cells of primary tissues and may also occur, to a much lesser extent, in secondary tissues (figure 36.11*a*). Most parenchyma cells have only primary walls, which are walls laid down while the cells are still maturing. Parenchyma are less specialized than other plant cells, although many variations occur with special functions, such as nectar and resin secretion or storage of latex, proteins, and metabolic wastes.

Parenchyma cells have functional nuclei and are capable of dividing, and they usually remain alive after they mature; in some plants (for example, cacti), they may live to be over 100 years old. The majority of cells in fruits such as apples are parenchyma. Some parenchyma contain chloroplasts, especially in leaves and in the outer parts of herbaceous stems. Such photosynthetic parenchyma tissue is called *chlorenchyma*.

### Collenchyma

If celery “strings” have ever been caught between your teeth, you are familiar with tough, flexible **collenchyma cells**. Like parenchyma cells, collenchyma cells have living protoplasts and may live for many years. These cells, which are usually a little longer than wide, have walls that vary in thickness (figure 36.11*b*).

Flexible collenchyma cells provide support for plant organs, allowing them to bend without breaking. They often form strands or continuous cylinders beneath the epidermis of stems or leaf petioles (stalks) and along the veins in leaves. Strands of collenchyma provide much of the support for stems in the primary plant body.

### Sclerenchyma

**Sclerenchyma cells** have tough, thick walls. Unlike collenchyma and parenchyma, they usually lack living protoplasts at maturity. Their secondary cell walls are often impregnated with **lignin**, a highly branched polymer that makes cell walls more rigid; for example, lignin is an important component in wood. Cell walls containing lignin are said to be *lignified*. Lignin is common in the walls of plant cells that have a structural or mechanical function. Some kinds of cells have lignin deposited in primary as well as secondary cell walls.

Sclerenchyma is present in two general types: fibers and sclereids. *Fibers* are long, slender cells that are usually grouped

**Figure 36.11 The three types of ground tissue.** *a.* Parenchyma cells. Only primary cell walls are seen in this cross section of parenchyma cells from grass. *b.* Collenchyma cells. Thickened side walls are seen in this cross section of collenchyma cells from a young branch of elderberry (*Sambucus*). In other kinds of collenchyma cells, the thickened areas may occur at the corners of the cells or in other kinds of strips. *c.* Sclereids. Clusters of sclereids (“stone cells”), stained red in this preparation. The surrounding thin-walled cells, stained green, are parenchyma. Sclereids are one type of sclerenchyma tissue, which also contains fibers.

together in strands. Linen, for example, is woven from strands of sclerenchyma fibers that occur in the phloem of flax (*Linum* spp.) plants. *Sclereids* are variable in shape but often branched. They may occur singly or in groups; they are not elongated, but may have many different forms, including that of a star. The gritty texture of a pear is caused by groups of sclereids that occur throughout the soft flesh of the fruit (figure 36.11c). Sclereids are also found in hard seed coats. Both of these tough, thick-walled cell types serve to strengthen the tissues in which they occur.

## Vascular tissue conducts water and nutrients throughout the plant

Vascular tissue, as mentioned earlier, includes two kinds of conducting tissues: (1) *xylem*, which conducts water and dissolved minerals, and (2) *phloem*, which conducts a solution of carbohydrates—mainly sucrose—used by plants for food. The phloem also transports hormones, amino acids, and other substances that are necessary for plant growth. Xylem and phloem differ in structure as well as in function.

### Xylem

Xylem, the principal water-conducting tissue of plants, usually contains a combination of *vessels*, which are continuous tubes formed from dead, hollow, cylindrical cells arranged end-to-end, and *tracheids*, which are dead cells that taper at the ends and overlap one another (figure 36.12). Primary xylem is derived from the procambium produced by the apical meristem. Secondary xylem is formed by the vascular cambium, a lateral meristem. Wood consists of accumulated secondary xylem.

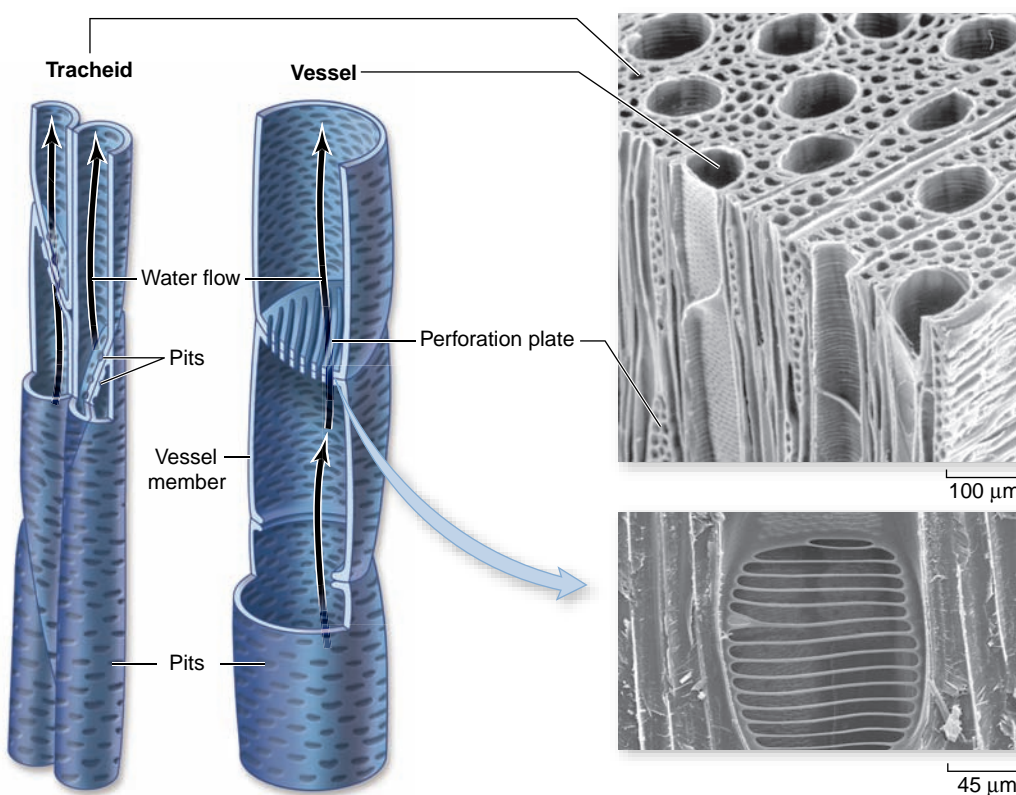

In some plants (but not flowering plants), tracheids are the only water-conducting cells present; water passes in an un-

broken stream through the xylem from the roots up through the shoot and into the leaves. When the water reaches the leaves, much of it diffuses in the form of water vapor into the intercellular spaces and out of the leaves into the surrounding air, mainly through the stomata. This diffusion of water vapor from a plant is known as **transpiration** (see chapter 38). In addition to conducting water, dissolved minerals, and inorganic ions such as nitrates and phosphates throughout the plant, xylem supplies support for the plant body.

Vessel members tend to be shorter and wider than tracheids. When viewed with a microscope, they resemble beverage cans with both ends removed. Both vessel members and tracheids have thick, lignified secondary walls and no living protoplasts at maturity. Lignin is produced by the cell and secreted to strengthen the cellulose cell walls before the protoplast dies, leaving only the cell wall.

Tracheids contain *pits*, which are small, mostly rounded-to-elliptical areas where no secondary wall material has been deposited. The pits of adjacent cells occur opposite one another; the continuous stream of water flows through these pits from tracheid to tracheid. In contrast, vessel members, which are joined end to end, may be almost completely open or may have bars or strips of wall material across the open ends (see figure 36.12). Vessels appear to conduct water more efficiently than do the overlapping strands of tracheids. We know this partly because vessel members have evolved from tracheids independently in several groups of plants, suggesting that they are favored by natural selection.

In addition to conducting cells, xylem typically includes fibers and parenchyma cells (ground tissue cells). It is probable that some types of fibers have evolved from tracheids, becoming specialized for strengthening rather than conducting. The parenchyma cells, which are usually produced in horizontal

**Figure 36.12 Comparison between tracheids and vessel members.** In tracheids, the water passes from cell to cell by means of pits. In vessel members, water moves by way of perforation plates (as seen in the photomicrograph in this figure). In gymnosperm wood, tracheids both conduct water and provide support; in most kinds of angiosperms, vessels are present in addition to tracheids. These two types of cells conduct water, and fibers provide additional support. The wood of red maple, *Acer rubrum*, contains both tracheids and vessels as seen in the electron micrographs in this figure.

rows called *rays* by special *ray initials* of the vascular cambium, function in lateral conduction and food storage. (An *initial* is another term for a meristematic cell. It divides to produce another initial and a cell that differentiates.)

In cross sections of woody stems and roots, the rays can be seen radiating out from the center of the xylem like the spokes of a wheel. Fibers are abundant in some kinds of wood, such as oak (*Quercus* spp.), and the wood is correspondingly dense and heavy. The arrangements of these and other kinds of cells in the xylem make it possible to identify most plant genera and many species from their wood alone.

Over 2000 years ago paper as we recognize it today was made in China by mashing herbaceous plants in water and separating out a thin layer of phloem fibers on a screen. Not until the third century of the common era did the secret of making paper make its way out of China. Today the ever-growing demand for paper is met by extracting xylem fibers from wood, including spruce, that is relatively soft, having fewer ray fibers than oak. The lignin-rich cell walls yield brown paper that is often bleached. In addition, tissues from many other plants have been developed as sources of paper, including kenaf and hemp. United States paper currency is 75% cotton and 25% flax.

### Phloem

Phloem, which is located toward the outer part of roots and stems, is the principal food-conducting tissue in vascular plants. If a plant is *girdled* (by removing a substantial strip of bark down to the vascular cambium around the entire circumference), the plant eventually dies from starvation of the roots.

Food conduction in phloem is carried out through two kinds of elongated cells: sieve cells and sieve-tube members. Gymnosperms, ferns, and horsetails have only sieve cells; most angiosperms have sieve-tube members. Both types of cells have clusters of pores known as sieve areas because the cell walls resemble sieves. Sieve areas are more abundant on the overlapping ends of the cells and connect the protoplasts of adjoining sieve cells and sieve-tube members. Both of these types of cells

are living, but most sieve cells and all sieve-tube members lack a nucleus at maturity.

In sieve-tube members, some sieve areas have larger pores and are called sieve plates (figure 36.13). Sieve-tube members occur end to end, forming longitudinal series called sieve tubes. Sieve cells are less specialized than sieve-tube members, and the pores in all of their sieve areas are roughly of the same diameter. Sieve-tube members are more specialized, and presumably, more efficient than sieve cells.

Each sieve-tube member is associated with an adjacent, specialized parenchyma cell known as a *companion cell*. Companion cells apparently carry out some of the metabolic functions needed to maintain the associated sieve-tube member. In angiosperms, a common initial cell divides asymmetrically to produce a sieve-tube member cell and its companion cell. Companion cells have all the components of normal parenchyma cells, including nuclei, and numerous plasmodesmata (cytoplasmic connections between adjacent cells) connect their cytoplasm with that of the associated sieve-tube members.

Sieve cells in nonflowering plants have albuminous cells that function as companion cells. Unlike a companion cell, an albuminous cell is not necessarily derived from the same mother cell as its associated sieve cell. Fibers and parenchyma cells are often abundant in phloem.

### Learning Outcomes Review 36.2

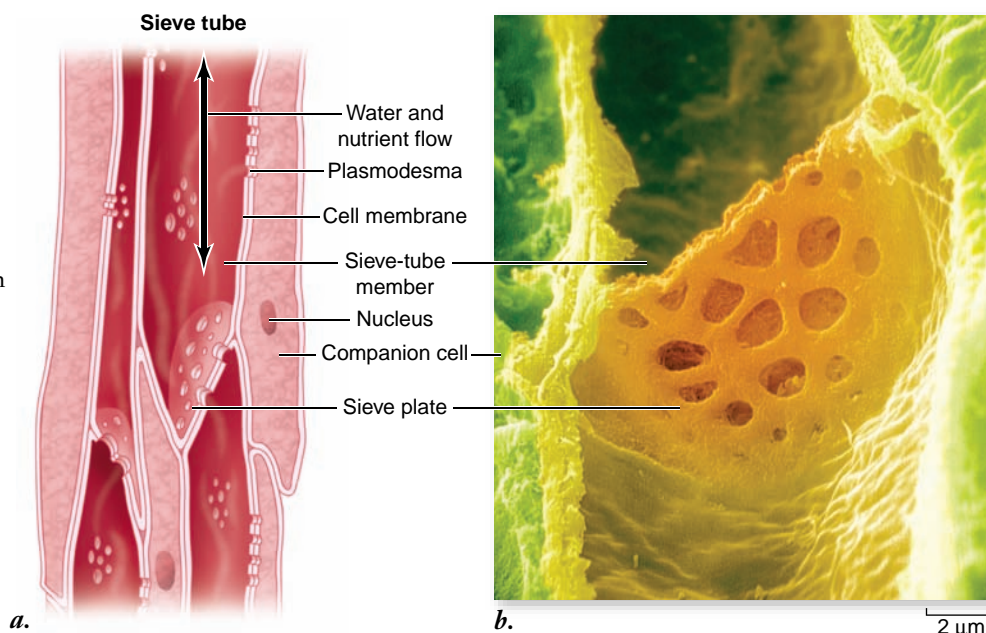

Dermal tissue protects a plant from its environment and contains specialized cells such as guard cells, trichomes, and root hairs. Ground tissue serves several functions, including storage (parenchyma cells), photosynthesis (specialized parenchyma called chlorenchyma), and structural support (collenchyma and sclerenchyma). Vascular tissue carries water through the xylem (primarily vessels) and nutrients through the phloem (primarily sieve-tube members).

- Contrast the structure and function of mature vessels and sieve-tube members.

**Figure 36.13 A sieve-tube member.**

*a.* Sieve-tube member cells are stacked, with sieve plates forming the connection. The narrow cell with the nucleus at the right of the sieve-tube member is a companion cell. This cell nourishes the sieve-tube members, which have plasma membranes, but no nuclei.  
*b.* Looking down into sieve plates in squash phloem reveals the perforations through which sucrose and hormones move.

## 36.3 Roots: Anchoring and Absorption Structures

### Learning Outcomes

1. Describe the four regions of a typical root.
2. Explain the function of root hairs.
3. Describe functions of modified roots.

Roots have a simpler pattern of organization and development than stems, and we will consider them first. Keep in mind, however, that roots evolved after shoots and are a major innovation for terrestrial living.

### Roots are adapted for growing underground and absorbing water and solutes

Four regions are commonly recognized in developing roots: the *root cap*, the *zone of cell division*, the *zone of elongation*, and the *zone of maturation* (figure 36.14). In these last three zones, the boundaries are not clearly defined.

When apical initials divide, daughter cells that end up on the tip end of the root become root cap cells. Cells that divide in the opposite direction pass through the three other zones before they finish differentiating. As you consider the different zones, visualize the tip of the root moving deeper into the soil, actively growing. This counters the static image of a root that diagrams and photos convey.

**Figure 36.14** Root structure. A root tip in corn, *Zea mays*.

### The root cap

The **root cap** has no equivalent in stems. It is composed of two types of cells: the inner *columella cells* (they look like columns), and the outer, lateral *root cap cells*, which are continuously replenished by the root apical meristem. In some plants with larger roots, the root cap is quite obvious. Its main function is to protect the delicate tissues behind it as growth extends the root through mostly abrasive soil particles.

Golgi bodies in the outer root cap cells secrete and release a slimy substance that passes through the cell walls to the outside. The root cap cells, which have an average life of less than a week, are constantly being replaced from the inside, forming a mucilaginous lubricant that eases the root through the soil. The slimy mass also provides a medium for the growth of beneficial nitrogen-fixing bacteria in the roots of plants such as legumes. A new root cap is produced when an existing one is artificially or accidentally removed from a root.

The root cap also functions in the perception of gravity. The columella cells are highly specialized, with the endoplasmic reticulum in the periphery and the nucleus located at either the middle or the top of the cell. They contain no large vacuoles. Columella cells contain *amyloplasts* (plastids with starch grains) that collect on the sides of cells facing the pull of gravity. When a potted plant is placed on its side, the amyloplasts drift or tumble down to the side nearest the source of gravity, and the root bends in that direction.

Lasers have been used to ablate (kill) individual columella cells in *Arabidopsis*. It turns out that only two columella cells are sufficient for gravity sensing! The precise nature of the gravitational response is unknown, but some evidence indicates that calcium ions in the amyloplasts influence the distribution of growth hormones (auxin in this case) in the cells. Multiple signaling mechanisms may exist, because bending has been observed in the absence of auxin. A current hypothesis is that an electrical signal moves from the columella cell to cells in the elongation zone (the region closest to the zone of cell division).

### The zone of cell division

The apical meristem is located in the center of the root tip in the area protected by the root cap. Most of the activity in this **zone of cell division** takes place toward the edges of the meristem, where the cells divide every 12 to 36 hours, often coordinately, reaching a peak of division once or twice a day.

Most of the cells are essentially cuboidal, with small vacuoles and proportionately large, centrally located nuclei. These rapidly dividing cells are daughter cells of the apical meristem. A group of cells in the center of the root apical meristem, termed the *quiescent center*, divide only very infrequently. The presence of the quiescent center makes sense if you think about a solid ball expanding—the outer surface would have to increase far more rapidly than the very center.

The apical meristem daughter cells soon subdivide into the three primary tissues previously discussed: protoderm, procambium, and ground meristem. Genes have been identified in the relatively simple root of *Arabidopsis* that regulate the patterning of these tissue systems. The patterning of these cells begins in this zone, but the anatomical and morphological expression of this patterning is not fully revealed until the cells reach the zone of maturation.

**Figure 36.15 Tissue-specific gene expression.** *a.* The *WEREWOLF* (*WER*) gene of *Arabidopsis* is expressed in some, but not all, epidermal cells and suppresses root hair development. The *wer* mutant is covered with root hairs because *WER* is needed to prevent root hair development in nonhair epidermal cells. Similarly, the *SCARECROW* (*SCR*) gene is necessary in ground cell differentiation (figure 36.16). A ground meristem cell undergoes an asymmetrical cell division that gives rise to two nested cylinders of cells from one if *SCR* is present. The outer cell layer becomes ground tissue and serves a storage function. The inner cell layer forms the endodermis, which regulates the intercellular flow of water and solutes into the vascular core of the root (see figure 36.5). The *scr* mutant, in contrast, forms a single layer of cells that have both endodermal and ground cell traits.

For example, the *WEREWOLF* (*WER*) gene is required for the patterning of the two root epidermal cell types, those with and those without root hairs (figure 36.15). Plants with the *wer* mutation have an excess of root hairs because *WER* is needed to prevent root hair development in nonhair epidermal cells. Similarly, the *SCARECROW* (*SCR*) gene is necessary in ground cell differentiation (figure 36.16). A ground meristem cell undergoes an asymmetrical cell division that gives rise to two nested cylinders of cells from one if *SCR* is present. The outer cell layer becomes ground tissue and serves a storage function. The inner cell layer forms the endodermis, which regulates the intercellular flow of water and solutes into the vascular core of the root (see figure 36.5). The *scr* mutant, in contrast, forms a single layer of cells that have both endodermal and ground cell traits.

*SCR* illustrates the importance of the orientation of cell division. If a cell's relative position changes because of a mistake in cell division or the ablation of another cell, the cell develops according to its new position. The fate of most plant cells is determined by their position relative to other cells.

### The zone of elongation

In the **zone of elongation**, roots lengthen because the cells produced by the primary meristems become several times longer than wide, and their width also increases slightly. The small vacuoles present merge and grow until they occupy 90% or more of the volume of each cell. No further increase in cell size occurs above the zone of elongation. The mature parts of the root, except for increasing in girth, remain stationary for the life of the plant.

### The zone of maturation

The cells that have elongated in the zone of elongation become differentiated into specific cell types in the **zone of maturation** (see figure 36.14). The cells of the root surface cylinder mature into *epidermal cells*, which have a very thin cuticle, and include both root hair and nonhair cells. Although the root hairs are not visible until this stage of development, their fate was established much earlier, as you saw with the expression patterns of *WER* (see figure 36.15).

**Figure 36.16 Scarecrow regulates asymmetrical cell division.** *a.* *SCR* is needed for an asymmetrical cell division leading to the differentiation of daughter cells into endodermal and ground cells. *b.* The *SCR* promoter was attached to a gene coding for a green fluorescent protein to find out exactly where in the wild type root *SCR* is expressed. *SCR* is only expressed in the endodermal cells, not the ground cells.

Root hairs can number over 37,000 cm<sup>2</sup> of root surface and many billions per plant; they greatly increase the surface area and therefore the absorptive capacity of the root. Symbiotic bacteria that fix atmospheric nitrogen into a form usable by legumes enter the plant via root hairs and “instruct” the plant to create a nitrogen-fixing nodule around it (see chapter 39).

Parenchyma cells are produced by the ground meristem immediately to the interior of the epidermis. This tissue, called the **cortex**, may be many cell layers wide and functions in food storage. As just described, the inner boundary of the cortex differentiates into a single-layered cylinder of **endodermis**, after an asymmetrical cell division regulated by *SCR* (see figures 36.16 and 36.17). Endodermal primary walls are impregnated with *suberin*, a fatty substance that is impervious to water. The suberin is produced in bands, called **Casparian strips**, that surround each

adjacent endodermal cell wall perpendicular to the root’s surface (see figure 36.17). These strips block transport between cells. The two surfaces that are parallel to the root surface are the only way into the vascular tissue of the root, and the plasma membranes control what passes through. Plants with a *scr* mutation lack this waterproof Casparian strip.

All the tissues interior to the endodermis are collectively referred to as the **stele**. Immediately adjacent and interior to the endodermis is a cylinder of parenchyma cells known as the **pericycle**. Pericycle cells divide, even after they mature. They can give rise to lateral (branch) roots or, in eudicots, to the two lateral meristems, the vascular cambium and the cork cambium.

The water-conducting cells of the primary xylem are differentiated as a solid core in the center of young eudicot roots. In a cross section of a eudicot root, the central core of primary xylem often is somewhat star-shaped, having from two to several radiating arms that point toward the pericycle (see figure 36.17). In monocot (and a few eudicot) roots, the primary xylem is in discrete vascular bundles arranged in a ring, which surrounds

**Figure 36.17** Cross sections of the zone of maturation of roots. Both monocot and eudicot roots have a Casparian strip as seen in the cross section of greenbriar (*Smilax*), a monocot, and buttercup (*Ranunculus*), a eudicot. The Casparian strip is a waterproofing band that forces water and minerals to pass through the plasma membranes, rather than through the spaces in the cell walls.

parenchyma cells, called *pith*, at the very center of the root (see figure 36.17). Primary phloem, composed of cells involved in food conduction, is differentiated in discrete groups of cells adjacent to the xylem in both eudicot and monocot roots.

In eudicots and other plants with secondary growth, part of the pericycle and the parenchyma cells between the phloem patches and the xylem become the root vascular cambium, which starts producing secondary xylem to the inside and secondary phloem to the outside. Eventually, the secondary tissues acquire the form of concentric cylinders. The primary phloem, cortex, and epidermis become crushed and are sloughed off as more secondary tissues are added.

In the pericycle of woody plants, the cork cambium contributes to the outer bark, which will be discussed in more detail when we look at stems. In the case of secondary growth in eudicot roots, everything outside the stele is lost and replaced with bark. Figure 36.18 summarizes the process of differentiation that occurs in plant tissue.

### Modified roots accomplish specialized functions

Most plants produce either a taproot system, characterized by a single large root with smaller branch roots, or a fibrous root system, composed of many smaller roots of similar diameter. Some plants, however, have intriguing root modifications with specific functions in addition to those of anchorage and absorption.

Not all roots are produced by preexisting roots. Any root that arises along a stem or in some place other than the root of the plant is called an **adventitious root**. For example, climbing plants such as ivy produce roots from their stems; these can anchor the stems to tree trunks or to a brick wall. Adventitious root formation in ivy depends on the developmental stage of the shoot. When the shoot enters the adult phase of development, it is no longer capable of initiating these roots. Below we investigate functions of modified roots.

**Prop roots.** Some monocots, such as corn, produce thick adventitious roots from the lower parts of the stem. These so-called prop roots grow down to the ground and brace

the plants against wind (figure 36.19a). Adventitious roots are common in wetland plants, allowing them to tolerate wet conditions.

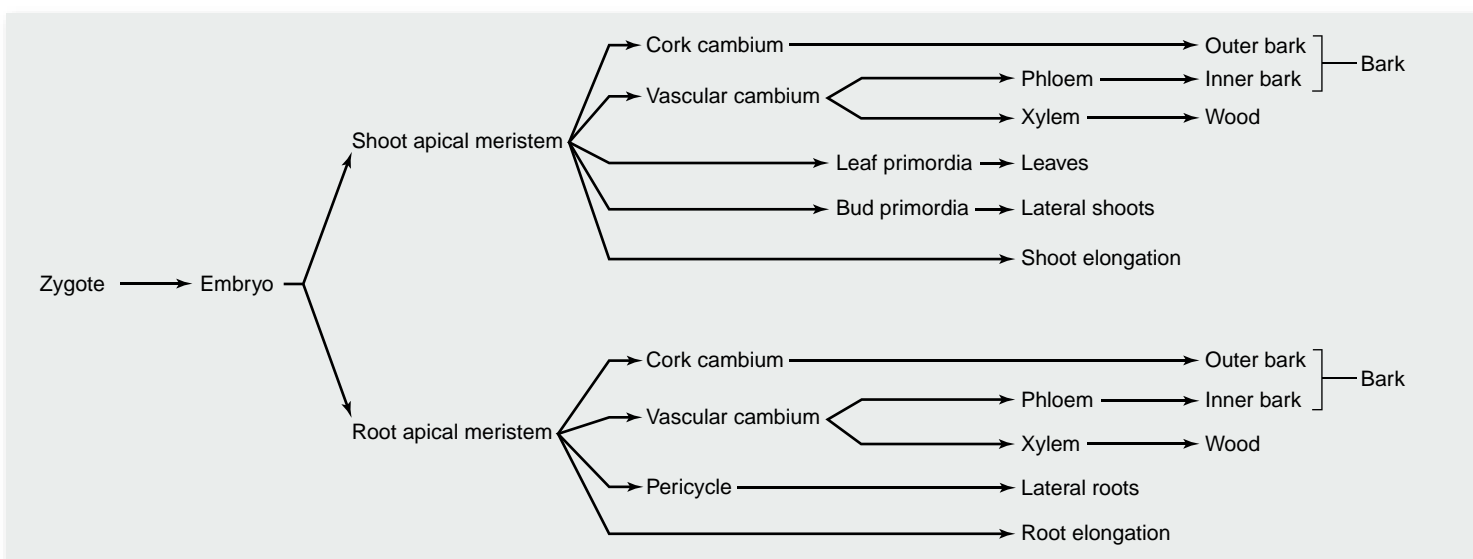

**Aerial roots.** Plants such as epiphytic orchids, which are attached to tree branches and grow unconnected to the ground (but are not parasites), have roots that extend into the air (figure 36.19b). Some aerial roots have an epidermis that is several cell layers thick, an adaptation to reduce water loss. These aerial roots may also be green and photosynthetic, as in the vanilla orchid (*Vanilla planifolia*).

**Pneumatophores.** Some plants that grow in swamps and other wet places may produce spongy outgrowths called *pneumatophores* from their underwater roots (figure 36.19c). The pneumatophores commonly extend several centimeters above water, facilitating oxygen uptake in the roots beneath (figure 36.19c).

**Contractile roots.** The roots from the bulbs of lilies and from several other plants, such as dandelions, contract by spiraling to pull the plant a little deeper into the soil each year, until they reach an area of relatively stable temperature. The roots may contract to one-third their original length as they spiral like a corkscrew due to cellular thickening and constricting.

**Parasitic roots.** The stems of certain plants that lack chlorophyll, such as dodder (*Cuscuta* spp.), produce peglike roots called *haustoria* that penetrate the host plants around which they are twined. The haustoria establish contact with the conducting tissues of the host and effectively parasitize their host. Dodder not only weakens plants but can also spread disease when it grows and attaches to several plants.

**Food storage roots.** The xylem of branch roots of sweet potatoes and similar plants produce at intervals many extra parenchyma cells that store large quantities of carbohydrates. Carrots, beets, parsnips, radishes, and turnips have combinations of stem and root that also function in food storage. Cross sections of these roots reveal multiple rings of secondary growth.

**Figure 36.19** Five types of modified roots. *a.* Maize (corn) prop roots originate from the stem and keep the plant upright. *b.* Epiphytic orchids attach to trees far above the tropical soil. Their roots are adapted to obtain water from the air rather than the soil. *c.* Pneumatophores (*foreground*) are spongy outgrowths from the roots below. *d.* A water storage root weighing over 25 kg (60 pounds). *e.* Buttress roots of a tropical fig tree.

**Water storage roots.** Some members of the pumpkin family (Cucurbitaceae), especially those that grow in arid regions, may produce water storage roots weighing 50 kg or more (figure 36.19*d*).

**Buttress roots.** Certain species of fig and other tropical trees produce huge buttress roots toward the base of the trunk, which provide considerable stability (figure 36.19*e*).

### Learning Outcomes Review 36.3

The root cap protects the root apical meristem and helps to sense gravity. New cells formed in the zone of cell division grow in length in the zone of elongation. Cells differentiate in the zone of maturation, and root hairs appear here. Root hairs greatly increase the absorptive surface area of roots. Modified roots allow plants to carry out many additional functions, including bracing, aeration, and storage of nutrients and water.

- Why do you suppose root hairs are not formed in the region of elongation?

The supporting structure of a vascular plant's shoot system is the mass of stems that extend from the root system below ground into the air, often reaching great height. Stiff stems capable of rising upward against gravity are an ancient adaptation that allowed plants to move into terrestrial ecosystems.

### Stems carry leaves and flowers and support the plant's weight

Like roots, stems contain the three types of plant tissue. Stems also undergo growth from cell division in apical and lateral meristems. The stem may be thought of as an axis from which other stems or organs grow. The shoot apical meristems are capable of producing these new stems and organs.

#### External stem structure

The shoot apical meristem initiates stem tissue and intermittently produces bulges (primordia) that are capable of developing into leaves, other shoots, or even flowers (figure 36.20).

## 36.4 Stems: Support for Above-Ground Organs

### Learning Outcomes

1. List the potential products of an axillary bud.
2. Differentiate between cross sections of a monocot stem and a eudicot stem.
3. Describe three functions of modified stems.

**Figure 36.20** A shoot apex. Scanning electron micrograph of the apical meristem of wheat (*Triticum*).

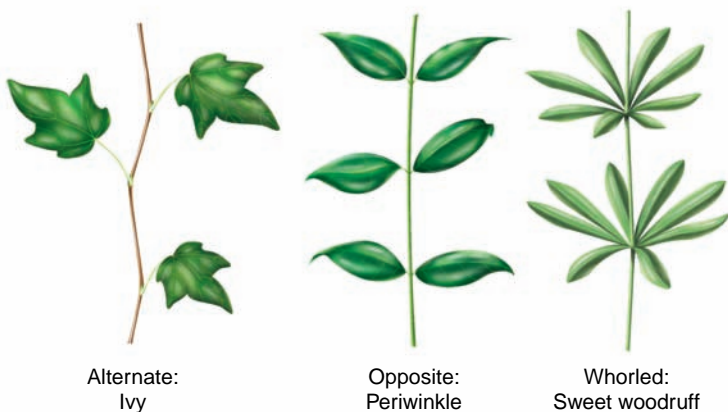

Leaves may be arranged in a spiral around the stem, or they may be in pairs opposite or alternate to one another; they also may occur in whorls (circles) of three or more (figure 36.21). The spiral arrangement is the most common, and for reasons still not understood, sequential leaves tend to be placed  $137.5^\circ$  apart. This angle relates to the golden mean, a mathematical ratio found in nature. The angle of coiling in shells of some gastropods is the same. The golden mean has been used in classical architecture (the Greek Parthenon wall dimensions), and even in modern art (for example, in paintings by Mondrian). In plants, this pattern of leaf arrangement, called **phyllotaxy**, may optimize the exposure of leaves to the sun.

The region or area of leaf attachment to the stem is called a **node**; the area of stem between two nodes is called an **internode**. A leaf usually has a flattened blade and sometimes a petiole (stalk). The angle between a leaf's petiole (or blade) and the stem is called an **axil**. An **axillary bud** is produced in each axil. This bud is a product of the primary shoot apical meristem, and it is itself a shoot apical meristem. Axillary buds frequently develop into branches with leaves or may form flowers.

Neither monocots nor herbaceous eudicot stems produce a cork cambium. The stems in these plants are usually green and photosynthetic, with at least the outer cells of the cortex containing chloroplasts. Herbaceous stems commonly have stomata, and may have various types of trichomes (hairs).

Woody stems can persist over a number of years and develop distinctive markings in addition to the original organs that form (figure 36.22). Terminal buds usually extend the length of the shoot system during the growing season. Some buds, such as those of geraniums, are unprotected, but most buds of woody plants have protective winter bud scales that drop off, leaving tiny bud scale scars as the buds expand.

Some twigs have tiny scars of a different origin. A pair of butterfly-like appendages called *stipules* (part of the leaf) develop at the base of some leaves. The stipules can fall off and leave stipule scars. When the leaves of deciduous trees drop in the fall, they leave leaf scars with tiny bundle scars, marking where vascular connections were. The shapes, sizes, and other features of leaf scars can be distinctive enough to identify deciduous plants in winter, when they lack leaves (see figure 36.22).

**Figure 36.21 Types of leaf arrangements.** The three common types of leaf arrangements are alternate, opposite, and whorled.

**Figure 36.22 A woody twig.** *a.* In summer. *b.* In winter.

### Internal stem structure

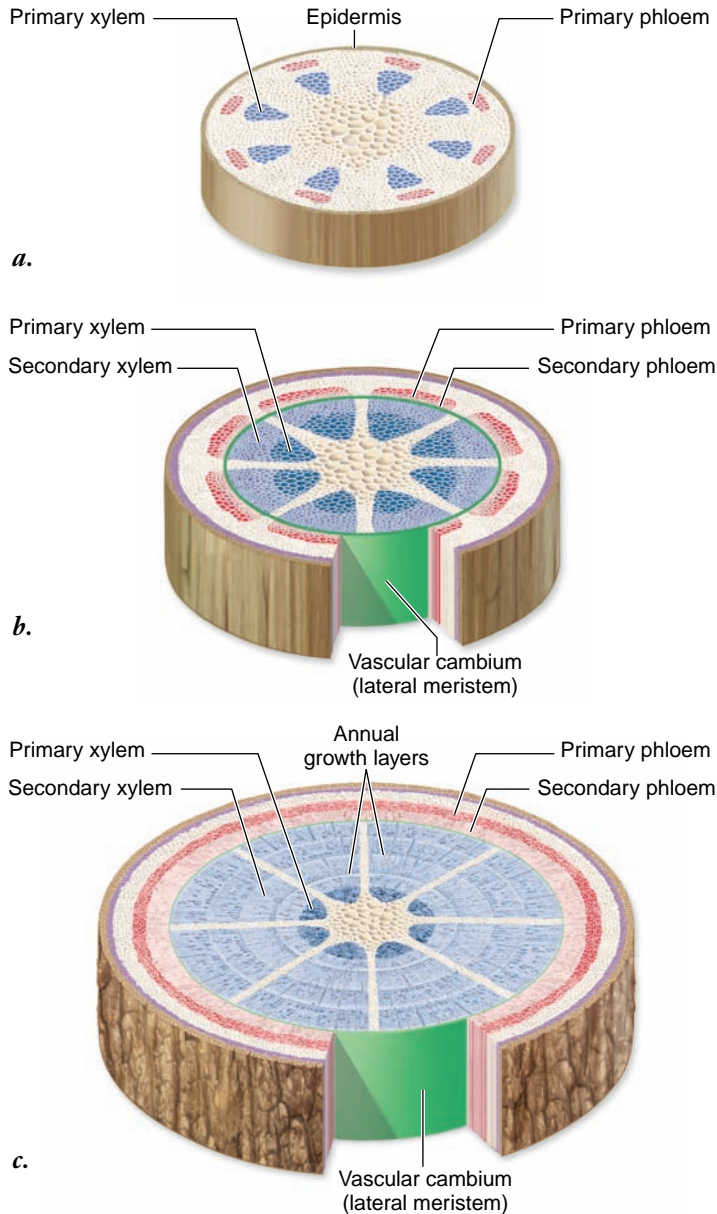

A major distinguishing feature between monocot and eudicot stems is the organization of the vascular tissue system (figure 36.23). Most monocot vascular bundles are scattered throughout the ground tissue system, whereas eudicot vascular tissue is arranged in a ring with internal ground tissue (*pith*) and external ground tissues (*cortex*). The arrangement of vascular tissue is directly related to the ability of the stem to undergo

**Figure 36.23 Stems.** Transverse sections of a young stem in (a) a eudicot, the common sunflower (*Helianthus annuus*), in which the vascular bundles are arranged around the outside of the stem; and (b) a monocot, corn (*Zea mays*), with characteristically scattered vascular bundles.

secondary growth. In eudicots, a vascular cambium may develop between the primary xylem and primary phloem (figure 36.24). In many ways, this is a connect-the-dots game in which the vascular cambium connects the ring of primary vascular bundles. There is no logical way to connect primary monocot vascular tissue that would allow a uniform increase in girth. Lacking a vascular cambium, therefore, monocots do not have secondary growth.

Rings in the stump of a tree reveal annual patterns of vascular cambium growth; cell size varies, depending on growth

**Figure 36.24 Secondary growth.** *a.* Before secondary growth begins in eudicot stems, primary tissues continue to elongate as the apical meristems produce primary growth. *b.* As secondary growth begins, the vascular cambium produces secondary tissues, and the stem's diameter increases. *c.* In this four-year-old stem, the secondary tissues continue to widen, and the trunk has become thick and woody. Note that the vascular cambium forms a cylinder that runs axially (up and down) in the roots and shoots that have them.

**Figure 36.25 Tree stump.** The vascular cambium produces rings of xylem (sapwood and nonconducting heartwood) and phloem, and the cork cambium produces the cork.

conditions (figure 36.25). Large cells form under favorable conditions such as abundant rainfalls. Rings of smaller cells mark the seasons where growth is limited. In woody eudicots and gymnosperms, a second cambium, the cork cambium, arises in the outer cortex (occasionally in the epidermis or phloem); it produces boxlike cork cells to the outside and also may produce parenchyma-like phelloderm cells to the inside (figure 36.26).

The cork cambium, cork, and phelloderm are collectively referred to as the *periderm* (see figure 36.26). Cork tissues, the cells of which become impregnated with water-repellent suberin shortly after they are formed and which then die, constitute the *outer bark*. The cork tissue cuts off water and food to the epidermis, which dies and sloughs off. In young stems, gas exchange between stem tissues and the air takes place through stomata, but as the cork cambium produces cork, it also produces patches of unsuberized cells beneath the stomata. These unsuberized cells, which permit gas exchange to continue, are called *lenticels* (figure 36.27).

### Modified stems carry out vegetative propagation and store nutrients

Although most stems grow erect, some have modifications that serve special purposes, including natural vegetative propagation. In fact, the widespread artificial vegetative propagation of plants,

**Figure 36.26 Section of periderm.** An early stage in the development of periderm in cottonwood, *Populus* sp.

**Figure 36.27 Lenticels.** *a.* Lenticels, the numerous small, pale, raised areas shown here on cherry tree bark (*Prunus cerasifera*), allow gas exchange between the external atmosphere and the living tissues immediately beneath the bark of woody plants. *b.* Transverse section through a lenticel in a stem of elderberry, *Sambucus canadensis*.

both commercial and private, frequently involves cutting modified stems into segments, which are then planted, producing new plants. As you become acquainted with the following modified stems, keep in mind that stems have leaves at nodes, with internodes between the nodes, and buds in the axils of the leaves, whereas roots have no leaves, nodes, or axillary buds.

**Bulbs.** Onions, lilies, and tulips have swollen underground stems that are really large buds with adventitious roots at the base (figure 36.28*a*). Most of a bulb consists of fleshy leaves attached to a small, knoblike stem. For most bulbs,

next year's foliage comes from the tip of the shoot apex, protected by storage leaves from the previous year

**Corms.** Crocuses, gladioluses, and other popular garden plants produce corms that superficially resemble bulbs. Cutting a corm in half, however, reveals no fleshy leaves. Instead, almost all of a corm consists of stem, with a few papery, brown nonfunctional leaves on the outside, and adventitious roots below.

**Rhizomes.** Perennial grasses, ferns, bearded iris, and many other plants produce rhizomes, which typically are horizontal stems that grow underground, often close to the surface (figure 36.28*b*). Each node has an inconspicuous scalelike leaf with an axillary bud; much larger photosynthetic leaves may be produced at the rhizome tip. Adventitious roots are produced throughout the length of the rhizome, mainly on the lower surface.

**Runners and stolons.** Strawberry plants produce horizontal stems with long internodes that unlike rhizomes, usually grow along the surface of the ground. Several runners may radiate out from a single plant (figure 36.28*c*). Some biologists use the term *stolon* synonymously with runner; others reserve the term *stolon* for a stem with long internodes (but no roots) that grows underground, as seen in potato plants (*Solanum* sp.). A potato itself, however, is another type of modified stem—a tuber.

**Tubers.** In potato plants, carbohydrates may accumulate at the tips of rhizomes, which swell, becoming tubers; the rhizomes die after the tubers mature (figure 36.28*d*). The “eyes” of a potato are axillary buds formed in the axils of scalelike leaves. These leaves, which are present when the potato is starting to form, soon drop off; the tiny ridge adjacent to each “eye” of a mature potato is a leaf scar.

**Figure 36.28**  
**Types of modified stems.** *a.* Bulb.  
*b.* Adventitious roots.  
*c.* Runner. *d.* Stolon.  
*e.* Tendril.  
*f.* Cladophyll.

*a.*

*b.*

*c.*

*d.*

*e.*

*f.*

Crop potatoes are not grown from seeds produced by potato flowers, but propagated vegetatively from “seed potatoes.” A tuber is cut up into pieces that contain at least one eye, and these pieces are planted. The eye then grows into a new potato plant.

**Tendrils.** Many climbing plants, such as grapes and English ivy, produce modified stems known as tendrils that twine around supports and aid in climbing (figure 36.28e). Some other tendrils, such as those of peas and pumpkins, are actually modified leaves or leaflets.

**Cladophylls.** Cacti and several other plants produce flattened, photosynthetic stems called cladophylls that resemble leaves (figure 36.28f). In cacti, the real leaves are modified as spines (see the following section).

### Learning Outcomes Review 36.4

Shoots grow from apical and lateral meristems. Auxillary buds may develop into branches, flowers, or leaves. In monocots, vascular tissue is evenly spaced throughout the stem ground tissue; in eudicots, vascular tissue is arranged in a ring with inner and outer ground tissues. Some plants produce modified stems for support, vegetative reproduction, or nutrient storage.

- Why don't stems produce the equivalent of root caps?

## 36.5 Leaves: Photosynthetic Organs

### Learning Outcomes

1. Distinguish between a simple and a compound leaf.
2. Compare the mesophyll of a monocot leaf with that of a eudicot leaf.

Leaves, which are initiated as primordia by the apical meristems (see figure 36.20), are vital to life as we know it because they are the principal sites of photosynthesis on land, providing the base of the food chain. Leaves expand by cell enlargement and cell division. Like arms and legs in humans, they are determinate structures, which means their growth stops at maturity. Because leaves are crucial to a plant, features such as their arrangement, form, size, and internal structure are highly significant and can differ greatly. Different patterns have adaptive value in different environments.

Leaves are an extension of the shoot apical meristem and stem development. When they first emerge as primordia, they are not committed to being leaves. Experiments in which very young leaf primordia are isolated from fern and coleus plants and grown in culture have demonstrated this feature: If the primordia are young enough, they will form an entire shoot rather than a leaf. The positioning of leaf primordia and the initial cell divisions occur before those cells are committed to the leaf developmental pathway.

## External leaf structure reflects vascular morphology

Leaves fall into two different morphological groups, which may reflect differences in evolutionary origin. A **microphyll** is a leaf with one vein branching from the vascular cylinder of the stem and not extending the full length of the leaf; microphylls are mostly small and are associated primarily with the phylum Lycopphyta (see chapter 30). Most plants have leaves called **megaphylls**, which have several to many veins.

Most eudicot leaves have a flattened **blade** and a slender stalk, the **petiole**. The flattening of the leaf blade reflects a shift from radial symmetry to dorsal–ventral (top–bottom) symmetry. Leaf flattening increases the photosynthetic surface. Plant biologists are just beginning to understand how this shift occurs by analyzing mutants lacking distinct tops and bottoms (figure 36.29).

In addition, leaves may have a pair of **stipules**, which are outgrowths at the base of the petiole. The stipules, which may be leaf-like or modified as spines (as in the black locust, *Robinia pseudo-acacia*) or glands (as in the purple-leaf plum tree *Prunus cerasifera*), vary considerably in size from the microscopic to almost half the size of the leaf blade. Grasses and other monocot leaves usually lack a petiole; these leaves tend to sheathe the stem toward the base.

**Veins** (a term used for the vascular bundles in leaves) consist of both xylem and phloem and are distributed

**Figure 36.29** Establishing top and bottom in leaves.

Several genes, including *PHABULOSA* (*PHB*), *PHAVOLUTA* (*PHV*), *KANADI* (*KAN*), and *YABBY* (*YAB*) make a flattened *Arabidopsis* leaf with a distinct upper and lower surface. *PHB* and *PHV* RNAs are restricted to the top; *KAN* and *YAB* are expressed in the bottom cells of a leaf. *PHB* and *KAN* have an antagonistic relationship, restricting expression of each to separate leaf regions. *KAN* leads to *YABBY* expression and lower leaf development. Without *KAN*, both sides of the leaf develop like the top portion.

a.

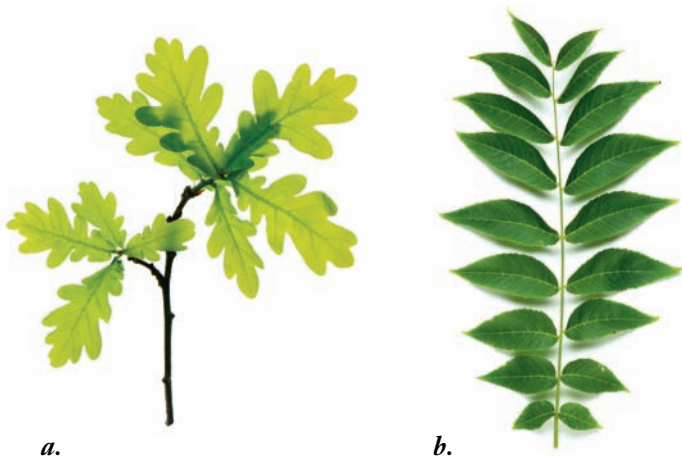

b.

**Figure 36.30 Eudicot and monocot leaves.** *a.* The leaves of eudicots, such as this African violet relative from Sri Lanka, have netted, or reticulate, veins. *b.* Those of monocots, such as this cabbage palmetto, have parallel veins. The eudicot leaf has been cleared with chemicals and stained with a red dye to make the veins show more clearly.

throughout the leaf blades. The main veins are parallel in most monocot leaves; the veins of eudicots, on the other hand, form an often intricate network (figure 36.30).

Leaf blades come in a variety of forms, from oval to deeply lobed to having separate leaflets. In **simple leaves** (figure 36.31*a*), such as those of lilacs or birch trees, the blades are undivided, but simple leaves may have teeth, indentations, or lobes of various sizes, as in the leaves of maples and oaks.

In **compound leaves** (figure 36.31*b*), such as those of ashes, box elders, and walnuts, the blade is divided into *leaflets*. The relationship between the development of compound and simple leaves is an open question. Two explanations are being debated: (1) A compound leaf is a highly lobed simple leaf, or (2) a compound leaf utilizes a shoot development program, and each leaflet was once a leaf. To address this question, researchers are using single mutations that are known to convert compound leaves to simple leaves (figure 36.32).

**Figure 36.31 Simple versus compound leaves.** *a.* A simple leaf, its margin deeply lobed, from the oak tree (*Quercus robur*). *b.* A pinnately compound leaf, from a black walnut (*Juglans nigra*). A compound leaf is associated with a single lateral bud, located where the petiole is attached to the stem.

## SCIENTIFIC THINKING

**Hypothesis:** The gene UNIFOLIATA (UNI) is necessary for compound leaf development in garden pea, *Pisum sativum*.

**Prediction:** Developing leaf primordia of a wild-type pea plant will express the UNI gene while uni mutant plants will not express the gene.

**Test:** Cut thin sections of wild-type and mutant pea shoots and place them on a microscope slide. Test for the presence of UNI RNA using a color-labeled, single-stranded DNA probe that will hybridize (bind) only the UNI RNA. View the labeled sections under a microscope.

**Result:** UNI RNA was found in the wild-type and also in mutant leaves, but at lower levels.

**Conclusion:** The mutant uni gene is transcribed but at lower levels than the wild-type gene. Thus the prediction was incorrect.

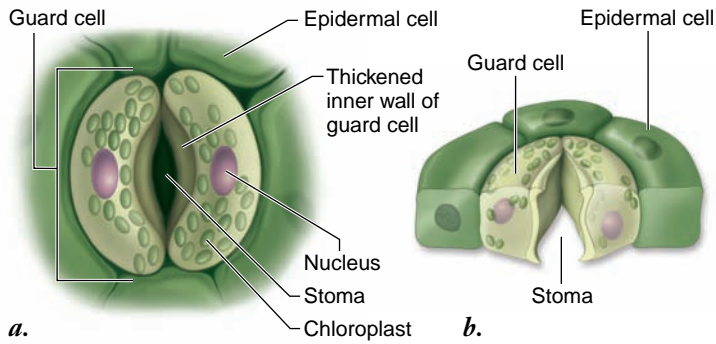

**Further Experiments:** Although the uni gene is expressed, compound leaves do not develop. Refine the hypothesis and propose an experiment to test the revised hypothesis.

**Figure 36.32 Genetic regulation of leaf development.**

## Internal leaf structure regulates gas exchange and evaporation

The entire surface of a leaf is covered by a transparent epidermis, and most of these epidermal cells have no chloroplasts. As described earlier, the epidermis has a waxy cuticle, and different types of glands and trichomes may be present. Also, the lower epidermis (and occasionally the upper epidermis) of most leaves contains numerous slitlike or mouth-shaped stomata flanked by guard cells (figure 36.33).

The tissue between the upper and lower epidermis is called **mesophyll**. Mesophyll is interspersed with veins of various sizes.

**Figure 36.33 A stoma.** *a.* Surface view. *b.* View in cross section.

Most eudicot leaves have two distinct types of mesophyll. Closest to the upper epidermis are one to several (usually two) rows of tightly packed, barrel-shaped to cylindrical chlorenchyma cells (parenchyma with chloroplasts) that constitute the palisade mesophyll (figure 36.34). Some plants, including species of *Eucalyptus*, have leaves that hang down, rather than extend horizontally. They have palisade mesophyll on both sides of the leaf.

Nearly all eudicot leaves have loosely arranged spongy mesophyll cells between the palisade mesophyll and the lower epidermis, with many air spaces throughout the tissue. The interconnected intercellular spaces, along with the stomata, function in gas exchange and the passage of water vapor from the leaves.

The mesophyll of monocot leaves often is not differentiated into palisade and spongy layers, and there is often little distinction between the upper and lower epidermis. Instead, cells surrounding the vascular tissue are distinctive and are the site of carbon fixation. This anatomical difference often correlates with a modified photosynthetic pathway,  $C_4$  photosynthesis, that maximizes the amount of  $CO_2$  relative to  $O_2$  to reduce energy loss through photorespiration (see chapter 9). The anatomy of a leaf directly relates to its juggling act of balancing

water loss, gas exchange, and transport of photosynthetic products to the rest of the plant.

## Modified leaves are highly versatile organs

As plants colonized a wide variety of environments, from deserts to lakes to tropical rain forests, plant organ modifications arose that would adapt the plants to their specific habitats. Leaves, in particular, have evolved some remarkable adaptations. A brief discussion of a few of these modifications follows:

**Floral leaves (bracts).** Poinsettias and dogwoods have relatively inconspicuous, small, greenish yellow flowers. However, both plants produce large modified leaves called *bracts* (mostly colored red in poinsettias and white or pink in dogwoods). These bracts surround the white flowers and perform the same function as showy petals. In other plants, however, bracts can be quite small and inconspicuous.

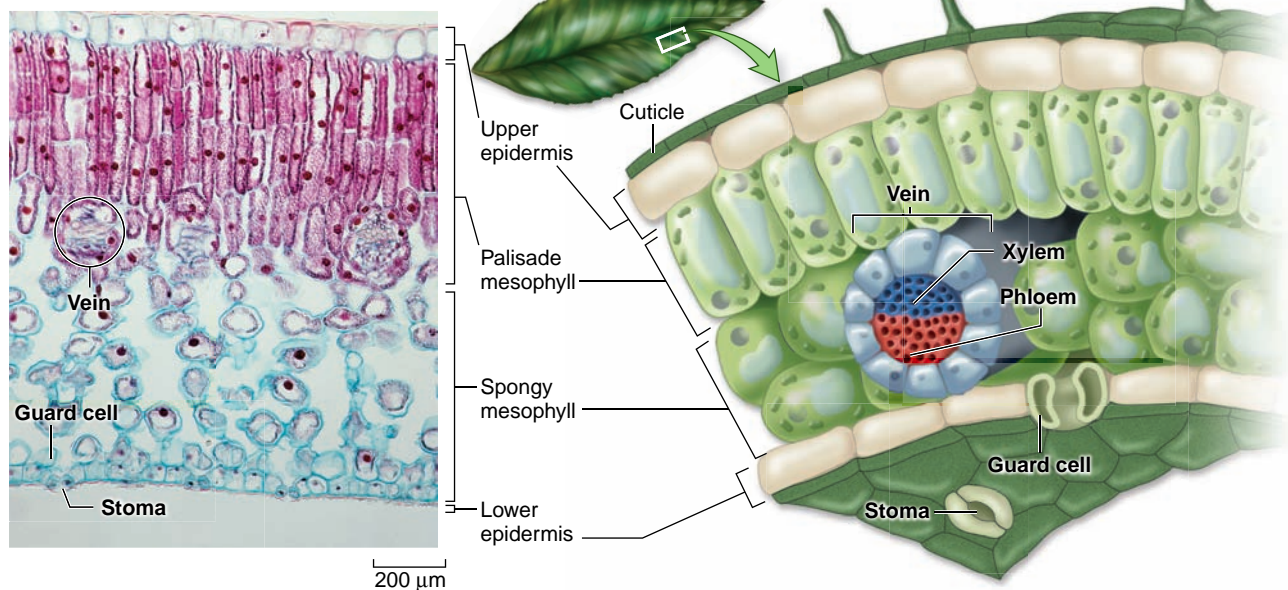

**Spines.** The leaves of many cacti and other plants are modified as *spines* (see figure 36.28f). In cacti, having less leaf surface reduces water loss, and the sharp spines also may deter predators. Spines should not be confused with *thorns*, such as those on the honey locust (*Gleditsia triacanthos*), which are modified stems, or with the prickles on raspberries, which are simply outgrowths from the epidermis or the cortex just beneath it.

**Reproductive leaves.** Several plants, notably *Kalanchoë*, produce tiny but complete plantlets along their margins. Each plantlet, when separated from the leaf, is capable of growing independently into a full-sized plant. The walking fern (*Asplenium rhizophyllum*) produces new plantlets at the tips of its fronds. Although many species can regenerate a whole plant from isolated leaf tissue, this in vivo regeneration is found among just a few species.

**Window leaves.** Several genera of plants growing in arid regions produce succulent, cone-shaped leaves with transparent tips. The leaves often become mostly buried

## Figure 36.34

**A leaf in cross section.** Transection of a leaf showing the arrangement of palisade and spongy mesophyll, a vascular bundle or vein, and the epidermis with paired guard cells flanking the stoma.

in sand blown by the wind, but the transparent tips, which have a thick epidermis and cuticle, admit light to the hollow interiors. This strategy allows photosynthesis to take place beneath the surface of the ground.

**Shade leaves.** Leaves produced in the shade, where they receive little sunlight, tend to be larger in surface area, but thinner and with less mesophyll than leaves on the same tree receiving more direct light. This plasticity in development is remarkable. Environmental signals can have a major effect on development.

**Insectivorous leaves.** Almost 200 species of flowering plants are known to have leaves that trap insects; some plants digest the insects' soft parts. Plants with insectivorous leaves often grow in acid swamps that are deficient in needed elements or contain elements in forms not readily available to the plants; this inhibits the plants' capacities to maintain metabolic processes needed for their growth and reproduction. Their needs are met, however, by the supplementary absorption of nutrients from the animal kingdom.

Pitcher plants (for example, *Sarracenia*, *Darlingtonia*, or *Nepenthes* spp.) have cone-shaped leaves in which rainwater can accumulate. The insides of the leaves are very smooth, but stiff, downward-pointing hairs line the rim. An insect falling into such a leaf finds it very difficult to escape and eventually drowns. The leaf absorbs the nutrients released when bacteria, and in most species the plant's own digestive enzymes, decompose the insect bodies. Other plants, such as sundews (*Drosera*), have

glands that secrete sticky mucilage that traps insects, which are then digested by enzymes.

The Venus flytrap (*Dionaea muscipula*) produces leaves that look hinged at the midrib. When tiny trigger hairs on the leaf blade are stimulated by a moving insect, the two halves of the leaf snap shut, and digestive enzymes break down the soft parts of the trapped insect into nutrients that can be absorbed through the leaf surface. Nitrogen is the most common nutrient needed. Curiously, the Venus flytrap cannot survive in a nitrogen-rich environment, perhaps as a result of a biochemical trade-off during the intricate evolutionary process that developed its ability to capture and digest insects.

### Learning Outcomes Review 36.5

Leaves come in a range of forms. A simple leaf is undivided, whereas a compound leaf has a number of separate leaflets. Pinnate leaves have a central rib like a feather; palmate leaves have several ribs radiating from a central point, like the palm of the hand. Monocots typically produce leaves with parallel veins, while those of eudicots are netted. Mesophyll cells carry out photosynthesis; in monocots, mesophyll is undifferentiated, whereas in eudicots it is divided into palisade and spongy mesophyll. Leaves may be modified for reproduction, protection, water conservation, uptake of nutrients, and even as traps for insects.

- Why would a plant with vertically oriented leaves produce palisade, but not spongy mesophyll cells?

## Chapter Review

### 36.1 Organization of the Plant Body: An Overview

#### **Vascular plants have roots and shoots.**

The root system is primarily below ground; roots anchor the plant and take up water and minerals. The shoot system is above ground and provides support for leaves and flowers.

#### **Roots and shoots are composed of three types of tissues.**

The three types of tissues are dermal tissue, ground tissue, and vascular tissue.

#### **Meristems elaborate the body plan throughout the plant's life.**

Apical meristems are located on the tips of stems and near the tips of roots. Lateral meristems are found in plants that exhibit secondary growth. They add to the diameter of a stem or root.

### 36.2 Plant Tissues

#### **Dermal tissue forms a protective interface with the environment.**

Dermal tissue is primarily the epidermis, which is usually one cell thick and is covered with a fatty or waxy cuticle to retard water loss.

Guard cells in the epidermis control water loss through stomata. Root hairs are epidermal cell structures that help increase the absorptive area of roots.

#### **Ground tissue cells perform many functions, including storage, photosynthesis, and support.**

Ground tissue is mainly composed of parenchyma cells, which function in storage, photosynthesis, and secretion. Collenchyma cells provide flexible support, and sclerenchyma cells provide rigid support.

#### **Vascular tissue conducts water and nutrients throughout the plant.**

Xylem tissue conducts water through dead cells called tracheids and vessel elements.

Phloem tissue conducts nutrients such as dissolved sucrose through living cells called sieve-tube members and sieve cells.

### 36.3 Roots: Anchoring and Absorption Structures

Roots evolved after shoots and are a major innovation for terrestrial living.

#### **Roots are adapted for growing underground and absorbing water and solutes.**

Developing roots exhibit four regions: (1) the root cap, which protects the root; (2) the zone of cell division, which contains the apical meristem; (3) the zone of elongation, which extends the root through the soil; and (4) the zone of maturation, in which cells become differentiated.

### **Modified roots accomplish specialized functions.**

Most plants produce either a taproot system containing a single large root with smaller branch roots, or a fibrous root system composed of many small roots.

Adventitious roots may be modified for support, stability, acquisition of oxygen, storage of water and food, or parasitism of a host plant.

## **36.4 Stems: Support for Above-Ground Organs**

### **Stems carry leaves and flowers and support the plant's weight.**

Leaves are attached to stems at nodes. The axil is the area between the leaf and stem, and an axillary bud develops in axils of eudicots.

The vascular bundles in stems of monocots are randomly scattered, whereas in eudicots the bundles are arranged in a ring.

Vascular cambium develops between the inner xylem and the outer phloem, allowing for secondary growth.

### **Modified stems carry out vegetative propagation and store nutrients.**

Bulbs, corms, rhizomes, runners and stolons, tubers, tendrils, and cladophylls are examples of modified stems. The tubers of potatoes are both a food source and a means of propagating new plants.

## **36.5 Leaves: Photosynthetic Organs**

Leaves are the principle sites of photosynthesis. Leaf features such as their arrangement, form, size, and internal structure can be highly variable across environments.

### **External leaf structure reflects vascular morphology.**

Vascular bundles are parallel in monocots, but form a network in eudicots. The leaves of most eudicots have a flattened blade and a slender petiole; monocots usually do not have a petiole.

Leaf blades may be simple or compound (divided into leaflets). Leaves may also be pinnate (with a central rib, like a feather) or palmate (with ribs radiating from a central point).

### **Internal leaf structure regulates gas exchange and evaporation.**

The tissues of the leaf include the epidermis with guard cells, vascular tissue, and mesophyll in which photosynthesis takes place.

In eudicot leaves with a horizontal orientation, the mesophyll is partitioned into palisade cells near the upper surface and spongy cells near the lower surface.

The mesophyll of monocot leaves is often not differentiated.

### **Modified leaves are highly versatile organs.**

Leaves are highly variable in form and are adapted to serve many different functions. Leaves may be modified for reproduction, protection, storage, mineral uptake, or even as insect traps in carnivorous plants.

## **Review Questions**

### **UNDERSTAND**

- Which cells lack living protoplasts at maturity?
  - Parenchyma
  - Companion
  - Collenchyma
  - Sclerenchyma
- The food-conducting cells in an oak tree are called
  - tracheids.
  - vessels.
  - companion cells.
  - sieve-tube members.
- Root hairs form in the zone of
  - cell division.
  - elongation.
  - maturation.
  - more than one of the above
- Roots differ from stems because roots lack
  - vessel elements.
  - nodes.
  - an epidermis.
  - ground tissue.
- A plant that produces two axillary buds at a node is said to have what type of leaf arrangement?
  - Opposite
  - Alternate
  - Whorled
  - Palmate
- Unlike eudicot stems, monocot stems lack
  - vascular bundles.
  - parenchyma.
  - pith.
  - epidermis.
- The function of guard cells is to
  - allow carbon dioxide uptake.
  - repel insects and other herbivores.
  - support leaf tissue.
  - allow water uptake.
- Palisade and spongy parenchyma are typically found in the mesophyll of
  - monocots.
  - eudicots.
  - monocots and eudicots.
  - neither monocots or eudicots
- In vascular plants, one difference between root and shoot systems is that:
  - root systems cannot undergo secondary growth.
  - root systems undergo secondary growth, but do not form bark.
  - root systems contain pronounced zones of cell elongation, whereas shoot systems do not.
  - root systems can store food reserves, whereas stem structures do not.
- Which of the following statements is not true of the stems of vascular plants?
  - Stems are composed of repeating segments, including nodes and internodes.
  - Primary growth only occurs at the shoot apical meristem.
  - Vascular tissues may be arranged on the outside of the stem or scattered throughout the stem.
  - Stems can contain stomata.
- Which of the following plant cell type is mismatched to its function?
  - Xylem—conducts mineral nutrients
  - Phloem—serves as part of the bark
  - Trichomes—reduces evaporation
  - Collenchyma—performs photosynthesis

## APPLY

- Fifteen years ago, your parents hung a swing from the lower branch of a large tree growing in your yard. When you go and sit in it today, you realize it is exactly the same height off the ground as it was when you first sat in it 15 years ago. The reason the swing is not higher off the ground as the tree has grown is that
  - the tree trunk lacks secondary growth.
  - the tree trunk is part of the primary growth system of the plant, but elongation is no longer occurring in that part of the tree.
  - trees lack apical meristems and so do not get taller.
  - you are hallucinating, because it is impossible for the swing not to have been raised off the ground as the tree grew.
- A unique feature of plants is indeterminate growth. Indeterminate growth is possible because
  - meristematic regions for primary growth occur throughout the entire plant body.
  - all cell types in a plant often give rise to meristematic tissue.
  - meristematic cells continually replace themselves.
  - all cells in a plant continue to divide indefinitely.
- If you were to relocate the pericycle of a plant root to the epidermal layer, how would it affect root growth?
  - Secondary growth in the mature region of the root would not occur.
  - The root apical meristem would produce vascular tissue in place of dermal tissue.
  - Nothing would change because the pericycle is normally located near the epidermal layer of the root.
  - Lateral roots would grow from the outer region of the root and fail to connect with the vascular tissue.
- Many vegetables are grown today through hydroponics, in which the plant roots exist primarily in an aqueous solution. Which of the following root structures is no longer beneficial in hydroponics?
  - Epidermis
  - Xylem
  - Root cap
  - Bark
- When you peel your potatoes for dinner, you are removing the majority of their
  - dermal tissue.
  - vascular tissue.
  - ground tissue.

# Vegetative Plant Development

## Chapter Outline

---

- 37.1** Embryo Development
- 37.2** Seeds
- 37.3** Fruits
- 37.4** Germination

## Introduction

---

*How does a fertilized egg develop into a complex adult plant body? Because plant cells cannot move, the timing and directionality of each cell division must be carefully orchestrated. Cells need information about their location relative to other cells so that cell specialization is coordinated. The developing embryo is quite fragile, and numerous protective structures have evolved since plants first colonized land.*

*Only a portion of the plant has actually formed when its seedling first emerges from the soil. New plant organs develop throughout the plant's life.*

## 37.1 Embryo Development

### Learning Outcomes

1. Name the two axes of the plant body that are established during embryonic development.
2. List the three tissue systems that develop in an embryo.
3. Describe the three critical events that must accompany seed development.

Embryo development begins once the egg cell is fertilized. As described briefly in chapter 30, the growing pollen tube from a pollen grain enters the angiosperm embryo sac through one of the synergids, releasing two sperm cells (figure 37.1). One sperm cell fertilizes the central cell with its polar nuclei, and the resulting cell division produces a nutrient source, the **endosperm**, for the embryo. The other sperm cell fertilizes the egg to produce a zygote, and cell division soon follows, creating the **embryo**.

### A single cell divides to produce a three-dimensional body plan

The first division of the zygote (fertilized egg) in a flowering plant is asymmetrical and generates cells with two different fates (figure 37.2). One daughter cell is small, with dense cytoplasm. That cell, which is destined to become the embryo, begins to divide repeatedly in different planes, forming a ball of cells. The other, larger daughter cell divides repeatedly, forming an elongated structure called a **suspensor**, which links the embryo to the nutrient tissue of the seed. The suspensor also provides a route for nutrients to reach the developing embryo. The root-shoot axis also forms at this time; cells near the sus-

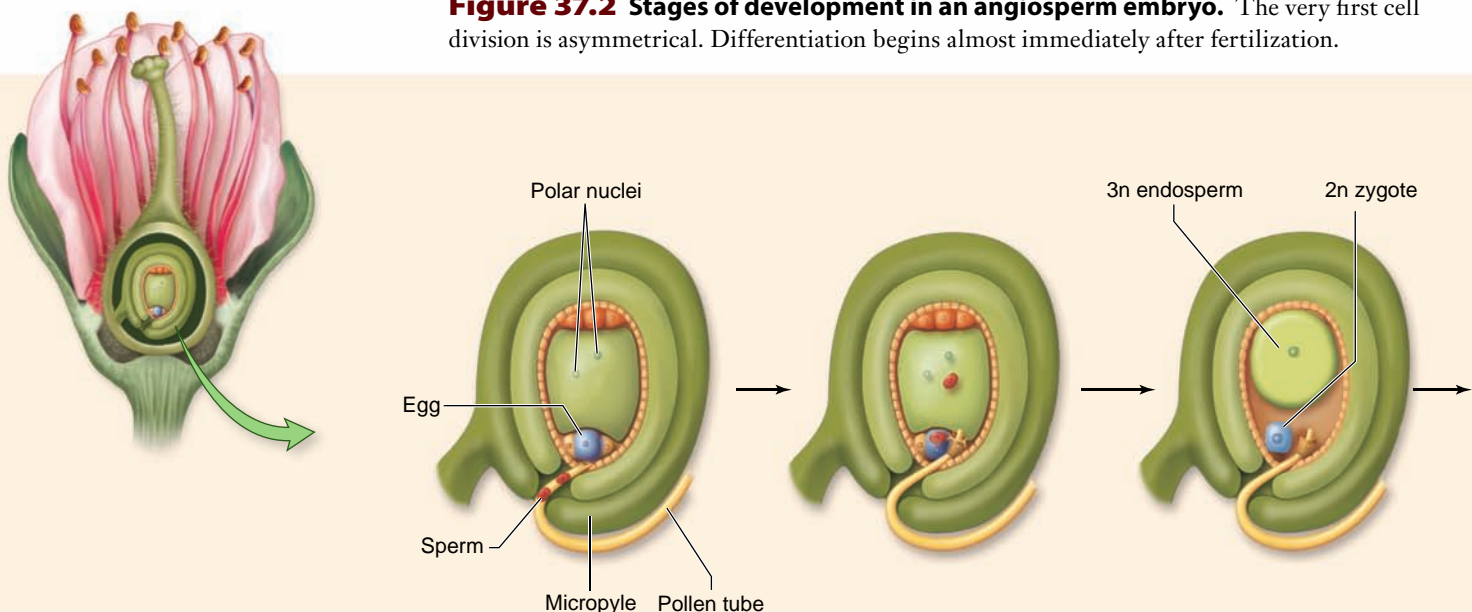

**Figure 37.1 Fertilization triggers embryogenesis.** The egg cell, within the embryo sac, is fertilized by one sperm cell released from the pollen tube. The second sperm cell fertilizes the central cell and initiates endosperm development. This diagram shows sperm just before fertilization.

pensor are destined to form a root, while those at the other end of the axis ultimately become a shoot.

Investigating mechanisms for establishing asymmetry in plant embryo development is difficult because the zygote is embedded within the female gametophyte, which is surrounded by sporophyte tissue (ovule and carpel tissue) (see chapter 30). To understand the cell biology of the first asymmetrical division of zygotes, biologists have studied the brown alga *Fucus*. We must be cautious about inferring too much about angiosperm asymmetrical divisions from the brown algae because the last common ancestor of brown algae and the angiosperm line was a single-celled organism. Nevertheless,

**Figure 37.2 Stages of development in an angiosperm embryo.** The very first cell division is asymmetrical. Differentiation begins almost immediately after fertilization.

**Figure 37.3 Asymmetrical cell division in a *Fucus* zygote.** An unequal distribution of material in the zygote leads to a bulge where the first cell division will occur. This division results in a smaller cell that will go on to divide and produce the rhizoid that anchors the alga; the larger cell divides to form the thallus, or main algal body. The point of sperm entry determines where the smaller rhizoid cell will form, but light and gravity can modify this to ensure that the rhizoid will point downward where it can anchor this brown alga. Calcium-mediated currents set up an internal gradient of charged molecules, which leads to a weakening of the cell wall where the rhizoid will form. The fate of the two resulting cells is held “in memory” by cell wall components.

asymmetrical division extends far back in the tree of life. Even prokaryotes can divide asymmetrically

### Zygote development in *Fucus*

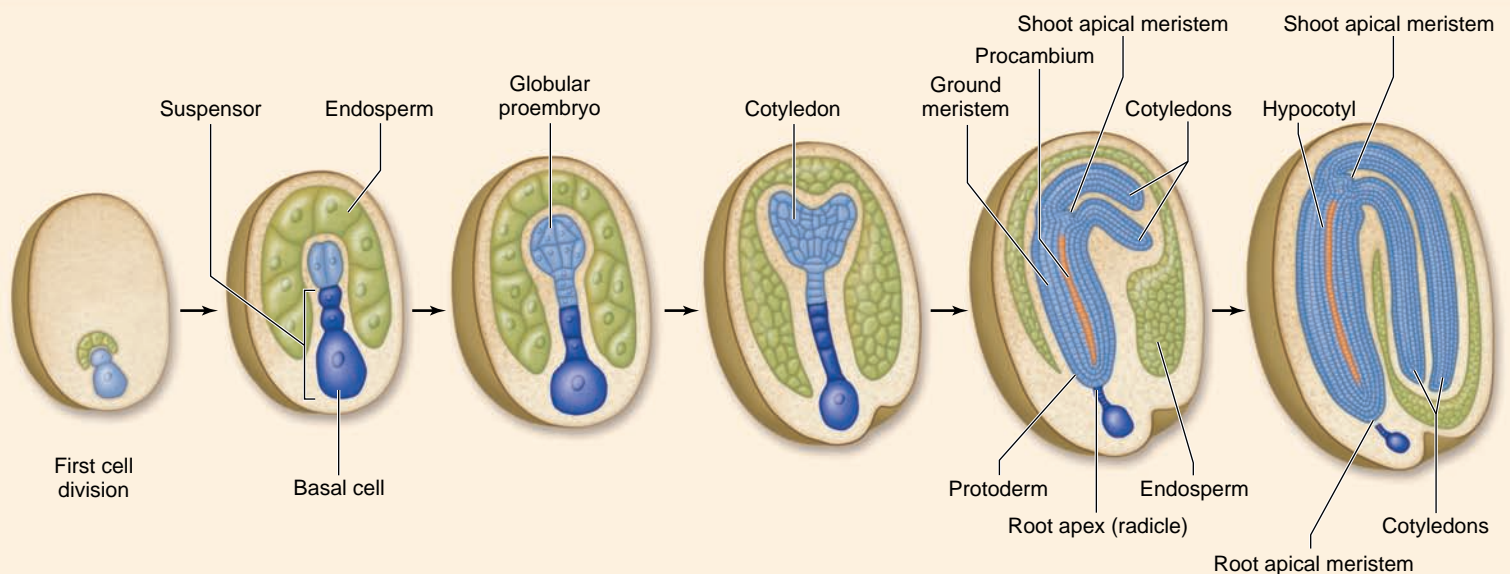

In the brown alga *Fucus*, the egg is released prior to fertilization, so no extra tissues surround the zygote, making its development easier to observe. A bulge that develops on one side of the zygote establishes the vertical axis. Cell division occurs, and the original bulge becomes the smaller of the two daughter cells. The smaller cell develops into a rhizoid that anchors the alga, and the larger cell develops into the main body, or thallus, of the sporophyte (figure 37.3).

This axis is first established by the point of sperm entry, but it can be changed by environmental signals, especially light and gravity, which ensure that the rhizoid attaches to a solid

base and the thallus is oriented toward a light source. Internal gradients are established that specify where the rhizoid forms in response to environmental signals.

### Establishing asymmetry in angiosperms

Genetic approaches make it possible to explore asymmetrical development in angiosperms. Studies of mutants reveal what can go wrong in development, which often makes it possible to infer normal developmental mechanisms. For example, the suspensor mutant in *Arabidopsis thaliana* undergoes aberrant development in the embryo followed by embryo-like development of the suspensor (figure 37.4). Analysis of this mutant led to the conclusion that the presence of the embryo normally prevents the suspensor from developing into a second embryo.

**Figure 37.4** The embryo suppresses development of the suspensor as a second embryo. This *suspensor (sus)* mutant of *Arabidopsis* has a defect in embryo development. Aborted embryo development is followed by embryo-like development of the suspensor. *SUS* is required to suppress embryo development in suspensor cells.

## A simple body plan emerges during embryogenesis

In plants, three-dimensional shape and form arise by regulating the amount and the pattern of cell division. We have just described how a vertical axis (root–shoot axis) becomes established at a very early stage; the same is true for establishment of a radial axis (inner–outer axis) (figure 37.5). Although the first cell division gives rise to a single row of cells, cells soon begin dividing in different directions, producing a three-dimensional solid ball of cells. The root–shoot axis lengthens as cells divide. New cell walls form perpendicular to the root–shoot axis, stacking new cells along the root–shoot axis.

The cells must divide in two directions in the radial plane in order to maintain proper three dimensional shape in early development. The body plan that emerges is shown in figure 37.6. Apical meristems, the actively dividing cell regions at the tips of roots and shoots, establish the root–shoot axis in the globular stage, from which the three basic tissue systems arise: *dermal*, *ground*, and *vascular* tissue (see chapter 36). These tissues are organized radially around the root–shoot axis.

### Root and shoot formation

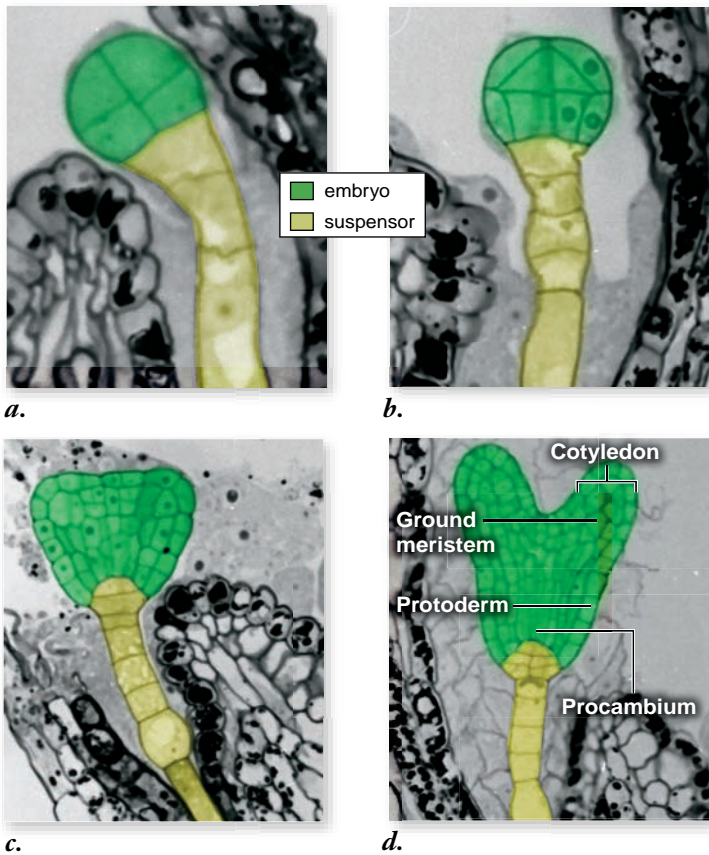

Both the shoot and root meristems are apical meristems, but their formation is controlled independently. Shoot formation requires the *SHOOTMERISTEMLESS (STM)* gene in *Arabidopsis*. Plants that do not make STM protein fail to produce viable shoots, but do produce roots (figure 37.7).

The *STM* gene codes for a transcription factor with a homeobox region, sharing a common evolutionary origin with the *Hox* genes that are important in establishing animal body plans (see chapters 19 and 25). Compared with animals, however, *Hox*-like genes have a more limited role in regulating plant body plans. Other gene families, encoding different transcription factors, also play key roles in patterning in plants.

### Figure 37.5 Two axes are established in the developing embryo.

The root–shoot axis is vertical, and the radial axis creates a two-dimensional plane perpendicular to the root–shoot axis. The ends of the root–shoot axis become the root and shoot apical meristems. Three tissue systems develop around the radial axis. Embryos form concentric rings of cells around the root–shoot axis by regulating the planes of cell division. Early in embryogenesis cells alternate between coordinated divisions that produce new cell walls parallel to the plane containing the radial axis and cell divisions that produce new cell walls perpendicular to the plane containing the radial axis. The orange lines show the formation of new cell walls. The diagram shows one plane of cells parallel to the ground. Cell divisions are also adding cells above and below this plane as the root–shoot axis lengthens.

**Figure 37.6** Early developmental stages of *Arabidopsis thaliana*. *a.* Early cell division has produced the embryo and suspensor. *b.* Globular stage results from cell divisions along both the root–shoot and radial axes. Cell differentiation, including establishment of the root and shoot apical meristems occurs at this stage. *c.* *d.* Heart-shaped stage. The cotyledons (seed leaves) are now visible, and the three tissue systems continue to differentiate.

**Figure 37.7** *SHOOTMERISTEMLESS* is needed for shoot formation. Shoot-specific genes specify formation of the shoot apical meristem, but are not necessary for root development. The *stm* mutant of *Arabidopsis* (shown on top) has a normal root meristem but fails to produce a shoot meristem between its two cotyledons. The *STM* wild type is shown below the *stm* mutant for comparison.

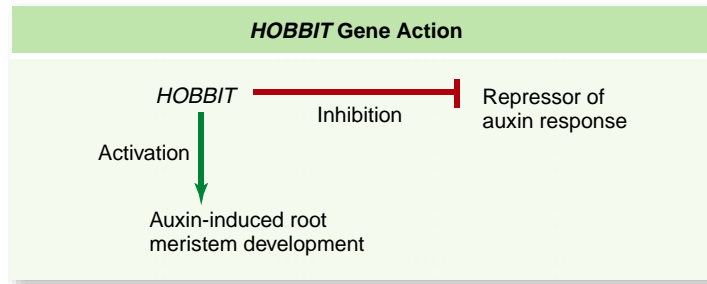

Root formation requires the *HOBBIT* gene in *Arabidopsis* (figure 37.8). The *hobbit* mutants form shoot meristems, but no root meristems form. Cell divisions in *hobbit* roots occur in the wrong directions. Plants with a *hobbit* mutation accumulate a biochemical repressor of genes that are induced by auxin (a plant hormone). Based on the mutant phenotype, *HOBBIT* appears to repress the production of the repressor of auxin-induced genes. Or, more simply stated, *HOBBIT* protein allows auxin to induce the expression of a gene or genes needed for correct cell division to make a root meristem. Auxin is one of seven classes of hormones that regulate plant development and

**Figure 37.8 Genetic control of embryonic root development in *Arabidopsis*.** *a.* *HOBBIT* represses the repression of the auxin response, allowing auxin-induced root development to occur. *b.* *MONOPTEROS* cannot act as a transcription factor when it is bound by a repressor. Auxin releases the repressor from *MONOPTEROS*, which then activates transcription of a root development gene. *c.* A wild-type seedling depends on auxin-induced genes for normal root initiation during embryogenesis. *d.* The *hobbit* seedling has a stub rather than a root because abnormal cell divisions prevent root meristem formation. *e.* The *monopteros* seedling also fails to develop a root.

### Inquiry question

? Referring to part (e) of figure 37.8, explain why this mutant fails to develop an embryonic root.

*a.*

*b.*

function; we will explore each of these classes of hormones in chapter 41.

One way that auxin induces gene expression is by activating a transcription factor. *MONOPTEROS* (*MP*) is a gene that codes for an auxin-induced transcription factor (see figure 37.8), and like *HOBBIT*, it is necessary for root formation, but not shoot formation, in *Arabidopsis*. Once activated, *MP* protein binds to the promoter of another gene, leading to transcription of a gene or genes needed for root meristem formation.

### Inquiry question

? Predict the phenotype of a plant with a mutation in the *MP* gene that results in an *MP* protein that can no longer bind its repressor.

### Formation of the three tissue systems

Three basic tissues, called *primary meristems*, differentiate while the plant embryo is still a ball of cells (called the globular stage; see figure 37.6). No cell movements are involved in plant embryo development. The protoderm consists of the outermost cells in a plant embryo and will become *dermal tissue* (see chapter 36). These cells almost always divide with their cell plate perpendicular to the body surface, thus perpetuating a single outer layer of cells. Dermal tissue protects the plant from desiccation. Stomata that open and close to facilitate gas exchange and minimize water loss are derived from dermal tissue.

A ground meristem gives rise to the bulk of the embryonic interior, consisting of *ground tissue* cells that eventually function in food and water storage.

Finally, procambium at the core of the embryo will form the future *vascular tissue*, which is responsible for water and nutrient transport.

Cell fates are generally more limited after embryogenesis, however, when embryo-specific genes are not expressed. For example, the *LEAFY COTYLEDON* gene in *Arabidopsis* is active in early and late embryo development, and it may be responsible for maintaining an embryonic environment. It is possible to turn this gene on later in development using recombinant DNA techniques described in chapter 16. When it is turned on, embryos can form on leaves!

### Morphogenesis

The globular stage gives rise to a heart-shaped embryo with two bulges in one group of angiosperms (the eudicots, such as *A. thaliana* in figure 37.6c, d), and a ball with a bulge on a single side in another group (the monocots). These bulges are **cotyledons** (“first leaves”) and are produced by the embryonic cells, and not by the shoot apical meristem that begins forming during the globular stage. This process, called morphogenesis (generation of form), results from changes in planes and rates of cell division (see figure 37.5).

Because plant cells cannot move, the form of a plant body is largely determined by the plane in which its cells divide. It is

**Figure 37.9 Cell division and expansion.**

**a.** Orientation of microtubules determines the orientation of cell plate formation and thus the new cell wall. **b.** Not all sides of a plant cell have the same amount of cellulose reinforcement. With water uptake, cells expand in directions that have the least amount of cell wall reinforcement.

also controlled by changes in cell shape as cells expand osmotically after they form (figure 37.9). The position of the cell plate determines the direction of division, and both microtubules and actin play a role in establishing the cell plate’s position. Plant hormones and other factors influence the orientation of bundles of microtubules on the interior of the plasma membrane. These microtubules also guide cellulose deposition as the cell wall forms around the outside of a new cell (see figure 36.2) where four of the six sides are reinforced more heavily with cellulose; the cell tends to expand and grow in the direction of the two sides having less reinforcement (figure 37.9b).

Much is being learned about morphogenesis at the cellular level from mutants that are able to divide, but cannot control their plane of cell division or the direction of cell expansion. The lack of root meristem development in *hobbit* mutants is just one such example. As the procambium begins differentiating in the root, a critical division parallel to the root’s surface is regulated by the gene *WOODEN LEG* (*WOL*, figure 37.10). Without that division, the cylinder of cells that would form phloem is missing. Only xylem forms in the vascular tissue system, giving the root a “wooden leg.”

Early in embryonic development, most cells can give rise to a wide range of cell and organ types, including leaves. As development proceeds, the cells with multiple potentials are mainly restricted to the meristem regions. Many meristems have been established by the time embryogenesis ends and the seed becomes dormant. After germination, apical meristems continue adding cells to the growing root and shoot tips. Apical meristem cells of corn, for example, divide every 12 hours, producing half a million cells per day in an actively growing corn plant. Lateral meristems can cause an increase in the girth of some plants, while intercalary meristems in the stems of grasses allow for elongation.

### Food reserves form during embryogenesis

While the embryo is developing, three other critical events are occurring in angiosperms: (1) development of a food supply, (2) development of the seed coat, and (3) development of the

**Figure 37.10 WOODEN LEG is needed for phloem development.** The *wol* mutant (right) has less vascular tissue than wild-type *Arabidopsis* (left), but all of it is xylem.

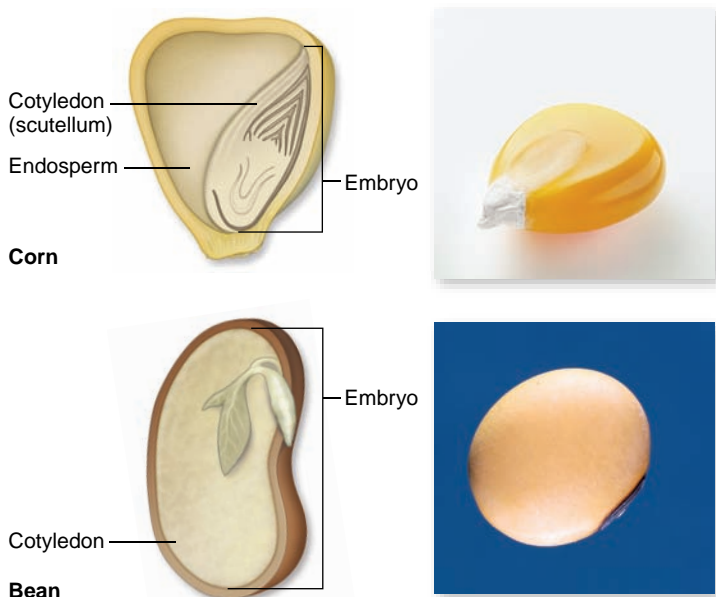

fruit surrounding the seed. Nutritional reserves support the embryo during germination, while it gains photosynthetic capacity. In angiosperms, double fertilization produces endosperm for nutrition; in gymnosperms, the megagametophyte is the food source (see chapter 30). The seed coat is the result of the differentiation of ovule tissue (from the parental sporophyte) to form a hard, protective covering around the embryo. The seed then enters a dormant phase, signaling the end of embryogenesis. In angiosperms, the fruit develops from the carpel wall surrounding the ovule. Seed development and germination, as well as fruit development, are addressed later in this chapter. In this section, we focus on nutrient reserves.

Throughout embryogenesis, starch, lipids, and proteins are synthesized. The seed storage proteins are so abundant that the genes coding for them were the first cloning targets for plant molecular biologists. Providing nutritional resources is part of the evolutionary trend toward enhancing embryo survival.

The sporophyte transfers nutrients via the suspensor in angiosperms. (In gymnosperms, the suspensor serves only to push the embryo closer to the megagametophytic nutrient source.) This happens concurrently with the development of the endosperm, which is present only in angiosperms (although double fertilization has been observed in the gymnosperm *Ephedra*). Endosperm formation may be extensive or minimal.

Endosperm in coconut includes the “milk,” a liquid. In corn, the endosperm is solid. In popping corn it expands with heat to form the white edible part of popped corn. In peas and beans, the endosperm is used up during embryo development, and nutrients are stored in thick, fleshy cotyledons (figure 37.11).

Because the photosynthetic machinery is built in response to light, it is critical that seeds have stored nutrients to aid in germination until the growing sporophyte can photosynthesize. A seed buried too deeply in the soil will use up all its reserves in cellular respiration before reaching the surface and sunlight.

**Figure 37.11 Endosperm in maize and bean.** The maize kernel has endosperm that is still present at maturity, but the endosperm in the bean has disappeared. The bean embryo’s cotyledons take over food storage functions.

### Learning Outcomes Review 37.1

The root-shoot axis and the radial axis form during plant embryogenesis. The three tissues formed in an embryo are the protoderm, ground meristem, and procambium, which give rise to the three adult tissues. While the embryo is being formed, a food supply is being established for the embryo in the form of endosperm; a seed coat is forming from ovule tissues; and the fruit is developing from the carpel wall.

- How does the nutritive tissue of a gymnosperm seed differ from that of an angiosperm seed?

## 37.2 Seeds

### Learning Outcomes

1. Describe four ways in which seeds help to ensure the survival of a plant’s offspring.
2. List environmental conditions that can lead to seed germination in some plants.

Early in the development of an angiosperm embryo, a profoundly important event occurs: The embryo stops developing. In many plants, development of the embryo is arrested soon after the meristems and cotyledons differentiate. The integuments—the outer cell layers of the ovule—develop into a relatively impermeable **seed coat**, which encloses the seed with its dormant embryo and stored food (figure 37.12).

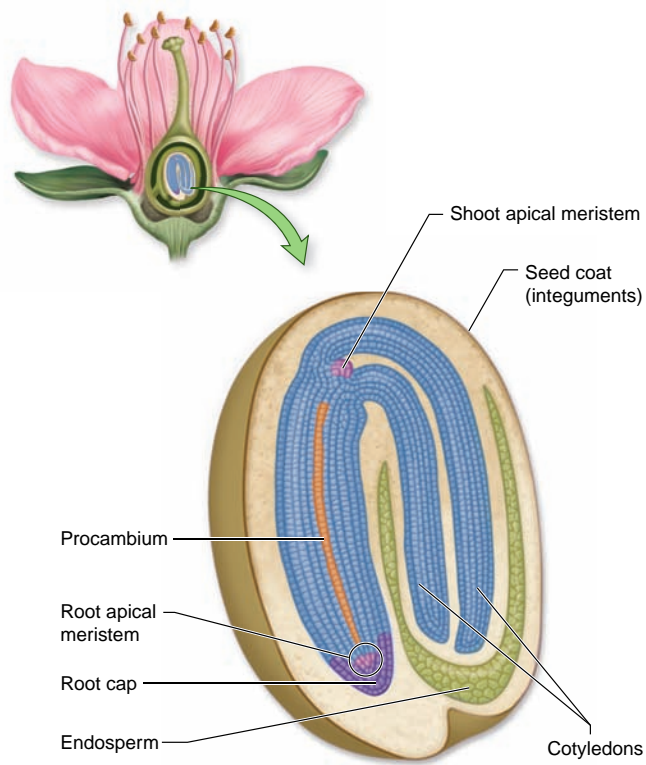

### Seeds protect the embryo

The seed is a vehicle for dispersing the embryo to distant sites. Being encased in the protective layers of a seed allows a plant embryo to survive in environments that might kill a mature plant.

Seeds are an important adaptation in at least four ways:

1. Seeds maintain dormancy under unfavorable conditions and postpone development until better conditions arise. If conditions are marginal, a plant can “afford” to have some seeds germinate, because some of those that germinate may survive, while others remain dormant.
2. Seeds afford maximum protection to the young plant at its most vulnerable stage of development.
3. Seeds contain stored food that allows a young plant to grow and develop before photosynthetic activity begins.
4. Perhaps most important, seeds are adapted for dispersal, facilitating the migration of plant genotypes into new habitats.

A mature seed contains only about 5 to 20% water. Under these conditions, the seed and the young plant within it are very stable; its arrested growth is primarily due to the progressive and severe desiccation of the embryo and the associated reduction in metabolic activity. Germination cannot take place until water and oxygen reach the embryo. Seeds of some

**Figure 37.12 Seed development.** The integuments of this mature angiosperm ovule are forming the seed coat. Note that the two cotyledons have grown into a bent shape to accommodate the tight confines of the seed. In some embryos, the shoot apical meristem will have already initiated a few leaf primordia as well.

### Inquiry question

? Is this embryo a monocot or a eudicot?

plants have been known to remain viable for hundreds and, in rare instances, thousands of years.

## Specialized seed adaptations improve survival

Specific adaptations often help ensure that seeds will germinate only under appropriate conditions. Sometimes, seeds lie within tough cones that do not open until they are exposed to the heat of a fire (figure 37.13). This strategy causes the seed to germinate in an open, fire-cleared habitat where nutrients are relatively abundant, having been released from plants burned in the fire.

Seeds of other plants germinate only when inhibitory chemicals leach from their seed coats, thus guaranteeing their germination when sufficient water is available. Still other seeds germinate only after they pass through the intestines of birds or mammals or are regurgitated by them, which both weakens the seed coats and ensures dispersal. Sometimes seeds of plants thought to be extinct in a particular area may germinate under unique or improved environmental circumstances, and the plants may then reestablish themselves.

a.

b.

**Figure 37.13 Fire induces seed release in some pines.**

Fire can destroy adult jack pines, but stimulate growth of the next generation. *a.* The cones of a jack pine are tightly sealed and cannot release the seeds protected by the scales. *b.* High temperatures lead to the release of the seeds.

### Learning Outcomes Review 37.2

The seed coat originates from the integuments and encloses the embryo and stored nutrients. The four advantages conferred by seeds are dormancy, protection of the embryo, nourishment, and a method of dispersal. Fire, heavy rains, or passage through an animal's digestive tract may be required for germination in some species.

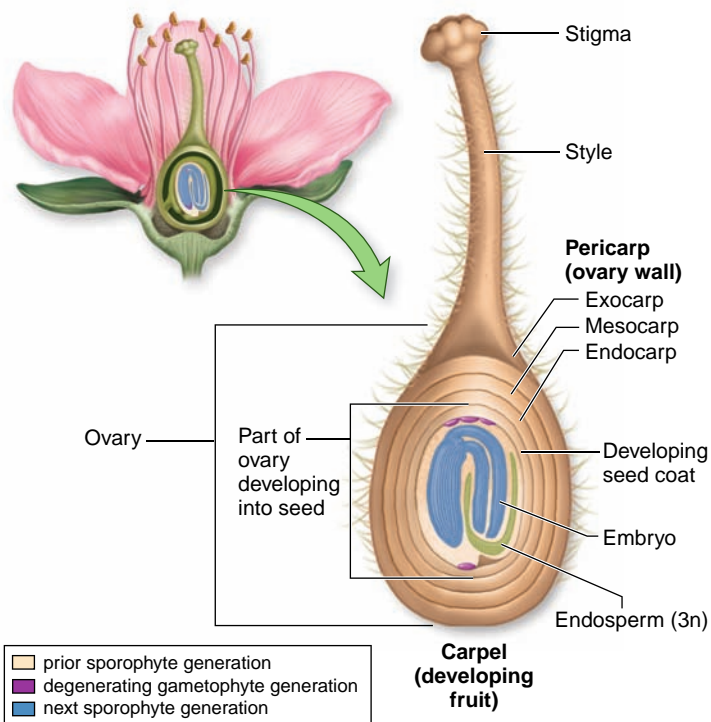

- What type of seed dormancy would you expect to find in trees living in climates with cold winters?

## 37.3 Fruits

### Learning Outcomes

1. Identify the structures from which fruits develop.
2. Distinguish among berries, legumes, drupes, and samaras.

Survival of angiosperm embryos depends on fruit development as well as seed development. Fruits are most simply defined as mature ovaries (carpels). During seed formation,

**Figure 37.14 Fruit development.** The carpel (specifically the ovary) wall is composed of three layers: the exocarp, mesocarp, and endocarp. One, some, or all of these layers develops to contribute to the recognized fruit in different species. The seed matures within this developing fruit.

### Inquiry question

? Three generations are represented in this diagram. Label the ploidy levels of the tissues of different generations shown here.

the flower ovary begins to develop into fruit (figure 37.14). In some cases, pollen landing on the stigma can initiate fruit development, but more frequently the coordination of fruit, seed coat, embryo, and endosperm development follow fertilization.

It is possible for fruits to develop without seed development. Commercial bananas for example have aborted seed development, but do produce mature, edible ovaries. Bananas are propagated asexually since no embryo develops.

### Fruits are adapted for dispersal

Fruits form in many ways and exhibit a wide array of adaptations for dispersal. Three layers of ovary wall, also called the *pericarp*, can have distinct fates, which account for the diversity of fruit types from fleshy to dry and hard. The differences among some of the fruit types are shown in figure 37.15.

Developmentally, fruits are fascinating organs that contain three genotypes in one package. The fruit and seed coat are from the prior sporophyte generation. Remnants of the gametophyte generation that produced the egg are found in the de-

veloping seed, and the embryo represents the next sporophyte generation (see figure 37.14).

### Fruits allow angiosperms to colonize large areas

Aside from the many ways fruits can form, they also exhibit a wide array of specialized dispersal methods. Fruits with fleshy coverings, often shiny black or bright blue or red, normally are dispersed by birds or other vertebrates (figure 37.16a). Like red flowers, red fruits signal an abundant food supply. By feeding on these fruits, birds and other animals may carry seeds from place to place and thus transfer plants from one suitable habitat to another. Such seeds require a hard seed coat to resist stomach acids and digestive enzymes.

Fruits with hooked spines, such as those of burrs (figure 37.16b), are typical of several genera of plants that occur in the northern deciduous forests. Such fruits are often disseminated by mammals, including humans, when they hitch a ride on fur or clothing. Squirrels and similar mammals disperse and bury fruits such as acorns and other nuts. Some of these sprout when conditions become favorable, such as after the spring thaw.

Other fruits, including those of maples, elms, and ashes, have wings that aid in their distribution by the wind. Orchids have minute, dustlike seeds, which are likewise blown away by the wind. The dandelion provides another familiar example of a fruit type that is wind-dispersed (figure 37.16c), and the dispersal of seeds from plants such as milkweeds, willows, and cottonwoods is similar. Water dispersal adaptations include air-filled chambers surrounded by impermeable membranes to prevent the entrance of H<sub>2</sub>O.

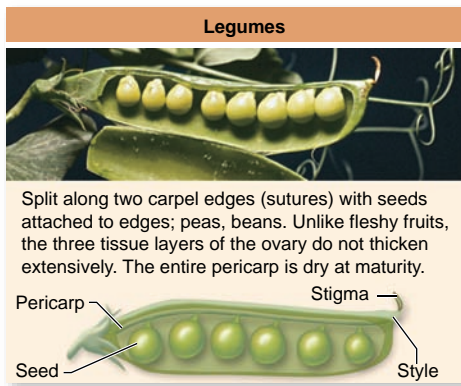

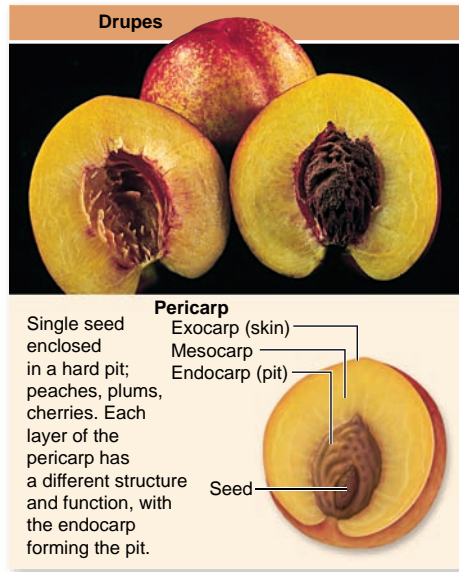

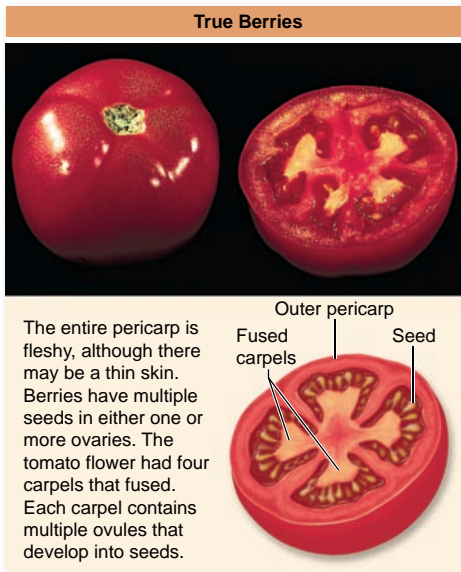

Coconuts and other plants that characteristically occur on or near beaches are regularly spread throughout a region by floating in water (figure 37.16d). This sort of dispersal is especially important in the colonization of distant island groups, such as the Hawaiian Islands.

It has been calculated that the seeds of about 175 angiosperms, nearly one-third from North America, must have reached Hawaii to have evolved into the roughly 970 species found there today. Some of these seeds blew through the air, others were transported on the feathers or in the guts of birds, and still others floated across the Pacific. Although the distances are rarely as great as the distance between Hawaii and the mainland, dispersal is just as important for mainland plant species that have discontinuous habitats, such as mountaintops, marshes, or north-facing cliffs.

### Learning Outcomes Review 37.3

As a seed develops, the pericarp layers of the ovary wall develop into the fruit. A berry has a fleshy pericarp; a legume has a dry pericarp that opens to release seeds; the outer layers of a drupe pericarp are fleshy; and a samara is a dry structure with a wing. Animals often distribute the seeds of fleshy fruits and fruits with spines or hooks. Wind disperses lightweight seeds and samara forms.

■ What features of fruits might encourage animals to eat them?

**Figure 37.15** Examples of some kinds of fruits. Legumes and samaras are examples of dry fruits. Legumes open to release their seeds, while samaras do not. Drupes and true berries are simple fleshy fruits; they develop from a flower with a single pistil composed of one or more carpels. Aggregate and multiple fruits are compound fleshy fruits; they develop from flowers with more than one pistil or from more than one flower.

## 37.4 Germination

### Learning Outcomes

1. Describe the events that occur during seed germination.
2. Contrast the pattern of shoot emergence in bean (dicot) with that in maize (monocot).

When conditions are satisfactory, the embryo emerges from its previously desiccated state, utilizes food reserves, and resumes growth. Although **germination** is a process characterized by several stages, it is often defined as the emergence of the **radicle** (first root) through the seed coat.

### External signals and conditions trigger germination

Germination begins when a seed absorbs water and its metabolism resumes. The amount of water a seed can absorb is phenomenal, and osmotic pressure creates a force strong enough to break the seed coat. At this point, it is important that oxygen be available to the developing embryo because plants, like animals, require oxygen for cellular respiration. Few plants produce seeds that germinate successfully under water, although some, such as rice, have evolved a tolerance to anaerobic conditions.

Even though a dormant seed may have imbibed a full supply of water and may be respiring, synthesizing proteins and RNA, and apparently carrying on normal metabolism, it may fail to germinate without an additional signal from the environ-

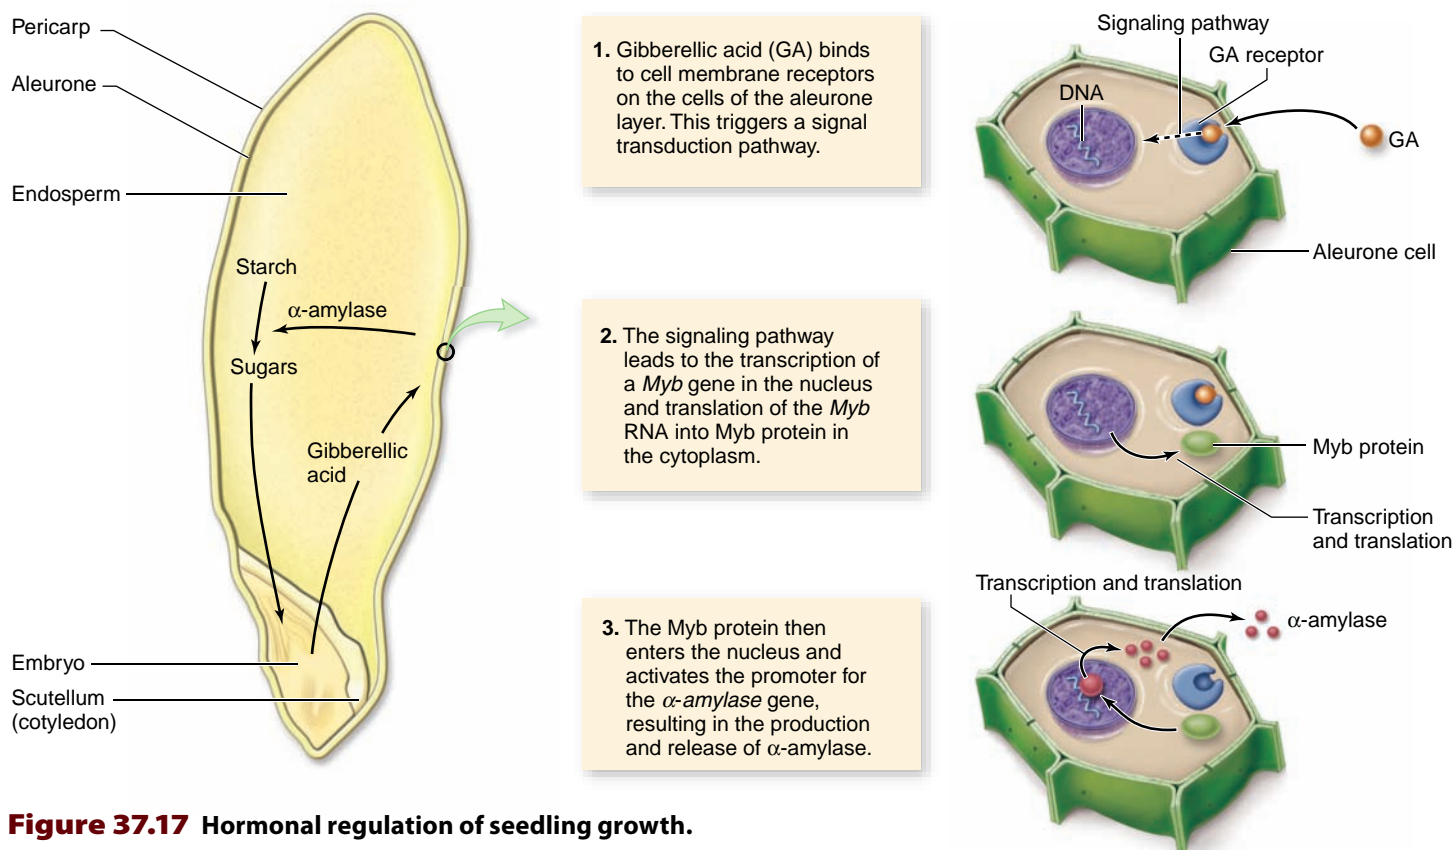

ment. This signal may be light of the correct wavelength and intensity, a series of cold days, or simply the passage of time at temperatures appropriate for germination. The seeds of many plants will not germinate unless they have been **stratified**—held for periods of time at low temperatures. This phenomenon prevents the seeds of plants that grow in seasonally cold areas from germinating until they have passed the winter, thus protecting their tender seedlings from harsh, cold conditions.

Germination can occur over a wide temperature range (5° to 30°C), although certain species may have relatively narrow optimum ranges. Some seeds will not germinate even under the best conditions. In some species, a significant fraction of a season's seeds remain dormant for an indeterminate length of time, providing a gene pool of great evolutionary significance to the future plant population. The presence of ungerminated seeds in the soil of an area is referred to as the **seed bank**.

### Nutrient reserves sustain the growing seedling

Germination occurs when all internal and external requirements are met. Germination and early seedling growth require the utilization of metabolic reserves stored as starch in amyloplasts (colorless plastids) and protein bodies. Fats and oils, also stored, in some kinds of seeds, can readily be digested during germination to produce glycerol and fatty acids, which yield energy through cellular respiration. They can also be converted to glucose. Depending on the kind of plant, any of these reserves may be stored in the embryo or in the endosperm.

In the kernels of cereal grains, the single cotyledon is modified into a relatively massive structure called the **scutellum** (figure 37.17). The abundant food stored in the scutellum is used up first during germination. Later, while the seedling is

**Figure 37.17** Hormonal regulation of seedling growth.

becoming established, the scutellum serves as a nutrient conduit from the endosperm to the rest of the embryo.

The utilization of stored starch by germinating plants is one of the best examples of how hormones modulate plant development (see figure 37.17). The embryo produces gibberellic acid, a hormone, that signals the outer layer of the endosperm, called the **aleurone**, to produce  $\alpha$ -amylase. This enzyme is responsible for breaking down the endosperm's starch, primarily amylose, into sugars that are passed by the scutellum to the embryo. Abscisic acid, another plant hormone, which is important in establishing dormancy, can inhibit starch breakdown. Abscisic acid levels may be reduced when a seed beginning to germinate absorbs water. (The action of plant hormones is covered in chapter 41.)

## The seedling becomes oriented in the environment, and photosynthesis begins

As the sporophyte pushes through the seed coat, it orients with the environment so that the root grows down and the shoot grows up. New growth comes from delicate meristems that are protected from environmental rigors. The shoot becomes photosynthetic, and the postembryonic phase of growth and development is under way. Figure 37.18 shows the process of germination and subsequent development of the plant body in eudicots and monocots.

The emerging shoot and root tips are protected by additional tissue layers in the monocots—the *coleoptile* surrounding the shoot, and the *coleorhiza* surrounding the radicle. Other

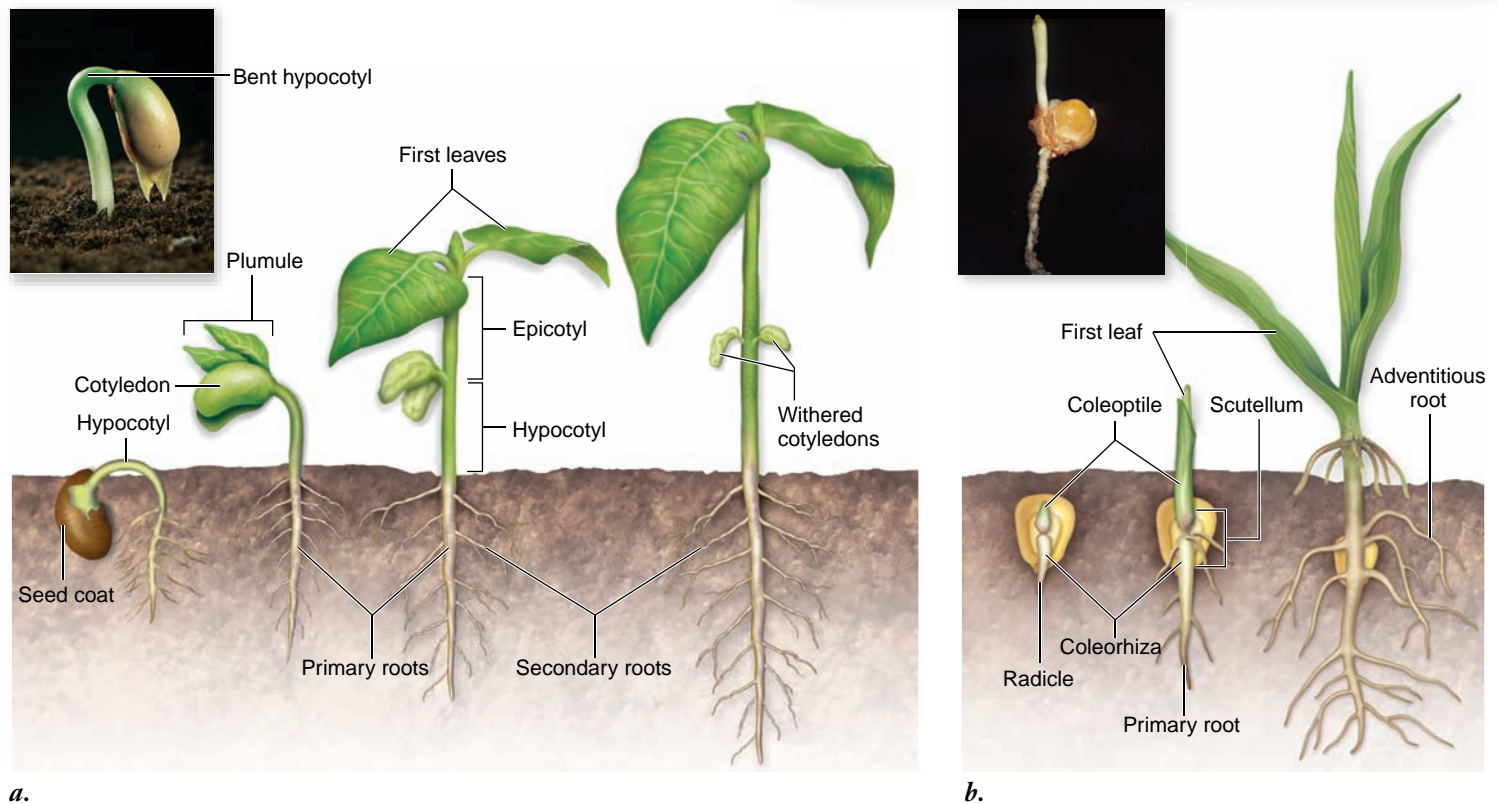

protective strategies include having a bent shoot emerge so tissues with more rugged cell walls push through the soil.

The emergence of the embryonic root and shoot from the seed during germination varies widely from species to species. In most plants, the root emerges before the shoot appears and anchors the young seedling in the soil (see figure 37.18). In plants such as peas, the cotyledons may be held below ground; in other plants, such as beans, radishes, and onions, the cotyledons are held above ground. The cotyledons may become green and contribute to the nutrition of the seedling as it becomes established, or they may shrivel relatively quickly. The period from the germination of the seed to the establishment of the young plant is critical for the plant's survival; the seedling is unusually susceptible to disease and drought during this period. Soil composition and pH can also affect the survival of a newly germinated plant (figure 37.19).

### Learning Outcomes Review 37.4

During germination, the seed and embryo take up water, increase respiration, and synthesize protein and RNA. Metabolic reserves in seeds include starch, fats, and oils. During seedling emergence, the cotyledons and seed coat may be pulled out of the ground and become photosynthetic, as they do in dicots such as beans. Alternatively, the cotyledon and seed coat may remain in the ground, as they do in monocots such as maize.

- What might be an advantage of retaining a seed in the ground during seedling emergence?

**Figure 37.18 Germination.** The stages shown are for (a) a eudicot, the common bean (*Phaseolus vulgaris*), and (b) a monocot, maize (*Zea mays*). Note that the bending of the hypocotyl (region below the cotyledons) protects the delicate bean shoot apex as it emerges through the soil. Maize radicles are protected by a protective layer of tissue called the coleorhiza, in addition to the root cap found in both bean and maize. A sheath of cells called the coleoptile, rather than a hypocotyl tissue, protects the emerging maize shoot tip.

## SCIENTIFIC THINKING

**Hypothesis:** Glandular trichomes prevent leafhoppers from feeding and reproducing on alfalfa plants.

**Prediction:** Rates of leafhopper survival and reproduction will be lower on plants with glandular trichomes than on those without glandular trichomes.

**Test:** Place alfalfa variety that produces glandular trichomes in a cage and a variety that lacks glandular trichomes in another cage. Place the same number of leafhoppers in each cage. Return after a period of time and count the number of live leafhoppers in each cage.

**Result:** There are fewer live leafhoppers in the cage with the trichome-bearing plant.

**Conclusion:** The hypothesis is supported. The survival and reproduction rate of leafhoppers on plants with trichomes was lower than that on plants lacking trichomes.

**Further Experiments:** Design an experiment to determine if trichomes in general or just glandular trichomes can deter leafhoppers.

**Figure 37.19** Glandular trichomes can protect plants from insects.

## Chapter Review

### 37.1 Embryo Development

**A single cell divides to produce a three-dimensional body plan.**

An angiosperm zygote divides to produce an embryo surrounded by endosperm (see figure 37.1). In early divisions, the root-shoot axis and radial axis become established.

Developmental mutants in model plants reveal what can go wrong, allowing inferences about how development proceeds under normal conditions.

**A simple body plan emerges during embryogenesis.**

Shoot and root apical meristems develop, and protoderm, ground meristem, and procambium differentiate; these will become the three types of tissue in an adult plant.

Morphogenesis creates a three-dimensional embryo that includes one or two cotyledons.

**Food reserves form during embryogenesis.**

While the embryo is being formed, a food supply is being established for the embryo. In angiosperms, this consists of the endosperm produced by double fertilization; in gymnosperms, the megagametophyte is the food source. In addition, a seed coat forms, and the fruit develops.

### 37.2 Seeds (see figure 37.12)

**Seeds protect the embryo.**

Seeds help to ensure the survival of the next generation by maintaining dormancy during unfavorable conditions, protecting the embryo, providing food for the embryo, and providing a means for dispersal.

**Specialized seed adaptations improve survival.**

Before a seed germinates, its seed coat must become permeable so that water and oxygen can reach the embryo. Adaptations have evolved to ensure germination under appropriate survival conditions. In certain gymnosperms, seeds may be released from cones after a fire. Alternatively, seeds may require passage through a digestive tract, freeze-thaw cycles, or abundant moisture.

### 37.3 Fruits (see figure 37.14)

**Fruits are adapted for dispersal.**

In angiosperms, a fruit is a mature ovary. Fruit development is coordinated with embryo, endosperm, and seed coat development. Angiosperms produce many types of fruit, which vary depending on the fate of the pericarp (carpel wall). Fruits can be dry or fleshy, and

they can be simple (single carpel), aggregate (multiple carpels), or multiple (multiple flowers).

A fruit is genetically unique because it contains tissues from the parent sporophyte (the seed coat and fruit tissue), the gametophyte (remnants in the developing seed) and the offspring sporophyte (the embryo).

#### **Fruits allow angiosperms to colonize large areas.**

Fruits exhibit a wide array of dispersal mechanisms. They may be ingested and transported by animals, buried in caches by herbivores, carried away by birds and mammals, blown by the wind, or float away on water.

### **37.4 Germination**

Seed germination is defined as the emergence of the radical through the seed coat.

#### **External signals and conditions trigger germination.**

A seed must imbibe water in order to germinate. Abundant oxygen is necessary to support the high metabolic rate of a germinating seed.

Environmental signals are often needed for germination. Examples include light of a certain wavelength, an appropriate temperature, and stratification (a period of chilling).

#### **Nutrient reserves sustain the growing seedling.**

Germination is a high-energy process, requiring stored nutrients such as starch, fats, and oils.

The endosperm acts as a starch reserve. Utilization of stored starch begins when the embryo produces the plant hormone gibberellic acid, which in turn stimulates production of an amylase to break down amylose. Starch metabolism can be inhibited by abscisic acid, a plant hormone that has a role in dormancy.

#### **The seedling becomes oriented in the environment, and photosynthesis begins.**

In most plants, the root emerges before the shoot appears, anchoring the young seedling.

In many eudicots, the shoot is bent as it emerges from the soil, protecting the growing tip (see figure 37.18). Monocots produce additional tissues to protect emerging shoots and roots.

During seedling emergence in dicots such as beans, the cotyledons are often pulled up with the growing shoot. In monocots such as corn, the cotyledon remains underground.

A seedling enters the postembryonic phase of growth and development when the emerging shoot becomes photosynthetic.

## **Review Questions**

### **UNDERSTAND**

- After the first mitotic division of the zygote, the larger of the two cells becomes the
  - embryo.
  - endosperm.
  - suspensor.
  - micropyle.
- Endosperm is produced by the union of
  - a central cell with a sperm cell.
  - a sperm cell with a synergid cell.
  - an egg cell with a sperm cell.
  - a suspensor with an egg cell.
- During the globular stage of embryo development, apical meristems establish the
  - embryo–suspensor axis.
  - inner–outer axis.
  - embryo–endosperm axis.
  - root–shoot axis.
- Which of the following is not a primary meristem?
  - Cork cambium
  - Ground meristem
  - Procambium
  - Protoderm
- The integuments of an ovule will develop into the
  - embryo.
  - endosperm.
  - fruit.
  - seed coat.
- An example of a drupe is a
  - strawberry.
  - plum.
  - bean.
  - pineapple.
- The pericarp is the
  - ovary wall.
  - developing seed coat.
  - ovary.
  - mature endosperm.

- During seed germination, this hormone produces the signal for the aleurone to begin starch breakdown.
  - Abscisic acid
  - Ethylene
  - Gibberellic acid
  - Auxin
- The shoot tip of an emerging maize seedling is protected by
  - hypocotyl.
  - epicotyl.
  - coleoptile.
  - plumule.

### **APPLY**

- A plant lacking the *WOODEN LEG* gene will likely
  - be incapable of transporting water to its leaves.
  - lack xylem and phloem.
  - be incapable of transporting photosynthate.
  - all of the above
- Explore how plant development changes if the functions of the genes *SHOOTMERISTEMLESS (STM)* and *MONOPTEROUS (MP)* were reversed?
  - The embryo–suspensor axis would be reversed.
  - The embryo–suspensor axis would be duplicated.
  - The root–shoot axis would be reversed.
  - The root–shoot axis would be duplicated.
- How would a loss-of-function mutation in the  $\alpha$ -amylase gene affect seed germination?
  - The seed could not imbibe water.
  - The embryo would starve.
  - The seed coat would not rupture.
  - The seed would germinate prematurely.

4. Fruits are complex organs that are specialized for dispersal of seeds. Which of the following plant tissues does *not* contribute to mature fruit?
  - a. Sporophytic tissue from the previous generation
  - b. Gametophytic tissue from the previous generation
  - c. Sporophytic tissue from the next generation
  - d. Gametophytic tissue from the next generation
5. Loss-of-function mutations in the *suspensor* gene in *Arabidopsis* lead to the development of two embryos in a seed. After analyzing the expression of this gene in early wild-type embryos, you find high levels of mRNA transcribed from the *suspensor* gene in the developing suspensor cells. What is the likely function of the suspensor protein?
  - a. Suspensor protein likely stimulates development of the embryonic tissue.
  - b. Suspensor protein likely stimulates development of the suspensor tissue.
  - c. Suspensor protein likely inhibits embryonic development in the suspensor.
  - d. Suspensor protein likely inhibits suspensor development in the embryo.
2. In gymnosperms, the nutritive tissue in the seed is megagametophyte tissue. It is a product of meiosis. A major evolutionary advance in the angiosperms is that the nutritive tissue is endosperm, a triploid product of fertilization. Why do you suppose endosperm is a richer source of nutrition than megagametophyte tissue?
3. As you are eating an apple one day, you decide that you'd like to save the seeds and plant them. You do so, but they fail to germinate. Discuss all possible reasons that the seeds did not germinate and strategies you could try to improve your chances of success.

### SYNTHESIZE

1. Design an experiment to determine whether light or gravity is more important in determining the orientation of the rhizoid during zygote development in *Fucus*.

Chapter

## Transport in Plants

### Chapter Outline

---

- 38.1** Transport Mechanisms
- 38.2** Water and Mineral Absorption
- 38.3** Xylem Transport
- 38.4** The Rate of Transpiration
- 38.5** Water-Stress Responses
- 38.6** Phloem Transport

### Introduction

---

*Terrestrial plants face two major challenges: maintaining water and nutrient balance, and providing sufficient structural support for upright growth. The vascular system transports water, minerals, and organic molecules over great distances. Whereas the secondary growth of vascular tissue allows trees to achieve great heights, water balance alone keeps herbaceous plants upright. Think of a plant cell as a water balloon pressing against the insides of a soft-sided box, with many other balloon/box cells stacked on top. If the balloon springs a leak, the support is gone, and the box can collapse. How water, minerals, and organic molecules move between the roots and shoots of small and tall plants is the topic of this chapter.*

## 38.1 Transport Mechanisms

### Learning Outcomes

1. Define transpiration.
2. Explain how to predict the direction of movement of water based on water potential.
3. Explain the driving force for transpiration.

How does water get from the roots to the top of a 10-story-high tree? Throughout human existence, curious people have wondered about this question. Plants lack muscle tissue or a circulatory system like animals have to pump fluid throughout a plant's body. Nevertheless, water moves through the cell wall spaces between the protoplasts of cells, through plasmodesmata (connections between cells), through plasma membranes, and through the interconnected, conducting elements extending throughout a plant (figure 38.1). Water first enters the roots and then moves to the xylem, the innermost vascular tissue of plants. Water rises through the xylem because of a combination of factors, and most of that water exits through the stomata in the leaves (figure 38.2).

### Local changes result in long-distance movement of materials

The greatest distances traveled by water molecules and dissolved minerals are in the xylem. Once water enters the xylem of a redwood, for example, it can move upward as much as 100 m. Most of the force is “pulling” caused by transpiration—evaporation from thin films of water in the stomata. This pulling occurs because water molecules stick to each other (cohesion) and to the walls of the tracheid or xylem vessel (ad-

hesion). The result is an unusually stable column of liquid reaching great heights.

The movement of water at the cellular level plays a significant role in bulk water transport in the plant as well, although over much shorter distances. Although water can diffuse through plasma membranes, charged ions and organic compounds, including sucrose, depend on protein transporters to cross membranes through facilitated diffusion or active transport (see figure 38.1 and chapter 5). ATP-dependent hydrogen ion pumps often fuel active transport. They create a hydrogen ion gradient across a membrane. This hydrogen ion gradient can be used in a variety of ways, including transporting sucrose (see figure 38.1). Unequal concentrations of solutes (for example, ions and organic molecules), drive osmosis as you saw in chapter 5. Using a quantitative approach to osmosis you can predict which way water will move.

### Water potential regulates movement of water through the plant

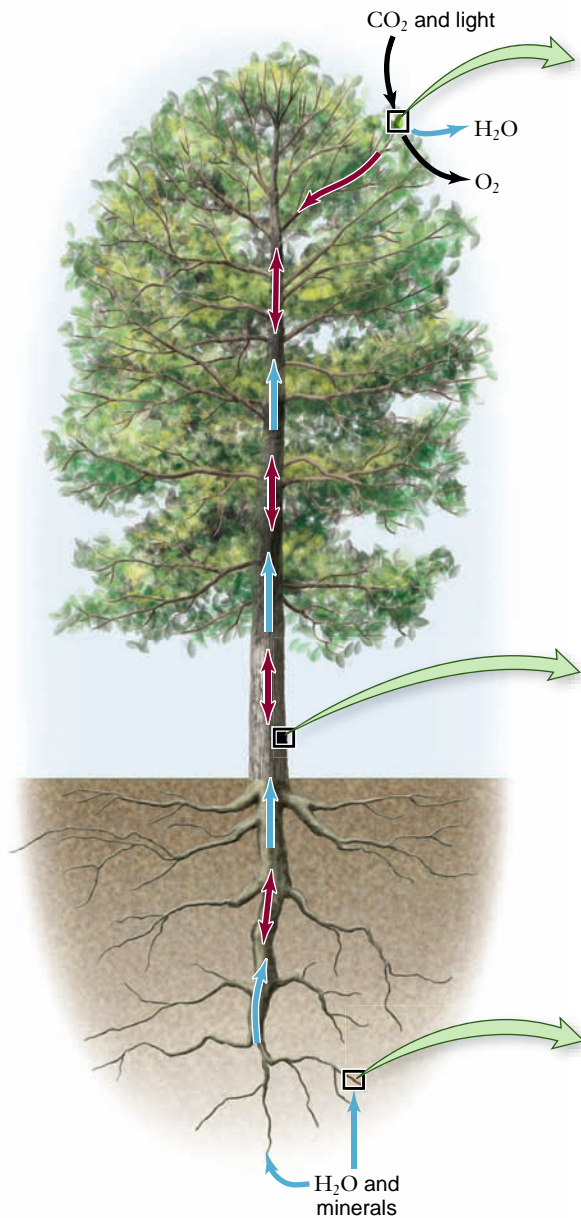

Plant biologists explain the forces that act on water within a plant in terms of potentials. *Potentials* are a way of representing free energy (the potential to do work; see chapter 5). **Water potential**, abbreviated by the Greek letter psi with a subscript W ( $\Psi_w$ ), is used to predict which way water will move. The key is to remember that water will move from a cell or solution with higher water potential to a cell or solution with lower water potential. Water potential is measured in units of pressure called **megapascals (MPa)**. If you turn on your kitchen or bathroom faucet full blast, the water pressure should be between 0.2 and 0.3 MPa (30 to 45 psi).

### Movement of water by osmosis

If a single plant cell is placed into water, then the concentration of solutes inside the cell is greater than that of the external

**Figure 38.1** Transport between cells. Water, minerals, and organic molecules can diffuse across membranes, be actively or passively transported by membrane-bound transporters, or move through plasmodesmata. Details of membrane transport are found in chapter 5.

**Figure 38.2** Water and mineral movement through a plant. This diagram illustrates the path of water and inorganic materials as they move into, through, and out of the plant body.

solution, and water moves into the cell by the process of **osmosis**, which you may recall from the discussion of membranes in chapter 5. The cell expands and presses against the cell wall, making it *turgid*, or swollen, because of the cell's increased turgor pressure. By contrast, if the cell is placed into a solution with a very high concentration of sucrose, water leaves the cell and turgor pressure drops. The cell membrane pulls away from the cell wall as the volume of the cell shrinks. This

process is called **plasmolysis**, and if the cell loses too much water it will die. Even a tiny change in cell volume causes large changes in turgor pressure. When the turgor pressure falls to zero, most plants will wilt.

### Calculation of water potential

A change in turgor pressure can be predicted more accurately by calculating the water potential of the cell and the surrounding

solution. Water potential has two components: (1) physical forces, such as pressure on a plant cell wall or gravity, and (2) the concentration of solute in each solution.

In terms of physical forces, the contribution of gravity to water potential is so small that it is generally not included in calculations unless you are considering a very tall tree. The turgor pressure, resulting from pressure against the cell wall, is referred to as **pressure potential ( $\Psi_p$ )**. As turgor pressure increases,  $\Psi_p$  increases. A beaker of water containing dissolved sucrose, however, is not bounded by a cell membrane or a cell wall. Solutions that are not contained within a vessel or membrane cannot have turgor pressure, and they always have a  $\Psi_p$  of 0 MPa (figure 38.3a).

Water potential also arises from an uneven distribution of a solute on either side of a membrane, which results in osmosis. Applying pressure on the side of the membrane that has the greater concentration of solute prevents osmosis. The smallest amount of pressure needed to stop osmosis is proportional to the osmotic or **solute potential ( $\Psi_s$ )** of the solution (figure 38.3b). Pure water has a solute potential of zero. As a solution increases in solute concentration, it decreases in  $\Psi_s$  ( $< 0$  MPa). A solution with a higher solute concentration has a more negative  $\Psi_s$ .

The total water potential ( $\Psi_w$ ) of a plant cell is the sum of its pressure potential ( $\Psi_p$ ) and solute potential ( $\Psi_s$ ); it represents the total potential energy of the water in the cell:

$$\Psi_w = \Psi_p + \Psi_s$$

When the  $\Psi_w$  inside the cell equals that of the solution, there is no net movement of water (figure 38.3c).

When a cell is placed into a solution with a different  $\Psi_w$ , the tendency is for water to move in the direction that eventually results in equilibrium—both the cell and the solution have the same  $\Psi_w$  (figure 38.4). The  $\Psi_p$  and  $\Psi_s$  values may differ for cell and solution, but the sum ( $=\Psi_w$ ) should be the same.

## Aquaporins enhance osmosis

For a long time, scientists did not understand how water moved across the lipid bilayer of the plasma membrane. Water, however, was found to move more rapidly than predicted by osmosis alone. We now know that osmosis is enhanced by membrane water channels called aquaporins, which you first encountered in chapter 5 (figure 38.5). These transport channels occur in both plants and animals; in plants, they exist in vacuoles and plasma membranes and also allow for bulk flow across the membrane.

At least 30 different genes code for aquaporin-like proteins in *Arabidopsis*. Aquaporins speed up osmosis, but they do not change the direction of water movement. They are important in maintaining water balance within a cell and in moving water into the xylem.

Water potential and pressure gradients form a foundation for understanding local and long-distance transport in plants. The remaining sections of this chapter explore transport within and among different tissues and organs of the plant in more depth.

**Figure 38.3** Determining water potential. *a.* Cell walls exert pressure in the opposite direction of cell turgor pressure. *b.* Using the given solute potentials, predict the direction of water movement based only on solute potential. *c.* Total water potential is the sum of  $\Psi_s$  and  $\Psi_p$ . Since the water potential inside the cell equals that of the solution, there is no net movement of water.

**Figure 38.4 Water potential at equilibrium.**

**a.** This cell initially had a larger  $\Psi_w$  than the solution surrounding it. **b.** At osmotic equilibrium, the  $\Psi_w$  of the cell and the solution should be the same. We assume that the cell is in a very large volume of solution of constant concentration. The final  $\Psi_w$  of the cell should therefore equal the initial  $\Psi_w$  of the solution. When a cell is plasmolyzed,  $\Psi_p = 0$ . As the cell loses water, the cell's solution becomes concentrated.

**Inquiry question**

? What would  $\Psi_w$ ,  $\Psi_s$ , and  $\Psi_p$  of the cell in (a) be at equilibrium if it had been placed in a solution with a  $\Psi_s$  of  $-0.5$ ?

**b.**

**Figure 38.5 Aquaporins.** Aquaporins are water-selective pores in the plasma membrane that increase the rate of osmosis because they allow bulk flow across the membrane. They do not alter the direction of water movement, however.

### Learning Outcomes Review 38.1

Transpiration is the evaporation of thin films of water from the stomata, exerting a lifting force on water in the xylem. Water potential is the sum of the pressure potential and the solute potential; water moves from an area of high water potential to an area of low water potential. This difference moves water from the soil into roots, and from the roots to the rest of the plant body. The vapor pressure gradient between the inside and the outside of a leaf drives transpiration.

- Explain how physical pressure and solute concentration contribute to water potential.

## 38.2 Water and Mineral Absorption

### Learning Outcomes

1. Explain the function of root hairs.
2. List the three water transport routes through plants.
3. Describe the function of Casparian strips.

Most of the water absorbed by the plant comes in through the region of the root with root hairs (figures 38.6 and 38.7). As you learned in chapter 36, root hairs are extensions of root epidermal cells located just behind the tips of growing roots.

Surface area for the absorption of water and minerals is further increased in many species of plants by interacting with mycorrhizal fungi. These fungi extend the absorptive net far beyond that of root hairs and are particularly helpful in the uptake of phosphorous in the soil. Mycorrhizae are discussed in detail in chapter 31.

**Figure 38.6** Water potential is higher in soil and roots than at the shoot tip. Water evaporating from the leaves through the stomata causes additional water to move upward in the xylem and also to enter the plant through the roots. Water potential drops substantially in the leaves due to transpiration.

**Figure 38.7** Water and minerals move into roots in regions rich with root hairs.

Once absorbed through root hairs, water and minerals must move across cell layers until they reach the vascular tissues; water and dissolved ions then enter the xylem and move throughout the plant.

### Three transport routes exist through cells

Water and minerals can follow three pathways to the vascular tissue of the root (figure 38.8). The **apoplast route** includes movement through the cell walls and the space between cells. Transport through the apoplast avoids membrane transport. The **symplast route** is the continuum of cytoplasm between cells connected by plasmodesmata. Once molecules are inside a cell, they can move between cells through plasmodesmata without crossing a plasma membrane. The **transmembrane route** involves membrane transport between cells and also across the membranes of vacuoles within cells. This route permits each

cell the greatest amount of control over what substances enter and leave. These three routes are not exclusive, and molecules can change pathways at any time, until reaching the endodermis of the root.

### Transport through the endodermis is selective

Eventually, on their journey inward, molecules reach the endodermis. Any further passage through the cell walls is blocked by the Casparian strips. As described in chapter 36, all cells in the cylinder of endodermis have connecting walls embedded with the waterproof material suberin (figure 38.9). Molecules must pass through the plasma membranes and protoplasts of the endodermal cells to reach the xylem. The endodermis, with its unique structure, along with the cortex and epidermis, controls water and nutrient flow to the xylem to regulate water potential and helps limit leakage of water out of the root.

Because the mineral ion concentration in the soil water is usually much lower than it is in the plant, an expenditure of energy (supplied by ATP) is required for these ions to accumulate in root cells. The plasma membranes of endodermal cells contain a variety of protein transport channels, through which proton pumps transport specific ions against even larger concentration gradients (refer to figure 38.1). Once inside the vascular stele, the ions, which are plant nutrients, are transported via the xylem throughout the plant.

#### Learning Outcomes Review 38.2

Water and minerals move into the plant from the soil, particularly in the region rich with root hairs. The three water transport routes are the apoplast route through the cell walls, the symplast route through plasmodesmata, and the transmembrane route across cell and vacuole membranes. Casparian strips force water and nutrients to move through the cell membranes of the endodermis, allowing selective control.

- *What qualities of the cell membrane allow it to act as a selective barrier?*

**Figure 38.8** Transport routes between cells.

#### Inquiry question

? Which route would be the fastest for water movement? Would this always be the best way to move nutrients into the plant?

## 38.3 Xylem Transport

### Learning Outcomes

1. Describe the environmental conditions in which guttation occurs.
2. List the properties of water that cause it to have a high tensile strength.
3. Explain how cavitation interrupts water flow.

The aqueous solution that passes through the membranes of endodermal cells enters the plant's vascular tissues and moves into the tracheids and vessel members of the xylem. As ions are actively pumped into the root or move via facilitated diffusion, their presence increases the water potential and increases turgor pressure in the roots due to osmosis.

### Root pressure is present even when transpiration is low or not occurring

**Root pressure**, which often occurs at night, is caused by the continued accumulation of ions in the roots at times when transpiration from the leaves is very low or absent. This accumula-

tion results in an increasingly high ion concentration within the cells, which in turn causes more water to enter the root hair cells by osmosis. Ion transport further decreases the  $\Psi_s$  of the roots. The result is movement of water into the plant and up the xylem columns despite the absence of transpiration.

Under certain circumstances, root pressure is so strong that water will ooze out of a cut plant stem for hours or even days. When root pressure is very high, it can force water up to the leaves, where it may be lost in a liquid form through a process known as **guttation**. Guttation cannot move water up great heights or at rapid speeds. It does not take place through the stomata, but instead occurs through special groups of cells located near the ends of small veins that function only in this process. Guttation produces what is more commonly called dew on leaves.

Root pressure alone, however, is insufficient to explain xylem transport. Transpiration provides the main force for moving water and ionic solutes from roots to leaves.

### A water potential gradient from roots to shoots enables transport

Water potential regulates the movement of water through a whole plant, as well as across cell membranes. Roots are the entry point. Water moves from the soil into the plant only if water potential of the soil is greater than in the root. Too much fertilizer or drought conditions lower the  $\Psi_w$  of the soil and limit water flow into the plant. Water in a plant moves along a  $\Psi_w$  gradient from the soil (where the  $\Psi_w$  may be close to zero under wet conditions) to successively more negative water potentials in the roots, stems, leaves, and atmosphere (see figure 38.6).

**Figure 38.9** The pathways of mineral transport in roots. Minerals are absorbed at the surface of the root. In passing through the cortex, they must either follow the cell walls and the spaces between them or go directly through the plasma membranes and the protoplasts of the cells, passing from one cell to the next by way of the plasmodesmata. When they reach the endodermis, however, their further passage through the cell walls is blocked by the Casparian strips, and they must pass through the membrane and protoplast of an endodermal cell before they can reach the xylem.

Evaporation of water in a leaf creates negative pressure or tension in the xylem, which literally pulls water up the stem from the roots. The strong pressure gradient between leaves and the atmosphere cannot be explained by evaporation alone. As water diffuses from the xylem of tiny, branching veins in a leaf, it forms a thin film along mesophyll cell walls. If the surface of the air–water interface is fairly smooth (flat), the water potential is higher than if the surface becomes rippled.

The driving force for transpiration is the humidity gradient from 100% relative humidity inside the leaf to much less than 100% relative humidity outside the stomata. Molecules diffusing from the xylem replace evaporating water molecules. As the rate of evaporation increases, diffusion cannot replace all the water molecules. The film is pulled back into the cell walls and becomes rippled rather than smooth. The change increases the pull on the column of water in the xylem, and concurrently increases the rate of transpiration.

### Vessels and tracheids accommodate bulk flow

Water has an inherent **tensile strength** that arises from the cohesion of its molecules, their tendency to form hydrogen bonds with one another (see chapter 2). These two factors are the basis of the cohesion–tension theory of the bulk flow of water in the xylem. The tensile strength of a column of water varies inversely with the diameter of the column; that is, the smaller the diameter of the column, the greater the tensile strength. Because plant tracheids and vessels are tiny in diameter, the cohesive force of water is stronger than the pull of gravity. The water molecules also adhere to the sides of the tracheid or xylem vessels, further stabilizing the long column of water.

Given that a narrower column of water has greater tensile strength, it is intriguing that vessels, having diameters that are larger than tracheids, are found in so many plants. The difference in diameter has a larger effect on the mass of water in the column than on the tensile strength of the column. The volume of liquid moving in a column per second is proportional to  $r^4$ , where  $r$  is the radius of the column, at constant pressure. A twofold increase in radius would result in a 16-fold increase in the volume of liquid moving through the column. Given equal cross-sectional areas of xylem, a plant with larger-diameter vessels can move more water up its stems than a plant with narrower tracheids.

#### Inquiry question

If a mutation increased the radius of a xylem vessel threefold, how would the movement of water through the plant be affected?

#### The effect of cavitation

Tensile strength depends on the continuity of the water column; air bubbles introduced into the column when a vessel is broken or cut would cause the continuity and the cohesion to fail. A gas-filled bubble can expand and block the tracheid or vessel, a process called **cavitation**. Cavitation stops water transport and can lead to dehydration and death of part or all of a plant (figure 38.10).

**Figure 38.10**

**Cavitation.** An air bubble can break the tensile strength of the water column. Bubbles are larger than pits and can block transport to the next tracheid or vessel. Water drains to surrounding tracheids or vessels.

Anatomical adaptations can compensate for the problem of cavitation, including the presence of alternative pathways that can be used if one path is blocked. Individual tracheids and vessel members are connected to other tracheids or vessels by pits in their walls, and air bubbles are generally larger than these openings. In this way, bubbles cannot pass through the pits to further block transport. Freezing or deformation of cells can also cause small bubbles of air to form within xylem cells, especially with seasonal temperature changes. Cavitation is one reason older xylem often stops conducting water.

#### Mineral transport

Tracheids and vessels are essential for the bulk transport of minerals. Ultimately, the minerals that are actively transported into the roots are removed and relocated through the xylem to other metabolically active parts of the plant. Phosphorus, potassium, nitrogen, and sometimes iron may be abundant in the xylem during certain seasons. In many plants, this pattern of ionic concentration helps conserve these essential nutrients, which may move from mature deciduous parts such as leaves and twigs to areas of active growth, namely meristem regions.

Keep in mind that minerals that are relocated via the xylem must move with the generally upward flow through the xylem. Not all minerals can reenter the xylem conduit once they leave. Calcium, an essential nutrient, cannot be transported elsewhere once it has been deposited in a particular plant part. But some other nutrients can be transported in the phloem.

#### Learning Outcomes Review 38.3

Guttation occurs when root pressure is high but transpiration is low. It commonly occurs at night in temperate climates when the air is cool and the humidity is high. Water's high tensile strength results from the cohesiveness of water molecules for each other and adhesiveness to the walls of cells in the xylem; both of these are effects of hydrogen bonding. Cavitation, which stops water movement, results from a bubble in the water transport system that breaks cohesion.

- What controls the rate of transpiration when the humidity is low?
- What happens to minerals once they leave the xylem?

## 38.4 The Rate of Transpiration

### Learning Outcomes

1. Explain the process by which guard cells regulate the opening of stomata.
2. Name the two conflicting requirements that influence opening and closing of stomata.

More than 90% of the water taken in by the roots of a plant is ultimately lost to the atmosphere. Water moves from the tips of veins into mesophyll cells, and from the surface of these cells it evaporates into pockets of air in the leaf. As discussed in chapter 36, these intercellular spaces are in contact with the air outside the leaf by way of the stomata.

### Stomata open and close to balance H<sub>2</sub>O and CO<sub>2</sub> needs

Water is essential for plant metabolism, but it is continuously being lost to the atmosphere. At the same time, photosynthesis requires a supply of CO<sub>2</sub> entering the chlorenchyma cells from the atmosphere. Plants therefore face two somewhat conflicting requirements: the need to minimize the loss of water to the atmosphere and the need to admit carbon dioxide. Structural features such as stomata and the cuticle have evolved in response to one or both of these requirements.

The rate of transpiration depends on weather conditions, including humidity and the time of day. As stated earlier, transpiration from the leaves decreases at night, when stomata are closed and the vapor pressure gradient between the leaf and the atmosphere is less. During the day, sunlight increases the temperature of the leaf, while transpiration cools the leaf through evaporative cooling.

On a short-term basis, closing the stomata can control water loss. This occurs in many plants when they are subjected to water

stress. But the stomata must be open at least part of the time so that CO<sub>2</sub> can enter. As CO<sub>2</sub> enters the intercellular spaces, it dissolves in water before entering the plant's cells where it is used in photosynthesis. The gas dissolves mainly in water on the walls of the intercellular spaces below the stomata. The continuous stream of water that reaches the leaves from the roots keeps these walls moist.

### Turgor pressure in guard cells causes stomata to open and close

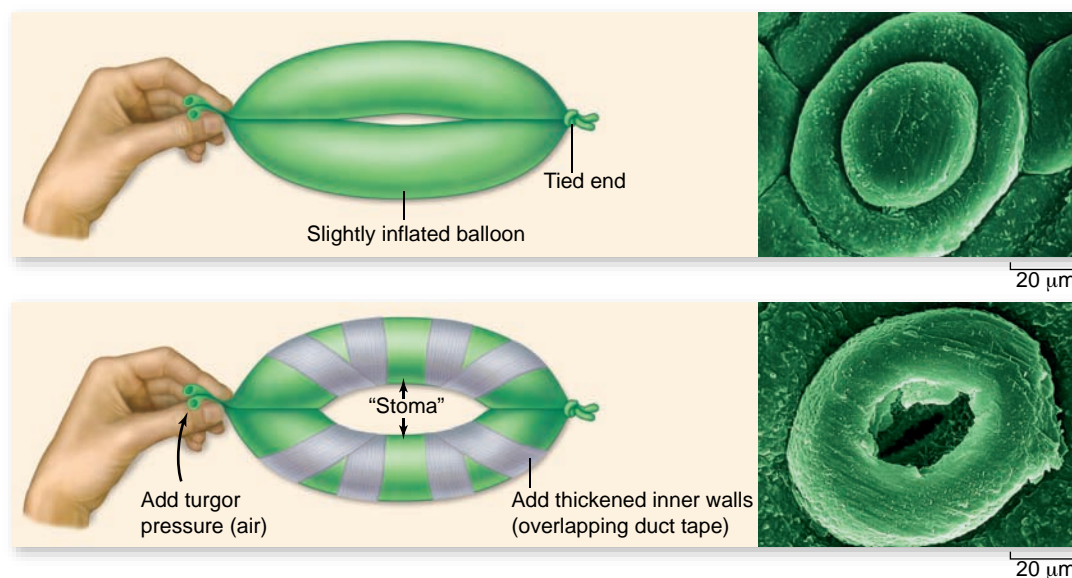

The two sausage-shaped guard cells on each side of a stoma stand out from other epidermal cells not only because of their shape, but also because they are the only epidermal cells containing chloroplasts. Their distinctive wall construction, which is thicker on the inside and thinner elsewhere, results in a bulging out and bowing when they become turgid.

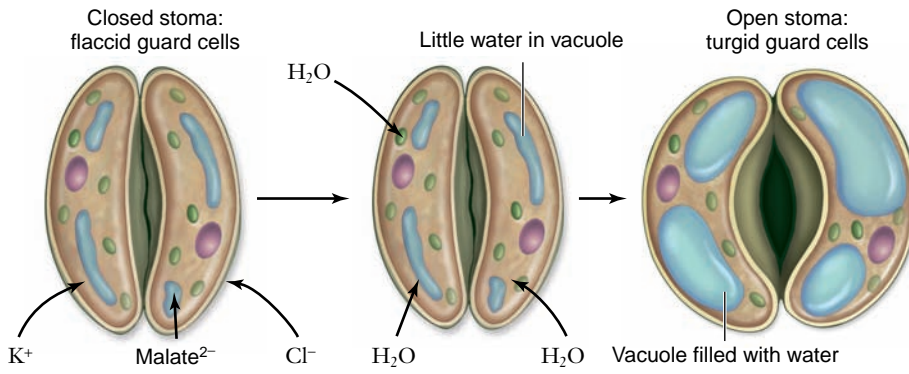

You can make a model of this for yourself by taking two elongated balloons, tying the closed ends together, and inflating both balloons slightly. When you hold the two open ends slightly together, there should be very little space between the two balloons. Now wrap duct tape around both balloons as shown in figure 38.11 (without releasing any air) and inflate each one a bit more. Hold the open ends together again. You should now be holding a roughly doughnut-shaped pair of “guard cells” with a “stoma” in the middle. Real guard cells rely on the influx and efflux of water, rather than air, to open and shut.

Turgor in guard cells results from the active uptake of potassium (K<sup>+</sup>), chloride (Cl<sup>-</sup>), and malate. As solute concentration increases, water potential decreases in the guard cells, and water enters osmotically. As a result, these cells accumulate water and become turgid, opening the stomata (figure 38.12). The energy required to move the ions across the guard cell membranes comes from the ATP-driven H<sup>+</sup> pump shown in figure 38.1.

The guard cells of many plant species regularly become turgid in the morning, when photosynthesis occurs, and lose turgor in the evening, regardless of the availability of water. During the course of a day, sucrose accumulates in the photosynthetic guard cells. The active pumping of sucrose out of guard cells in the evening may lead to loss of turgor and close the guard cell.

**Figure 38.11** Unequal cell wall thickenings on guard cells result in the opening of stomata when the guard cells expand.

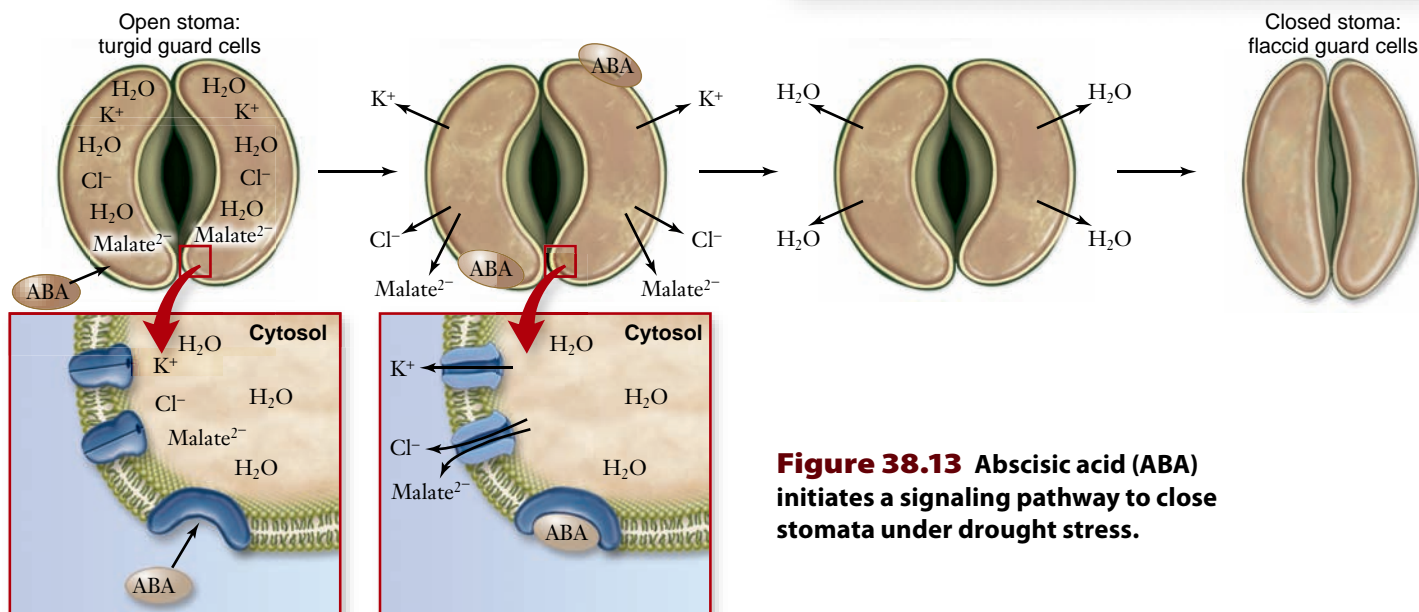

**Figure 38.12 How a stoma opens.** When  $H^+$  ions are pumped from guard cells,  $K^+$  and  $Cl^-$  ions move in, and the guard cell turgor pressure increases as water enters by osmosis. The increased turgor pressure causes the guard cells to bulge, with the thick walls on the inner side causing each guard cell to bow outward, thereby opening the stoma.

## Environmental factors affect transpiration rates

Transpiration rates increase with temperature and wind velocity because water molecules evaporate more quickly. As humidity increases, the water potential difference between the leaf and the atmosphere decreases, but even at 95% relative humidity in the atmosphere, the vapor pressure gradient can sustain full transpiration. On a catastrophic level, when a whole plant wilts because insufficient water is available, the guard cells may lose turgor, and as a result, the stomata may close. Fluctuations in transpiration rate are tempered by opening or closing stomata.

Experimental evidence has indicated that several pathways regulate stomatal opening and closing. **Abscisic acid (ABA)**, a plant hormone discussed in chapter 41, plays a primary role in allowing  $K^+$  to pass rapidly out of guard cells, causing the stomata to close in response to drought. ABA binds to receptor sites in the plasma membranes of guard cells, triggering a signaling pathway that opens  $K^+$ ,  $Cl^-$ , and malate ion channels. Turgor pressure decreases as water loss follows, and the guard cells close (figure 38.13).

### Learning Outcomes Review 38.4

When guard cells of the stomata actively take up ions, their water potential decreases and they take up water by osmosis. When they become turgid they change shape, creating an opening in the stoma. Stomata close when a plant is under water stress, but they open when carbon dioxide is needed and transpiration does not cause excess water loss. Transpiration rates increase with high wind velocity, high temperatures, and low humidity.

- Why is it critical that carbon dioxide dissolve in water upon entering plants?

**Figure 38.13 Abscisic acid (ABA) initiates a signaling pathway to close stomata under drought stress.**

$CO_2$  concentration, light, and temperature also affect stomatal opening. When  $CO_2$  concentrations are high, the guard cells of many plant species are triggered to decrease the stomatal opening. Additional  $CO_2$  is not needed at such times, and water is conserved when the guard cells are closed.

Blue light regulates stomatal opening. This helps increase turgor to open the stomata when sunlight increases the evaporative cooling demands.  $K^+$  transport against a concentration gradient is promoted by light. Blue light in particular triggers proton ( $H^+$ ) transport, creating a proton gradient that drives the opening of  $K^+$  channels.

The stomata may close when the temperature exceeds  $30^\circ$  to  $34^\circ C$  and water relations are unfavorable. To ensure sufficient gas

exchange, these stomata open when it is dark and the temperature has dropped. Some plants are able to collect  $CO_2$  at night in a modified form to be utilized in photosynthesis during daylight hours. In chapter 9, you learned about Crassulacean acid metabolism (CAM), which occurs in succulent plants such as cacti. In this process, stomata open and  $CO_2$  is taken in at night and stored in organic compounds. These compounds are decarboxylated during the day, providing a source of  $CO_2$  for fixation when stomata are closed. CAM plants are able to conserve water in dry environments.

## 38.5 Water-Stress Responses

### Learning Outcomes

1. List three drought adaptations in plants.
2. Describe the negative effects of flooding on plant growth.
3. Outline three ways in which a plant may deal with a salty environment.

Because plants cannot simply move on when water availability or salt concentrations change, adaptations have evolved to allow plants to cope with environmental fluctuations, including drought, flooding, and changing salinity.

### Plant adaptations to drought include strategies to limit water loss

Many mechanisms for controlling the rate of water loss have evolved in plants. Regulating the opening and closing of stomata provides an immediate response. Morphological adaptations provide longer term solutions to drought periods. For example, for some plants dormancy occurs during dry times of the year; another mechanism involves loss of leaves, limiting transpiration. Deciduous plants are common in areas that periodically experience severe drought. In a broad sense, annual plants conserve water when conditions are unfavorable simply by going into “dormancy” as seeds.

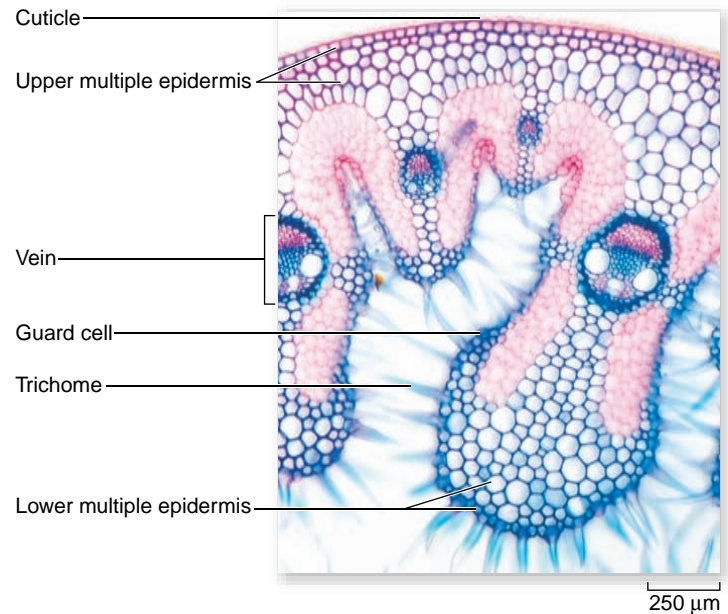

Thick, hard leaves often with relatively few stomata—and frequently with stomata only on the lower side of the leaf—lose water far more slowly than large, pliable leaves with abundant stomata. Leaves covered with masses of wooly-looking trichomes (hairs) reflect more sunlight and thereby reduce the heat load on the leaf and the demand for transpiration for evaporative cooling.

Plants in arid or semiarid habitats often have their stomata in crypts or pits in the leaf surface (figure 38.14). Within these depressions, the water surface tensions are altered, reducing the rate of water loss.

### Plant responses to flooding include short-term hormonal changes and long-term adaptations

Plants can also receive too much water, in which case they ultimately “drown.” Flooding rapidly depletes available oxygen in the soil and interferes with the transport of minerals and carbohydrates in the roots. Abnormal growth often results. Hormone levels change in flooded plants; ethylene, a hormone associated with suppression of root elongation, increases, while gibberellins and cytokinins, which enhance growth of new roots, usually decrease (see chapter 41). Hormonal changes contribute to the abnormal growth patterns.

Oxygen deprivation is among the most significant problems because it leads to decreased cellular respiration. Standing water has much less oxygen than moving water. Generally, standing-water flooding is more harmful to a plant (riptides excluded). Flooding that occurs when a plant is dormant is much less harmful than flooding when it is growing actively.

**Figure 38.14** Anatomical protection from drought in leaves. Deeply embedded stomata, extensive trichomes, and multiple layers of epidermis minimize water loss in this leaf, shown in cross section.

Physical changes that occur in the roots as a result of oxygen deprivation may halt the flow of water through the plant. Paradoxically, even though the roots of a plant may be standing in water, its leaves may be drying out. Plants can respond to flooded conditions by forming larger lenticels (which facilitate gas exchange) and adventitious roots that reach above flood level for gas exchange.

Whereas some plants survive occasional flooding, others have adapted to living in fresh water. One of the most frequent adaptations among plants to growing in water is the formation of **aerenchyma**, loose parenchymal tissue with large air spaces in it (figure 38.15). Aerenchyma is very prominent in water lilies and many other aquatic plants. Oxygen may be transported from the parts of the plant above water to those below by way of passages in the aerenchyma. This supply of oxygen allows oxidative respiration to take place even in the submerged portions of the plant.

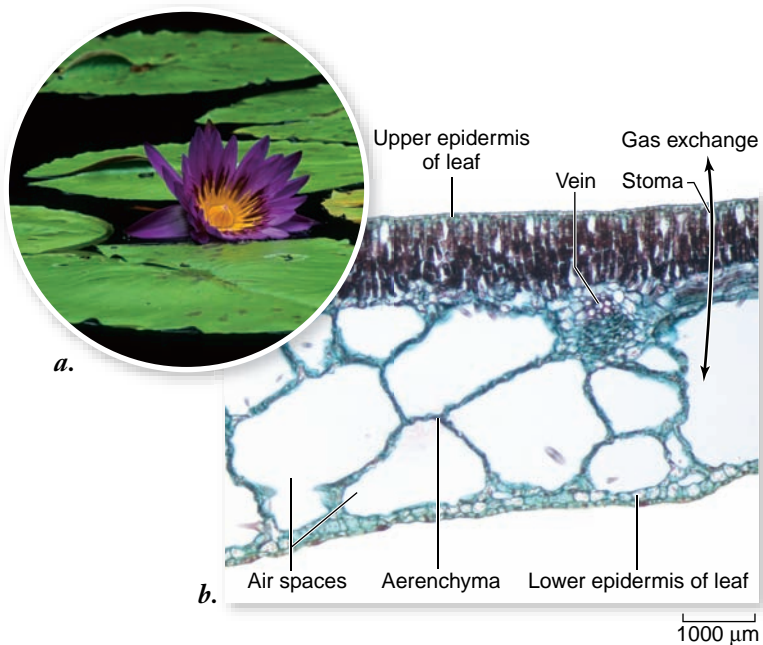

Some plants normally form aerenchyma, whereas others, subject to periodic flooding, can form it when necessary. In corn, increased ethylene due to flooding induces aerenchyma formation.

### Plant adaptations to high salt concentration include elimination methods

The algal ancestors of plants adapted to a freshwater environment from a saltwater environment before the “move” onto land. This adaptation involved a major change in controlling salt balance.

#### Growth in salt water

Plants such as mangroves that grow in areas normally flooded with salt water must not only provide a supply of oxygen to their submerged parts, but also control their salt balance. The salt must be excluded, actively secreted, or diluted as it enters. The black mangrove (*Avicennia germinans*) has long, spongy, air-filled roots that emerge above the mud. These roots, called

**Figure 38.15 Aerenchyma.** This tissue facilitates gas exchange in aquatic plants. *a.* Water lilies float on the surface of ponds, collecting oxygen and then transporting it to submerged portions of the plant. *b.* Large air spaces in the leaves of the water lily add buoyancy. The specialized parenchyma tissue that forms these open spaces is called aerenchyma. Gas exchange occurs through stomata found only on the upper surface of the leaf.

*pneumatophores* (see chapter 36), have large lenticels on their above-water portions through which oxygen enters; it is then transported to the submerged roots (figure 38.16). In addition, the succulent leaves of some mangrove species contain large quantities of water, which dilute the salt that reaches them. Many plants that grow in such conditions also either secrete large quantities of salt or block salt uptake at the root level.

### Growth in saline soil

Soil salinity is increasing, often caused by salt accumulation from irrigation. Currently 23% of the world's cultivated land has high levels of saline that reduce crop yield. The low water potential of saline soils results in water-stressed crops. Some plants, called **halophytes** (salt lovers), can tolerate soils with high salt concentrations. Mechanisms for salt tolerance are being studied with the goal of breeding more salt-tolerant plants. Some halophytes produce high concentrations of organic molecules within their roots to alter the water potential gradient between the soil and the root so that water flows into the root.

### Learning Outcomes Review 38.5

Adaptations to drought include dormancy, leaf loss, leaves that minimize water loss, and stomata that lie in depressions. When plants are exposed to flooding, oxygen deprivation leads to lower cellular respiration rates, impedance of mineral and carbohydrate transport, and changes in hormone levels. If a plant is exposed to a salty environment, it may exclude the salt from uptake, secrete it after it has been taken up, or dilute it.

- **Why are flooded plants in danger of oxygen deprivation when photosynthesis produces oxygen?**

**Figure 38.16 How mangroves get oxygen to their submerged parts.** The black mangrove (*Avicennia germinans*) grows in areas that are commonly flooded, and much of each plant is usually submerged. However, modified roots called pneumatophores supply the submerged portions of the plant with oxygen because these roots emerge above the water and have large lenticels. Oxygen diffuses into the roots through the lenticels, passes into the abundant aerenchyma, and moves to the rest of the plant.

## 38.6 Phloem Transport

### Learning Outcomes

1. Define translocation.
2. List the substances found in plant sap.
3. Explain the pressure-flow hypothesis.

Most carbohydrates manufactured in leaves and other green parts are distributed through the phloem to the rest of the plant. This process, known as translocation, provides suitable carbohydrate building blocks for the roots and other actively growing regions of the plant. Carbohydrates concentrated in storage organs such as tubers, often in the form of starch, are also converted into transportable molecules, such as sucrose, and moved through the phloem. In this section we discuss the ways by which carbohydrate- and nutrient-rich fluid, termed **sap**, is moved through the plant body.

### Organic molecules are transported up and down the plant

The movement of sugars and other substances can be followed in phloem using radioactive labels (figure 38.17). Radioactive carbon dioxide ( $^{14}\text{CO}_2$ ) can be incorporated into glucose as a result of photosynthesis. Glucose molecules are used to make the disaccharide sucrose, which is transported in the phloem. Such studies have shown that sucrose moves both up and down in the phloem.

## SCIENTIFIC THINKING

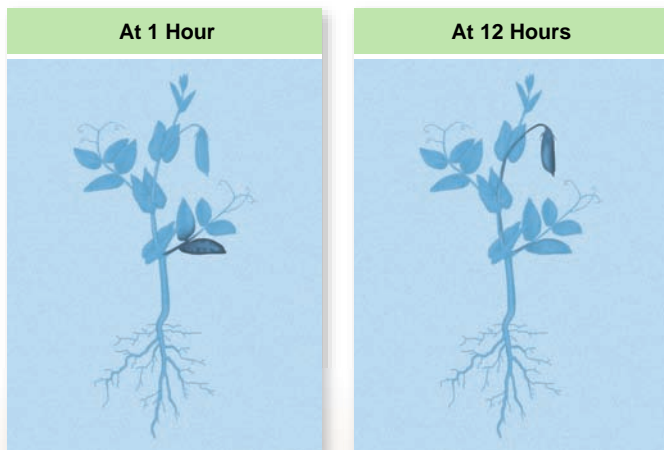

**Hypothesis:** As pea embryos develop in a pod, sugars will be transported through the phloem to the developing embryos.

**Prediction:** Radioactively labeled sugars will accumulate in developing pea embryos.

**Test:** Expose a healthy pea leaf to radioactive carbon dioxide ( $^{14}\text{CO}_2$ ). Place photographic film over the entire plant at 1 and 12 hours after treatment and develop film.

**Result:** After 1 hour the radioactivity is concentrated near the application site. After 12 hours the radioactivity is concentrated in the developing embryo.

**Conclusion:** The  $^{14}\text{CO}_2$  is incorporated into sugars during photosynthesis and transported to the developing embryo in the pod.

**Further Experiments:** Carrots take two years to flower. During the first season an underground root, the 'carrot', develops and sugars are stored to be used for reproduction the next year. How could you test the hypothesis that sugars are transported to the developing storage root during the first season of growth for a carrot plant?

### Figure 38.17 Sucrose flow in phloem during fruit development.

Aphids, a group of insects that extract plant sap for food, have been valuable tools in understanding translocation. Aphids thrust their stylets (piercing mouthparts) into phloem cells of

leaves and stems to obtain the abundant sugars there. When a feeding aphid is removed by cutting its stylet, the liquid from the phloem continues to flow through the detached mouthpart and is thus available in pure form for analysis (figure 38.18). The liquid in the phloem, when evaporated, contains 10 to 25% of dry-weight matter, almost all of which is sucrose. Using aphids to obtain the critical samples and radioactive tracers to mark them, plant biologists have demonstrated that substances in phloem can move remarkably fast, as much as 50 to 100 cm/h.

Phloem also transports plant hormones, and as will be explored in chapter 41, environmental signals can result in the rapid translocation of hormones in the plant. Recent evidence also indicates that mRNA can move through the phloem, providing a previously unknown mechanism for long-distance communication among cells. In addition, phloem carries other molecules, such as a variety of sugars, amino acids, organic acids, proteins, and ions.

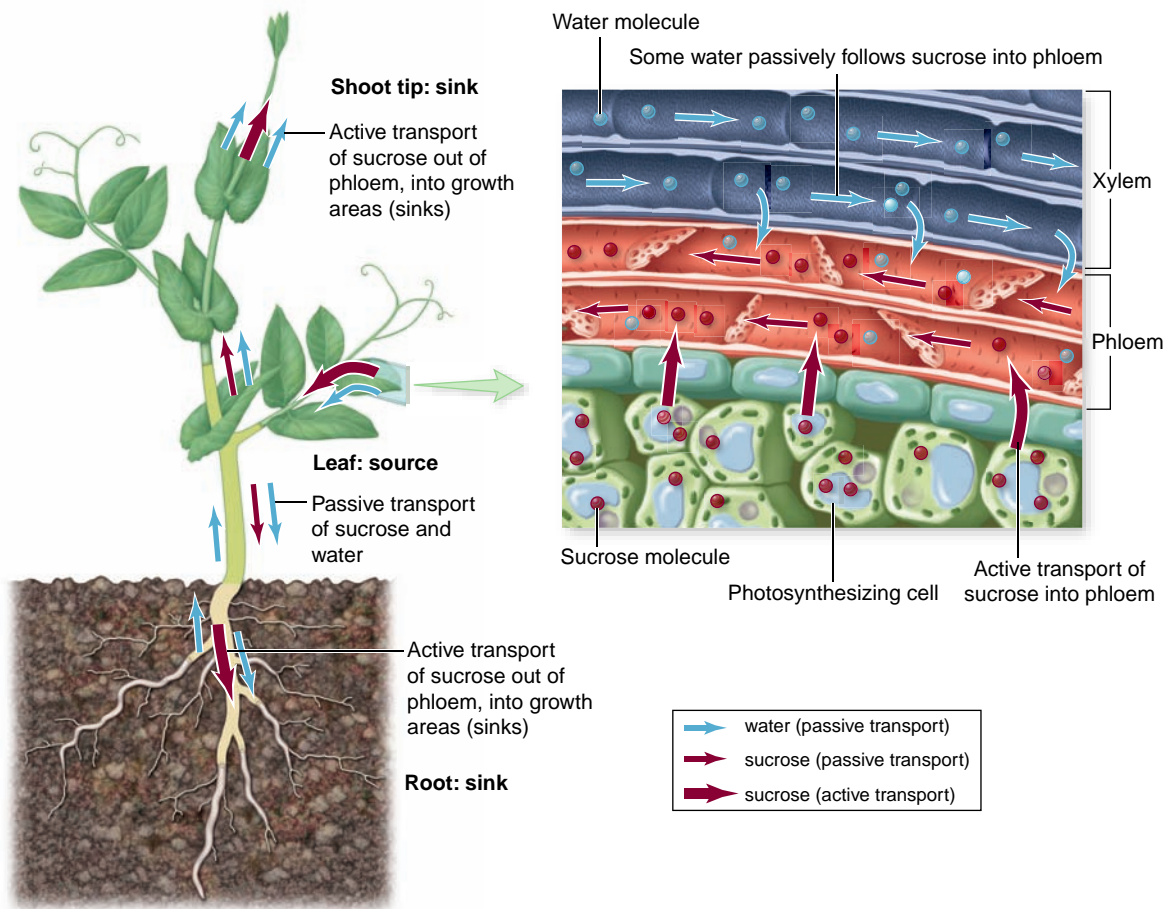

### Turgor pressure differences drive phloem transport

The most widely accepted model of how carbohydrates in solution move through the phloem has been called the **pressure-flow theory**. Dissolved carbohydrates

flow from a *source* and are released at a *sink*, where they are utilized. Carbohydrate sources include photosynthetic tissues, such as the mesophyll of leaves. Food-storage tissues, such as the cortex of roots, can be either sources

**Figure 38.18 Feeding on phloem.** *a.* Aphids, including this individual shown on the edge of a leaf, feed on the food-rich contents of the phloem, which they extract through (*b*) their piercing mouthparts, called stylets. When an aphid is separated from its stylet and the cut stylet is left in the plant, the phloem fluid oozes out of it and can then be collected and analyzed.

**Figure 38.19**  
**Diagram of mass flow.**  
 In this diagram, *red* dots represent sucrose molecules and *blue* dots symbolize water molecules. After moving from the mesophyll cells of a leaf or another part of the plant into the conducting cells of the phloem, the sucrose molecules are transported to other parts of the plant by mass flow and unloaded where they are required.

or sinks. Sinks also occur at the growing tips of roots and stems and in developing fruits. Also, because sources and sinks can change through time as needs change, the direction of phloem flow can change.

In a process known as **phloem loading**, carbohydrates (mostly sucrose) enter the sieve tubes in the smallest veins at the source. Some sucrose travels from mesophyll cells to the companion and sieve cells via the symplast (see figure 38.8). Much of the sucrose arrives at the sieve cell through apoplastic transport and is moved across the membrane via a sucrose and  $H^+$  symporter (see chapter 5). This energy-requiring step is driven by a proton pump (see figure 38.1). Companion cells and parenchyma cells adjacent to the sieve tubes provide the ATP energy to drive this transport. Unlike vessels and tracheids, sieve cells must be alive to participate in active transport.

Bulk flow occurs in the sieve tubes without additional energy requirements. Because of the difference between the water potential in the sieve tubes and in the nearby xylem cells, water flows into the sieve tubes by osmosis. Turgor pressure in the sieve tubes thus increases, and this pressure drives the fluid throughout the plant's system of sieve tubes. At the sink, sucrose and hormones are actively removed from the sieve tubes,

and water follows by osmosis. The turgor pressure at the sink drops, causing a mass flow from the stronger pressure at the source to the weaker pressure at the sink (figure 38.19). Most of the water at the sink then diffuses back into the xylem, where it may either be recirculated or lost through transpiration.

Transport of sucrose and other carbohydrates within sieve tubes does not require energy. But the pressure needed to drive the movement is created through energy-dependent loading and unloading of these substances from the sieve tubes.

### Learning Outcomes Review 38.6

Translocation is the movement of dissolved carbohydrates and other substances from one part of the plant to another through the phloem. Sap in the phloem contains sucrose and other sugars, hormones, mRNA, amino acids, organic acids, proteins, and ions. According to the pressure-flow hypothesis, carbohydrates are loaded into sieve tubes, creating a difference in water potential. As a result, water enters the tubes and creates pressure to move fluid through the phloem.

- **What is the key difference between the fluid in xylem and the fluid in phloem?**

### 38.1 Transport Mechanisms (see figure 38.2)

#### *Local changes result in long-distance movement of materials.*

Properties of water, osmosis, and cellular activities predict the directions of water movement.

#### *Water potential regulates movement of water through the plant (see figures 38.3 and 38.4).*

The major force for water transport in a plant is the pulling of water by transpiration. Cohesion, adhesion, and osmosis all contribute to water movement.

Water potential is the sum of pressure potential and solute potential. Water moves from an area of high water potential to an area of low water potential.

#### *Aquaporins enhance osmosis (see figure 38.5).*

Aquaporins are water channels in plasma membranes that allow water to move across the membrane more quickly.

### 38.2 Water and Mineral Absorption

Root hairs and mycorrhizal fungi can increase the surface area for absorption of water and minerals.

#### *Three transport routes exist through cells.*

The apoplast route is through cell walls and spaces between cells. The symplast route is through the cytoplasm and between cells via plasmodesmata. The transmembrane route is also through the cytoplasm, but across membranes, where entry and exit of substances can be controlled.

#### *Transport through the endodermis is selective.*

Casparian strips in the endoderm force water and nutrients to move across the cell membranes, allowing selective flow of water and nutrients to the xylem.

### 38.3 Xylem Transport

#### *Root pressure is present even when transpiration is low or not occurring.*

Root pressure results from the active transport of ions into the root cells, which causes water to move in through osmosis. Guttation occurs when water is forced out of a plant as a result of high root pressure.

Water has a high tensile strength due to its cohesive and adhesive properties, which are related to hydrogen bonding.

#### *A water potential gradient from roots to shoots enables transport.*

Water moves into plants when the soil water potential is greater than that of roots. Evaporation of water from leaves creates a negative water potential that pulls water upward through the xylem.

#### *Vessels and tracheids accommodate bulk flow.*

The volume of water that can be transported by a xylem vessel or tracheid is a function of its diameter. As diameter decreases, tensile strength increases; however, a larger volume of water can be transported through a tube with a larger radius.

Cavitation occurs when a gas bubble forms in a water column and water movement ceases.

### 38.4 The Rate of Transpiration

#### *Stomata open and close to balance H<sub>2</sub>O and CO<sub>2</sub> needs.*

More than 90% of the water absorbed by the roots is lost by evaporation through stomata. Stomata must open to take up carbon dioxide for photosynthesis and to allow evaporation for transpiration and cooling for the leaf (see figure 39.12).

#### *Turgor pressure in guard cells causes stomata to open and close.*

Stomata open when the turgor pressure of guard cells increases due to the uptake of ions. The turgid guard cells change shape and create an opening between them. Stomata close when guard cells lose turgor pressure and become flaccid.

#### *Environmental factors affect transpiration rates.*

Transpiration rates increase as temperature and wind velocity increase and as humidity decreases. Stomata close at high temperatures or when carbon dioxide concentrations increase.

### 38.5 Water-Stress Responses

#### *Plant adaptations to drought include strategies to limit water loss.*

Plant adaptations to minimize water loss include closing stomata, becoming dormant, altering leaf characteristics to minimize water loss, and losing leaves.

#### *Plant responses to flooding include short-term hormonal changes and long-term adaptations.*

Flooding reduces oxygen availability for cellular respiration, results in abnormal growth, and reduces the efficiency of transport mechanisms.

Plants adapted to wet environments exhibit a variety of strategies, including lenticels, adventitious roots such as pneumatophores, and aerenchyma tissue to ensure oxygen for submerged parts.

#### *Plant adaptations to high salt concentration include elimination methods.*

Plants found in saline waters may exclude, secrete, or dilute salts that have been taken up.

Halophytes can take up water from saline soils by decreasing the water potential of their roots with high concentrations of organic molecules.

### 39.6 Phloem Transport

#### *Organic molecules are transported up and down the plant.*

Movement of organic nutrients from leaves to other parts of the plant through the phloem is called translocation.

The sap that moves through phloem contains sugars, plant hormones, mRNA, and other substances. Carbohydrates must be actively transported into the sieve tubes.

#### *Turgor pressure differences drive phloem transport.*

At the carbohydrate source, such as a photosynthetic leaf, active transport of sugars into the phloem causes a reduction in water potential.

As water moves into the phloem, turgor pressure drives the contents to a sink, such as a nonphotosynthetic tissue, where the sugar is unloaded.

## Review Questions

### UNDERSTAND

- Which of the following is an active transport mechanism?
  - Proton pump
  - Ion channel
  - Symport
  - Osmosis
- The water potential of a plant cell is the
  - sum of the membrane potential and gravity.
  - difference between membrane potential and gravity.
  - sum of the pressure potential and solute potential.
  - difference between pressure potential and solute potential.
- Hydrogen bonding between water molecules results in
  - submersion.
  - adhesion.
  - evaporation.
  - cohesion.
- Water movement through cell walls is
  - apoplastic.
  - symplastic.
  - both a and b
  - neither a nor b
- Casparian strips are found in the root
  - cortex.
  - dermal tissue.
  - endodermis.
  - xylem.
- The formation of an air bubble in the xylem is called
  - agitation.
  - cohesion.
  - adhesion.
  - cavitation.
- Guttation is most likely to be observed on
  - cold winter day.
  - cool summer night.
  - warm sunny day.
  - warm cloudy day.
- Stomata open when guard cells
  - take up potassium.
  - lose potassium.
  - take up sugars.
  - lose sugars.
- Which of the following is not an adaptation to a high saline environment?
  - Secretion of salts
  - Lowering of root water potential
  - Exclusion of salt
  - Production of pneumatophores
- A plant must expend energy to drive
  - transpiration.
  - translocation.
  - both transpiration and translocation.
  - neither transpiration nor translocation.

### APPLY

- Which of the following statements is inaccurate?
  - Water moves to areas of low water potential.
  - Xylem transports materials up the plant while phloem transports materials down the plant.
  - Water movement in the xylem is largely due to the cohesive and adhesive properties of water.
  - Water movement across membranes is often due to differences in solute concentrations.
- If you could override the control mechanisms that open stomata and force them to remain closed, what would you expect to happen to the plant?
  - Sugar synthesis would likely slow down.
  - Water transport would likely slow down.

- Both a and b could be the result of keeping stomata closed.
  - Neither a nor b would be the result of keeping stomata closed.
- What will happen if a cell with a solute potential of  $-0.4$  MPa and a pressure potential of  $0.2$  MPa is placed in a chamber filled with pure water that is pressurized with  $0.5$  MPa?
    - Water will flow out of the cell.
    - Water will flow into the cell.
    - The cell will be crushed.
    - The cell will explode.
  - If you were able to remove the aquaporins from cell membranes, which of the following would be the likely consequence?
    - Water would no longer move across membranes.
    - Plants would no longer be able to control the direction of water movement across membranes.
    - The potassium symport would no longer function.
    - Turgor pressure would increase.
  - What would be the consequence of removing the Casparian strip?
    - Water and mineral nutrients would not be able to reach the xylem.
    - There would be less selectivity as to what passed into the xylem.
    - Water and mineral nutrients would be lost from the xylem back into the soil.
    - Water and mineral nutrients would no longer be able to pass through the cell walls of the endodermis.

### SYNTHESIZE

- If you fertilize your houseplant too often, you may find that it looks wilted even when the soil is wet. Explain what has happened in terms of water potential.
- How could you detect a plant with a mutation in a gene for an important aquaporin protein?
- Contrast water transport mechanisms in plants with those in animals.
- Measurements of tree trunk diameters indicate that the trunk shrinks during the day, with shrinkage occurring in the upper part of the trunk before it occurs in the lower part. Explain how these observations support the hypothesis that water is pulled through the trunk as a result of transpiration.
- A carrot is a biennial plant. In the first year of growth, the seed germinates and produces a plant with a thick storage root. In the second year, a shoot emerges from the storage root and produces a flower stalk. Following fertilization, seeds are formed to start the life cycle again. Draw a carrot plant during the spring, summer, and fall of the two years of its life cycle and indicate the carbohydrate sources and sinks in each season.

# Chapter 39

## Plant Nutrition and Soils

### Chapter Outline

---

- 39.1** Soils: The Substrates on Which Plants Depend
- 39.2** Plant Nutrients
- 39.3** Special Nutritional Strategies
- 39.4** Carbon–Nitrogen Balance and Global Change
- 39.5** Phytoremediation

### Introduction

---

*Vast energy inputs are required for the building and ongoing growth of a plant. In this chapter, you'll learn what inputs, besides energy from the Sun, a plant needs to survive. Plants, like animals, need various nutrients to remain healthy. The lack of an important nutrient may slow a plant's growth or make the plant more susceptible to disease or even death. Plants acquire these nutrients mainly through photosynthesis and from the soil. In addition to contributing nutrients, the soil hosts bacteria and fungi that aid plants in obtaining nutrients in a usable form. Getting sufficient nitrogen is particularly problematic because plants cannot directly convert atmospheric nitrogen into amino acids. A few plants are able to capture animals and secrete digestive juices to make nitrogen available for absorption.*

## 39.1 Soils: The Substrates on Which Plants Depend

### Learning Outcomes

1. List the three main components of topsoil.
2. Explain how the charge of soil particles can affect the relative balance of positively and negatively charged molecules and ions in the soil water.
3. Describe cultivation approaches that can reduce soil erosion.

Much of the activity that supports plant life is hidden within the soil. **Soil** is the highly weathered outer layer of the Earth's crust. It is composed of a mixture of ingredients, which may include sand, rocks of various sizes, clay, silt, humus (partially decomposed organic matter), and various other forms of mineral and organic matter. Pore spaces containing water and air occur between the particles of soil.

### Soil is composed of minerals, organic matter, water, air, and organisms

The mineral fraction of soils varies according to the composition of the rocks. The Earth's crust includes about 92 naturally

**Figure 39.1** Most roots grow in the topsoil. Leaf litter and animal remains cover the uppermost layer in soil called topsoil. Topsoil contains organic matter, such as roots, small animals, humus, and mineral particles of various sizes. Subsoil lies underneath the topsoil and contains larger mineral particles and relatively little organic matter. Beneath the subsoil are layers of bedrock, the raw material from which soil is formed over time and through weathering.

occurring elements (see chapter 2). Most elements are found in the form of inorganic compounds called *minerals*; most rocks consist of several different minerals.

The soil is also full of microorganisms that break down and recycle organic debris. For example, about 5 metric tons of carbon is tied up in the organisms present in the soil under a hectare of wheat land in England—an amount that approximately equals the weight of 100 sheep!

Most roots are found in **topsoil** (figure 39.1), which is a mixture of mineral particles of varying size (most less than 2 mm in diameter), living organisms, and **humus**. Topsoils are characterized by their relative amounts of sand, silt, and clay. Soil composition determines the degree of water and nutrient binding to soil particles. Sand binds molecules minimally, but clay adsorbs (binds) water and nutrients quite tightly.

### Water and mineral availability is determined by soil characteristics

Only minerals that are dissolved in water in the spaces or pores among soil particles are available for uptake by roots. Both mineral and organic soil particles tend to have negative charges, so they attract positively charged molecules and ions. The negatively charged anions stay in solution, creating a charge gradient between the soil solution and the root cells, so that positive ions would normally tend to move out of the cells. Proton pumps move  $H^+$  out of the root to form a strong membrane potential ( $\approx -160$  mV). The strong electrochemical gradient then causes  $K^+$  and other ions to enter via ion channels. Some ions, especially anions, use cotransporters (figure 39.2). The membrane potential maintained by the root, as well as the water potential difference inside and outside the root, affects root transport. (Water potential is described in chapter 38.)

About half of the total soil volume is occupied by pores, which may be filled with air or water, depending on moisture

**Figure 39.2** Role of soil charge in transport. Active transport is required to move positively charged ions into a root hair.

**Figure 39.3 Water and air fill pores among soil particles.** *a.* Without some space for air circulation in the soil, roots cannot respire. *b.* A balance of air and water in the soil is essential for root growth. *c.* Too little water decreases the soil water potential and prevents transpiration in plants.

conditions (figure 39.3). Some of the soil water is unavailable to plants. In sandy soil, for example, a substantial amount of water drains away immediately due to gravity. Another fraction of the water is held in small soil pores, which are generally less than about 50  $\mu\text{m}$  in diameter. This water is readily available to plants. When this water is depleted through evaporation or root uptake, the plant wilts and will eventually die unless more water is added to the soil. However, as plants deplete water near the roots, the soil water potential decreases. This helps to move more water toward the roots since the soil water further away has a higher water potential.

Soils have widely varying composition, and any particular soil may provide more or fewer plant nutrients. In addition, the soil's acidity and salinity, described shortly, can affect the availability of nutrients and water.

### Cultivation can result in soil loss and nutrient depletion

When topsoil is lost because of erosion or poor landscaping, both the water-holding capacity and the nutrient relationships of

the soil are adversely affected. Up to 50 billion tons of topsoil have been lost from fields in the United States in a single year.

Whenever the vegetative cover of soil is disrupted, such as by plowing and harvesting, erosion by water and wind increases—sometimes dramatically, as was the case in the 1930s in the southwestern Great Plains of the United States. This region became known as the “Dust Bowl” when a combination of poor farming practices and several years of drought made the soil particularly susceptible to wind erosion (figure 39.4*a*).

New approaches to cultivation are aimed at reducing soil loss. Intercropping (mixing crops in a field), conservation tillage, and not plowing fall crop detritus under (no-till) are all erosion-prevention measures. Conservation tillage includes minimal till and even no-till approaches to farming.

Overuse of fertilizers in agriculture, lawns, and gardens can cause significant water pollution and its associated negative effects, such as overgrowth of algae in lakes (see chapter 58). Maintaining nutrient levels in the soil and preventing nutrient runoff into lakes, streams, and rivers improves crop growth and minimizes ecosystem damage.

**Figure 39.4 Soil degradation.** *a.* Drought and poor farming practices led to wind erosion of farmland in the southwestern Great Plains of the United States in the 1930s. *b.* Draining marshland in Iraq resulted in a salty desert.

*a.*

*b.*

One approach, site-specific farming, uses variable-rate fertilizer applicators guided by a computer and the global positioning system (GPS). Variable-rate application relies on information about local soil nutrient levels, based on analysis of soil samples. Another approach, integrated nutrient management, maximizes nutritional inputs using “green manure” (such as alfalfa tilled back into the soil), animal manure, and inorganic fertilizers. Green manures and animal manure have the advantage of releasing nutrients slowly as they are broken down by decomposer organisms, so that nutrients may be utilized before leaching away. Sustainable agriculture integrates these conservation approaches.

## pH and salinity affect water and mineral availability

Anything that alters water pressure differences or ionic gradient balance between soil and roots can affect the ability of plants to absorb water and nutrients. Acid soils (having low pH) and saline soils (high in salts) can present problems for plant growth.

### Acid soils

The pH of a soil affects the release of minerals from weathering rock. For example, at low pH aluminum, which is toxic to many plants, is released from rocks. Furthermore, aluminum can also combine with other nutrients and make them inaccessible to plants.

Most plants grow best at a neutral pH, but about 26% of the world’s arable land is acidic. In the tropical Americas, 68% of the soil is acidic. Aluminum toxicity in acid soils in Colombian fields can reduce maize (corn) yield fourfold (figure 39.5).

Breeding efforts in Colombia are producing aluminum-tolerant plants, and crop yields have increased 33%. In a few test fields, the yield increases have been as high as 70% compared with that for nontolerant plants. The ability of plants to take up toxic metals can also be employed to clean up polluted soil, a topic explored later in this chapter.

### Salinity

The accumulation of salt ions, usually  $\text{Na}^+$  and  $\text{Cl}^-$ , in soil alters water potential, leading to the loss of turgor in plants. Approximately 23% of all arable land has salinity levels that limit plant growth. Saline soil is most common in dry areas where salts are introduced through irrigation. In such areas, precipitation is insufficient to remove the salts, which gradually accumulate in the soil.

One of the more dramatic examples of soil salinity occurs in the “cradle of civilization,” Mesopotamia. The region once called the Fertile Crescent for its abundant agriculture is now largely a desert. Desertification was accelerated in southern Iraq. In the 1990s, most of 20,000  $\text{km}^2$  of marshlands was drained by redirecting water flow with dams, turning the marshes into a salty desert (see figure 39.4b). The dams were destroyed later, allowing water to enter the marshlands once again. Recovery of the marshlands is not guaranteed, but in areas where the entering water has lowered the salinity there is hope.

## SCIENTIFIC THINKING

**Hypothesis:** Acidic or basic soils inhibit the growth of corn plants.

**Prediction:** Plants grown in soil with neutral pH will be more vigorous than those grown at high or low pH.

**Test:** Sow equal numbers of corn kernels in identical pots with soil adjusted to pH values of 6.0, 7.0, and 8.0. Allow plants to grow and, after 16 weeks, measure the biomass.

**Result:** Corn plant biomass is highest in pots with pH 7.0 soil and lowest in pH 6.0 soil.

**Conclusion:** The hypothesis is supported. Soil pH influences plant growth. Among the pH levels tested, the best for plant growth was 7.0. Acidic soil resulted in the lowest growth.

**Further Experiments:** How could you test the hypothesis that soil pH affects mineral uptake and that changes in mineral uptake were responsible for differences in plant growth?

**Figure 39.5** Soil pH affects plant growth.

### Learning Outcomes Review 39.1

Topsoil is composed of mineral particles, living organisms, and humus. Roots use proton pumps to move protons ( $\text{H}^+$ ) out of the root and into the soil. The result is an electrochemical gradient that causes positive mineral ions to enter the root through ion channels. The loss of topsoil by erosion can be reduced by intercropping, planting crop mixtures, conservation tillage, and no-till farming.

■ In what way would alkaline soil affect plant nutrition?

## 39.2 Plant Nutrients

### Learning Outcomes

1. Distinguish between macronutrients and micronutrients.
2. Explain how scientists determine the nutritional needs of plants.
3. Describe the goal of food fortification research.

The major source of plant nutrition is the fixation of atmospheric carbon dioxide ( $\text{CO}_2$ ) into simple sugars using the energy of the Sun.  $\text{CO}_2$  enters through the stomata; oxygen ( $\text{O}_2$ ) is a waste

product of photosynthesis and an atmospheric component that also moves through the stomata. Oxygen is used in cellular respiration to support growth and maintenance in the plant.

$\text{CO}_2$  and light energy are not sufficient, however, for the synthesis of all the molecules a plant needs. Plants require a number of inorganic nutrients as well. Some of these are **macronutrients**, which plants need in relatively large amounts, and others are **micronutrients**, required in trace amounts (table 39.1).

### Plants require nine macronutrients and seven micronutrients

The nine macronutrients are carbon, oxygen, and hydrogen—the three elements found in all organic compounds—plus nitrogen (essential for amino acids), potassium, calcium, magnesium (the

**TABLE 39.1** Essential Nutrients in Plants

Element	Principal Form in Which Element Is Absorbed	Approximate Percent of Dry Weight	Examples of Important Functions
<i>M A C R O N U T R I E N T S</i>			
Carbon	$\text{CO}_2$	44	Major component of organic molecules
Oxygen	$\text{O}_2, \text{H}_2\text{O}$	44	Major component of organic molecules
Hydrogen	$\text{H}_2\text{O}$	6	Major component of organic molecules
Nitrogen	$\text{NO}_3^-, \text{NH}_4^+$	1–4	Component of amino acids, proteins, nucleotides, nucleic acids, chlorophyll, coenzymes, enzymes
Potassium	$\text{K}^+$	0.5–6	Protein synthesis, operation of stomata
Calcium	$\text{Ca}^{2+}$	0.2–3.5	Component of cell walls, maintenance of membrane structure and permeability; activates some enzymes
Magnesium	$\text{Mg}^{2+}$	0.1–0.8	Component of chlorophyll molecule, activates many enzymes
Phosphorus	$\text{H}_2\text{PO}_4^-, \text{HPO}_4^{2-}$	0.1–0.8	Component of ADP and ATP, nucleic acids, phospholipids, several coenzymes
Sulfur	$\text{SO}_4^{2-}$	0.05–1	Components of some amino acids and proteins, coenzyme A
<i>M I C R O N U T R I E N T S ( C O N C E N T R A T I O N S i n p p m )</i>			
Chlorine	$\text{Cl}^-$	100–10,000	Osmosis and ionic balance
Iron	$\text{Fe}^{2+}, \text{Fe}^{3+}$	25–300	Chlorophyll synthesis, cytochromes, nitrogenase
Manganese	$\text{Mn}^{2+}$	15–800	Activator of certain enzymes
Zinc	$\text{Zn}^{2+}$	15–100	Activator of many enzymes; active in formation of chlorophyll
Boron	$\text{BO}_3^-, \text{B}_4\text{O}_7^-,$ or $\text{H}_2\text{BO}_3^-$	5–75	Possibly involved in carbohydrate transport, nucleic acid synthesis
Copper	$\text{Cu}^2$ or $\text{Cu}^+$	4–30	Activator or component of certain enzymes
Molybdenum	$\text{MoO}_4^-$	0.1–5	Nitrogen fixation, nitrate reduction

**Figure 39.6 Mineral deficiencies in plants.** *a.* Leaves of a healthy wheat plant. *b.* Chlorine-deficient plants with necrotic leaves (leaves with patches of dead tissue). *c.* Copper-deficient plant with dry, bent leaf tips. *d.* Zinc-deficient plant with stunted growth and chlorosis (loss of chlorophyll) in patches on leaves. The agricultural implications of deficiencies such as these are obvious; a trained observer can determine the nutrient deficiencies affecting a plant simply by inspecting it.

center of the chlorophyll molecule), phosphorus, and sulfur. Each of these nutrients approaches or, in the case of carbon, may greatly exceed 1% of the dry weight of a healthy plant.

The seven micronutrient elements—chlorine, iron, manganese, zinc, boron, copper, and molybdenum—constitute from

**Figure 39.7 Identifying nutritional requirements of plants.** A seedling is first grown in a complete nutrient solution. The seedling is then transplanted to a solution that lacks one nutrient thought to be essential. The growth of the seedling is studied for the presence of symptoms indicative of abnormal growth, such as discolored leaves or stunting. If the seedling's growth is normal, the nutrient that was left out may not be essential; if the seedling's growth is abnormal, the nutrient that is lacking is essential for growth.

less than one to several hundred parts per million in most plants. A deficiency of any one can have severe effects on plant growth (figure 39.6). The macronutrients were generally discovered in the last century, but the micronutrients have been detected much more recently as technology developed to identify and work with such small quantities.

Nutritional requirements are assessed by growing plants in hydroponic cultures in which the plant roots are suspended in aerated water containing nutrients. For the purposes of testing, the solutions contain all the necessary nutrients in the right proportions, but with certain known or suspected nutrients left out. The plants are then allowed to grow and are studied for altered growth patterns and leaf coloration that might indicate a need for the missing element (figure 39.7). To give an idea of how small the needed quantities of micronutrients may be, the standard dose of molybdenum added to seriously deficient soils in Australia amounts to about 34 g (about one handful) per hectare (a square 100 meters on a side—about 2.5 acres), once every 10 years!

Most plants grow satisfactorily in hydroponic cultures, if the roots are properly aerated. The method, although expensive, is occasionally practical for commercial purposes (figure 39.8). Analytical chemistry has made it much easier to test plant material for levels of different molecules.

**Figure 39.8 Hydroponics.** Soil provides nutrients and support, but both of these functions can be replaced in hydroponic systems. Here, tomato plants are suspended in the air, and the roots rotate through a nutrient bath.

## Food security is related to crop productivity and nutrient levels

Nutrient levels and crop productivity are a significant human concern. **Food security**, avoiding starvation, is a global issue. Increasing the nutritional value of crop species, especially in developing countries, could have tremendous human health benefits.

Food fortification is an active area of research focused on ways to increase plants' uptake of minerals and the storage of minerals in roots and shoots for later human consumption. Phosphate uptake can be increased, for example, if it is more soluble in the soil. Some plants have been genetically modified to secrete citrate, an organic acid that solubilizes phosphate. As an added benefit, the citrate binds to aluminum, which can be toxic to plants and animals, and thus limits the uptake of aluminum into plants.

For other nutrients, such as iron, manganese, and zinc, plasma membrane transport is a limiting factor. Genes coding for these plasma membrane transporters have been cloned in other species and are being incorporated into crop plants. Eventually, breakfast cereals may be fortified with additional nutrients while the grains are growing in the field, as opposed to when they are processed in the factory.

### Learning Outcomes Review 39.2

Plants require nine macronutrients in relatively large amounts and seven micronutrients in trace amounts. Plants are grown in controlled hydroponic solutions to determine which nutrients are required for growth. Scientists are studying ways to enhance the nutritional composition of food crops through enhancing nutrient uptake and storage. These methods of food fortification may enhance food security, the avoidance of human starvation.

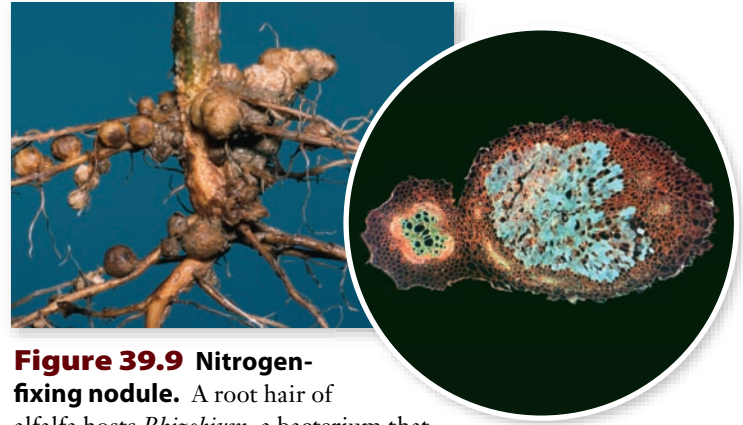

- Why would a lack of magnesium in the soil limit food production?

## 39.3 Special Nutritional Strategies

### Learning Outcomes

1. Explain the significance of nitrogen-fixing bacteria for plant nutrition.
2. Explain how mycorrhizal fungi benefit plants.
3. Describe the benefit gained by carnivorous plants when they capture insects.

In some species, scarce nutrients have been obtained through the evolution of mutualistic associations with other organisms, parasitism, or even predation. One example is the requirement for nitrogen: Plants need ammonia ( $\text{NH}_3$ ) or nitrate ( $\text{NO}_3^-$ ) to build amino acids, but most of the nitrogen in the atmosphere is in the form of gaseous nitrogen ( $\text{N}_2$ ). Plants lack the bio-

**Figure 39.9 Nitrogen-fixing nodule.** A root hair of alfalfa hosts *Rhizobium*, a bacterium that fixes nitrogen in exchange for carbohydrates.

chemical pathways (including the enzyme nitrogenase) necessary to convert gaseous nitrogen to ammonia, but some bacteria have this capacity.

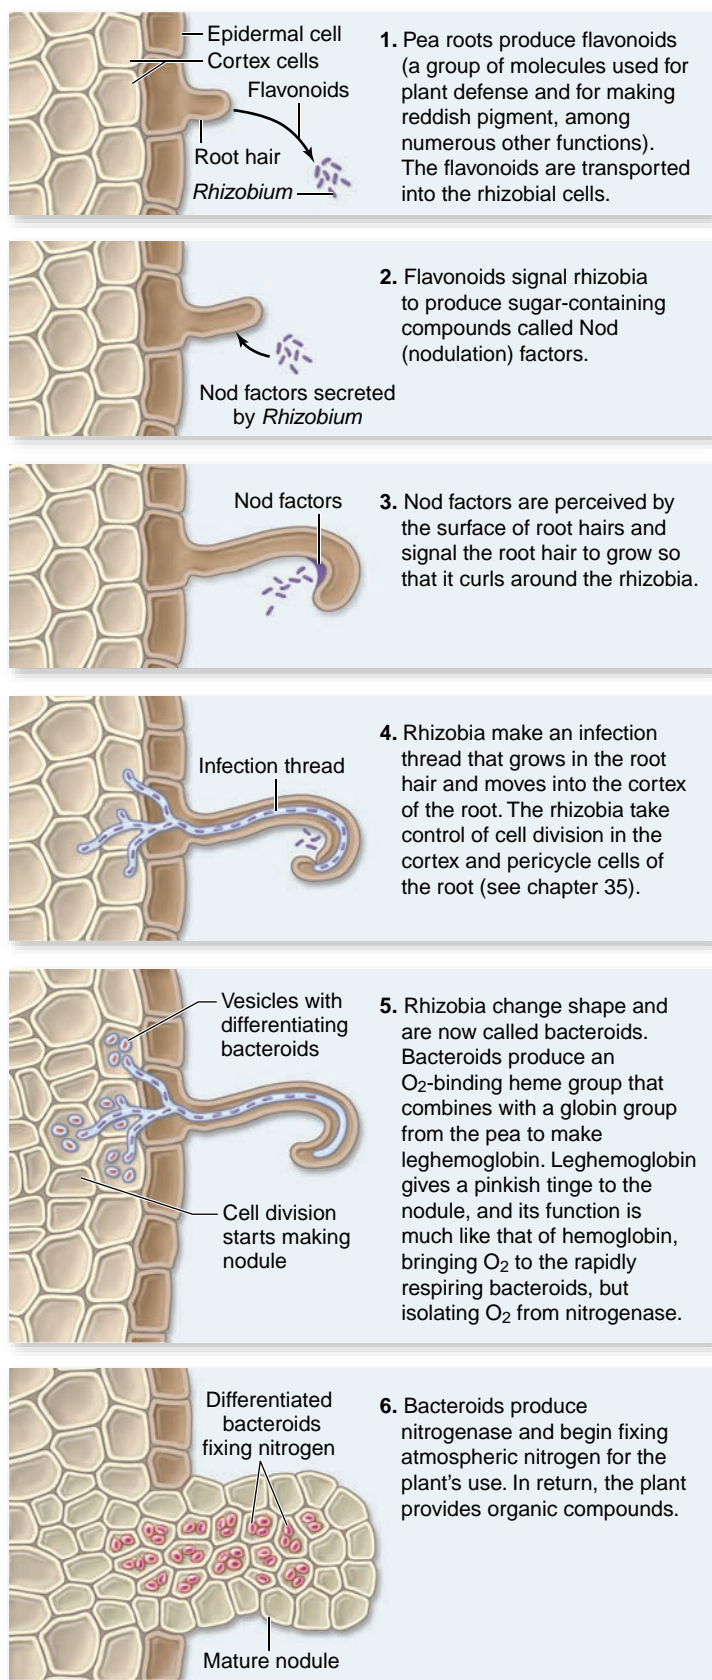

### Bacteria living in close association with roots can provide nitrogen

Symbiotic relationships have evolved between some plant groups and bacteria that can convert gaseous nitrogen. Some of these bacteria live in close association with the roots of plants. Others end up being housed in tissues the plant grows especially for this purpose, called **nodules** (figure 39.9). Legumes and a few other plants can form root nodules. Hosting these bacteria costs the plant energy, but is well worth it when the soil lacks nitrogen compounds. To conserve energy, legume root hairs do not respond to bacterial signals when nitrogen levels are high.

Nitrogen fixation is the most energetically expensive reaction known to occur in any cell. Why should it be so difficult to add  $\text{H}_2$  to  $\text{N}_2$ ? The answer lies in the strength of the triple bond in  $\text{N}_2$ . Nitrogenase requires 16 ATPs to make two molecules of  $\text{NH}_3$ . Making  $\text{NH}_3$  without nitrogenase requires a contained system maintained at  $450^\circ\text{C}$  and 500 atm pressure—far beyond the maximums under which plants can survive.

*Rhizobium* bacteria require oxygen and carbohydrates to support their energetically expensive lifestyle as nitrogen fixers. Carbohydrates are supplied through the vascular tissue of the plant, and leghemoglobin, which is structurally similar to animal hemoglobin, is produced by the plant to regulate oxygen availability to the bacteria. Without oxygen, the bacteria die; within the bacteria, however, nitrogenase has to be isolated from oxygen, which inhibits its activity. Leghemoglobin binds oxygen and controls its availability within the nodule to optimize both nitrogenase activity and cellular respiration.

Just how do legumes and nitrogen-fixing *Rhizobium* bacteria get together (figure 39.10)? Extensive signaling between the bacterium and the legume not only lets each organism know the other is present, but also checks whether the bacterium is the correct species for the specific legume. These highly evolved symbiotic relationships depend on exact species matches. Soybean and garden peas are both legumes, but each requires its own species of symbiotic *Rhizobium*.

**Figure 39.10** *Rhizobium* induced nodule formation.

## Mycorrhizae aid a large portion of terrestrial plants

Nitrogen is not the only nutrient that is difficult for plants to obtain without assistance. Whereas symbiotic relationships with nitrogen-fixing bacteria are generally limited to some legume species, symbiotic associations with mycorrhizal fungi, described in chapter 31, are found in about 90% of vascular plants. Mycorrhizae play a significant role in enhancing phosphorus transfer to the plant, and the uptake of some of the micronutrients is also facilitated. Functionally, the mycorrhizae extend the surface area available for nutrient uptake substantially.

Fungi most likely aided early rootless plants in colonizing land. Evidence now indicates that the signaling pathways that lead to plant symbiosis with some mycorrhizae may have been exploited to bring about the *Rhizobium*–legume symbiosis.

## Carnivorous plants trap and digest animals to extract additional nutrients

Some plants are able to obtain nitrogen directly from other organisms, just as animals do. These carnivorous plants often grow in acidic soils, such as bogs, that lack organic nitrogen. By capturing and digesting small animals, primarily insects, directly, such plants obtain adequate nitrogen supplies and are able to grow in these seemingly unfavorable environments. Carnivorous plants have modified leaves adapted for luring and trapping prey. The plants often digest their prey with enzymes secreted from specialized types of glands.

Pitcher plants (*Nepenthes* spp.) attract insects by the bright, flowerlike colors within their pitcher-shaped leaves, by scents, and perhaps also by sugar-rich secretions (figure 39.11a). Once inside the pitcher, insects slide down into the cavity of the leaf, which is filled with water and digestive enzymes. This passive mechanism provides pitcher plants with a steady supply of nitrogen.

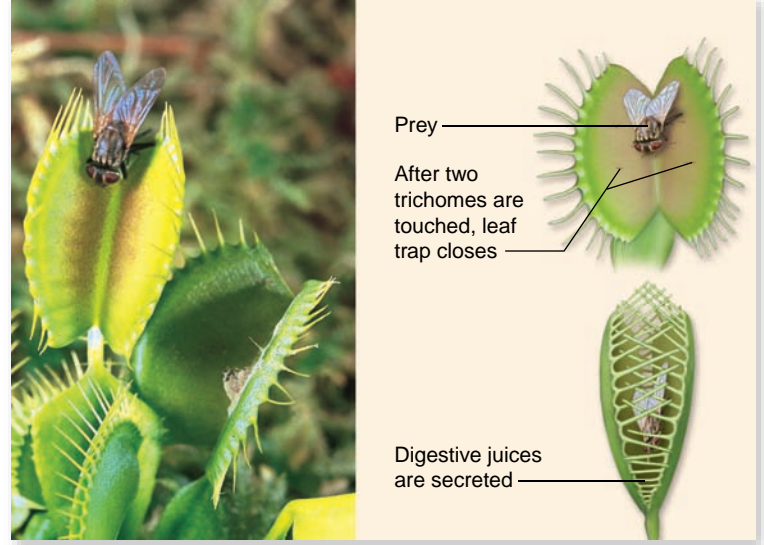

The Venus flytrap (*Dionaea muscipula*) grows in the bogs of coastal North and South Carolina. Three sensitive hairs on a leaf that, when touched, trigger the two halves of the leaf to snap together in about 100 ms (figure 39.11b). The speed of trap closing has puzzled biologists as far back as Darwin. Turgor pressure changes can account for the movement; the speed, however, depends on the curved geometry of the leaf, which can snap between convex and concave shapes.

Once the Venus flytrap enfolds prey within a leaf, enzymes secreted from the leaf surfaces digest the prey. These flytraps use a growth mechanism to close, not just a decrease in turgor pressure. The cells on the outer leaf surface irreversibly increase in size each time the trap shuts. As a result, they can only open and close a limited number of times.

In the sundews (*Drosera* spp.), another carnivorous group, glandular trichomes secrete both sticky mucilage, which traps small animals, and digestive enzymes; they do not close rapidly (figure 39.11c). Venus flytraps and the sundews share a common ancestor that lacked the snap-trap mechanism characteristic of the flytrap lineage (figure 39.12).

a.

b.

**Figure 39.11 Nutritional adaptations.** *a.* Asian pitcher plant, *Nepenthes*. Insects enter this carnivorous plant and are trapped and digested. Complex communities of invertebrate animals and protists inhabit the pitchers. *b.* Venus flytrap, *Dionaea*. If this fly touches two of the trichomes (hairs) on this modified leaf in a short time span, the trap will close. The plant will secrete digestive enzymes that release nitrogen compounds from the fly, which will then be absorbed by the flytrap. *c.* Sundew, *Drosera*, traps insects with sticky secretions and then excretes digestive enzymes to obtain nutrients from the insect's body. *d.* Aquatic waterwheel, *Aldrovanda*. This close relative of the Venus flytrap snaps shut to capture and digest small aquatic animals. This aquatic plant's ancestor was a land dweller.

*Aldrovanda vesicularis*, the aquatic waterwheel, is a closer relative of the flytraps. The waterwheel is a rootless plant that uses trigger hairs and a snap-trap mechanism like that of the Venus flytrap to capture and digest small animals (figure 39.11d). Molecular phylogenetic studies indicate that Venus flytraps are sister species with sundews, forming a sister clade. It appears that the snap-trap mechanism evolved only once in descendants of a sundew ancestor. Therefore, the waterwheel's common ancestor must have been a terrestrial plant that made its way back into the water.

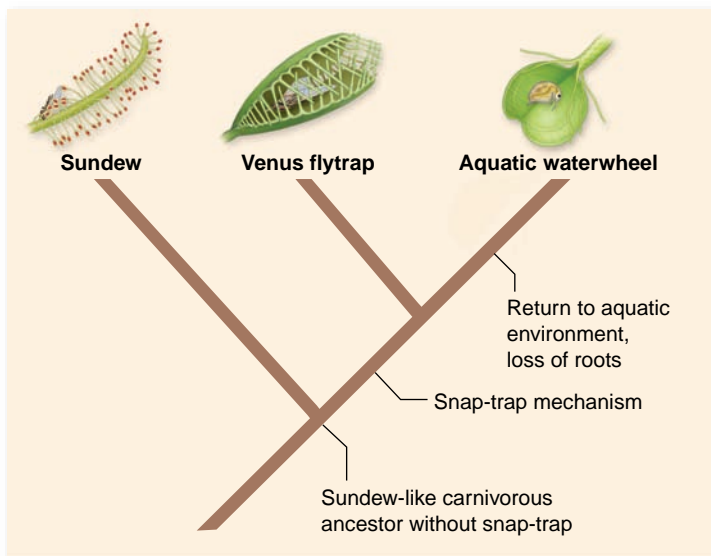

Bladderworts (*Utricularia*) are aquatic, but appear to have different origins from the waterwheel, as well as a different mechanism for trapping organisms. Small animals are swept

into their bladderlike leaves by the rapid action of a springlike trapdoor; then the leaves digest these animals.

### Parasitic plants exploit resources of other plants

Parasitic plants come in photosynthetic and nonphotosynthetic varieties. In total, at least 3000 types of plants are known to tap into the nutrient resources of other plants. Adaptations include structures that are inserted into the vascular tissue of the host plant so that nutrients can be siphoned into the parasite. One example is dodder (*Cuscuta* spp.), which looks like brown twine wrapped around its host. Dodder lacks chlorophyll and relies totally on its host for all its nutritional needs.

Indian pipe, *Hypopitys uniflora*, also lacks chlorophyll. This parasitic plant hooks into host trees through the fungal hyphae of the host's mycorrhizae (figure 39.13). The above-ground portion of the plant consists of flowering stems.

**Figure 39.12 Phylogenetic relationships among carnivorous plants.** The snap-trap mechanism was acquired by a common ancestor of the Venus flytrap and the aquatic waterwheel. Pitcher plants are not related to this clade.

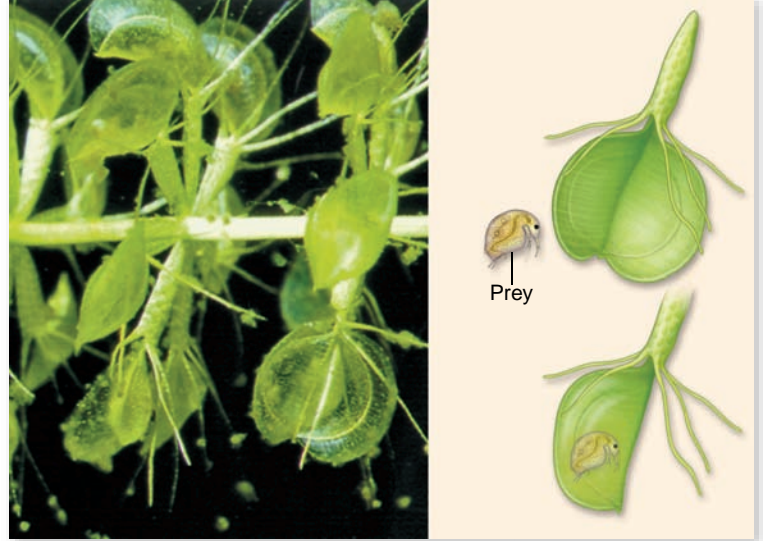

### Figure 39.13 Indian pipe, *Hypopitys uniflora*.

This plant lacks chlorophyll and depends completely on nutrient transfer through the invasion of mycorrhizae and associated roots of other plants. Indian pipes are frequently found in northeastern United States forests.

c.

d.

### Learning Outcomes Review 39.3

Certain types of plants, such as legumes, produce root nodules in which nitrogen-fixing bacteria grow. These bacteria provide nitrogen compounds that the plant can use for growth. Mycorrhizal fungi live in association with plant roots and are important for phosphorus uptake. Carnivorous plants typically live in low-nitrogen soils and obtain nitrogen from the insects they capture and digest.

- *Why is nitrogen a critical macronutrient for plant growth and reproduction?*

## 39.4 Carbon–Nitrogen Balance and Global Change

### Learning Outcomes

1. Describe the predicted effect of increased atmospheric carbon dioxide on the rate of photosynthesis in  $C_3$  plants.
2. Explain the main effect on herbivores of a higher carbon:nitrogen ratio in plants.
3. Discuss why respiration rates increase with warmer temperatures.

The Intergovernmental Panel on Climate Change (IPCC), established by the United Nations and the World Meteorological Organization, has concluded that  $CO_2$  is probably at its highest concentration in the atmosphere in at least 20 million years. In only the last 250 years, atmospheric  $CO_2$  has increased 31%, which correlates with increases in many human activities, including the burning of fossil fuels.

The long-term effects of elevated  $CO_2$  are complex and are not fully understood, but are associated with increased temperatures. The IPCC predicts the average global surface temperatures will continue to increase to between  $1.4^\circ C$  and  $5.8^\circ C$  above 1990 levels, by 2100. Chapter 59 explores the causal link between elevated  $CO_2$  and global warming. Here, we consider how increased  $CO_2$  may alter nutrient balance within plants, specifically the carbon and nitrogen balance.

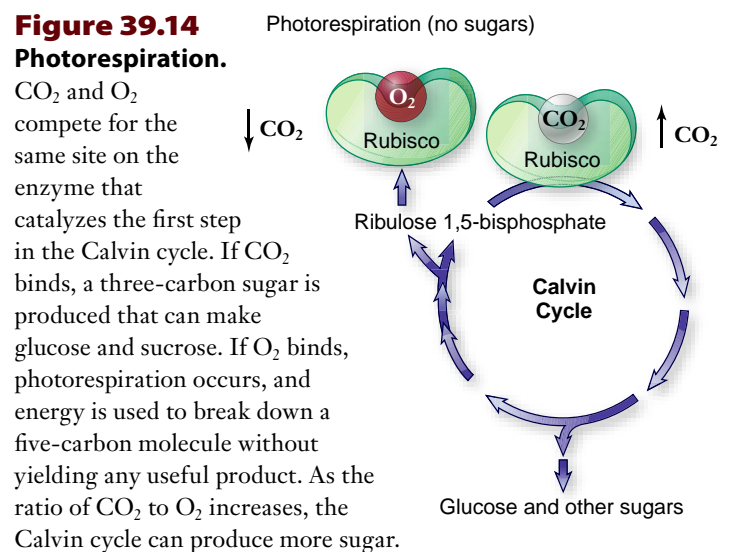

The ratio of carbon to nitrogen in a plant is important for both plant health and the health of herbivores. Altering this ratio could alter plant–pest interactions as well as affect human nutrition.

### Elevated $CO_2$ levels can alter photosynthesis and carbon levels in plants

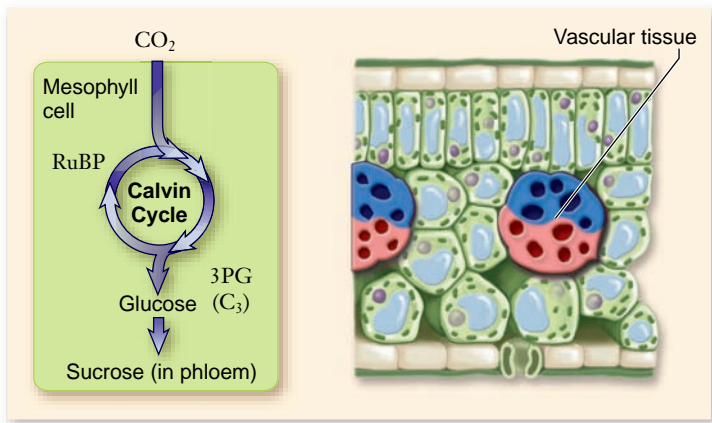

First, we investigate the relationship between photosynthesis and the relative concentration of atmospheric  $CO_2$ . The two questions to be addressed in this section are (1) Does elevated  $CO_2$  increase the rate of photosynthesis? and (2) Will elevated levels of  $CO_2$  change the ratio of carbohydrates and proteins in plants?

#### The rate of photosynthesis

The Calvin cycle of photosynthesis fixes atmospheric  $CO_2$  into sugar (see chapter 8). The first step of the Calvin cycle starts the most abundant protein on Earth, ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco). The active site of this enzyme can bind either  $CO_2$  or  $O_2$ , and it catalyzes the addition of either molecule to a five-carbon molecule, ribulose 1,5-bisphosphate (RuBP) (figure 39.14).  $CO_2$  is used to

**a.** C<sub>3</sub> leaf

**b.** C<sub>4</sub> leaf (Kranz anatomy)

**Figure 39.15** C<sub>4</sub> plants reduce photorespiration by limiting the Calvin cycle to cells surrounding the vascular tissue, where O<sub>2</sub> levels are reduced. **a.** C<sub>3</sub> photosynthesis occurs in the mesophyll cells. **b.** C<sub>4</sub> photosynthesis uses an extra biochemical pathway to shuttle carbon deep within the leaf.

produce a three-carbon sugar that can in turn be used to synthesize glucose and sucrose; in contrast, O<sub>2</sub> is used in photorespiration, which results in neither nutrient nor energy storage. Photorespiration is a wasteful process.

You may recall that C<sub>4</sub> plants have evolved a novel anatomical and biochemical strategy to reduce photorespiration (figure 39.15). CO<sub>2</sub> does not enter the Calvin cycle until it has been transported via another pathway to cells surrounding the vascular tissue. Here the level of CO<sub>2</sub> is increased relative to O<sub>2</sub> levels, and thus CO<sub>2</sub> has less competition for rubisco's binding site.

In C<sub>3</sub> plants, as the relative amount of CO<sub>2</sub> increases, the Calvin cycle becomes more efficient. Thus, it is reasonable to hypothesize that the global increase in CO<sub>2</sub> should lead to increased photosynthesis and increased plant growth. Assuming that nutrient availability in the soil remains the same, the more rapidly growing plants should have lower levels of nitrogen-containing compounds, such as proteins, and also lower levels of minerals obtained from the soil. The ratio of carbon to nitrogen should increase. Long-term studies of plants grown under elevated CO<sub>2</sub> confirm this prediction.

The optimal way to determine how CO<sub>2</sub> concentrations affect plant nutrition is to grow plants in an environment in which CO<sub>2</sub> levels can be precisely controlled. Experiments with potted plants in growth chambers are one approach, but far more information can be obtained in natural areas enriched with CO<sub>2</sub>, called Free Air CO<sub>2</sub> Enrichment (FACE) studies. For example, the Duke Experimental Forest has rings of towers that release CO<sub>2</sub> toward the center of the ring (figure 39.16). These rings are 30 m in diameter and allow studies to be conducted at the ecosystem level. Such facilities allow for long-term studies of the effects of altered atmospheric conditions on ecosystems.

**a.**

**b.**

**Figure 39.16** Experimentally elevating CO<sub>2</sub>. CO<sub>2</sub> rings in the Duke Experimental Forest FACE site provide ecosystem-level comparisons of plants grown in ambient and elevated CO<sub>2</sub> environments. **a.** Each ring is 30 m in diameter. **b.** Towers surrounding the rings blow CO<sub>2</sub> inward under closely monitored conditions.

Extensive studies have yielded complex results. Potatoes grown in a European facility had a 40% higher photosynthetic rate when the concentration of CO<sub>2</sub> was approximately doubled. Potted plants often show an initial increase in photosynthesis, followed by a decrease over time that is associated with lower levels of rubisco production. Different species of plants in a Florida oak-shrub system showed different responses to elevated CO<sub>2</sub> levels, while over three years in the Duke Experimental Forest, plants achieved more biomass in the CO<sub>2</sub> enclosures than outside the enclosures, if the soil contained sufficient nitrogen availability to support enhanced growth. C<sub>3</sub> plants show a greater increase in biomass than C<sub>4</sub> plants, and nitrogen fixing legumes, especially soybean, had larger increases in biomass than plants depending on nitrogen from the soil. In general, increased CO<sub>2</sub> corresponds to some increase in biomass, but also to an increase in the carbon:nitrogen ratio.

### The ratio of proteins and carbohydrates

You learned earlier in this chapter that nitrogen availability limits plant growth. As CO<sub>2</sub> levels increase, relatively less nitrogen and other macronutrients are found in leaves. Legumes, because of their nitrogen-fixing ability, have less of a decrease in nitrogen under elevated CO<sub>2</sub> conditions. In that event, herbivores need to eat more biomass to obtain adequate nutrients, particularly protein. This situation would be of significant concern in agriculture, and it could affect human health. Insect infestations could be more devastating if each herbivore consumed more biomass. Protein deficiencies in human diets could result from decreased nitrogen in crops.

The relative decreases in nitrogen in some plants is greater than would be predicted by an increase in CO<sub>2</sub> fixation alone. The additional decrease in nitrogen incorporation into proteins has been accounted for by a decrease in photorespiration in plants using NO<sub>3</sub><sup>-</sup> as their primary nitrogen source, but not in plants using ammonia. It is possible that energy-wasting photorespiration may actually be necessary for nitrogen to be incorporated into proteins in some plants.

This example illustrates how interdependent the biochemical pathways are that regulate carbon and nitrogen levels. Although global change is an ecosystem-level problem, predictions about long-term effects hinge on understanding the physiological complexities of plant nutrition—an area of active research.

## Elevated temperature can affect respiration and carbon levels in plants

As much as half of all the carbohydrates produced from photosynthesis each day can be used in plant respiration that same day. The amount of carbohydrate available for respiration may be affected by atmospheric CO<sub>2</sub> and photosynthesis, as just discussed. Further-

more, the anticipated rise in temperature over the next century may affect the rate of respiration in other ways. Altered respiration rates can affect overall nutrient balance and plant growth.

### Inquiry question

? Why is plant respiration affected by both short-term and long-term temperature changes?

Biologists have known for a long time that respiration rates are temperature-sensitive in a broad range of plant species. Why does respiration rate change with temperature? One important factor is the effect of temperature on enzyme activity (see chapter 3). This effect is particularly important at very low temperatures and also very high temperatures that lead to protein denaturation.

Many responses of respiration rate to temperature change may be short-term, rather than long-term. Growing evidence indicates that respiration rate acclimates to a temperature increase over time, especially in leaves and roots that develop after the temperature shift. Over a long period at an elevated temperature, a plant could end up respiring at the same rate at which it had previously respired at a lower temperature.

### Learning Outcomes Review 39.4

As atmospheric carbon dioxide increases, the rate of photosynthesis and the carbon:nitrogen ratio in plants are expected to increase as long as available soil nutrients do not change. A higher than normal carbon:nitrogen ratio would require herbivores to eat more biomass to meet their protein needs, which could, in turn, affect human health. As temperature increases, enzyme activity increases, accelerating the rate of respiration and breakdown of carbohydrates.

- What strategies could help keep the carbon:nitrogen ratio in crop plants lower?

## 39.5 Phytoremediation

### Learning Outcomes

1. Define phytoremediation.
2. Explain how poplar trees have been used for phytoremediation.
3. Describe an advantage and a disadvantage of phytoremediation.

Some root cell membrane channels and transporters lack absolute specificity and can take up heavy metals like aluminum and other toxins. Although in most cases uptake of toxins is lethal or growth-limiting, some plants have evolved the ability to sequester or release these compounds into the atmosphere. These plants have potential for **phytoremediation**, the use of plants to concentrate or breakdown pollutants (figure 39.17).

Phytoremediation can work in a number of ways with both aquatic and soil pollutants. Plants may secrete a substance from

### Figure 39.17 Phytoremediation.

Plants can use the same mechanisms to remove both nutrients and toxins from the soil. **a.** TCE (trichloroethylene) can be taken up by plants and degraded into  $\text{CO}_2$  and chlorine before being released into the atmosphere. This process is called *phytodegradation*. Some of the TCE moves so rapidly through the xylem that it is not degraded before it is released through the stomata as a gas in a process called *phytovolatilization*. **b.** Other toxins, including heavy metals such as lead, can be taken up by plants, but not degraded. Such *phytoaccumulation* is particularly effective in removing toxins if they are stored in the shoot, where they can more easily be harvested.

their roots that breaks down the contaminant. More often, the harmful chemical enters the roots and is preferably transported to the shoot system, making it easier to remove the chemical from the site. Some substances are simply stored by the plant; later, the plant material is harvested, dried, and removed to a storage site.

For example, after the nuclear reactor disaster at Chernobyl in northern Ukraine, sunflowers effectively removed radioactive cesium from nearby lakes. The plants were floated in foam supports on the surface of the lakes and later collected. Because up to 85% of the weight of herbaceous plants can be water, drying down phytoremediators can restrict toxins like radioactive cesium to a small area.

In this section, we will explore several examples of soil phytoremediation.

### Trichloroethylene may be removed by poplar trees

Trichloroethylene (TCE) is a volatile solvent that has been widely used as spot remover in the dry-cleaning industry, for degreasing engine turbines, as an ingredient in paints and cosmetics, and even as an anesthetic in human and veterinary medicine. Unfortunately, TCE is also a confirmed carcinogen, and chronic exposure can damage the liver.

In 1980, the Environmental Protection Agency (EPA) established a Superfund to clean up contamination in the United States. Forty percent of all sites funded by the Superfund in-

clude TCE contamination. How can we clean up 1900 hectares of soil in a Marine Corps Air Station in Orange County, California, that contain TCE once used to clean fighter jets? Landfills can isolate, but not eliminate, this volatile substance. Burning eliminates it from the site, but may release harmful substances into the atmosphere. A promising approach is to use plants to remove TCE from the soil.

Plants may take up a toxin from soil, allowing the toxin to be removed and concentrated elsewhere; but an even more successful strategy is for the plant to break down the contaminant into nontoxic by-products. Poplar trees (genus *Populus*) may provide just such a solution for TCE-contaminated sites (figure 39.18). Poplars naturally take up TCE from the soil and metabolize it into  $\text{CO}_2$  and chlorine.

Other plant species can break down TCE as well, but poplars have the advantage of size and rapid transpiration. A five-year-old poplar can move between 100 and 200 L of water from its roots out through its leaves in a day. A plant that transpires less would not be able to remove as much TCE in a day.

**Figure 39.18**  
**Phytoremediation for TCE.** The U.S. Air Force is testing phytoremediation technology to clean up TCE at a former Air Force base in Fort Worth, Texas.

Although removing TCE with poplar trees sounds like the perfect solution, this method has some limitations. Not all the TCE is metabolized, and given the rapid rate of transpiration in the poplar, some of the TCE enters the atmosphere via the leaves. Once in the air, TCE has a half-life of 9 hours (half of it will break down into smaller molecules every 9 hours). Clearly, more risk assessment is needed before poplars are planted on every TCE-containing Superfund site.

The TCE that remains in the plant is metabolized quickly, and it is possible that the wood could be used after remediation is complete. It has been suggested that any remaining TCE would be eliminated if the wood were processed to make paper. Genetically modified poplars have been shown to metabolize about four times as much TCE as nonmodified poplars, so perhaps greater metabolic rates can be obtained.

As with any phytoremediation plan, it is critically necessary to estimate how much of a contaminant can be removed from a site by plants, and arriving at this estimate can be difficult. Possible risks, particularly when genetic modification is involved, must be weighed against the dangers posed by the contaminant.

### Trinitrotoluene can be removed in limited amounts

In addition to volatile chemicals such as TCE, phytoremediation also holds promise for dealing with other environmental contaminants, including the explosive trinitrotoluene (TNT) and heavy metals. TNT is a solid, yellow material that was used widely in grenades and bombs until 1980. Contamination is found around factories that made TNT.

In some places, there is enough TNT in the soil to detonate, and thus incineration is not a viable option for removing TNT from most sites. Another issue is that TNT can seep into the groundwater; this is a matter of concern because TNT is carcinogenic and associated with liver disease.

TNT tends to stay near the top of the soil and to wash away quickly. Bean (*Phaseolus vulgaris*), poplar, and the aquatic parrot feather (*Myriophyllum spicatum*) can take up and degrade low levels of TNT, but at higher concentrations, TNT is toxic to these plants.

### Heavy metals can be successfully removed at lower cost

**Heavy metals**, including arsenic, cadmium, and lead, persist in soils and are toxic to animals in even small quantities. Many plants are also susceptible to heavy-metal toxicity, but species near mines have evolved strategies to partition certain heavy metals from the rest of the plant (see figure 39.17b).

Four hundred species of plants have been identified that have the ability to hyperaccumulate toxic metals from the soil. For example, *Brassica juncea* (a relative of broccoli and mustard plants) is especially effective at hyperaccumulating lead in the shoots of the plant. Unfortunately, *B. juncea* is a small, slow-growing plant, and eventually it becomes saturated with lead.

How would lead or cadmium travel from the soil into the leaves of a plant? There are some hints that root cell membranes may contain metal transporters that load the metal in the soil

into the xylem. Citrate, mentioned earlier, can increase the rate of metal transport in xylem. The metals are sequestered inside vacuoles in the leaves. Trichomes, which are modified leaf epidermal cells, can sequester both lead and cadmium.

These hyperaccumulating plants are not a panacea for metal-contaminated soil because of concern that animals might move into the site and graze on lead- or cadmium-enriched plants. Harvesting and consolidating dried plant material is not a simple matter, but still phytoremediation is a promising technique. Estimated costs for phytoremediation are 50 to 80% lower than cleanup strategies that involve digging and dumping the contaminated soil elsewhere.

Phytoremediation may be a solution to the contamination resulting from a 1998 accident at the Aznalcóllar mine in Spain. A dam that contained the sludge from the mining operation broke, releasing 5 million cubic meters of sludge, composed of arsenic, cadmium, lead, and zinc, over 4300 hectares of land (figure 39.19). Much of the sludge was physically removed

a.

b.

c.

**Figure 39.19 Aznalcóllar mine spill.** a. When the dike of a holding lagoon for mine waste broke, 5 million cubic meters of black sludge containing heavy metals was released into a national park and the Guadiamar River. b. Large amounts of sludge were removed mechanically. c. Phytoremediation appears to be a promising solution for treating the remaining heavy metals.

and dumped into an open mine pit. Phytoremediation solutions are being sought for the remaining contaminated soil.

Since the original spill, three plant species with the potential to hyperaccumulate some of the metals have begun growing in the area. These plants are fairly large and can accumulate a substantial amount of metal. They offer the advantage of being native species, thus reducing the dangers associated with introducing a nonnative, potentially invasive species to clean up the spill.

### Learning Outcomes Review 39.5

Phytoremediation is the use of plants to concentrate or break down pollutants. Poplar trees can take up the soil contaminant trichloroethylene and break it down into nontoxic by-products. Compared with the alternative of removing contaminated soil, phytoremediation is less costly. A disadvantage is that animals could be harmed if they graze in an area where plants have taken up high levels of toxic compounds.

- How could animals be protected from ingesting plants used for phytoremediation?

## Chapter Review

### 39.1 Soils: The Substrates on Which Plants Depend

**Soil is composed of minerals, organic matter, water, air, and organisms.**

Topsoil is a mixture of mineral particles, living organisms, and humus, which is partially decayed organic material. Microorganisms in the soil are important for nutrient recycling.

**Water and mineral availability is determined by soil characteristics.**

Minerals and organic soil particles are typically negatively charged so they draw positively charged ions away from the roots. Therefore, active transport of positively charged ions into the roots is required. Proton pumps in roots pump out  $H^+$ , creating an electrochemical gradient that draws mineral ions into the roots.

Approximately one-half the soil volume is made up of pores filled with air or water. Water added to the soil may drain through or be held in the pores, where it is available for root uptake.

**Cultivation can result in soil loss and nutrient depletion.**

Loss of topsoil through soil erosion results in reduced water-holding capacity and nutrient availability. Cultivation practices have been developed to reduce soil erosion.

Overuse of fertilizers, pesticides, and herbicides causes water pollution.

**pH and salinity affect water and mineral availability.**

Acidic soils release minerals, such as aluminum, at levels that are toxic to plants.

Saline soils alter water potential, leading to a loss of water and turgor in plants. Saline soils are common where irrigation is practiced.

### 39.2 Plant Nutrients

**Plants require nine macronutrients and seven micronutrients.**

The nine macronutrients required by plants are carbon, oxygen, hydrogen, nitrogen, potassium, calcium, magnesium, phosphorus, and sulfur. The eight micronutrients are chlorine, iron, manganese, zinc, boron, copper, molybdenum, and nickel.

**Food security is related to crop productivity and nutrient levels.**

Plant breeding efforts to increase nutrient levels in food crops aim to provide health benefits and improve food security.

### 39.3 Special Nutritional Strategies

**Bacteria living in close association with roots can provide nitrogen.**

Some plants, such as legumes, have a symbiotic relationship with nitrogen-fixing bacteria to obtain the nitrogen needed for protein synthesis. In exchange, the plants provide carbohydrates to the bacteria.

**Mycorrhizae aid a large portion of terrestrial plants.**

More than 90% of plants live in symbiotic association with mycorrhizal fungi. By extending the surface area of the root system, these fungi facilitate the uptake of phosphorus and micronutrients.

**Carnivorous plants trap and digest animals to extract additional nutrients.**

Some plants that live in acidic, nitrogen-poor environments obtain mineral nutrients by capturing and digesting small animals such as insects.

**Parasitic plants exploit resources of other plants.**

Some parasitic plants produce chlorophyll, while others do not. They tap into host plants to obtain nutrients, including carbohydrates.

### 39.4 Carbon–Nitrogen Balance and Global Change

**Elevated  $CO_2$  levels can alter photosynthesis and carbon levels in plants.**

As  $CO_2$  concentrations increase, the rate of photosynthesis increases and consequently biomass increases; however, the plant tissue that is produced is high in carbon relative to nitrogen, with a shift toward more carbohydrate and less protein.

As nutritional value decreases, more plant matter must be consumed to obtain the same amount of nutrients; the result is greater plant loss by herbivory.

**Elevated temperature can affect respiration and carbon levels in plants.**

The rate of enzyme reactions increases with ambient temperatures, increasing respiration. Because respiration breaks down carbohydrates, higher temperatures could cause additional changes in plant nutrient balance.

### 39.5 Phytoremediation

Phytoremediation utilizes plants to remove toxic contaminants from soil or water.

**Trichloroethylene may be removed by poplar trees.**

Poplar trees have been used to remove trichloroethylene from the soil and convert it to nontoxic carbon dioxide and chlorine compounds.

**Trinitrotoluene can be removed in limited amounts.**

Some plants can take up low levels of trinitrotoluene (TNT) in the soil and degrade it. However, high levels are toxic to the plants.

**Heavy metals can be successfully removed at lower cost.**

Plants may accumulate high levels of contaminants in their shoots and store them there. The plants can be harvested and removed. If

animals feed on these plants, however, they may be exposed to high concentrations of toxic compounds.

Phytoremediation is less expensive than removing contaminated soils.

## Review Questions

### UNDERSTAND

- Which of the following is not found in topsoil?
  - Humus
  - Bedrock
  - Bacteria
  - Air
- Mineral soil particles are typically
  - negatively charged.
  - positively charged.
  - neutral.
- What proportion of the soil volume is occupied by air and water?
  - 10%
  - 25%
  - 50%
  - 75%
  - 90%
- Which of the following is a micronutrient?
  - Nitrogen
  - Calcium
  - Phosphorus
  - Iron
- The nodules of legume roots contain nitrogen-fixing
  - bacteria.
  - fungi.
  - algae.
  - plants.
- Photorespiration occurs when
  - glucose interacts with carbon dioxide.
  - rubisco binds with oxygen.
  - RuBP is converted to a sugar.
  - the Sun provides energy for the breakdown of sugar.
- In a  $C_4$  plant, the Calvin cycle occurs in
  - the epidermis.
  - vascular tissue.
  - bundle sheath cells.
  - mesophyll cells.
- One potential problem with using poplars to remove TCE from soils is that
  - some TCE enters the atmosphere via the transpiration stream.
  - poplar trees grow slowly.
  - most TCE will wash away from the soil before it is removed.
  - TCE interferes with chlorophyll production.

### APPLY

- You are performing an experiment to determine the nutrient requirements for a newly discovered plant and find that for some reason your plants die if you leave boron out of the growth medium but do fine with as low as 5 ppm in solution. This suggests that boron is
  - an essential macronutrient.
  - a nonessential micronutrient.
  - an essential micronutrient.
  - a nonessential macronutrient.

- If you wanted to conduct an experiment to determine the effects of varying levels of macronutrients on plant growth and did so in your small greenhouse at home, which of the following macronutrients would be the most difficult to regulate?
  - Carbon
  - Nitrogen
  - Potassium
  - Phosphorus
- Which of the following would decrease nitrogen availability for a pea plant?
  - Inability of the plant to produce flavonoids
  - Formation of Nod factors
  - Presence of oxygen in the soil
  - Production of leghemoglobin
- Which of the following might you do to increase nutrient uptake by crop plants?
  - Decrease the solubility of nutrients
  - Create nutrients as positive ions
  - Frequently plow the soil
  - Genetically modify plants to increase the density of plasma membrane transporters in root cells
- If you were to eat one ton (1000 kg) of potatoes, calculate approximately how much of the following minerals would you eat?
  - Copper between 4–30 ppm
  - Zinc between 15–100 ppm
  - Potassium between 0.5 and 6%
  - Iron between 25–300 ppm

### SYNTHESIZE

- A common farming practice involves fumigating the soil to kill harmful fungi. Fumigants may not be selective, though, so they may kill most microorganisms in the soil. What short-term and long-term effects might fumigation have on the soil?
- Describe an experiment to determine the amount of boron needed for the normal growth of tomato seedlings.
- Growers of commercial crops in greenhouses often use supplemental carbon dioxide to enhance plant growth. What other inputs do you suppose they must provide to maximize plant growth?

# Plant Defense Responses

## Chapter Outline

- 40.1 Physical Defenses
- 40.2 Chemical Defenses
- 40.3 Animals That Protect Plants
- 40.4 Systemic Responses to Invaders

## Introduction

Plants are constantly under attack by viruses, bacteria, fungi, animals, and even other plants. An amazing array of defense mechanisms has evolved to block or temper an invasion. Many plant–pest relationships undergo coevolution, with the plant winning sometimes and the pest winning with a new offensive adaptation at other times. The first line of plant defense is thick cell walls covered with a strong cuticle. Bark, thorns, and even trichomes can deter a hungry insect. When that first line of defense fails, a chemical arsenal of toxins is waiting. Many of these molecules have no effect on the plant. Some are modified by microbes in the intestine of an herbivore into a poisonous compound. Maintaining a toxin arsenal is energy-intensive; so, an alternative means of defense uses induced responses to protect and prevent future attacks.

## 40.1 Physical Defenses

### Learning Outcomes

1. Identify the compounds produced by the epidermis to protect against invasion.
2. Outline the steps taken by a fungus to invade a plant leaf.
3. Describe two beneficial associations between plants and microorganisms.

There are no tornado shelters for trees. Storms and changing environmental conditions can be life-threatening to plants. Structurally, trees can often withstand high winds and the weight of ice and snow, but there are limits. Winds can uproot a tree, or snap the main shoot off a small plant. Axillary buds give many plants a second chance as they grow out and replace the lost shoot (figure 40.1).

Although abiotic factors such as weather constitute genuine threats to a plant, even greater daily threats exist in the form of viruses, bacteria, fungi, animals, and other plants. These enemies can tap into the nutrient resources of plants or use

**Figure 40.1 Shoots in reserve.** Axillary shoots give plants a second chance when the terminal shoot breaks off, as is the case with this storm-felled tree.

their DNA-replicating mechanisms to self-replicate. Some invaders kill the plant cells immediately, leading to necrosis (brown, dead tissue). Certain insects may tap into the phloem of a plant seeking carbohydrates, but leave behind a hitchhiking virus or bacterium.

The threat of these attackers is reduced when they have natural predators themselves. One of the greatest problems with nonnative invasive species, such as the alfalfa plant bug (figure 40.2), is the lack of natural predators in the new environment.

### Dermal tissue provides first-line defense

The first defense all plants have is the dermal tissue system (see chapter 36). Epidermal cells throughout the plant secrete wax, which is a mixture of hydrophobic lipids. Layers of lipid material protect exposed plant surfaces from water loss and attack. Above-ground plant parts are also covered with cutin, a macromolecule consisting of long-chain fatty acids linked together. **Suberin**, another version of linked fatty acid chains, is found in cell walls of subterranean plant organs; suberin forms the water-impermeable Casparian strips of roots. Silica inclusions, trichomes, bark, and even thorns can also protect the nutrient-rich plant interior.

**Figure 40.2 Alfalfa plant bug.** This invasive species is an agricultural problem because it arrived in the United States without any natural predators and feeds on alfalfa.

### Invaders can penetrate dermal defenses

Unfortunately, these exterior defenses can be penetrated in many ways. Mechanical wounds leave an open passageway through which microbial organisms can enter. Parasitic nematodes use their sharp mouthparts to get through the plant cell walls. Their actions either trigger the plant cells to divide, forming a tumorous growth, or, in species that attach to a single plant cell, cause the cell to enlarge and transfer carbohydrates from the plant to the hungry nematode (figure 40.3). In some cases, the wounding makes it

*a.*

*b.*

**Figure 40.3 Nematodes attack the roots of crop plants.** *a.* A nematode breaks through the epidermis of the root. *b.* Root-knot nematodes form tumors on roots.

## SCIENTIFIC THINKING

**Hypothesis:** Nematodes increase the severity of a potato wilt fungal disease by wounding roots and allowing the fungus to penetrate root tissue.

**Prediction:** Leaf wilt will be more severe when the root system is exposed to both the nematode and the fungus than when the root system is exposed to neither or either separately.

**Test:** Establish four treatments with four plants in each treatment group. Add the nematodes and the fungal pathogen to the soil of plants in group 1. Group 2 will only have fungus. Group 3 will have only nematodes, and group 4 will be untreated. Allow plants to grow for 42 days and record the extent of leaf wilt on each plant.

**Nematodes and fungus**  
(severe effect)

**Fungus**  
(moderate effect)

**Nematodes**  
(moderate effect)

**Untreated (control)**  
(no effect)

**Result:** Plants that are coinfectd with the nematodes and fungus have more severe wilting than plants treated with nematodes or fungus alone. Control plants do not wilt.

**Conclusion:** Nematodes increase the severity of the wilting infection.

**Further Experiments:** Design an experiment to test the hypothesis that increased fungal wilt symptoms are the result of damage to the roots by the nematode, making it easier for the fungus to enter the plant. Could you mechanically wound the roots instead of exposing them to nematodes?

**Figure 40.4** Nematodes increase susceptibility of plant to fungal infection.

easier for other pathogens, including fungi, to infect the plant (figure 40.4). In some cases simply having bacteria on the leaf surface can increase the risk of frost damage. The bacteria function as sites for ice nucleation; the resulting ice crystals severely damage the leaves.

Fungi strategically seek out the weak spot in the dermal system, the stomatal openings, to enter the plant. Some fungi have coevolved with a monocot that has evenly spaced stomata. These fungi appear to be able to measure distance to locate these evenly spaced stomatal openings and invade the plant. Figure 40.5 shows the phases of fungal invasion, which can include the following:

1. Windblown spores land on leaves. A germ tube emerges from the spore. Host recognition is necessary for spore germination.
2. The spore germinates and forms an adhesion pad, allowing it to stick to the leaf.
3. Hyphae grow through cell walls and press against the cell membrane.
4. Hyphae differentiate into specialized structures called haustoria. They expand, surrounded by cell membrane, and nutrient transfer begins.

## Bacteria and fungi can also be beneficial to plants

Mutualistic and parasitic relationships are often just opposite sides of the evolutionary coin. A parasitic relationship can evolve to become mutualistic, and a mutualistic relationship

**Figure 40.5** Fungi sneak in through stomata. Fungal hyphae penetrate cell walls, but not plasma membranes. The close contact between the fungal hyphae and the plant plasma membrane allows for ready transfer of plant nutrients to the fungus.

can transform into a parasitic one. In chapters 31 and 39, you saw how mycorrhizal fungi use a mechanism similar to the one just described to the mutual benefit of both the plant and the fungus. In the case of the relationship between legumes and nitrogen-fixing bacteria, the *Rhizobium* bacteria seeks out a root hair, infects it along with other tissues, and forms a root nodule. Other soil bacteria can also enhance plant growth, and are called plant growth-promoting rhizobacteria (PGPR). The term *rhizobacteria* refers to bacteria that live around the root system and often benefit from root exudates. In return they provide substances that support plant growth. *Azospirillum* spp., for example, provide gibberellins, which are growth hormones, for rice plants when the bacteria are living in close proximity to the root system. PGPR can also limit the growth of pathogenic soil bacteria.

### Learning Outcomes Review 40.1

Epidermal cells secrete protective compounds, including wax and suberin. Fungal spores may germinate and stick to plant leaves; hyphae enter the leaf through stomata, and produce haustoria to take up plant nutrients. Mutualistic partners with plants include mycorrhizal fungi that assist with nutrient absorption and nitrogen-fixing bacteria that provide nutrients.

- Why would protective substances on leaves include lipid-based compounds?

## 40.2 Chemical Defenses

### Learning Outcomes

1. Describe the role of secondary metabolites in plant defense.
2. Define allelopathy.
3. List three examples of the medicinal value of secondary metabolites.

Many plants are filled with toxins that kill herbivores or, at the very least, make them quite ill. One example is the production of cyanide, (HCN). Over 3000 species of plants produce cyanide-containing compounds called *cyanogenic glycosides* that break down into cyanide when cells are damaged. Cyanide stops electron transport, blocking cellular respiration.

Cassava (genus *Manihot*), a major food staple for many Africans, is filled with cyanogenic glycosides (specifically, manihotoxins) in the outer layers of the edible root. Unless these outer layers are scrubbed off, the cumulative effect of eating primarily cassava can be deadly.

Some toxins are unique to plants, but others are found in plants, vertebrates, and invertebrates and are called **defensins**. Defensins are small, cysteine-rich peptides with antimicrobial activity. The conservation of defensins in animals and plants

reveals the ancient origins of innate immunity. Between 15 and 50 defensin genes have been identified in plant genomes, and over 317 defensin-like genes exist in the *Arabidopsis* genome. The exact mechanisms are being worked out, but in some cases plant defensins inhibit protein synthesis. When expression of defensin genes is suppressed in plants, they are more susceptible to bacterial and fungal infections. In addition to toxins that kill, plants can produce chemical compounds that make potential herbivores ill or that repel them with strong flavors or odors.

### Plants maintain chemical arsenals

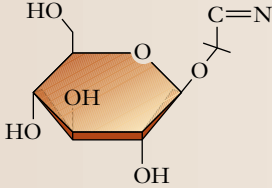

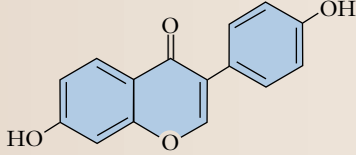

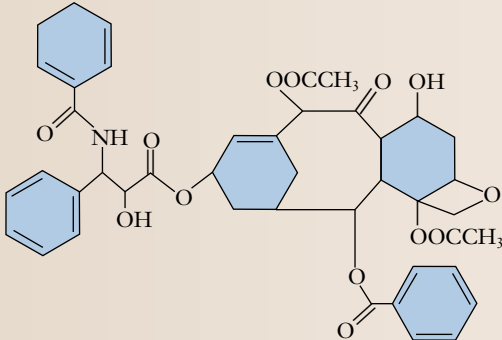

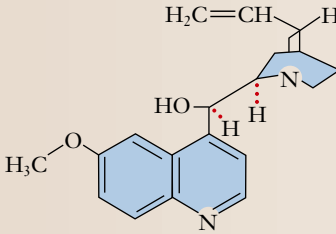

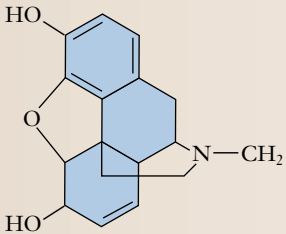

How did the biosynthetic pathways that produce these toxins evolve? Growing evidence indicates that the metabolic pathways needed to sustain life in plants have taken some evolutionary side trips, leading to the production of a stockpile of chemicals known as **secondary metabolites**. Many of these secondary metabolites affect herbivores as well as humans (table 40.1).

Alkaloids, including caffeine, nicotine, cocaine, and morphine, can affect multiple cellular processes; if a plant cannot kill its attackers, it can overstimulate them with caffeine or sedate them with morphine. For example, the tobacco hornworm (*Manduca sexta*) can level a field of tobacco (figure 40.6); however, wild species of tobacco appear to have elevated levels of nicotine that are lethal to tobacco hornworms.

Tannins bind to proteins and inactivate them. For example, some act by blocking enzymes that digest proteins, which reduces the nutritional value of the plant tissue. An insect that gets sick from a strong dose of tannins is likely to associate the flavor with illness and to avoid having that type of plant for lunch another time. Small doses of tannins and most other secondary metabolites are unlikely to cause any major digestive difficulties in larger animals, including humans. Animals, including humans, can avoid many of the cumulative toxic effects of secondary metabolites by eating a varied diet.

**Figure 40.6** Herbivores can kill plants. Tobacco hornworms, *Manduca sexta*, consume huge amounts of tobacco leaf tissue, as well as tomato leaves.

TABLE 40.1		Secondary Metabolites	
Compound	Source	Structure	Effect on Humans
Manihotoxin (cyanogenic glycoside)	Cassava, <i>Manihot esculenta</i> 		Metabolized to release lethal cyanide
Genistein (phytoestrogen)	Soybean, <i>Glycine max</i> 		Estrogen mimic
Taxol (terpenoid)	Pacific yew, <i>Taxus brevifolia</i> 		Anticancer drug
Quinine (alkaloid)	Quinine bark, <i>Cinchona officinalis</i> 		Antimalarial drug
Morphine (alkaloid)	Opium poppy, <i>Papaver somniferum</i> 		Narcotic pain killer

Plant oils, particularly those found in plants of the mint family, which includes peppermint, sage, pennyroyal, and many others, repel insects with their strong odors. At high concentrations, some of these oils can also be toxic if ingested.

Why don't the toxins kill the plant? One strategy is for a plant to sequester a toxin in a membrane-bound structure, so that it does not come into contact with the cell's metabolic processes. The second solution is for the plant to produce a compound that is not toxic unless it is metabolized, often by microorganisms, in the intestine of an animal. Cyanogenic glycosides are a good example of the latter solution. The plant produces a sugar-bound cyanide compound that does not affect electron transport chains. Once an animal ingests cyanogenic glycoside, the compound is enzymatically broken down, releasing the toxic hydrogen cyanide.

Coevolution has led to defenses against some plant toxins. A tropical butterfly, *Heliiconius sara*, can sequester the cyanogenic glycosides it ingests from its sole food source, the passion vine. Even more intriguing is a biochemical pathway that allows the butterfly to safely break down cyanogenic glycosides and use the released nitrogen in its own protein metabolism.

### Plants can poison other plants

Some chemical toxins protect plants from other plants. **Allelopathy** occurs when a chemical compound secreted by the roots of one plant blocks the germination of nearby seeds or inhibits the growth of a neighboring plant. This strategy minimizes shading and competition for nutrients, while it maximizes the ability of a plant to use radiant sunlight for photosynthesis. Allelopathy works with both a plant's own species and different species. Black walnut trees (*Juglans nigra*) are a good example. Very little vegetation will grow under a black walnut tree because of allelopathy (figure 40.7).

**Figure 40.7**  
**Black walnuts are allelopaths.**

Seedlings die when their roots come in contact with the root secretions of a black walnut tree.

### Humans are susceptible to plant toxins

Not only have humans been inadvertently poisoned by plants, but throughout much of human history, they have also been intentionally poisoned by other humans using plant products. Socrates, an important Greek philosopher who lived 2400 years ago, was sentenced to death in Athens, and he died after he drank a hemlock extract containing an alkaloid that paralyzes motor nerve endings.

Ricin, an alkaloid found in castor beans (*Ricinus communis*), is six times more lethal than cyanide and twice as lethal as cobra venom. A single seed from the plant, which is still grown in flower gardens, can kill a young child if ingested. Death occurs because ricin functions as a ribosome-binding protein that changes the structure of rRNA, thus inhibiting translation (figure 40.8).

**Figure 40.8** Ricin from castor beans blocks translation.

When the ricin A subunit is released from proricin, it binds to rRNA in ribosomes and prevents mRNA from being translated into protein.

Ricin is found in the endosperm of the seed as a heterodimer composed of ricin A and ricin B, joined by a single disulfide bond. This heterodimer (proricin) is nontoxic, but when the disulfide bond is broken in humans or other animals, ricin A targets the GAGA sequence of the 28s rRNA of the ribosome. A single ricin molecule can inactivate 1500 ribosomes per minute, blocking translation of proteins.

In 1978, Bulgarian expatriate and dissident Georgi Markov was about to board a bus in London on his way to work at the BBC when he felt a sharp stabbing pain in his thigh. A man near him picked up an umbrella from the ground and hurriedly left. Markov had been injected via a mechanism in the umbrella tip with a pinhead-sized metal sphere containing 0.2 mg of ricin. He died four days later. After the collapse of the Soviet Union, former KGB officers revealed that the KGB had set up the assassination at the behest of the Bulgarian Communist Party leadership.

### Inquiry question

? Explain how ricin led to Markov's death.

## Secondary metabolites may have medicinal value

Major research efforts on plant secondary metabolites are in progress because of their potential benefits, as well as dangers, to human health (see table 40.1).

### Soy and phytoestrogens

One example of the benefits and dangers is the presence of **phytoestrogens**, compounds very similar to the human hormone estrogen, in soybean products. In soybean plants, genistein is one of the major phytoestrogens.

Comparative studies between Asian populations that consume large amounts of soy foods and populations with lower dietary intake of soy products are raising intriguing questions and some conflicting results. For example, the lower rate of prostate cancer in Asian males might be accounted for by the down-regulation of androgen and estrogen receptors by a phytoestrogen. Soy is being marketed as a means for minimizing menopausal symptoms caused by declining estrogen levels in older women.

In humans, dietary phytoestrogens cross the placenta and can be found in the amniotic fluid during the second trimester of pregnancy. Questions have been raised about the effect of phytoestrogens on developing fetuses and even on babies who consume soy-based formula because of allergies to cow's milk formula. Because hormonal signaling is so complex, much more research is needed to fully understand how or even if phytoestrogens affect human physiology and development.

### Taxol and breast cancer

**Taxol**, a secondary metabolite found in the Pacific yew (*Taxus brevifolia*), is effective in fighting cancer, especially breast cancer. The discovery of taxol's pharmaceutical value raised an environmental challenge. The very existence of the Pacific yew was being threatened as the shrubs were destroyed so that taxol could be extracted. Fortunately, it became possible to synthesize taxol in the laboratory.

Taxol is not an isolated case of drug discovery in plants. The hidden pharmaceutical value of many plants may lead to increased conservation efforts to protect plants that have the potential to make contributions toward human health. Although the plant pharmaceutical industry is growing, it is certainly not a new field. Until recent times, almost all medicines used by humans came from plants.

### Quinine and malaria

In the 1600s, the Incas of Peru were treating malaria with a drink made from the bark of *Cinchona* trees. Malaria is caused by four types of human malaria parasites in the genus *Plasmodium*, which are carried by female *Anopheles* mosquitoes. *Plasmodium falciparum* is the most lethal of the four types. Symptoms include severe fevers and vomiting. The parasite feeds on red blood cells, and death can result from anemia or blocking of blood flow to the brain.

By 1820, the active ingredient in the bark of *Cinchona* trees, **quinine**, had been identified (see table 40.1). In the 19th century, British soldiers in India used quinine-containing "tonic water" to fight malaria. They masked the bitter taste of quinine with gin, creating the first gin and tonic drinks. In 1944, Robert Woodward and William Doering synthesized quinine. Now several other synthetic drugs are available to treat malaria.

Exactly how quinine and synthetic versions of this drug family work has puzzled researchers for a long time. Quinine can affect DNA replication, and also, when *P. falciparum* breaks down hemoglobin from red blood cells in its digestive vacuole, an intermediary toxic form of heme is released. Quinine may interfere with the subsequent polymerization of these hemes, leading to a build up of toxic hemes that poison the parasite.

Unfortunately, even today malaria is a major threat to human health, causing over a million deaths per year. Ninety percent of these deaths occur in sub-Saharan Africa. An estimated 300,000,000 individuals are infected. *P. falciparum* strains have acquired resistance to synthetic drugs, and quinine is once again the drug of choice in some cases.

Herbal remedies have been used for centuries in most cultures. A resurgence of interest in plant-based remedies is resulting in a growing and unregulated industry. Although herbal remedies have great promise, we need to be aware that each plant contains many secondary metabolites, many of which have evolved to cause harm to herbivores including humans.

### Learning Outcomes Review 40.2

Plants accumulate secondary metabolites that can poison or otherwise harm herbivores. Plants also secrete chemicals that inhibit the growth of neighboring plants, a process termed allelopathy. Secondary metabolites may also have beneficial uses, such as phytoestrogens from soy, which may reduce menopausal symptoms in women; taxol from the Pacific yew, which acts as an anticancer agent; and quinine from *Cinchona* trees, which helps treat malaria.

- In what ways would a drug prepared from a whole plant differ from a drug prepared from an isolated chemical compound?

## 40.3 Animals That Protect Plants

### Learning Outcomes

1. Describe the benefit *Acacia* trees receive from ants that live in them.
2. Explain how some plants use parasitoid wasps to destroy caterpillars.

Not only do individual species and their traits evolve over time, but so do relationships between species. For example, evolution of chemicals to deter herbivores may often be accompanied over time by adaptation on the part of herbivores to withstand these chemicals. This evolutionary pattern is called coevolution. Here we consider two cases of mutualism that coevolved between animal and plant species.

**Acacia trees and ants.** Several species of ants provide small armies to protect some species of *Acacia* trees from other herbivores. These stinging ants may inhabit an enlarged thorn of the tree; they attack other insects (figure 40.9) and sometimes small mammals and epiphytic plants. Some of the *Acacia* species provide their ants with sugar in nectaries located away from the flowers, and even with lipid food bodies at the tips of leaves.

The only problem with ants chasing away other insects is that acacia trees depend on bees to pollinate their flowers. What keeps the ants from swarming and stinging a bee that stops by to pollinate? Evidence indicates that when a flower opens on an acacia tree, it produces some type of chemical ant deterrent that does not deter the bees. This chemical has not yet been identified.

**Parasitoid wasps, caterpillars, and leaves.** Caterpillars fill up on leaf tissue before they metamorphose into a moth or a butterfly. In some cases, proteinase inhibitors in leaves are sufficient to deter very hungry caterpillars. But some plants have developed another strategy: As the caterpillar

**Figure 40.9** Ants attacking a katydid to protect “their” *Acacia*. Through coevolution, ants are sheltered by acacia trees and attack otherwise harmful herbivores.

chews away, a wound response in the plant leads to the release of a volatile compound. This compound wafts through the air, and if a female parasitoid wasp happens to be in the neighborhood, it is immediately attracted to the source. Parasitoid wasps are so named because they are parasitic on caterpillars. The wasp lays her fertilized eggs in the body of the caterpillar that is feeding on the leaf of the plant. These eggs hatch, and the emerging larvae kill and eat the caterpillar (figure 40.10).

### Learning Outcomes Review 40.3

Mutualism is an interaction between species that is beneficial to both. Ants protect *Acacia* by attacking feeding herbivores. Parasitoid wasps are attracted by compounds released from plant tissues damaged by feeding caterpillars; they lay eggs in the caterpillars, which later are killed by the emerging larvae.

- Would you expect that wasps kill all the caterpillars? Explain.

**Figure 40.10** Parasitoid wasps provide protection from herbivory.

## 40.4 Systemic Responses to Invaders

### Learning Outcomes

1. Outline the sequence of events that leads to the production of a wound response.
2. Describe the gene-for-gene hypothesis.
3. Define systemic acquired resistance.

So far, we have focused mainly on static plant responses to threats. Most of the deterrent chemicals such as toxins are maintained at steady-state levels. In addition, the morphological structures such as thorns or trichomes that help defend plants are part of the normal developmental program. Because these defenses are maintained whether an herbivore or other invader is present or not, they have an energetic downside. By contrast, resources could be conserved if the response to being under siege was inducible—that is, if the defense response could be launched only when a threat had been recognized. In this section, we explore these inducible defense mechanisms.

### Wound responses protect plants from herbivores

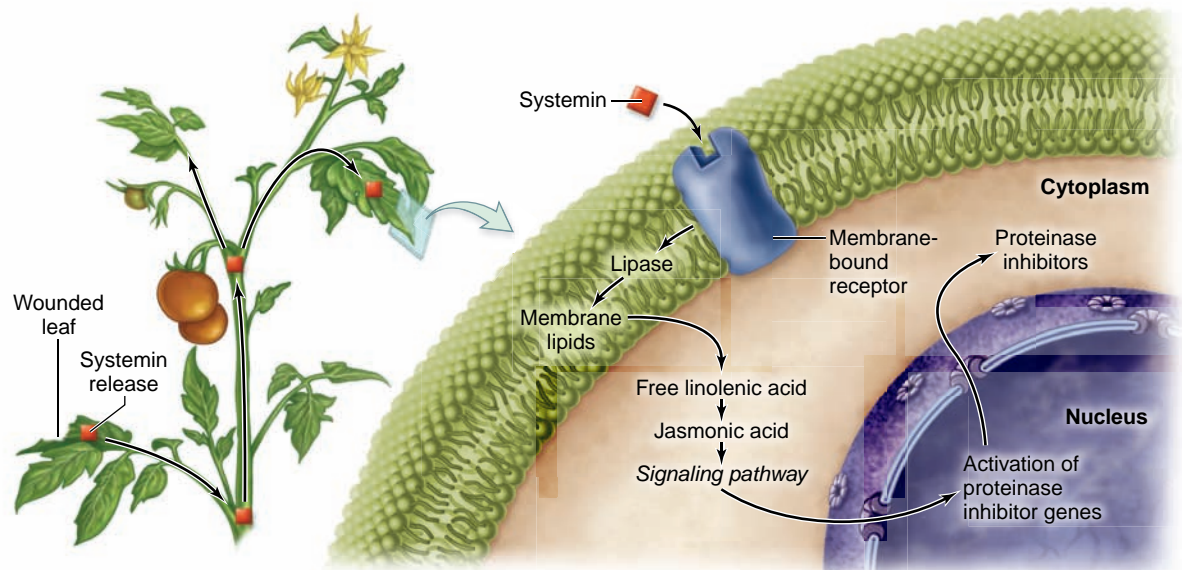

As you just learned from the example of the parasitoid wasp, a **wound response** may occur when a leaf is chewed or injured. One induced outcome is the rapid production of proteinase inhibitors. These chemical toxins do not exist in the stockpile of defenses, but instead are produced in response to wounding.

Proteinase inhibitors bind to digestive enzymes in the gut of the herbivore. The proteinase inhibitors are produced throughout the plant, and not just at the wound site. How are cells in distant parts of the plant signaled to produce proteinase inhibitors? In tomato plants, the following sequence of events is responsible for this systemic response (figure 40.11):

1. Wounded leaves produce an 18-amino-acid peptide called **systemin** from a larger precursor protein.

### Figure 40.11 Wound response in tomato.

Wounding a tomato leaf leads to the production of jasmonic acid in other parts of the plant. Jasmonic acid initiates a signaling pathway that turns on genes needed to synthesize a proteinase inhibitor.

2. Systemin moves through the apoplast (the space between cell walls) of the wounded tissue and into the nearby phloem. This small peptide-signaling molecule then moves throughout the plant in the phloem.
3. Cells with a systemin receptor bind the systemin, which leads to the production of **jasmonic acid**.
4. Jasmonic acid activates the transcription of defense genes, including the production of a proteinase inhibitor.

Although we know the most about the signaling pathway involving jasmonic acid, other molecules are involved in wound response as well. **Salicylic acid**, which is found in the bark of plants such as the white willow (*Salix alba*) is one example. Cell fragments also appear to be important signals for triggering an induced response, as is discussed shortly.

Mechanical damage separate from herbivore attack also elicits wound responses, which presents a challenge in designing plant experiments that involve cutting or otherwise mechanically damaging the tissue. Experimental controls, which should be cut or manipulated in the same way but without the test treatment, are especially important to ensure that any changes observed are not due only to the wound response.

### Defense responses can be pathogen-specific

Wound responses are independent of the type of herbivore or other agent causing the damage, but other responses are triggered by a specific pathogen that carries a specific allele in its genome.

## Pathogen recognition

Half a century ago, the geneticist H. H. Flor proposed the existence of a plant resistance gene (*R*), the product of which interacts with the product of an avirulence gene (*avr*) carried by a pathogen. *Avirulent* means not virulent (disease-causing). An **avirulent pathogen** is one that can utilize host resources for its own use and reproduction without causing severe damage or death. The product of this pathogen's *avr* protein interacts with the plant's *R* protein to signal the pathogen's presence. In this way, the plant under attack can mount defenses, thus ensuring that the pathogen remains avirulent. If the pathogen's *avr* protein is not recognized by the plant, disease symptoms appear.

Flor's proposal is called the **gene-for-gene hypothesis** (figure 40.12), and several pairs of *avr* and *R* genes have been cloned in different species pathogenized by microbes, fungi, and even insects in one case. This research has been motivated partially by the agronomic benefit of identifying genes that can be added via gene technology to crop plants to protect them from invaders.

The *avr/R* gene interaction is an example of ongoing coevolution. An avirulent invader can be detected and recognized. Mutations arising in the avirulent pathogen can result in a virulent pathogen that overcomes a plant's defenses and kills it—often leading to the pathogen's demise as well.

## Specific defenses and the hypersensitive response

Much is now known about the signal transduction pathways that follow the recognition of the pathogen by the *R* gene product. These pathways lead to the triggering of the **hypersensitive response (HR)**, which leads to rapid cell death around the source of the invasion and also to a longer term, whole-plant resistance (figures 40.12 and 40.13). A gene-for-gene response does not always occur, but plants still have defense responses to pathogens in general as well as to mechanical wounding. Some of the response pathways may be similar. Also, fragments of cell wall carbohydrates may serve as recognition and signaling molecules.

When a plant is attacked and a gene-for-gene recognition occurs, the HR leads to very rapid cell death around the site of attack. This seals off the wounded tissue to prevent the pathogen or pest from moving into the rest of the plant. Hydrogen peroxide and nitric oxide are produced and may signal a cascade of bio-

chemical events resulting in the localized death of host cells. These chemicals may also have negative effects on the pathogen, although protective mechanisms have coevolved in some pathogens.

Other antimicrobial agents produced include the **phytoalexins**, which are antimicrobial chemical defense agents. A variety of pathogenesis-related genes (*PR* genes) are also expressed, and their proteins can function as either antimicrobial agents or signals for other events that protect the plant.

In the case of virulent invaders for which there is no *R* recognition, changes in local cell walls at least partially block the pathogen or pest from moving further into the plant. In this case, an HR does not occur, and the local plant cells do not die.

## Long-term protection

In addition to the HR or other local responses, plants are capable of a systemic response to a pathogen or pest attack, called a **systemic acquired resistance (SAR)** (see figure 40.12). Several pathways lead to broad-ranging resistance that lasts for a period of days.

The long-distance signal that induces SAR is likely salicylic acid, rather than systemin, which is the long-distance signal in wound responses. At the cellular level, jasmonic acid (which was mentioned earlier in the context of the wound response pathways) is involved in SAR signaling. SAR allows the plant to respond more quickly if it is attacked again. This response, however, is not the same as the human or mammalian immune response, in which antibodies (proteins) that recognize specific antigens (foreign proteins) persist in the body. SAR is neither as specific nor as long-lasting.

## Learning Outcomes Review 40.4

A wounded leaf initiates a signaling chain that stimulates production of proteinase inhibitors. When a plant has a resistance gene with a product that recognizes the product of an avirulence gene in the pathogen, the plant carries out a defense response; this recognition is called the gene-for-gene hypothesis. Systemic acquired resistance is a temporary broad form of resistance that may be induced by exposure to a pathogen.

- How does local cell death help preserve a plant under attack by a pathogen?

## Figure 40.12 Gene-for-gene hypothesis.

Flor proposed that pathogens have an avirulence (*avr*) gene that recognizes the product of a plant resistance gene (*R*). If the virus, bacterium, fungus, or insect has an *avr* gene product that matches the *R* gene product, a defense response will occur.

**Figure 40.13 Plant defense responses.**

In the gene-for-gene response, a cascade of events is triggered, leading to local cell death (HR) and to the production of a mobile signal that provides longer term resistance in the rest of the plant (SAR).

## Chapter Review

### 40.1 Physical Defenses

Pathogens can harm plants in many ways, including exploiting nutrient resources and taking over DNA replication machinery.

**Dermal tissue provides first-line defense.**

Dermal tissues are covered with lipids such as cutin and suberin, which reduce water loss and prevent attack. Morphological features such as trichomes, bark, and thorns protect some plants.

**Invaders can penetrate dermal defenses.**

In spite of defense mechanisms, invaders can cause damage by piercing plants, eating plant parts, or entering the plant through the stomata.

**Bacteria and fungi can also be beneficial to plants.**

Mycorrhizal fungi form beneficial relationships with plants by enhancing uptake of water and minerals. Nitrogen-fixing bacteria provide nitrogen to plants in a usable form.

### 40.2 Chemical Defenses

**Plants maintain chemical arsenals.**

Plants may produce and stockpile secondary metabolites such as alkaloids, tannins, and oils that provide protection from predators (see table 40.1). Plants protect themselves from their own toxins either by sequestering them in vesicles or producing compounds that are not toxic until they are ingested by a predator.

**Plants can poison other plants.**

Allelopathic plants secrete chemicals to block seed germination or inhibit growth of nearby plants. This strategy minimizes competition for resources such as light and nutrients.

**Humans are susceptible to plant toxins.**

Ricin is an example of a powerful plant toxin. It is found in the endosperm of castor beans (see figure 40.8). Ricin is six times more lethal than cyanide.

**Secondary metabolites may have medicinal value.**

Plant secondary metabolites such as phytoestrogens, taxol, and quinine have pharmaceutical value for humans. Many other plant-based remedies have been used for centuries in human cultures.

### 40.3 Animals That Protect Plants

Mutualistic associations are beneficial to both the plant and animal partners. One example is the relationship between acacia trees and ants, in which ants protect the trees from herbivores.

Another example is the association between certain plants, caterpillars, and parasitoid wasps. When chewed or damaged, the leaves release compounds that attract the wasps, which lay their eggs in the caterpillars. The wasps' larvae feed on the caterpillar, killing it (see figure 40.10).

### 40.4 Systemic Responses to Invaders

Plants avoid an unnecessary expenditure of energy if they produce defense mechanisms only when needed.

**Wound responses protect plants from herbivores.**

Wound responses are generalized reactions that occur regardless of the cause of the injury.

During a wound response, a signal spreads throughout the phloem, inducing the production of proteinase inhibitors that bind to digestive enzymes in the gut of the animal eating the plant (see figure 40.11).

**Defense responses can be pathogen-specific.**

In many plants, the plant *R* gene product may interact with an avirulence gene product of a pathogen in a gene-for-gene reaction that induces a defense response.

Plants can also produce antimicrobial agents such as phytoalexins as defense compounds.

After exposure to a pathogen, a plant may be protected against pathogen attack in the short-term future through a mechanism called systemic acquired resistance.

## Review Questions

### UNDERSTAND

- Nonnative invasive species are often a threat to native species because they
  - typically grow larger than other plants.
  - are not susceptible to any diseases.
  - are parasitic.
  - do not have natural enemies in their new location.
- Fungal pathogens transfer nutrients across a plant cell membrane using
  - an adhesion pad.
  - a haustorium.
  - guard cells.
  - tumors.
- Casparian strips in roots contain \_\_\_\_\_, which helps to defend against invaders.
  - wax
  - suberin
  - cutin
  - cuticle
- Which of the following is not a secondary metabolite?
  - Caffeine
  - Morphine
  - Taxol
  - Glucose
- Parasitoid wasps protect plants from caterpillars by
  - stinging them.
  - repelling them.
  - eating them.
  - enclosing them in a capsule.
- In response to wounding, a tomato plant first produces a peptide called
  - systemin.
  - jasmonic acid.
  - ricin.
  - salicylic acid.
- When a cell undergoes a hypersensitive response, it
  - builds cell walls quickly.
  - releases defense response molecules from its vacuole.
  - dies rapidly.
  - destroys avirulence gene products.
- The wound response products that bind to digestive enzymes in herbivores are
  - proteinase inhibitors.
  - proteinase promoters.
  - lipase inhibitors.
  - lipase promoters.
- If a plant has been attacked by a pathogen, then it is likely to be able to respond more quickly to a subsequent attack due to a mechanism called
  - basal defense.
  - induced hypersensitive response.
  - antimicrobial pathogen resistance.
  - systemic acquired resistance.

### APPLY

- Some plants have developed a mutualistic relationship with parasitoid wasps. This mutualistic relationship would not occur if
  - the plant quit producing nectar for the wasp.
  - the wasp ceased to live on the plant.
  - the plant quit producing volatile compounds that attract the wasp.
  - the plant attracted too many caterpillars.
- Both plant and animal immune systems can
  - develop memory of past pathogens to more effectively deal with subsequent infections.
  - initiate expression of proteins to help fight the infection.

- kill their own cells to prevent spread of the infection.
  - all of the above
- Your friend informs you that it is highly likely all of the plants in your yard are “infected” with some kind of fungi or bacteria. The plants look perfectly healthy to you at this time. The most prudent thing for you to do would be:
    - Remove all your plants because they are likely to die.
    - Spray your plants with chemicals to remove all bacteria and fungi.
    - Remove all your plants and replace the soil.
    - Do nothing because many of these bacteria and fungi may be beneficial.
  - Some plants are recognized by fungal pathogens on the basis of their stomatal pores. Which of the following would provide these plants immunity from fungal infection?
    - Removing all of the stomata from the plant
    - Changing the spacing of stomatal pores in these plants
    - Reinforcing the cell wall in the guard cells of stomatal pores
    - Increasing the number of trichomes on the surfaces
  - You decide to plant a garden with a beautiful black walnut at one end and a majestic white oak at the other end. You are quite disappointed, however, when none of the seeds you plant around the walnut tree grow. What might explain this observation?
    - The walnut tree filters out too much light, so the seeds fail to germinate.
    - The roots of the walnut tree deplete all of the nutrients from the soil, so the new seedlings starve.
    - The walnut tree produces chemical toxins that prevent seed germination.
  - If a pathogen contains an *avr* gene not recognized by a plant, the plant will most likely
    - develop a disease.
    - eliminate the pathogen because it is unrecognized.
    - develop proteinase inhibitors.
    - develop a different *R* gene.

### SYNTHESIZE

- During the domestication of crops, humans have intentionally or inadvertently selected for lower levels of toxic compounds. Explain why each of these two types of selection would have occurred.
- Parasitoid wasps seem like an effective method to control caterpillars. Discuss some limitations of this strategy. That is, outline some scenarios in which a plant might not be effectively protected by the wasps.
- Systemin is transported through the phloem of a tomato plant to induce a wound response to herbivores. However, the direction of phloem movement is always from source to sink. Explain how the sites that receive the wound signal may vary with stages of the plant's life cycle.

# Sensory Systems in Plants

## Chapter Outline

---

- 41.1 Responses to Light
- 41.2 Responses to Gravity
- 41.3 Responses to Mechanical Stimuli
- 41.4 Responses to Water and Temperature
- 41.5 Hormones and Sensory Systems

## Introduction

---

*All organisms sense and interact with their environments. This is particularly true of plants. Plant survival and growth are critically influenced by abiotic factors, including water, wind, and light. The effect of the local environment on plant growth also accounts for much of the variation in adult form within a species. In this chapter, we explore how a plant senses such factors and transduces these signals to elicit an optimal physiological, growth, or developmental response. Although responses can be observed on a macroscopic scale, the mechanism of response occurs at the level of the cell. Signals are perceived when they interact with a receptor molecule, causing a shape change and altering the receptor's ability to interact with signaling molecules. Hormones play an important role in the internal signaling that brings about environmental responses and are keyed in many ways to the environment.*

## 41.1 Responses to Light

### Learning Outcomes

1. Compare the pigments phytochrome and chlorophyll.
2. List growth responses influenced by phytochrome.
3. Define phototropism.

In chapter 8 we covered the details of photosynthesis, the process by which plants convert light energy into chemical bond energy. We described pigments, molecules that are capable of absorbing light energy; you learned that chlorophylls are the primary pigment molecules of photosynthesis. Plants contain other pigments as well, and one of the functions of these other pigments is to detect light and to mediate plants' response to light by passing on information.

Several environmental factors, including light, can initiate seed germination, flowering, and other critical developmental events in the life of a plant. **Photomorphogenesis** is the term used for nondirectional, light-triggered development. It can result in complex changes in form, including flowering.

Unlike photomorphogenesis, phototropisms are directional growth responses to light. Both photomorphogenesis and phototropisms compensate for the plant's inability to walk away from unfavorable environmental conditions.

### $P_{fr}$ facilitates expression of light-response genes

**Phytochrome** is present in all groups of plants and in a few genera of green algae, but not in other protists, bacteria, or fungi. Phytochrome systems probably evolved among the green algae and were present in the common ancestor of the plants.

The phytochrome molecule exists in two interconvertible forms: The first form,  $P_r$ , absorbs red light at 660 nm wavelength; the second,  $P_{fr}$ , absorbs far-red light at 730 nm. Sunlight has more red than far-red light.  $P_r$  is biologically inactive; it is converted into  $P_{fr}$ , the active form, when red photons are present.  $P_{fr}$  is converted back into  $P_r$  when far-red photons are available. In other words, biological reactions that are affected by phytochrome occur when  $P_{fr}$  is present. When most of the  $P_{fr}$  has been replaced by  $P_r$ , the reaction will not occur (figure 41.1).

The pigment-containing protein **phytochrome (P)** consists of two parts: a smaller part that is sensitive to light, called the *chromophore*, and a larger portion called the *apoprotein* (figure 41.2). The apoprotein facilitates expression of light-response genes. Over 2500 genes, 10% of the *Arabidopsis* genome, are involved in biological responses that begin with a conformational change in one of the phytochromes in response to red light. Phytochromes are involved in numerous signaling pathways that lead to gene expression. Some pathways also involve protein kinases or G proteins (described in chapter 9).

Phytochrome is found in the cytoplasm, but enters the nucleus to facilitate transcription of light response genes. When  $P_r$  is converted to  $P_{fr}$ , it can move into the nucleus. Once in the nucleus,  $P_{fr}$  binds with other proteins that form a transcription complex, leading to the expression of light-

**Figure 41.1** How phytochrome works. *PHYA* is one of the five *Arabidopsis* phytochrome genes. When exposed to red light,  $P_r$  changes to  $P_{fr}$ , the active form that elicits a response in plants.  $P_{fr}$  is converted to  $P_r$  when exposed to far-red light. The amount of  $P_{fr}$  is regulated by protein degradation. The protein ubiquitin tags  $P_{fr}$  for degradation in the proteasome.

regulated genes (figure 41.3). Phytochrome's protein-binding site (see figure 41.2) is essential for interactions with transcription factors.

Phytochrome also works through protein kinase-signaling pathways. When phytochrome converts to the  $P_{fr}$  form, the protein kinase domain of the apoprotein may phosphorylate a serine and the amino (N) terminus of the phytochrome itself

**Figure 41.2** Phytochrome. Different parts of the phytochrome molecule have distinct roles in light regulation of growth and development. Phytochrome changes conformation when the chromophore responds to relative amounts of red and far-red light. The shape change affects the ability of phytochrome to bind to other proteins that participate in the signaling process. The ubiquitin-binding sites allow for degradation, and the protein kinase domain allows for further signaling via phosphorylation.

**Figure 41.3**  $P_{fr}$  enters the nucleus and regulates gene expression.

(autophosphorylation), or it may phosphorylate the serine of another protein involved in light signaling (figure 41.4). Phosphorylation initiates a signaling cascade that can activate transcription factors and lead to the transcription of light-regulated genes.

Although phytochrome is involved in multiple signaling pathways, it does not directly initiate the expression of that 10% of the *Arabidopsis* plant genome. Rather, phytochrome initiates expression of master regulatory genes that manage the complex interactions leading to photomorphogenesis and phototropisms. Gene expression is just the first step, with hormones playing important roles as well.

### Inquiry question

? You are given seed of a plant with a mutation in the protein kinase domain of phytochrome. Would you expect to see any red-light-mediated responses when you germinate the seed? Explain your answer.

Chlorophyll also absorbs red light, but it is not a receptor like phytochrome. Unlike receptors that transduce information, chlorophyll transduces energy.

The amount of  $P_{fr}$  is also regulated by degradation. Ubiquitin is a protein that tags  $P_{fr}$  for transport to the **proteasome**, a protein shredder composed of 28 proteins. The proteasome has a channel in the center, and as proteins pass through, they are clipped into amino acids that can be used to build other proteins as described in chapter 16. The process of tagging and recycling  $P_{fr}$  is precisely regulated to maintain needed amounts of phytochrome in the cell.

Although we often refer to phytochrome as a single molecule here, several different phytochromes have been identified that appear to have specific functions. In *Arabidopsis* five forms of phytochrome, PHYA to PHYE, have been characterized, each playing overlapping but distinct roles in the light regulation of growth and development.

**Figure 41.4** The kinase domain of  $P_{fr}$  phosphorylates  $P_{fr}$ , leading directly or indirectly to light-regulated gene expression. In this example, signaling leads to the release of a transcription factor from a protein complex.

## Many growth responses are linked to phytochrome action

Phytochrome is involved in a number of plant growth responses, including seed germination, shoot elongation, and detection of plant spacing.

### Seed germination

Seed germination is inhibited by far-red light and stimulated by red light in many plants. Because chlorophyll absorbs red light strongly but does not absorb far-red light, light filtered through the green leaves of canopy trees above a seed contains a reduced amount of red light. The far-red light inhibits seed germination by converting  $P_{fr}$  into the biologically inactive  $P_r$  form.

Consequently, seeds on the ground under deciduous plants, which lose their leaves in winter, are more apt to germinate in the spring after the leaves have decomposed and the seeds are exposed to direct sunlight and a greater amount of red light. This adaptation greatly improves the chances that seedlings will become established before leaves on taller plants shade the seedlings and reduce sunlight available for photosynthesis.

### Shoot elongation

Elongation of the shoot in an etiolated seedling (one that is pale and slender from having been kept in the dark) is caused by a lack of red light. The morphology of such plants becomes normal when they are exposed to red light, increasing the amount of  $P_{fr}$ .

Etiolation is an energy conservation strategy to help plants growing in the dark reach the light before they die. They don't green up until light becomes available, and they divert energy to internode elongation. This strategy is useful for seedlings when they have sprouted underground or under leaf cover.

The de-etiolated (*det2*) *Arabidopsis* mutant has a poor etiolation response; seedlings fail to elongate in the dark (figure 41.5). The *det2* mutants are defective in an enzyme necessary for biosynthesis of a brassinosteroid hormone, leading researchers to propose that brassinosteroids play a role in plant responses to light through phytochrome. (Brassinosteroids and other hormones are discussed later in this chapter.)

### Detection of plant spacing

Red and far-red light also signal plant spacing. Again, leaf shading increases the amount of far-red light relative to red light. Plants somehow measure the amount of far-red light bounced back to them from neighboring plants. The closer together plants are, the more far-red relative to red light they perceive and the more likely they are to grow tall, a strategy for outcompeting others for sunshine. If their perception is distorted by putting a light-blocking collar around the stem, the elongation response no longer occurs.

## Light affects directional growth

*Phototropisms*, directional growth responses, contribute to the variety of overall plant shape we see within a species as shoots grow toward light. Tropisms are particularly intriguing because they challenge us to connect environmental signals with cellular perception of the signal, transduction into biochemical pathways, and ultimately an altered growth response.

**Figure 41.5** Etiolation is regulated by light and the *det2* gene in *Arabidopsis*. *det2* is needed for etiolation in dark grown plants.

### Positive phototropism in stems

Phototropic responses include the bending of growing stems and other plant parts toward sources of light with blue wavelengths (460-nm range) (figure 41.6). In general, stems are positively phototropic, growing toward a light source, but most roots do not respond to light, or in exceptional cases, exhibit only a weak negative phototropic response.

**Figure 41.6** Phototropism. Oat coleoptiles growing toward light with blue wavelengths. Colors indicate the color of light shining on coleoptiles. Arrows indicate the direction of light.

The phototropic reactions of stems are clearly of adaptive value, giving plants greater exposure to available light. They are also important in determining the development of plant organs and, therefore, the appearance of the plant. Individual leaves may also display phototropic responses; the position of leaves is important to the photosynthetic efficiency of the plant. A plant hormone called *auxin*, discussed in a later section, is probably involved in most, if not all, of the phototropic growth responses of plants.

### Blue-light receptors

The recent identification of blue-light receptors in plants is leading to exciting discoveries of how the light signal can ultimately be connected with a phototropic response. A blue-light receptor **phototropin 1 (PHOT1)** was identified through the characterization of a nonphototropic mutant.

The phot1 protein has two light-sensing regions, and they change conformation in response to blue light. This change activates another region of the protein that is a kinase. Both PHOT1 and a similar receptor, PHOT2, are receptor kinases unique to plants. A portion of PHOT1 is a kinase that autophosphorylates (figure 41.7). Currently, only the early steps in this signal transduction are understood. It will be intriguing to watch the story of the phot1 signal transduction pathway unfold, leading to an explanation of how plants grow toward the light.

### Circadian clocks are independent of light but are entrained by light

Although shorter and much longer naturally occurring rhythms also exist, **circadian rhythms** (“around the day”) are particularly common and widespread among eukaryotic organisms. They relate the day–night cycle on Earth, although they are not exactly 24 hr in duration.

Jean de Mairan, a French astronomer, first identified circadian rhythms in 1729. He studied the sensitive plant (*Mimosa pudica*), which closes its leaflets and leaves at night. When

de Mairan put the plants in total darkness, they continued “sleeping” and “waking” just as they had when exposed to night and day. This is one of four characteristics of a circadian rhythm—it must continue to run in the absence of external inputs. Plants with a circadian rhythm do not actually have to be experiencing a pattern of daylight and darkness for their cycle to occur.

In addition, a circadian rhythm must be about 24 hr in duration, and the cycle can be reset or entrained. Although plants kept in darkness will continue the circadian cycle, the cycle’s period may gradually move away from the actual day–night cycle, becoming desynchronized. In the natural environment, the cycle is entrained to a daily cycle through the action of phytochrome and blue-light photoreceptors.

Other eukaryotes, including humans, have circadian rhythms, and perhaps you have experienced jet lag when you traveled by airplane across a few time zones. Recovery from jet lag involves entrainment to the new time zone.

Another characteristic of a circadian cycle is that the clock can compensate for differences in temperature, so that the duration remains unchanged. This characteristic is unique, considering what we know about biochemical reactions, because most rates of reactions vary significantly based on temperature. Circadian clocks exist in many organisms, and they appear to have evolved independently multiple times.

The reversible circadian rhythm changes in leaf movements are typically brought about by alteration of cells’ turgor pressure; we describe these changes in a later section.

#### Learning Outcomes Review 41.1

Plants grow and develop in response to environmental signals. Phytochrome, a red-light receptor, transduces information, while chlorophyll transduces energy. Phytochrome influences seed germination, shoot elongation, and other growth. Phototropism is directional growth in response to light and is controlled by a blue-light receptor. Circadian rhythms are 24-hr cycles entrained to the day–night cycle.

- Why would it be an advantage to have both phytochromes and chlorophylls as pigments?

**Figure 41.7 Blue-light receptor.** Blue light activates the light-sensing region of PHOT1, which in turn stimulates the kinase region of PHOT1 to autophosphorylate. This is just the first step in a signal transduction pathway that leads to phototropic growth.

## 41.2 Responses to Gravity

### Learning Outcomes

1. Identify the structures in cells that perceive gravity.
2. Explain how stems and roots bend in response to gravity.

When a potted plant is tipped over and left in place, the shoot bends and grows upward. The same thing happens when a storm pushes plants over in a field. These are examples of **gravitropism**, the response of a plant to the gravitational field of the Earth (figure 41.8; see also chapter opener). Because plants also grow in response to light, separating out phototropic effects is important in the study of gravitropism.

### Plants align with the gravitational field: An overview

Gravitropic responses are present at germination, when the root grows down and the shoot grows up. Why does a shoot have a negative gravitropic response (growth away from gravity), while a root has a positive one? Auxins play a primary role in gravitropic responses, but they may not be the only way gravitational information is sent through the plant.

The opportunity to experiment on the Space Shuttle in a gravity-free environment has accelerated research in this area. Analysis of gravitropic mutants is also adding to our understanding of gravitropism. Investigators propose that four general steps lead to a gravitropic response:

1. Gravity is perceived by the cell.
2. A mechanical signal is transduced into a physiological signal in the cell that perceives gravity.
3. The physiological signal is transduced inside the cell and externally to other cells.
4. Differential cell elongation occurs, affecting cells in the “up” and “down” sides of the root or shoot.

**Figure 41.8** Plant response to gravity. This plant was placed horizontally and allowed to grow for seven days. Note the negative gravitational response of the shoot.

### Inquiry question

- ? Where would you expect to find the highest concentration of auxin?

Currently researchers are debating the steps involved in perception of gravity. In shoots, gravity is sensed along the length of the stem in the endodermal cells that surround the vascular tissue (figure 41.9a), and signaling occurs toward the outer epidermal cells. In roots, the cap is the site of gravity perception, and a signal must trigger differential cell elongation and division in the elongation zone (figure 41.9b).

In both shoots and roots, amyloplasts, plastids that contain starch, sink toward the center of the gravitational field and thus may be involved in sensing gravity. Amyloplasts interact with the cytoskeleton. Auxin evidently plays a role in transmitting a signal from the gravity-sensing cells that contain amyloplasts and the site where growth occurs. The link between amyloplasts and auxin is not fully understood.

### Stems bend away from a center of gravity

Increased auxin concentration on the lower side in stems causes the cells in that area to grow more than the cells on the upper side. The result is a bending upward of the stem against the

**Figure 41.9** Sites of gravity sensing and response in roots and shoots.

force of gravity—in other words, a *negative gravitropic response*. Such differences in hormone concentration have not been as well documented in roots. Nevertheless, the upper sides of roots oriented horizontally grow more rapidly than the lower sides, causing the root ultimately to grow downward; this phenomenon is known as *positive gravitropic response*.

Two *Arabidopsis* mutants, *scarecrow* (*scr*) and *short root* (*sbr*), were initially identified by aberrant root phenotypes, but they also affect shoot gravitropism (figure 41.10). Both genes are needed for normal endodermal development (see figure 36.16). Without a fully functional endodermis, stems lack a normal gravitropic response. These endodermal cells carry amyloplasts in the stems, and in the mutants, stem endodermis fails to differentiate and produce gravity-sensing amyloplasts.

### Roots bend toward a center of gravity

In roots, the gravity-sensing cells are located in the root cap, and the cells that actually undergo asymmetrical growth are in the distal elongation zone, which is closest to the root cap. How the information is transferred over this distance is an intriguing question. Auxin may be involved, but when auxin transport is suppressed, a gravitropic response still occurs in the distal elongation zone. Some type of electrical signaling involving membrane polarization has been hypothesized, and this idea was tested aboard the Space Shuttle. So far, the jury is still out on the exact mechanism.

The growing number of auxin mutants in roots do confirm that auxin has an essential role in root gravitropism, even if it may not be the long-distance signal between the root cap and the elongation zone. Mutations that affect both auxin influx and efflux can eliminate the gravitropic response by altering the directional transport of this hormone.

It may surprise you to learn that in tropical rain forests, the roots of some plants may grow up the stems of neighboring plants, instead of exhibiting the normal positive gravitropic responses typical of other roots. It appears that rainwater dissolves nutrients, both while passing through the lush upper canopy of the forest, and subsequently while trickling down the tree trunks. This water is a more reliable source of nutrients for the roots than the nutrient-poor rain forest soils in which the plants are anchored. Explaining this observation in terms of current hypotheses is a challenge. It has been proposed that roots are more sensitive to auxin than are shoots, and that auxin may actually inhibit growth on the lower side of a root, resulting in a positive gravitropic response. Perhaps in these tropical plants, the sensitivity to auxin in roots is reduced.

#### Learning Outcomes Review 41.2

Gravitropism is the response of a plant to gravity. In endodermis cells of shoots and root cap cells of roots, amyloplasts settle to the bottom, allowing the plant to sense the direction of gravitational pull. In response, cells on the lower side of stems and the upper side of roots grow faster than other cells, causing stems to grow upward and roots to grow downward.

- **What would happen to a plant growing under weightless conditions, such as in an orbiting spacecraft?**

**Figure 41.10** Amyloplasts in stem endodermis is needed for gravitropism. *a.* The *scr* and *sbr* mutants of *Arabidopsis* have abnormal root development because they lack a fully differentiated endodermal layer. *b.* The endodermal defect extends into the stem, eliminating the positive gravitropic response of wild-type stems.

## 41.3 Responses to Mechanical Stimuli

### Learning Outcomes

1. Define thigmomorphogenesis.
2. Contrast thigmotropism with thigmonastic responses.
3. Explain why the movement of leaves of a sensitive plant is not an example of a tropism.

Plants respond to touch and other mechanical stimuli in different ways, depending on the species and the type of stimulus. In some cases, plants permanently change form in response to mechanical stresses, a process termed **thigmomorphogenesis**. This change can be seen in trees growing where an almost constant wind blows from one direction. Other responses are reversible and occur in the short term, as when mimosa leaves droop in response to touch. These responses are not tropisms, but rather turgor movements that come about due to changes in the internal water pressure of cells.

### Touch can trigger irreversible growth responses

A **thigmotropism** is directional growth of a plant or plant part in response to contact with an object, animal, other plant, or even the wind. Thigmonastic responses are very similar to thigmotropisms, except that the direction of the growth response is the same regardless of the direction of the stimulus.

Tall, slender plants are more likely to snap during a wind or rain storm than are plants with short, wide internodes. Environmental signals such as regularly occurring winds or the rubbing of one plant against another are sufficient to induce morphogenetic change leading to thicker, shorter internodes. In some cases, even repeated touching of a plant with a finger is enough to cause a change in plant growth.

Tendrils are modified stems that some species use to anchor themselves in the environment (figure 41.11). When a tendril makes contact with an object, specialized epidermal cells perceive the contact and promote uneven growth, causing the tendril to curl around the object, sometimes within only 3 to 10 min. Two hormones, auxin and ethylene, appear to be involved in tendril movements, and they can induce coiling even in the absence of any contact stimulus. Curiously, the tendrils of some species coil toward the site of the stimulus (thigmotropic growth), while those of other species may always coil clockwise, regardless of the side of the tendril that makes contact with an object. In some other plants, such as clematis, bindweed, and dodder, leaf petioles or unmodified stems twine around other stems or solid objects.

Perhaps the most dramatic touch response is the snapping of a Venus flytrap. As discussed in chapter 39, the modified leaves of the flytrap close in response to a touch stimulus, trapping insects or other potential sources of protein. A flytrap can shut in a mere 0.5 sec. The enlarged epidermal or mesophyll cells of the flytrap cause the trap to close. The speed

**Figure 41.11 Thigmotropism.** The thigmotropic response of these twining stems causes them to coil around the object with which they have come in contact.

of trap closure is enhanced by the shape of the leaf, which flips between a concave and convex form.

What is particularly amazing about this response is that the outer cells actually grow. The cell walls may soften in response to an electrical signal that moves through the leaf when the trigger hairs are touched, and the high pressure (turgor) of the water inside the cells pushes against the softened walls to enlarge the cell. This growth mechanism is distinct from other turgor movements (to be discussed shortly) because the water is already within the cell, not transferred into it in response to the electrical signal.

If digestible prey is caught, the trap will open about 24 hr later through the growth of inner cells of the flytrap. This growth response can only be triggered about four times before the leaf dies, presumably because so much energy is required for the individual flytrap to do this trick.

*Arabidopsis* is proving valuable as a model system to explore plant responses to touch. A gene has been identified that is expressed in 100-fold higher levels 10 to 30 min after touch. The gene codes for a calmodulin-like protein that binds  $\text{Ca}^{2+}$ , which is involved in a number of plant physiological processes. Given the value of a molecular genetics approach in dissecting the pathways leading from an environmental signal to a growth response, the touch gene provides a promising first step in understanding how plants respond to touch.

### Reversible responses to touch and other stimuli involve turgor pressure

Unlike tropisms, some touch-induced plant movements are not based on growth responses, but instead result from reversible changes in the turgor pressure of specific cells. Turgor, as described in chapter 38, is pressure within a living cell resulting from diffusion of water into it. If water leaves turgid cells, the cells may collapse, causing plant movement; conversely, water

a.

b.

**Figure 41.12 Sensitive plant (*Mimosa pudica*).**

a. The blades of *Mimosa* leaves are divided into numerous leaflets; at the base of each leaflet is a swollen structure called a pulvinus.  
 b. Changes in turgor cause leaflets to fold in response to a stimulus. When leaves are touched (center two leaves), ions move to the outer side of the pulvinus, water follows by osmosis, and the decreased interior turgor pressure leads to folding.

**Figure 41.13 Heliotropism.** These sunflowers track the movement of the Sun every day.

entering a limp cell may also cause movement as the cell once more becomes turgid.

Many plants, including those of the legume family (Fabaceae), exhibit leaf movements in response to touch or other stimuli. After exposure to a stimulus, the changes in leaf orientation are mostly associated with rapid turgor pressure changes in pulvini (singular, *pulvinus*), two-sided multicellular swellings located at the base of each leaf or leaflet. When leaves with pulvini, such as those of the sensitive plant (*Mimosa pudica*), are stimulated by wind, heat, touch, or in some instances, intense light, an electrical signal is generated. The electrical signal is translated into a chemical signal, with potassium ions being pumped from the cells in one-half of a pulvinus to the intercellular spaces in the other half, leading to the rapid osmosis of water to one side of the pulvinus.

The loss of turgor in half of the pulvinus causes the leaf to “fold.” The movements of the leaves and leaflets of a sensitive plant are especially rapid; the folding occurs within a second or two after the leaves are touched (figure 41.12). Over a span of about 15 to 30 min after the leaves and leaflets have folded, water usually diffuses back into the same cells from which it left, and the leaf returns to its original position.

Some turgor movements are triggered by light. For example, the leaves of some plants may track the Sun, with their blades oriented at right angles to it; how their orientation is directed, however, is poorly understood. Such leaves can move quite rapidly (as much as 15 degrees an hour). This movement maximizes photosynthesis and is analogous to solar panels designed to track the Sun (figure 41.13).

Some of the most familiar reversible changes due to turgor pressure are the circadian rhythms seen in leaves and flowers that open during the day and close at night, or vice versa. For example, the flowers of four o’clocks open in the afternoon, and evening primrose petals open at night. As described earlier, sensitive plant leaves also close at night. Bean leaves are horizontal during the day when their pulvini are turgid, but become more or less vertical at night as the pulvini lose turgor (figure 41.14). These sleep movements reduce water loss from transpiration during the night, but maximize photosynthetic surface area during the day.

**Figure 41.14** Sleep movements in bean leaves. In the bean plant, leaf blades are oriented horizontally during the day and vertically at night.

### Learning Outcomes Review 41.3

Thigmomorphogenesis is a change in growth form in response to a mechanical stress (physical contact or wind). Thigmotropism is directional growth, whereas a thigmonastic response has no directionality. A tropism is an irreversible growth response; a touch-induced plant movement, such as exhibited by *Mimosa pudica*, is reversible and is based on changes in turgor pressure.

- What would be some advantages of having leaves that fold when stimulated?

## 41.4 Responses to Water and Temperature

### Learning Outcomes

1. List the environmental factors that can lead to dormancy.
2. Explain why seed dormancy is an important evolutionary innovation.
3. Identify the types of biological molecules that are most directly affected by low and high temperatures.

Sometimes, modifying the direction of growth is not enough to protect a plant from harsh conditions. The ability to cease growth and go into a dormant stage when conditions become unfavorable, such as during seasonal changes in temperate climates, provides a survival advantage. The extreme example is seed dormancy, but there are intermediate approaches to waiting out the bad times as well.

Plants also have developed adaptations to more short-term fluctuations in temperature, such as might occur during a heat wave or cold snap. These strategies include changes in membrane composition and the production of heat shock proteins.

## Dormancy is a response to water, temperature, and light

In temperate regions, we generally associate dormancy with winter, when freezing temperatures and the accompanying unavailability of water make it impossible for most plants to grow. During this season, buds of deciduous trees and shrubs remain dormant, and apical meristems remain well protected inside enfolding scales. Perennial herbs spend the winter underground, existing as stout stems or roots packed with stored food. Many other kinds of plants, including most annuals, pass the winter as seeds. Often dormancy begins with the dropping of leaves, which you have probably seen occur in deciduous trees in the autumn.

### Organ abscission

Deciduous leaves are often shed as the plant enters dormancy. The process by which leaves or petals are shed is called **abscission**.

Abscission can be useful even before dormancy is established. For example, shaded leaves that are no longer photosynthetically productive can be shed. Petals, which are modified leaves, may senesce once pollination occurs. Orchid flowers remain fresh for long periods of time, even in a florist shop; however, once pollination occurs, a hormonal change is triggered that leads to petal senescence. This strategy makes sense in terms of allocation of energy resources because the petals are no longer necessary to attract a pollinator. One advantage of organ abscission, therefore, is that nutrient sinks can be discarded, conserving resources.

On a larger scale, deciduous plants in temperate areas produce new leaves in the spring and then lose them in the fall. In the tropics, however, the production and subsequent loss of leaves in some species is correlated with wet and dry seasons. Evergreen plants, such as most conifers, usually have a complete change of leaves every two to seven years, periodically losing some but not all of their leaves.

Abscission involves changes that take place in an *abscission zone* at the base of the petiole (figure 41.15). Young leaves produce

**Figure 41.15** Leaf abscission. Hormonal changes in the leaf's abscission zone cause abscission. Two layers of cells in the abscission zone differentiate into a protective layer and a separation layer. As pectins in the separation layer break down, wind and rain can easily separate the leaf from the stem.

hormones (especially cytokinins) that inhibit the development of specialized layers of cells in this zone. Hormonal changes take place as the leaf ages, however, and two layers of cells become differentiated. A *protective layer*, which may be several cells wide, develops on the stem side of the petiole base. These cells become impregnated with suberin, which you may recall is a fatty substance impervious to moisture. A *separation layer* develops on the leaf-blade side; the cells of the separation layer sometimes divide, swell, and become gelatinous.

When temperatures drop, when the duration and intensity of light diminishes, or when other environmental changes occur, enzymes break down the pectins in the middle lamellae of the separation cells. Wind and rain can then easily separate the leaf from the stem. Left behind is a sealed leaf scar that is protected from invasion by bacteria and other disease organisms.

As the abscission zone develops, the green chlorophyll pigments present in the leaf break down, revealing the yellows and oranges of other pigments, such as carotenoids, that previously had been masked by the intense green colors. At the same time, water-soluble red or blue pigments called *anthocyanins* and *betacyanins* may also accumulate in the vacuoles of the leaf cells—all contributing to an array of fall colors in leaves (figure 41.16).

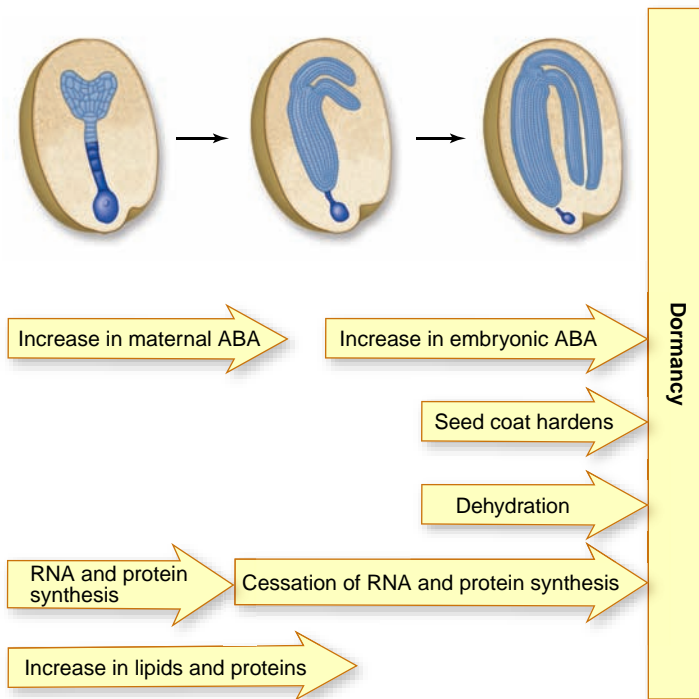

### Seed dormancy

The extraordinary evolutionary innovation of the seed plants is the dormant seed that allows plant offspring to wait until conditions for germination are optimal. Sometimes the seeds can endure a wait of hundreds of years (figure 41.17). In seasonally dry climates, seed dormancy occurs primarily during the dry season, often the summer. Rainfalls trigger germination when conditions for survival are more favorable.

Annual plants occur frequently in areas of seasonal drought. Seeds are ideal for allowing annual plants to bypass the dry season, when there is insufficient water for growth.

**Figure 41.16** Leaf color changes during abscission.

**Figure 41.17** Seed dormancy. Accumulating food reserves, forming a protective seed coat, and dehydration are essential steps leading to dormancy. Abscisic acid (ABA) from both maternal and embryonic tissue is necessary for dormancy.

When it rains, these seeds can germinate, and the plants can grow rapidly, having adapted to the relatively short periods when water is available.

Chapter 37 covered some of the mechanisms involved in breaking seed dormancy and allowing germination under favorable circumstances. These include water leaching away the chemicals that inhibit germination or mechanically cracking the seed coats due to osmotic swelling, a procedure particularly suitable for promoting growth in seasonally dry areas.

Seeds may remain dormant for a surprisingly long time. Many legumes have tough seeds that are virtually impermeable to water and oxygen. These seeds often last decades and even longer without special care; they will eventually germinate when their seed coats have been cracked and water is available. Seeds that are thousands of years old have been successfully germinated!

Favorable temperatures, day length, and amounts of water can release buds, underground stems and roots, and seeds from a dormant state. Requirements vary among species. For example, some weed seeds germinate in cooler parts of the year and are inhibited from germinating by warmer temperatures. Day length differences can have dramatic effects on dormancy. For example, tree dormancy is common in temperate climates when the days are short, but is unusual in tropical trees growing near the equator, where day length remains about the same regardless of season.

### Plants can survive temperature extremes

Sometimes temperatures change rapidly, and dormancy is not possible. How do plants survive temperature extremes? A number of adaptations, including some rapid response strategies, help plants overcome sudden chilling or extreme heat.

## Chilling

Knowing the lipid composition of a plant's membranes can help predict whether the plant will be sensitive or resistant to chilling. Saturated lipids solidify at a higher temperature because they pack together more closely (see chapter 5), so the more unsaturated the membrane lipids are, the more resistant the plant is to chilling. *Arabidopsis* plants genetically modified to contain a higher percentage of saturated fatty acids have proved to be more sensitive to chilling.

When chilling occurs, the enzyme desaturase converts the single bonds in the saturated lipids to double bonds. This process lowers the temperature at which the membrane becomes rigid and cannot function properly.

Even highly unsaturated membranes are not enough to protect plants from freezing temperatures. At freezing, ice crystals form and the cells die from dehydration—not enough liquid water is available for metabolism. Some plants, however, have the ability to undergo deep supercooling and survive temperatures as low as  $-40^{\circ}\text{C}$ . Supercooling occurs when ice crystal formation is limited, and the crystals occur in extracellular spaces where they cannot damage cell organelles. Furthermore, the cells of these plants must be able to withstand gradual dehydration.

Acquiring tolerance to chilling or freezing as the temperature drops can be explained by increased solute concentration. In addition, antifreeze proteins prevent ice crystals from forming. Ice crystals can also form (nucleate) around bacteria naturally found on the leaf surface. Some bacteria have been genetically engineered so that they do not nucleate ice crystals. Spraying leaves with these modified bacteria can provide frost tolerance in some crops.

## High temperatures

High temperatures can be harmful because proteins denature and lose their function when heated. If temperatures suddenly rise  $5^{\circ}$  to  $10^{\circ}\text{C}$ , heat shock proteins (HSPs) are produced. These proteins can stabilize other proteins so that they don't unfold or misfold at higher temperatures. In some cases, HSPs induced by temperature increases can also protect plants from other stresses, including chilling.

Plants can survive otherwise lethal temperatures if they are gradually exposed to increasing temperature. These plants have *acquired thermotolerance*. More is being learned about temperature acclimation by isolating mutants that fail to acquire thermotolerance, including the aptly named *hot* mutants in *Arabidopsis*. One of the *HOT* genes codes for an HSP. Characterization of other *HOT* genes indicates that thermotolerance requires more than the synthesis of HSPs; some *HOT* genes stabilize membranes and are necessary for protein activity.

### Learning Outcomes Review 41.4

Seasonal changes, such as reduction in temperature, light, and water availability, may lead to plant dormancy; in deciduous trees, leaf abscission is part of entering dormancy. Seed dormancy prevents germination until growth conditions are optimal. At low temperatures, lipids in membranes begin to solidify and ice crystals may form in tissues; at high temperatures, proteins denature.

- Why is it advantageous for broadleaf trees to drop leaves in autumn, when they must grow them again in spring?

## 41.5 Hormones and Sensory Systems

### Learning Outcomes

1. Discuss properties of hormones.
2. Compare auxins with cytokinins.
3. Describe the major roles of abscisic acid.

Sensory responses that alter morphology rely on complex physiological networks. Many internal signaling pathways involve plant hormones, which are the focus of this section. Hormones are involved in responses to the environment, as well as in internally regulated development (see chapter 37).

### The hormones that guide growth are keyed to the environment

Hormones are chemical substances produced in small, often minute quantities in one part of an organism and then transported to another part where they bring about physiological or developmental responses. How hormones act in a particular instance is influenced both by the hormone and the tissue that receives the message.

In animals, hormones are usually produced at definite sites, most commonly in organs such as glands. In plants, hormones are not produced in specialized tissues but, instead, in tissues that also carry out other, usually more obvious functions. Seven major kinds of plant hormones have been identified: auxin, cytokinins, gibberellins, brassinosteroids, oligosaccharins, ethylene, and abscisic acid (table 41.1). Current research is focused on the biosynthesis of hormones and on characterizing the hormone receptors involved in signal transduction pathways. Much of the molecular basis of hormone function remains enigmatic.

Because hormones are involved in so many aspects of plant function and development, we have chosen to integrate examples of hormone activity with specific aspects of plant biology throughout the text. In this section, our goal is to give a brief overview of these hormones.

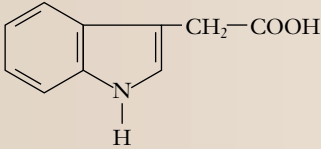

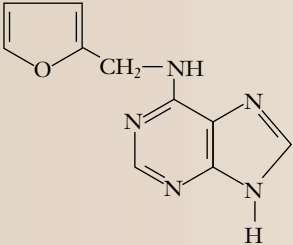

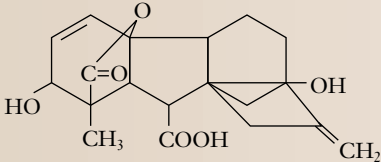

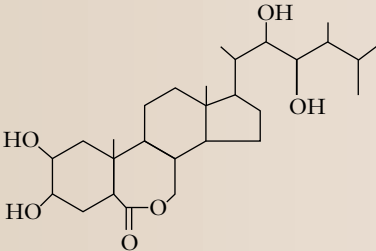

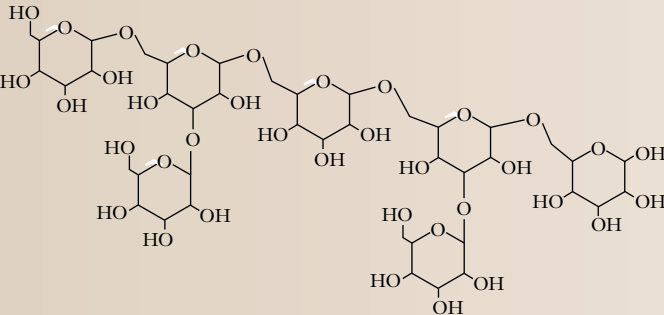

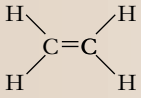

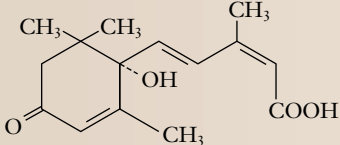

### Auxin allows elongation and organizes the body plan

More than a century ago, an organic substance known as **auxin** was the first plant hormone to be discovered. Auxin increases the plasticity of plant cell walls and is involved in elongation of stems. Cells can enlarge in response to changes in turgor pressure, but cell walls must be fairly plastic for this expansion to occur. Auxin plays a role in softening cell walls. The discovery of auxin and its role in plant growth is an elegant example of thoughtful experimental design and is recounted here for that reason.

### Discovery of auxin

Later in life, the great evolutionist Charles Darwin became increasingly devoted to the study of plants. In 1881, he and his

**TABLE 41.1** Functions of the Major Plant Hormones

Hormone		Major Functions	Where Produced or Found in Plant
Auxins		Promotion of stem elongation and growth; formation of adventitious roots; inhibition of leaf abscission; promotion of cell division (with cytokinins); inducement of ethylene production; promotion of lateral bud dormancy	Apical meristems; other immature parts of plants
Cytokinins		Stimulation of cell division, but only in the presence of auxin; promotion of chloroplast development; delay of leaf aging; promotion of bud formation	Root apical meristems; immature fruits
Gibberellins		Promotion of stem elongation; stimulation of enzyme production in germinating seeds	Roots and shoot tips; young leaves; seeds
Brassinosteroids		Overlapping functions with auxins and gibberellins	Pollen, immature seeds, shoots, leaves
Oligosaccharins		Pathogen defense, possibly reproductive development	Cell walls
Ethylene		Control of leaf, flower, and fruit abscission; promotion of fruit ripening	Roots, shoot apical meristems; leaf nodes; aging flowers; ripening fruits
Abscisic acid		Inhibition of bud growth; control of stomatal closure; some control of seed dormancy; inhibition of effects of other hormones	Leaves, fruits, root caps, seeds

son Francis published a book called *The Power of Movement of Plants*. In this book, the Darwins reported their systematic experiments on the response of growing plants to light—the responses that came to be known as phototropisms. They used germinating oat and canary grass seedlings in their experiments and made many observations in this field.

Charles and Francis Darwin knew that if light came primarily from one direction, seedlings would bend strongly toward it. If they covered the tip of a shoot with a thin glass tube, the shoot would bend as if it were not covered. However, if they used a metal foil cap to exclude light from the plant tip, the shoot would not bend (figure 41.18). They also found that using an opaque collar to exclude light from the stem below the tip did not keep the area above the collar from bending.

In explaining these unexpected findings, the Darwins hypothesized that when the shoots were illuminated from one side, they bent toward the light in response to an “influence” that was transmitted downward from its source at the tip of the shoot.

For some 30 years, the Darwins’ perceptive experiments remained the sole source of information about this interesting phenomenon. Then the Danish plant physiologist Peter Boysen-Jensen and the Hungarian plant physiologist Arpad Paal independently demonstrated that the substance causing the shoots to bend was a chemical. They showed that if the tip of a germinating grass seedling was cut off and then replaced, with a small block of agar separating it from the rest of the seedling, the seedling would still grow as if there had been no change. Something evidently was passing from the tip of the seedling through the agar into the region where the bending occurred.

On the basis of these observations under conditions of either uniform illumination or darkness, Paal suggested that an unknown substance continually moves down from the tips of grass seedlings and promotes growth on all sides. Such a light pattern would not, of course, cause the shoot to bend.

### Inquiry question

Propose a mechanism to explain how seedlings could bend in the light using what Paal discovered.

Then, in 1926, the Dutch plant physiologist Frits Went carried Paal’s experiments a step further. Went cut off the tips of oat seedlings that had been illuminated normally and set these tips on agar. He then took oat seedlings that had been grown in the dark and cut off their tips in a similar way. Finally, Went cut tiny blocks from the agar on which the tips of the light-grown seedlings had been placed and placed them off-center on the tops of the decapitated dark-grown seedlings (figure 41.19). Even though these seedlings had not been exposed to the light themselves, they bent away from the side on which the agar blocks were placed.

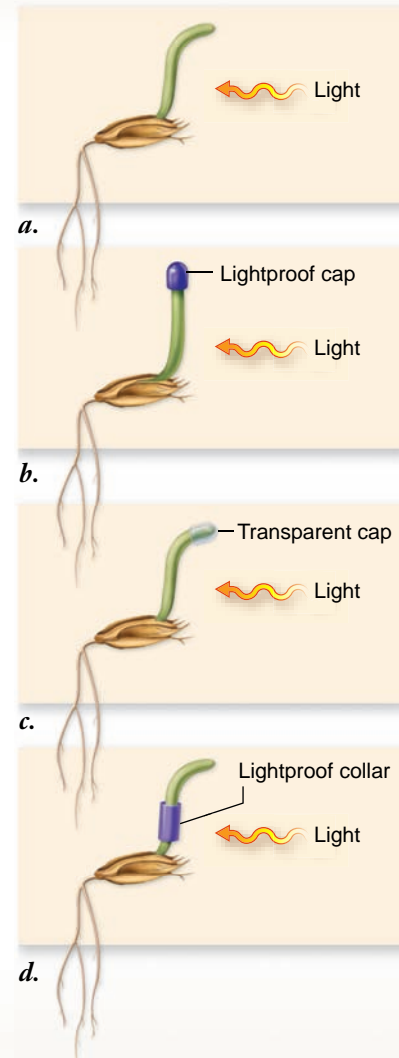

As an experimental control, Went put blocks of pure agar on the decapitated stem tips and noted either no effect or a slight bending toward the side where the agar blocks were placed. Finally, Went cut sections out of the lower portions of the light-grown seedlings. He placed these sections on the tips of decapitated, dark-green oat seedlings and again observed no effect.

### SCIENTIFIC THINKING

**Hypothesis:** The shoot tip of a plant detects the direction of light.

**Prediction:** The shoot tip of a grass seedling will grow toward a unidirectional light source if it is not covered.

**Test:** Make four treatment groups, including (1) untreated seedling, (2) tip covered with lightproof cap, (3) tip covered with transparent cap, and (4) lightproof collar placed below tip.

**Result:** a. Young grass seedlings normally bend toward the light. b. The bending did not occur when the tip of a seedling was covered with a lightproof cap. c. Bending did occur when it was covered with a transparent one. d. When a collar was placed below the tip, the characteristic light response took place.

**Conclusion:** In response to light, an “influence” that caused bending was transmitted from the tip of the seedling to the area below, where bending normally occurs.

**Further Experiments:** How could you determine if the light response in a shoot tip requires the movement of a signal from one side of the shoot to the other? (Hint: See Went’s experiment in figure 41.19).

**Figure 41.18** Shoot tips perceive unidirectional light.

**Figure 41.19 Frits Went's experiment.** Went concluded that a substance he named *auxin* promoted the elongation of the cells and that it accumulated on the side of an oat seedling away from the light.

As a result of his experiments, Went was able to show that the substance that had diffused into the agar from the tips of light-grown oat seedlings could make seedlings bend when they otherwise would have remained straight. He also showed that this chemical messenger caused the cells on the side of the seedling into which it flowed to grow more than those on the opposite side (figure 41.20). In other words, the chemical enhanced rather than retarded cell elongation. He named the substance that he had discovered *auxin*.

Went's experiments provided a basis for understanding the responses that the Darwins had obtained some 45 years earlier. The oat seedlings bent toward the light because of differences in the auxin concentrations on the two sides of the shoot.

**Figure 41.20 Auxin causes cells on the dark side to elongate.** Plant cells that are in the shade have more auxin and grow faster than cells on the lighted side, causing the plant to bend toward light. Further experiments showed exactly why there is more auxin on the shaded side of a plant.

The side of the shoot that was in the shade had more auxin, and its cells therefore elongated more than those on the lighted side, bending the plant toward the light.

### The effects of auxin

Auxin acts to adapt the plant to its environment in a highly advantageous way by promoting growth and elongation. Environmental signals directly influence the distribution of auxin in the plant. How does the environment—specifically, light—exert this influence? Theoretically, light might destroy the auxin, might decrease the cells' sensitivity to auxin, or might cause the auxin molecules to migrate away from the light into the shaded portion of the shoot. This last possibility has proved to be the case.

In a simple but effective experiment, Winslow Briggs inserted a thin sheet of transparent mica vertically between the half of the shoot oriented toward the light and the half of the shoot oriented away from it (figure 41.21). He found that light from one side does not cause a shoot with such a barrier to bend. When Briggs examined the illuminated plant, he found equal auxin levels on both the light and dark sides of the barrier. He concluded that a normal plant's response to light from one direction involves auxin migrating from the light side to the dark side, and that the mica barrier prevented a response by blocking the migration of auxin.

The effects of auxin are numerous and varied. Auxin promotes the activity of the vascular cambium and the vascular tissues. Also, auxin is present in pollen in large quantities and plays a key role in the development of fruits. Synthetic auxins are used commercially for the same purpose. Fruits will normally not develop if fertilization has not occurred and seeds are not present, but frequently they will develop if auxin is applied. Pollination may trigger auxin release in some species, leading to fruit development even before fertilization has taken place.

### How auxin works

In spite of this long history of research, auxin's molecular basis of action has been an enigma. The chemical structure of the most common auxin, **indoleacetic acid (IAA)**, resembles that of the amino acid tryptophan, from which it is probably

**Figure 41.21** Phototropism and auxin: The Winslow Briggs experiments. Directional light causes the accumulation of auxin in the dark side of the shoot tip, which can move down the stem. Barriers inserted in the tip revealed that light affects auxin displacement rather than rate of auxin production.

synthesized by plants (figure 41.22). Although other forms of auxin exist, IAA is the most common natural auxin.

An auxin-binding protein (ABP1) was identified two decades ago. ABP1 is found in the cytoplasm and its role in auxin response is still unclear. Mutants that lack ABP1 do not make it past embryogenesis because cell elongation is inhibited and the basic body plan described in chapter 36 is not organized. But, the *abp1* mutant cells divide, which indicates that part of the auxin pathway is still functioning.

More recently, two families of proteins that mediate rapid, auxin-induced changes in gene expression have been identified: the auxin response factors (ARFs) and the Aux/IAA proteins. Transcription can be either enhanced or suppressed by ARFs, which are known to bind DNA. The Aux/IAA pro-

teins function a bit earlier in the auxin response pathway and have been shown to bind to and repress proteins that activate the expression of *ARF* genes.

*ARF* genes are activated when Aux/IAA proteins are degraded by ubiquitin tagging and protein degradation in the proteasome. Auxin binding to ARF protein is not sufficient to initiate gene expression in response to auxin signaling because of Aux/IAA repression of ARF activity. How then does a plant sense auxin and degrade Aux/IAA proteins?

The identification of the elusive auxin receptor in 2005 hints at how plants sense and respond to auxin. Auxin binds directly to a protein called the transport inhibitor response protein 1 (TIR1). TIR1 is the enigmatic auxin receptor. It is part of a protein complex known as SCF which is found

**Figure 41.22** Auxins. *a.* Indoleacetic acid (IAA), the principal naturally occurring auxin. *b.* Tryptophan, the amino acid from which plants probably synthesize IAA. *c.* Dichlorophenoxyacetic acid (2,4-D), a synthetic auxin, is a widely used herbicide.

throughout eukaryotes. SCF is shorthand for the three polypeptide subunits found in the complex: *Skp*, *Cullin*, and *F-box*. Auxin binds to TIR1 in the SCF complex if Aux/IAA proteins are present. Once auxin binds, the SCF complex degrades the Aux/IAA proteins through the ubiquitin pathway.

Five steps lead from auxin perception to auxin-induced gene expression (figure 41.23):

1. Auxin binds TIR1 in the SCF complex.
2. The activated SCF complex tags Aux/IAA proteins with ubiquitin.
3. Aux/IAA proteins are degraded in the proteasome.
4. Aux/IAA proteins are no longer available to bind and repress ARF (auxin response factor) transcriptional activators.
5. ARF transcription factors facilitate transcription of auxin-response genes.

Unlike with animal hormones, a specific signal is not sent to specific cells, eliciting a predictable response. Most likely, multiple auxin perception sites are present. Auxin is also unique among the plant hormones in that it is transported toward the base of the plant. Two families of genes have been identified in *Arabidopsis* that are involved in auxin transport. For example, one family of proteins (the PINs) are involved in the top-to-bottom transport of auxin, while two other proteins function in the root tip to regulate the growth response to gravity, described earlier.

One of the direct effects of auxin is an increase in the plasticity of the plant cell wall, but this effect works only on young cell walls lacking extensive secondary cell wall formation and may or may not involve rapid changes in gene expression. The **acid**

**growth hypothesis** provides a model linking auxin to cell wall expansion (figure 41.24). According to this hypothesis, auxin causes responsive cells to actively transport hydrogen ions from the cytoplasm into the cell wall space. This decreases the pH, which activates enzymes that can break the bonds between cell wall fibers.

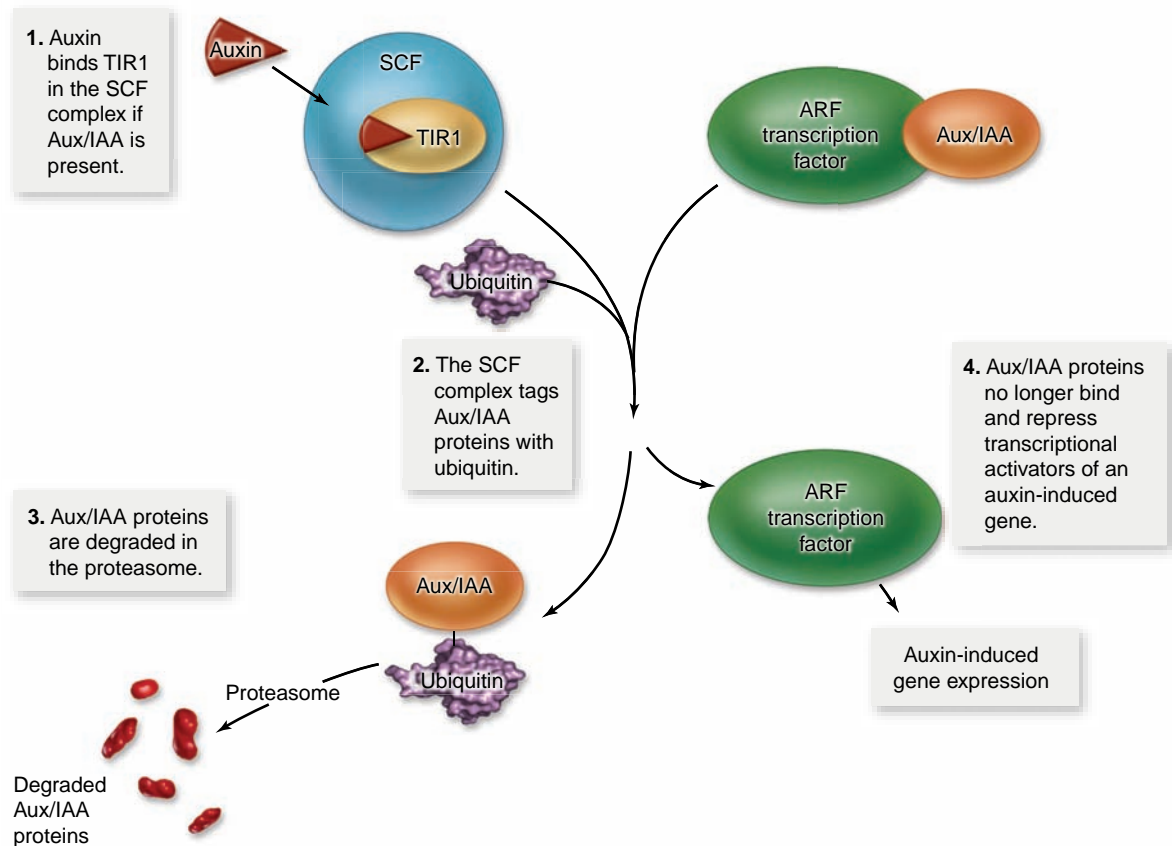

This hypothesis has been experimentally supported in several ways. Buffers that prevent cell wall acidification block cell expansion. And, other compounds that release hydrogen ions from the cell can also cause cell expansion. Finally, the movement of hydrogen ions has been observed in response to auxin treatment. The snapping of the Venus flytrap is postulated to involve an acid growth response that allows cells to grow in just 0.5 sec and close the trap.

### Synthetic auxins

Synthetic auxins, such as *naphthalene acetic acid* (NAA) and **indolebutyric acid** (IBA), have many uses in agriculture and horticulture. One of their most important uses is based on their prevention of abscission. Synthetic auxins are used to prevent fruit drop in apples before they are ripe and to hold berries on holly that is being prepared for shipping during the winter season. Synthetic auxins are also used to promote flowering and fruiting in pineapples and to induce the formation of roots in cuttings.

Synthetic auxins are routinely used to control weeds. When used as herbicides, they are applied in higher concentrations than IAA would normally occur in plants. One of the most important synthetic auxin herbicides is *2,4-dichlorophenoxyacetic acid*, usually known as **2,4-D** (see figure 41.22c). It kills weeds in grass lawns by selectively eliminating broad-leaved dicots. The stems of the dicot weeds cease all axial growth.

**Figure 41.23 Auxin regulation of gene expression.** Auxin activates a ubiquitination pathway that releases ARF transcription factors from repression by Aux/IAA proteins. The result is auxin-induced gene expression.

**Figure 41.24 Acid growth hypothesis.** Auxin stimulates the release of hydrogen ions from the target cells, which alters the pH of the cell wall. This optimizes the activity of enzymes that break bonds in the cell wall, allowing the wall to expand.

The herbicide 2,4,5-trichlorophenoxyacetic acid, better known as 2,4,5-T, is closely related to 2,4-D. 2,4,5-T was widely used as a broad-spectrum herbicide to kill weeds and the seedlings of woody plants. It became notorious during the Vietnam War as a component of a jungle defoliant known as Agent Orange. When 2,4,5-T is manufactured, it is unavoidably contaminated with minute amounts of dioxin. Dioxin, in doses as low as a few parts per billion, has produced liver and lung diseases, leukemia, miscarriages, birth defects, and even death in laboratory animals. This chemical was banned in 1979 for most uses in the United States.

### Cytokinins stimulate cell division and differentiation

Cytokinins comprise another group of naturally occurring growth hormones in plants. Studies by Gottlieb Haberlandt of Austria around 1913 demonstrated the existence of an unknown chemical in various tissues of vascular plants that, when applied

to cut potato tubers, would cause parenchyma cells to become meristematic, and would induce the differentiation of a cork cambium. In other research, coconut milk, subsequently found to contain cytokinins was used to promote the differentiation of organs in masses of plant tissue growing in culture. Subsequent studies have focused on the role cytokinins play in the differentiation of tissues from callus.

A *cytokinin* is a plant hormone that, in combination with auxin, stimulates cell division and differentiation. Most cytokinins are produced in the root apical meristems and transported throughout the plant. Developing fruits are also important sites of cytokinin synthesis. In mosses, cytokinins cause the formation of vegetative buds on the gametophyte. In all plants, cytokinins, working with other hormones, seem to regulate growth patterns.

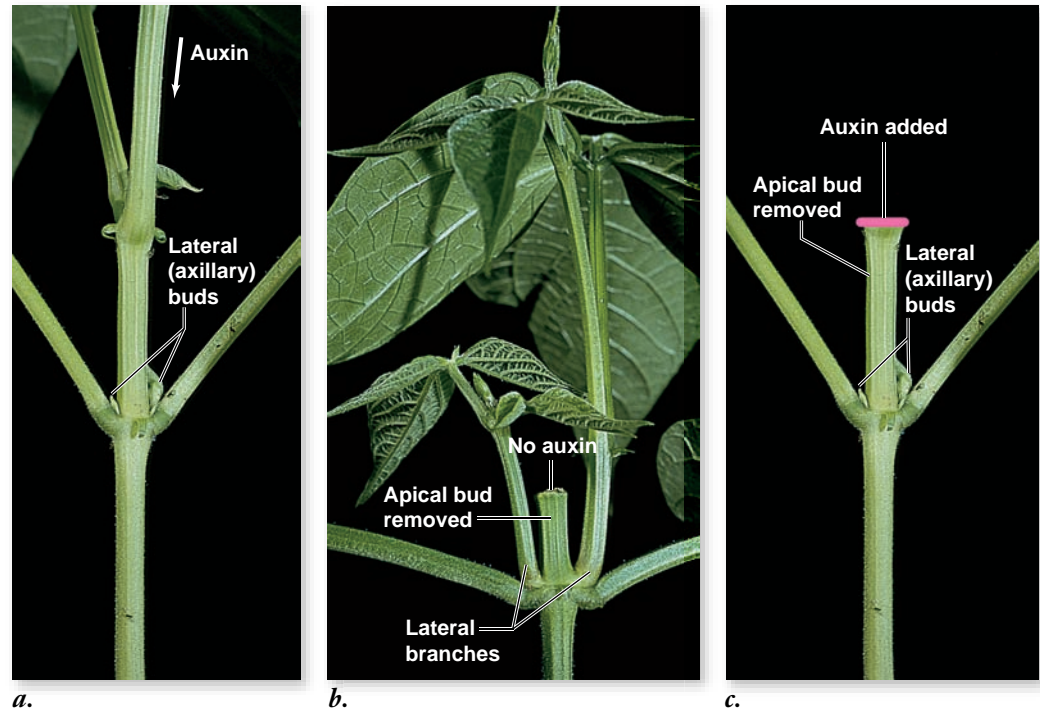

Cytokinins are purines that appear to be derivatives of adenine (figure 41.25). Other chemically diverse molecules, not known to occur naturally, have effects similar to those of cytokinins. Cytokinins promote the growth of lateral buds into

**Figure 41.25 Some cytokinins.** Two commonly used synthetic cytokinins: kinetin and 6-benzylamino purine. Note their resemblance to the purine base adenine.

**Figure 41.26 Cytokinins stimulate lateral bud growth.**

*a.* When the apical meristem of a plant is intact, auxin from the apical bud will inhibit the growth of lateral buds.  
*b.* When the apical bud is removed, cytokinins are able to induce the growth of lateral buds into branches.  
*c.* When the apical bud is removed and auxin is added to the cut surface, lateral bud outgrowth is suppressed.

branches (figure 41.26). Conversely, cytokinins inhibit the formation of lateral roots, while auxins promote their formation.

As a consequence of these relationships, the balance between cytokinins and auxin, along with many other factors, determines the form of a plant. In addition, the application of cytokinins to leaves detached from a plant retards their yellowing. Therefore, they function as antiaging hormones.

The action of cytokinins, like that of other hormones, has been studied in terms of its effects on the growth and differentiation of masses of tissue growing in defined media. Plant tissue can form shoots, roots, or an undifferentiated mass, depending on the relative amounts of auxin and cytokinin (figure 41.27).

In the early cell-growth experiments in culture, coconut milk was an essential factor. Eventually, researchers discovered that coconut milk is not only rich in amino acids and other reduced nitrogen compounds required for growth, but it also contains cytokinins. Cytokinins apparently promote the synthesis or activation of proteins specifically required for cytokinesis.

Cytokinins have also been used against plants by pathogens. The bacterium *Agrobacterium*, for example, introduces genes into the plant genome that increase the rate of cytokinin, as well as auxin, production. This causes massive cell division and the formation of a tumor called *crown gall* (figure 41.28). How these hormone-biosynthesis genes ended up in a bacterium is an intriguing evolutionary question. Coevolution does not always work to a plant's advantage.

**Gibberellins enhance plant growth and nutrient utilization**

Gibberellins are named after the fungus *Gibberella fujikuroi*, which causes rice plants, on which it is parasitic, to grow abnormally tall. The Japanese plant pathologist Eiichi Kurosawa investigated bakanae (“foolish seedling”) disease in the 1920s.

**Figure 41.27 Relative amounts of cytokinins and auxin affect organ regeneration in culture.** In tobacco, *a.* high auxin-to-cytokinin ratios favor root development; *b.* high cytokinin-to-auxin ratios favor shoot development; and *c.* intermediate concentrations result in the formation of undifferentiated cells. These developmental responses to cytokinin–auxin ratios in culture are species-specific.

**Figure 41.28 Crown gall tumor.** Sometimes cytokinins can be used against the plant by a pathogen. In this case, *Agrobacterium tumefaciens* (a bacterium) has incorporated a piece of its DNA into the plant genome. This DNA contains genes coding for enzymes necessary for cytokinin and auxin biosynthesis. The increased levels of these hormones in the plant cause massive cell division and the formation of a tumor.

He grew *Gibberella* in culture and obtained a substance that, when applied to rice plants, produced bakanae. This substance was isolated and its structural formula identified by Japanese chemists in 1939. British chemists reconfirmed the formula in 1954.

Although such chemicals were first thought to be only a curiosity, they have since turned out to belong to a large class of more than 100 naturally occurring plant hormones. All are acidic and are usually abbreviated GA (for gibberellic acid), with a different subscript ( $GA_1$ ,  $GA_2$ , and so forth) to distinguish each one.

Gibberellins, which are synthesized in the apical portions of stems and roots, have important effects on stem elongation. The elongation effect is enhanced if auxin is also present. The application of gibberellins to certain dwarf mutants is known to restore normal growth and development in many plants (figure 41.29). Some dwarf mutants produce insufficient amounts of gibberellin and respond to GA applications; others lack the ability to respond to gibberellin.

The large number of gibberellins are all part of a complex biosynthetic pathway that has been unraveled using gibberellin-deficient mutants in maize (corn). Although many of these gibberellins are intermediate forms in the production of  $GA_1$ , recent work shows that some forms may have specific biological roles.

In chapter 37, we noted the role of gibberellins in stimulating the production of  $\alpha$ -amylase and other hydrolytic enzymes needed for utilization of food resources during germination and establishment of cereal seedlings. How is transcription of the genes encoding these enzymes regulated?

**Figure 41.29 Effects of gibberellins.** This rapid-cycling member of the mustard family (*Brassica rapa*) will “bolt” and flower because of increased gibberellin levels. Mutants such as the rosette mutant (left) are defective in producing gibberellins. They can be rescued by applying gibberellins to the shoot tip (right). Other mutants have been identified that are defective in perceiving gibberellins, and they will not respond to gibberellin applications.

GA is used as a signal from the embryo that turns on transcription of one or more genes encoding hydrolytic enzymes in the aleurone layer. The GA receptor has been identified. When GA binds to its receptor, it frees GA-dependent transcription factors from a repressor. These transcription factors can now directly affect gene expression (figure 41.30). Synthesis of DNA does not seem to occur during the early stages of seed germination, but it becomes important when the radicle has grown through the seed coats.

Gibberellins also affect a number of other aspects of plant growth and development. In some cases, GAs hasten seed

**Figure 41.30 Gibberellins activate gibberellin-dependent transcription factors (GA-TRXN).** *a.* GA-TRXN cannot bind to a promoter when they are bound to DELLA proteins. *b.* GA activates a protein complex that degrades DELLA proteins, freeing GA-TRXN to bind to a promoter, inducing gene transcription.

**Figure 41.31 Applications of gibberellins increase the space between grapes.** Larger grapes (right) develop because there is more room between individual grapes.

germination, apparently by substituting for the effects of cold or light requirements. Gibberellins are used commercially to increase space between grape flowers by extending internode length, so that the fruits have more room to grow. The result is a larger bunch of grapes containing larger individual fruits (figure 41.31).

Although gibberellins function endogenously as hormones, they also function as pheromones in ferns. In ferns, gibberellin-like compounds released from one gametophyte can trigger the development of male reproductive structures on a neighboring gametophyte.

## Brassinosteroids are structurally similar to animal hormones

Although plant biologists have known about *brassinosteroids* for 30 years, it is only recently that they have claimed their place as a class of plant hormones. They were first discovered

### Figure 41.32 Brassinosteroids.

Brassinolide and other brassinosteroids have structural similarities to animal steroid hormones. Cortisol, testosterone, and estradiol (not shown) are animal steroid hormones.

in *Brassica* spp. pollen, hence the name. Their historical absence in discussions of hormones may be partially due to their functional overlap with other plant hormones, especially auxins and gibberellins. Additive effects among these three classes have been reported.

The application of molecular genetics to the study of brassinosteroids has advanced our understanding of how they are made and, to some extent, how they function in signal transduction pathways. What is particularly intriguing about brassinosteroids is their similarity to animal steroid hormones (figure 41.32). One of the genes coding for an enzyme in the brassinosteroid biosynthetic pathway has significant similarity to an enzyme used in the synthesis of testosterone and related steroids. Brassinosteroids have also been identified in algae, and they appear to be ubiquitous among the plants. It is plausible that their evolutionary origin predated the plant–animal split.

Brassinosteroids have a broad spectrum of physiological effects—elongation, cell division, bending of stems, vascular tissue development, delayed senescence, membrane polarization, and reproductive development. Environmental signals can trigger brassinosteroid actions. Mutants have been identified that alter the response to a brassinosteroid, but signal transduction pathways remain to be uncovered. From an evolutionary perspective, it will be quite interesting to see how these pathways compare with animal steroid signal transduction pathways.

## Oligosaccharins act as defense-signaling molecules

Plant cell walls are composed not only of cellulose but also of numerous complex carbohydrates called *oligosaccharides*. Some evidence indicates that these cell wall components (when degraded by pathogens) function as signaling molecules as well as structural wall components. Oligosaccharides that are proposed to have a hormone-like function are called *oligosaccharins*.

Oligosaccharins can be released from the cell wall by enzymes secreted by pathogens. These carbohydrates are believed to signal defense responses, such as the hypersensitive response (HR) discussed in chapter 40.

Another oligosaccharin has been shown to inhibit auxin-stimulated elongation of pea stems. These molecules are active at concentrations one to two orders of magnitude less than those of the traditional plant hormones; you have seen how

auxin and cytokinin ratios can affect organogenesis in culture (see figure 41.27).

Oligosaccharins also affect the phenotype of regenerated tobacco tissue, inhibiting root formation and stimulating flower production in tissues that are competent to regenerate flowers. How the culture results translate to in vivo systems remains an open question.

## Ethylene induces fruit ripening and aids plant defenses

Long before its role as a plant hormone was appreciated, the simple, gaseous hydrocarbon *ethylene* ( $H_2C=CH_2$ ) was known to defoliate plants when it leaked from gaslights in old-fashioned streetlamps. Ethylene is, however, a natural product of plant metabolism that, in minute amounts, interacts with other plant hormones.

When auxin is transported down from the apical meristem of the stem, it stimulates the production of ethylene in the tissues around the lateral buds and thus retards their growth. Ethylene also suppresses stem and root elongation, probably in a similar way. An ethylene receptor has been identified and characterized, and it appears to have evolved early in

the evolution of photosynthetic organisms, sharing features with environmental-sensing proteins identified in bacteria.

Ethylene plays a major role in fruit development. At first, auxin, which is produced in significant amounts in pollinated flowers and developing fruits, stimulates ethylene production; this, in turn, hastens fruit ripening. Complex carbohydrates are broken down into simple sugars, chlorophylls are broken down, cell walls become soft, and the volatile compounds associated with flavor and scent in ripe fruits are produced.

One of the first observations that led to the recognition of ethylene as a plant hormone was the premature ripening in bananas produced by gases coming from oranges. Such relationships have led to major commercial uses of ethylene. For example, tomatoes are often picked green and artificially ripened later by the application of ethylene. Ethylene is widely used to speed the ripening of lemons and oranges as well. Carbon dioxide has the opposite effect of arresting ripening; fruits are often shipped in an atmosphere of carbon dioxide.

Also, a biotechnology solution has been developed in which one of the genes necessary for ethylene biosynthesis has been cloned, and its antisense copy inserted into the tomato genome (figure 41.33). The antisense copy of the gene is a nucleotide sequence that is complementary to the sense copy of the gene. In this transgenic plant, both the sense and antisense

### Figure 41.33 Genetic regulation of fruit ripening.

An antisense copy of the gene for ethylene biosynthesis prevents the formation of ethylene and subsequent ripening of transgenic fruit. The antisense strand is complementary to the sequence for the ethylene biosynthesis gene. After transcription, the antisense mRNA pairs with the sense mRNA, and the double-stranded mRNA cannot be translated into a functional protein. Ethylene is not produced, and the fruit does not ripen. The fruit is sturdier for shipping in its unripened form and can be ripened later with exposure to ethylene. Thus, while wild-type tomatoes may already be rotten and damaged by the time they reach stores, transgenic tomatoes stay fresh longer.

sequences for the ethylene biosynthesis gene are transcribed. The sense and antisense mRNA sequences then pair with each other. This pairing blocks translation, which requires single-stranded RNA; as a result, ethylene is not synthesized, and the transgenic tomatoes do not ripen. In this way, the sturdy green tomatoes can be shipped without ripening and rotting. Exposing these tomatoes to ethylene later induces them to ripen.

Studies have shown that ethylene plays an important ecological role. Ethylene production increases rapidly when a plant is exposed to ozone and other toxic chemicals, temperature extremes, drought, attack by pathogens or herbivores, and other stresses. The increased production of ethylene that occurs can accelerate the loss of leaves or fruits that have been damaged by these stresses. Some of the damage associated with exposure to ozone is due to the ethylene produced by the plants.

The production of ethylene by plants attacked by herbivores or infected with pathogens may be a signal to activate the defense mechanisms of the plants and may include the production of molecules toxic to the pests.

## Abscisic acid suppresses growth and induces dormancy

Abscisic acid appears to be synthesized mainly in mature green leaves, fruits, and root caps. The hormone earned its name because applications of it appear to stimulate fruit abscission in cotton, but there is little evidence that it plays an important role in this process. Ethylene is actually the chemical that promotes senescence and abscission.

Abscisic acid probably induces the formation of winter buds—dormant buds that remain through the winter. The conversion of leaf primordia into bud scales follows (figure 41.34*a*). Like ethylene, abscisic acid may also suppress growth of dormant lateral buds. It appears that abscisic acid, by suppressing growth and elongation of buds, can counteract some of the effects of gibberellins; it also promotes senescence by counteracting auxin.

Abscisic acid plays a role in seed dormancy and is antagonistic to gibberellins during germination. Abscisic acid levels in seeds rise during embryogenesis (see figure 41.17). As maize embryos develop in the kernels on the cob, abscisic acid is necessary to

induce dormancy and prevent precocious germination, called vivipary (figure 41.34*b*). It is also important in controlling the opening and closing of stomata (figure 41.34*c*).

Found to occur in all groups of plants, abscisic acid apparently has been functioning as a growth-regulating substance since early in the evolution of the plant kingdom. Relatively little is known about the exact nature of its physiological and biochemical effects, but these effects are very rapid—often taking place within a minute or two—and therefore they must be at least partly independent of gene expression.

All of the genes have been sequenced in *Arabidopsis*, making it easier to identify which genes are transcribed in response to abscisic acid. Abscisic acid levels become greatly elevated when the plant is subject to stress, especially drought. Like other plant hormones, abscisic acid will probably prove to have valuable commercial applications when its mode of action is better understood.

### Learning Outcomes Review 41.5

Hormones are chemicals produced in small quantities in one region of the plant and then transported to another region, where they cause a physiological or developmental response. Both auxins and cytokinins are produced in meristems and promote growth; however, auxins stimulate growth by cell elongation, while cytokinins stimulate cell division. In contrast, abscisic acid inhibits growth and promotes dormancy.

- What methods could you use to test whether abscisic acid produced in root caps can affect bud growth in stems?

### Figure 41.34 Effects of abscisic acid.

- a.* Abscisic acid plays a role in the formation of these winter buds of an American basswood. These buds will remain dormant for the winter, and bud scales—modified leaves—will protect the buds from desiccation.
- b.* In addition to bud dormancy, abscisic acid is necessary for dormancy in seeds. This viviparous mutant in maize is deficient in abscisic acid, and the embryos begin germinating on the developing cob.
- c.* Abscisic acid also affects the closing of stomata by influencing the movement of potassium ions out of guard cells.

## Chapter Review

### 41.1 Responses to Light

***P<sub>fr</sub> facilitates expression of light response genes (figure 41.1)***

Phytochrome exists as two interconvertible forms. The inactive form, P<sub>r</sub>, absorbs red light and is converted to the active form, P<sub>fr</sub>. P<sub>fr</sub> absorbs far-red light and is converted to the inactive form, P<sub>r</sub>. P<sub>fr</sub> enters the nucleus and binds with other proteins to form a transcription complex, leading to expression of light-regulated genes. It can also activate a cascade of transcription factors.

***Many growth responses are linked to phytochrome action.***

P<sub>fr</sub> is involved in seed germination, shoot elongation, and detection of plant spacing. Far-red light inhibits germination by inactivating P<sub>fr</sub>, and red light stimulates it by activating P<sub>r</sub>.

Crowded plants receive a greater proportion of far-red light, which is reflected from neighboring plants. The plants respond by growing taller to compete more effectively for sunlight.

***Light affects directional growth.***

Phototropisms are directional growth responses of stems toward blue light. Blue-light receptors such as phototropin 1 are a recent discovery.

***Circadian clocks are independent of light but are entrained by light.***

Circadian rhythms entrain to the daily cycle through the action of phytochrome and blue-light photoreceptors. In the absence of light, the cycle's period may become desynchronized, but it resets when light is available.

### 41.2 Responses to Gravity

***Plants align with the gravitational field: An overview.***

Gravitropism is the growth response to a gravitational field.

Certain cells in plants perceive gravity when amyloplasts are pulled downward. Following the detection of gravity, a physiological signal causes cell elongation in other cells. The hormone auxin is believed to transmit the signal.

***Stems bend away from a center of gravity.***

Shoots bend away from gravity, so they exhibit negative gravitropism. When auxin accumulates on the lower side of the stem, those cells elongate, causing the stem to bend upward.

***Roots bend toward a center of gravity.***

Roots bend toward gravity, so they exhibit positive gravitropism. If the root cap is horizontally oriented, the cells on the upper side of the root become elongated, causing the root to grow downward.

### 41.3 Responses to Mechanical Stimuli

***Touch can trigger irreversible growth responses.***

Thigmotropism is a permanent directional growth of a plant toward or away from a physical stimulus. It results in thigmomorphogenesis, a change in growth form.

Thigmonastic responses are independent of the direction of the stimulus and are usually produced by changes in turgor pressure.

***Reversible responses to touch and other stimuli involve turgor pressure.***

Touch-induced responses result from changes in turgor pressure. A stimulus causes an electrical signal, which results in a loss of potassium ions and water from cells of the pulvini. The loss of turgor causes the leaves to move.

Light can induce changes in turgor pressure, resulting in leaf tracking of sunlight, flower opening, and leaf sleep movements.

### 41.4 Responses to Water and Temperature

***Dormancy is a response to water, temperature, and light.***

Dormancy is the cessation of growth that occurs when a plant is exposed to environmental stress. Seasonal leaf abscission occurs in deciduous trees in the fall. Seed dormancy suspends germination until environmental conditions are optimal.

***Plants can survive temperature extremes.***

Plants respond to cold temperatures by increasing unsaturated lipids in membranes, limiting ice crystal formation to extracellular spaces, and producing antifreeze proteins.

When exposed to rapid increases in temperature, plants produce heat shock proteins, which help to stabilize other proteins.

### 41.5 Hormones and Sensory Systems

***The hormones that guide growth are keyed to the environment.***

Hormones are produced in small quantities in one part of a plant and then transported to another, where they bring about physiological or developmental responses.

***Auxin allows elongation and organizes the body plan.***

Auxins are produced in apical meristems and immature parts of a plant. They affect DNA transcription by binding to proteins. Auxins promote stem elongation, adventitious root formation, cell division, and lateral bud dormancy. They also inhibit leaf abscission and induce ethylene production.

***Cytokinins stimulate cell division and differentiation.***

Cytokinins are purines produced in root apical meristems and immature fruits. They promote mitosis, chloroplast development, and bud formation. Cytokinins also delay leaf aging.

***Gibberellins enhance plant growth and nutrient utilization.***

Gibberellins are produced by root and shoot tips, young leaves, and seeds. They promote the elongation of stems and the production of enzymes in germinating seeds. In ferns, gibberellins function as pheromones.

***Brassinosteroids are structurally similar to animal hormones.***

Brassinosteroids are steroids produced in pollen, immature seeds, shoots, and leaves. They produce a broad spectrum of effects related to growth, senescence, and reproductive development.

***Oligosaccharins act as defense-signaling molecules.***

Pathogens secrete enzymes that release oligosaccharins from cell walls; these molecules induce pathogen defense responses. Oligosaccharins can also inhibit auxin-stimulated elongation, inhibit root formation, and stimulate flower production.

***Ethylene induces fruit ripening and aids plant defenses.***

Roots, shoot apical meristems, aging flowers, and ripening fruits produce ethylene, a gas that controls leaf, flower, and fruit abscission, promotes fruit ripening, and suppresses stem and root elongation. Ethylene may activate a defense response to attacks by pathogens and herbivores.

***Abscisic acid suppresses growth and induces dormancy.***

Mature green leaves, fruits, root caps, and seeds produce abscisic acid. Abscisic acid inhibits bud growth and the effects of other hormones, induces seed dormancy, and controls stomatal closure.

## Review Questions

### UNDERSTAND

- Which of the following is stimulated by blue light?
  - Seed germination
  - Detection of plant spacing
  - Phototropism
  - Shoot elongation
- Stems and roots, respectively, exhibit
  - a positive phototropic response and no phototropic response.
  - a negative phototropic response and no phototropic response.
  - no phototropic response and a positive phototropic response.
  - no phototropic response and a negative phototropic response.
- In stems, gravity is detected by cells of the
  - epidermis.
  - cortex.
  - periderm.
  - endodermis.
- Chilling most directly affects
  - nuclear proteins.
  - vacuolar inclusions.
  - the cytoskeleton.
  - membrane lipids.
- Which of the following does not happen as a seed approaches a state of dormancy?
  - The seed loses water.
  - Absciscic acid levels in the embryo decrease.
  - The seed coat hardens.
  - Protein synthesis stops.
- Dwarf mutants can sometimes be induced to grow normally by applying
  - auxin.
  - absciscic acid.
  - ethylene.
  - gibberellin.

### APPLY

- If you exposed seeds to a series of red-light versus far-red-light treatments, which of the following exposure treatments would result in seed germination?
  - Red; far-red
  - Far-red; red
  - Red; far-red; red; far-red; red; far-red; red; far-red
  - None of the above
- If you were to plant a de-etiolated (*det2*) mutant *Arabidopsis* seed and keep it in a dark box, what would you expect to happen?
  - The seed would germinate normally, but the plant would not become tall and spindly while it sought a light source.
  - The seed would fail to germinate because it would not have light.
  - The seed would germinate, and the plant would become tall and spindly while it sought a light source.
  - The seed would germinate, and the plant would immediately die because it could not make sugar in the dark.
- When Charles and Francis Darwin investigated phototropisms in plants, they discovered that
  - auxin was responsible for light-dependent growth.
  - light was detected at the shoot tip of a plant.

- light was detected below the shoot tip of a plant.
  - only red light stimulated phototropism.
- Auxin promotes a plant to grow toward a light source by
    - increasing the rate of cell division on the shaded side of the stem.
    - shortening the cells on the light side of the stem.
    - causing cells on the shaded side of the stem to elongate.
    - decreasing the rate of cell division on the light side of the stem.
  - You have come up with a brilliant idea to stretch your grocery budget by buying green fruit in bulk and then storing it in a bag that you have blown up like a balloon. As you need fruit, you would take it out of the bag, and it would miraculously ripen. How would this work?
    - The bag would block light from reaching the fruit, so it would not ripen.
    - The bag would keep the fruit cool, so it would not ripen.
    - The high CO<sub>2</sub> levels in the bag would prevent ripening.
    - The high O<sub>2</sub> levels in the bag would prevent ripening.
  - Gibberellins are used to increase productivity in grapes because they
    - cause fruits to be larger by promoting cell division within the fruit.
    - increase the internode length so the fruits have more room to grow.
    - increase the number of flowers produced, thus increasing the number of fruits.
    - do all of the above.
  - Which of the following might not be observed in a plant that is grown on the Space Shuttle in space?
    - Phototropism
    - Photomorphogenesis
    - Circadian rhythms
    - Gravitropism

### SYNTHESIZE

- If you buy a bag of potatoes and leave them in a dark cupboard for too long, they will begin to form long white sprouts with tiny leaves. Name this process and explain why the potatoes are behaving as they are.
- Find the discussion of taxis in this book. Compare and contrast tropism with taxis.
- The current model for gravitropism suggests that the accumulation of amyloplasts on the bottom of a cell allows the cell to sense gravity. Suggest a plausible mechanism for the sensing of gravity that does not involve the settling out of particles.
- Farmers who grow crops that are planted as seedlings may prepare them for their transition from the greenhouse to the field by brushing them gently every day for a few weeks. Why is this beneficial?

Chapter **42**

# Plant Reproduction

## Chapter Outline

---

- 42.1 Reproductive Development
- 42.2 Flower Production
- 42.3 Structure and Evolution of Flowers
- 42.4 Pollination and Fertilization
- 42.5 Asexual Reproduction
- 42.6 Plant Life Spans

## Introduction

---

*The remarkable evolutionary success of flowering plants can be linked to their novel reproductive strategies. In this chapter, we explore the reproductive strategies of the angiosperms and how their unique features—flowers and fruits—have contributed to their success. This is, in part, a story of coevolution between plants and animals that ensures greater genetic diversity by dispersing plant gametes widely. In a stable environment, however, there are advantages to maintaining the status quo genetically; asexual reproduction, for example, is a strategy that produces cloned individuals. An unusual twist to sexual reproduction in some flowering plants is that senescence and death of the parent plant immediately follow.*

## 42.1 Reproductive Development

### Learning Outcomes

1. Describe the general life cycle of a flowering plant.
2. Define phase change.
3. Identify two *Arabidopsis* mutants that have been used to study phase change.

In chapter 30, we noted that angiosperms represent an evolutionary innovation with their production of flowers and fruits. In chapter 37, we outlined the development of form, or morphogenesis, which a germinating seed undergoes to become a vegetative plant. In this section, we describe the additional changes that occur in a vegetative plant to produce the elaborate structures associated with flowering (figure 42.1).

Plants go through developmental changes leading to reproductive maturity just as many animals do. This shift from juvenile to adult development is seen in the metamorphosis of a tadpole to an adult frog or a caterpillar to a butterfly that can then reproduce. Plants undergo a similar metamorphosis that leads to the production of a flower. Unlike the juvenile frog, which loses its tail, plants just keep adding structures to existing structures with their meristems.

Carefully regulated processes determine when and where flowers will form. Moreover, plants must often gain compe-

**Figure 42.2** Factors involved in initiating flowering.

This model depicts the environmentally cued and internally processed events that result in a shoot meristem initiating flowers. During phase change, the plant acquires competence to respond to flowering signals.

tence to respond to internal or external signals regulating flowering. Once plants are competent to reproduce, a combination of factors—including light, temperature, and both promotive and inhibitory internal signals—determines when a flower is produced (figure 42.2). These signals turn on genes that specify formation of the floral organs—sepals, petals, stamens, and carpels. Once cells have instructions to become a specific floral organ, yet another developmental cascade leads to the three-dimensional construction of flower parts. We describe details of this process in the following sections.

### The transition to flowering competence is termed phase change

At germination, most plants are incapable of producing a flower, even if all the environmental cues are optimal. Internal developmental changes allow plants to obtain competence to respond to external or internal signals (or both) that trigger flower formation. This transition is referred to as **phase change**.

Phase change can be morphologically obvious or very subtle. Take a look at an oak tree in the winter: Leaves will still be clinging to the lower branches until spring when the new buds push them off, but leaves on the upper branches will have fallen earlier (figure 42.3a). Those lower branches were initiated by a juvenile meristem. The fact that they did not respond to environmental cues and drop their leaves indicates that they are juvenile branches and have not made a phase change. Although the lower branches are older, their juvenile state was established when they were initiated and will not change.

Ivy also has distinct juvenile and adult phases of growth (figure 42.3b). Stem tissue produced by a juvenile meristem initiates adventitious roots that can cling to walls. If you look at very old brick buildings covered with ivy, you will notice that the uppermost branches are falling off because they have transitioned to the adult phase of growth and have lost the ability to produce adventitious roots.

It is important to note that even though a plant has reached the adult stage of development, it may or may not produce reproductive structures. Other factors may be necessary to trigger flowering.

**Figure 42.1** Life cycle of a flowering plant (*Angiosperm*).

a.

b.

### Figure 42.3 Phase change.

**a.** The lower branches of this oak tree represent the juvenile phase of development; they cling to their leaves in the winter. The lower leaves are not able to form an abscission layer and break off the tree in the fall. Such visible changes are marks of phase change, but the real test is whether the plant is able to flower. **b.** Juvenile ivy (right) makes adventitious roots and has an alternating leaf phyllotaxy. Mature ivy (left) lacks adventitious roots, has spiral phyllotaxy, and can make flowers.

## Mutations have clarified how phase change is controlled

Generally it is easier to get a plant to revert from an adult to juvenile state than to induce phase change experimentally. Applications of the plant hormone gibberellin and severe pruning can cause reversion. In the latter case, new vegetative growth occurs, as when certain shrubs are cut back and put out lush new growth in response.

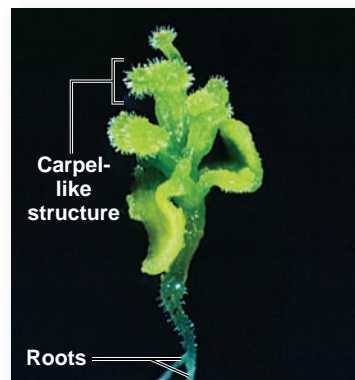

The *embryonic flower (emf)* mutant of *Arabidopsis* flowers almost immediately (figure 42.4), which is consistent with the hypothesis that the wild-type allele suppresses flowering. As the wild-type plant matures, *EMF* expression decreases. This finding suggests that flowering is the default state, and that mechanisms have evolved to delay flowering. This delay presumably allows the plant to store more energy to be allocated for reproduction.

An example of inducing the juvenile-to-adult transition comes from overexpressing a gene necessary for flowering that is found in many species. This gene, *LEAFY (LFY)*, was cloned in *Arabidopsis*, and its promoter was replaced with a viral promoter that results in constant, high levels of *LFY* transcription. *LFY* with its viral promoter was then introduced into cultured aspen cells that were used to regenerate plants. When *LFY* is overexpressed in aspen, flowering occurs in weeks instead of years (figure 42.5).

Phase change requires both a sufficiently strong promotive signal and the ability to perceive the signal. Phase change can result in the production of receptors in the shoot to perceive a signal of a certain intensity. Alternatively an increase of promotive signal(s) or a decrease of inhibitory signal(s) can trigger phase change.

### Figure 42.4 Embryonic flower (*EMF*) prevents early flowering.

Mutant plants that lack *EMF* protein flower as soon as they germinate. The flowers have malformed carpels and other defective floral structures close to the roots.

Phase change, as we said earlier, results in an adult plant, but not necessarily a flowering plant. The ability to reproduce is distinct from actual reproductive development. Flower production depends on a number of factors, which we explore next.

### Learning Outcomes Review 42.1

In a flowering plant life cycle, fertilization produces an embryo in a seed. The embryo develops into a plant that eventually flowers, and the flowers once again produce gametes. Phase change is the transition from vegetative to reproductive growth. In *Arabidopsis*, expression of the embryonic flower mutant (*emf*) or overexpression of the *LEAFY* gene (*LFY*) result in early flowering.

- In evolutionary terms, why is flower production the default state in plants?

Normal Flowering

a.

Accelerated Flowering

b.

**Figure 42.5 Overexpression of a flowering gene can accelerate phase change.** **a.** Normally, an aspen tree grows for several years before producing flowers (see inset). **b.** Overexpression of the *Arabidopsis* flowering gene, *LFY*, causes rapid flowering in a transgenic aspen (see inset).

## 42.2 Flower Production

### Learning Outcomes

1. Name the four genetically regulated flowering pathways.
2. Define floral determination.
3. Explain the relationship between floral meristem identity genes and floral organ identity genes.

Four genetically regulated pathways to flowering have been identified: (1) the light-dependent pathway, (2) the temperature-dependent pathway, (3) the gibberellin-dependent pathway, and (4) the autonomous pathway.

Plants can rely primarily on one pathway, but all four pathways can be present.

The environment can promote or repress flowering, and in some cases, it can be relatively neutral. For example, increasing light duration can be a signal that long summer days have arrived in a temperate climate and that conditions are favorable for reproduction. In other cases, plants depend on light to accumulate sufficient amounts of sucrose to fuel reproduction, but flower independently of day length.

Temperature can also be used as a signal. **Vernalization**, the requirement for a period of chilling of seeds or shoots for flowering, affects the temperature-dependent pathway. Assuming that regulation of reproduction first arose in more constant tropical environments, many of the day-length and temperature controls would have evolved as plants colonized more temperate climates. Plants with a vernalization requirement flower after, not during, a cold winter, enhancing reproductive success. The existence of redundant pathways to flowering helps ensure new generations.

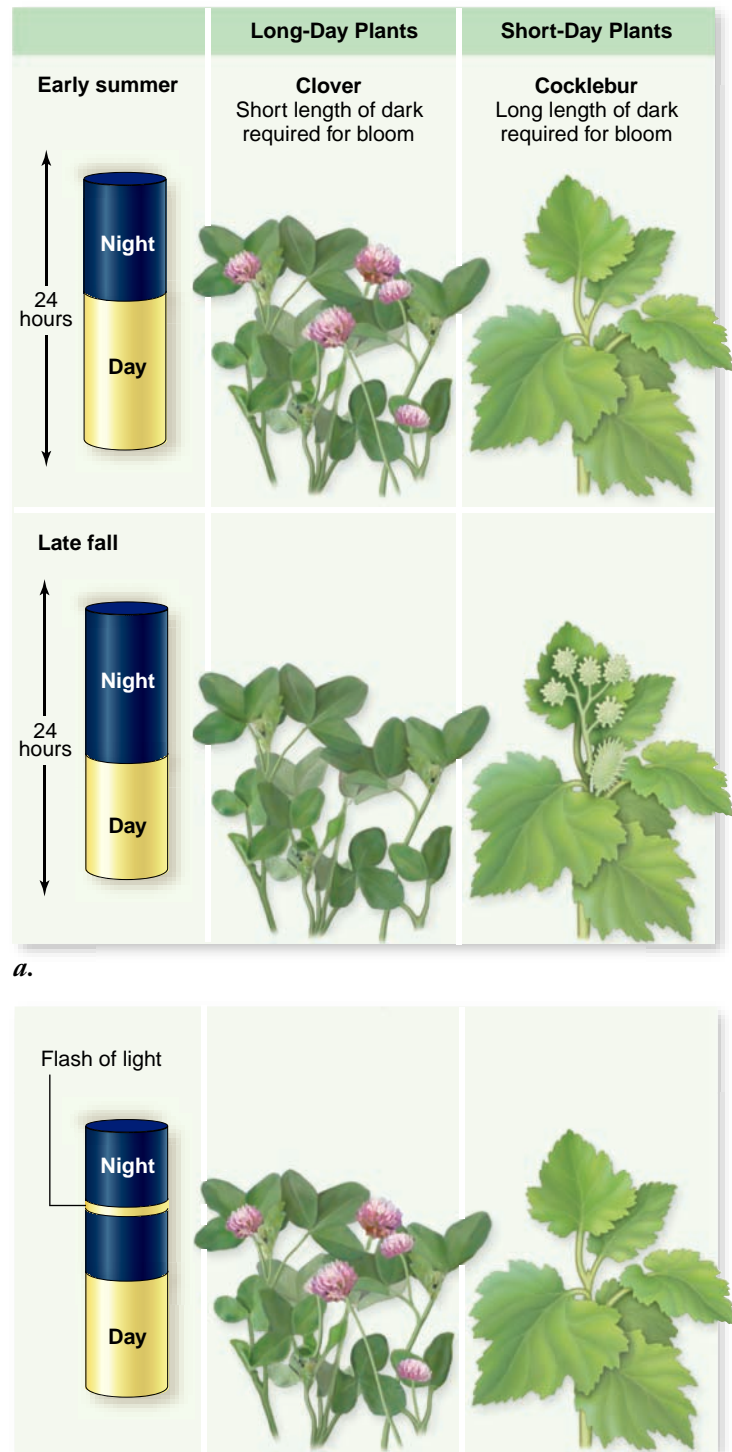

### The light-dependent pathway is geared to the photoperiod

Flowering requires much energy accumulated via photosynthesis. Thus, all plants require light for flowering, but this is distinct from the **photoperiodic**, or light-dependent, flowering pathway. Aspects of growth and development in most plants are keyed to changes in the proportion of light to dark in the daily 24-hr cycle (day length).

Sensitivity to the photoperiod provides a mechanism for organisms to respond to seasonal changes in the relative length of day and night. Day length changes with the seasons; the farther a region is from the equator, the greater the variation in day length.

### Short-day and long-day plants

The flowering responses of plants to day length fall into several basic categories. In short-day plants, flowering is initiated when daylight becomes shorter than a critical length (figure 42.6). In **long-day plants**, flowering begins when daylight becomes longer. Other plants, such as snapdragons, roses, and many native to the tropics, flower when mature

a.

### Figure 42.6 How flowering responds to day length.

a. Clover (center panels) is a long-day plant that is stimulated by short nights to flower in the spring. Cocklebur (right-hand panels) is a short-day plant that, throughout its natural distribution in the northern hemisphere, is stimulated by long nights to flower in the fall. b. If the long night of late fall is artificially interrupted by a flash of light, the cocklebur will not flower, and the clover will. Although the terms *long-day* and *short-day* refer to the length of day, in each case, it is the duration of uninterrupted darkness that determines when flowering will occur.

regardless of day length, as long as they have received enough light for normal growth. These are referred to as day-neutral plants. Still other plants, including ivy, have two critical photoperiods; they will not flower if the days are too long, and they also will not flower if the days are too short.

Although plants are referred to as long-day or short-day plants, it is actually the amount of darkness that determines whether a plant flowers. In obligate long- or short-day species, there is a sharp distinction between short and long nights, respectively. Flowering occurs in obligate long-day plants when the night length is less than the maximal amount of required darkness (critical night length) for that species. For obligate short-day plants, the amount of darkness must exceed the critical night length for the species.

In other long- or short-day plants, flowering occurs more rapidly or slowly depending on the length of day. These plants, which rely on other flowering pathways as well, are called **facultative long- or short-day** plants because the photoperiodic requirement is not absolute. The garden pea is an example of a facultative long-day plant.

### Advantages of photoperiodic control of flowering

Using light as a cue permits plants to flower when abiotic environmental conditions are optimal, pollinators are available, and competition for resources with other plants may be less. For example, the spring herbaceous plants termed *ephemerals* flower in the woods before the tree canopy leafs out and blocks the sunlight necessary for photosynthesis. An example is the trailing arbutus (*Epigaea repens*) of the Northeast woods, which is also known as mayflower because of the time of year in which it blooms.

At middle latitudes, most long-day plants flower in the spring and early summer; examples of such plants include clover, irises, lettuce, spinach, and hollyhocks. Short-day plants usually flower in late summer and fall; these include chrysanthemums, goldenrods, poinsettias, soybeans, and many weeds, such as ragweed. Commercial plant growers use these responses to day length to bring plants into flower at specific times. For example, photoperiod is manipulated in greenhouses so that poinsettias flower just in time for the winter holidays (figure 42.7). The geographic distribution of certain plants may be determined by their flowering responses to day length.

### The mechanics of light signaling

Photoperiod is perceived by several different forms of phytochrome and also by a blue-light-sensitive molecule (cryptochrome). Another type of blue-light-sensitive molecule (phototropin) was discussed in chapter 41. Phototropin affects photomorphogenesis, and cryptochrome affects photoperiodic responses.

The conformational change in a phytochrome or cryptochrome light-receptor molecule triggers a cascade of events that leads to the production of a flower. There is a link between light and the circadian rhythm regulated by an internal clock that facilitates or inhibits flowering. At a molecular level, the gaps in information about how light signaling and flower production are related are rapidly being filled in, and the control mechanisms have been found to be quite complex.

**Figure 42.7** Flowering time can be altered.

Manipulation of photoperiod in greenhouses ensures that short-day poinsettias flower in time for the winter holidays. Even after flowering is induced, many developmental events must occur in order to produce species-specific flowers.

**Photoperiodic Regulation of Transcription of the *CO* Gene.** *Arabidopsis*, which as you know is commonly used in plant studies, is a facultative long-day plant that flowers in response to both far-red and blue light. Phytochrome and cryptochrome, the red- and blue-light receptors, respectively, regulate flowering via the gene *CONSTANS* (*CO*). Precise levels of *CO* protein are maintained in accordance with the circadian clock, and phytochrome regulates the transcription of *CO*. Levels of *CO* mRNA are low at night and increase at daybreak. In addition, *CO* protein levels are modulated through the action of cryptochrome. *CO* is an important protein because it links the perception of day length with the production of a signal that moves from the leaves to the shoot where a change in gene transcription leads to the production of flowers.

### Inquiry question

? If levels of *CO* mRNA follow a circadian pattern, how could you determine whether protein levels are modulated by a mechanism other than transcription? Why would an additional level of control even be necessary?

The importance of posttranslational regulation of *CO* activity became apparent through studies of transgenic *Arabidopsis* plants. These plants contain a *CO* gene fused to a viral promoter that is always on and produces high levels of *CO* mRNA regardless of whether it is day or night. The regulation of *CO* gene expression by phytochrome A is therefore eliminated when this viral promoter is fused to the gene. Curiously, *CO* protein levels still follow a circadian pattern.

Although CO protein is produced day and night, levels of CO are lower at night because of targeted protein degradation. Ubiquitin tags the CO protein, and it is degraded by the proteasome as was described in chapter 41 for phytochrome degradation. Blue light acting via cryptochrome stabilizes CO during the day and protects it from ubiquitination and subsequent degradation.

**CO and LFY Expression.** CO is a transcription factor that turns on other genes, which results in the expression of *LFY*. As discussed in connection with phase change earlier in this section, *LFY* is one of the key genes that “tells” a meristem to switch over to flowering. We will see that other pathways also converge on this important gene. Genes that are regulated by *LFY* are discussed later in this chapter.

### Florigen—The elusive flowering hormone

Long before any genes regulating flowering were cloned, a flowering hormone called florigen was postulated to trigger flower production. A considerable amount of evidence demonstrates the existence of substances that promote flowering and substances that inhibit it. Grafting experiments have shown that these substances can move from leaves to shoots. The complexity of their interactions, as well as the fact that multiple chemical messengers are evidently involved, has made this scientifically and commercially interesting search very difficult. The existence of a flowering hormone remains strictly hypothetical even after a scientific quest of 50 years.

One intriguing possibility is that CO protein is a graft-transmissible flowering signal or that it affects such a signal. CO has been found in the phloem that moves throughout the plant body. When *co* mutant shoots are grafted to stocks that produce CO, flowering occurs. Because CO is found in the

phloem, it is possible that this is the protein that moves in the grafted plant to cause flowering. Equally likely, however, is the possibility that CO directly or indirectly affects a separate graft-transmissible factor that is essential for flowering.

### The temperature-dependent pathway is linked to cold

Cold temperatures can accelerate or permit flowering in many species. As with light, this environmental connection ensures that plants flower at more optimal times.

Some plants require a period of chilling before flowering, called *vernalization*. This phenomenon was discovered in the 1930s by the Ukrainian scientist T. D. Lysenko while trying to solve the problem of winter wheat rotting in the fields. Because winter wheat would not flower without a period of chilling, Lysenko chilled the seeds and then planted them in the spring. The seeds successfully sprouted, grew, and produced grain.

Although this discovery was scientifically significant, Lysenko erroneously concluded that he had converted one species, winter wheat, to another, spring wheat, by simply altering the environment. Lysenko’s point of view was supported by the communist philosophy of the time, which held that people could easily manipulate nature to increase production. Unfortunately, this philosophy led to a great many problems, including mistreatment of legitimate geneticists in the former Soviet Union. In addition, genetics and Darwinian evolution were suspect in the Soviet Union until the mid-1960s.

Vernalization is necessary for some seeds or plants in later stages of development. Analysis of mutants in *Arabidopsis* and pea plants indicate that vernalization is a separate flowering pathway.

**Figure 42.8** Plants can “count.” When axillary buds of flowering, day-neutral tobacco plants are released from apical dominance by removing the main shoot, they replace the number of nodes that were initiated by the main shoot.

**Figure 42.9** Plants can “remember.” At a certain point in the flowering process, shoots become committed to making a flower. This is called floral determination. *a.* Florally determined shoots “remember” their position when rooted in a pot. That is, they produce the same number of nodes that they would have if they had grown out on the plant, and then they flower. *b.* Shoots that are not yet florally determined cannot remember how many nodes they have left, so they start counting again. That is, they develop like a seedling and then flower.

### The gibberellin-dependent pathway requires an increased hormone level

In *Arabidopsis* and some other species, decreased levels of gibberellins delay flowering. Thus the gibberellin pathway is proposed to promote flowering. It is known that gibberellins enhance the expression of *LFY*. Gibberellin actually binds the promoter of the *LFY* gene, so its effect on flowering is direct.

### The autonomous pathway is independent of environmental cues

The autonomous pathway to flowering does not depend on external cues except for basic nutrition. Presumably, this was the first pathway to evolve. Day-neutral plants often depend primarily on the autonomous pathway, which allows plants to “count” and “remember.”

As an example, a field of day-neutral tobacco plants will produce a uniform number of nodes before flowering. If the shoots of these plants are removed at different positions, axillary buds will grow out and produce the same number of nodes as the removed portion of the shoot (figure 42.8). The upper axillary buds of flowering tobacco will remember their position when rooted or grafted. The terminal shoot tip becomes committed, or determined, to flower about four nodes before it actually initiates a flower (figure 42.9). In some other species, this commitment is less stable or it occurs later.

How do shoots “know” where they are and at some point “remember” that information? It has become clear that inhibitory signals are sent from the roots. When bottomless pots are

continuously placed over a growing tobacco plant and filled with soil, flowering is delayed by the formation of adventitious roots (figure 42.10). Control experiments with leaf removal show that the addition of roots, and not the loss of leaves, delays flowering. A balance between floral promoting and inhibiting signals may regulate when flowering occurs in the autonomous pathway and the other pathways as well.

**Figure 42.10** Roots can inhibit flowering. Adventitious roots formed as bottomless pots were continuously placed over growing tobacco plants, delaying flowering. The delay in flowering is caused by the roots, not by the loss of the leaves. This was shown by removing leaves on plants at the same time and in the same position as leaves on experimental plants that became buried as pots were added.

Determination for flowering is tested at the organ or whole-plant level by changing the environment and ascertaining whether the developmental fate has changed. In *Arabidopsis*, floral determination correlates with the increase of *LFY* gene expression, and it has already occurred by the time a second flowering gene, *APETALA1* (*API*), is expressed. Because all four flowering pathways appear to converge with increased levels of *LFY*, this determination event should occur in species with a variety of balances among the pathways (figure 42.11).

### Inquiry question

? Why would it be advantageous for a plant to have four distinct pathways that all affect the expression of *LFY*?

## Floral meristem identity genes activate floral organ identity genes

*Arabidopsis* and snapdragons are valuable model systems for identifying flowering genes and understanding their interactions. The four flowering pathways discussed earlier in this section lead to an adult meristem becoming a floral meristem by either activating or repressing the inhibition of floral meristem identity genes (see figure 42.11). Two of the key floral meristem identity genes are *LFY* and *API*. These genes establish the meristem as a flower meristem. They then turn on floral organ identity genes. The floral organ identity genes define four concentric whorls, moving inward in the floral meristem, as sepal, petal, stamen, and carpel.

### The ABC model

To explain how three classes of floral organ identity genes could specify four distinct organ types, the ABC model was developed

(figure 42.12). The ABC model proposes that three classes of organ identity genes (*A*, *B*, and *C*) specify the floral organs in the four floral whorls. By studying mutants, the researchers have determined the following:

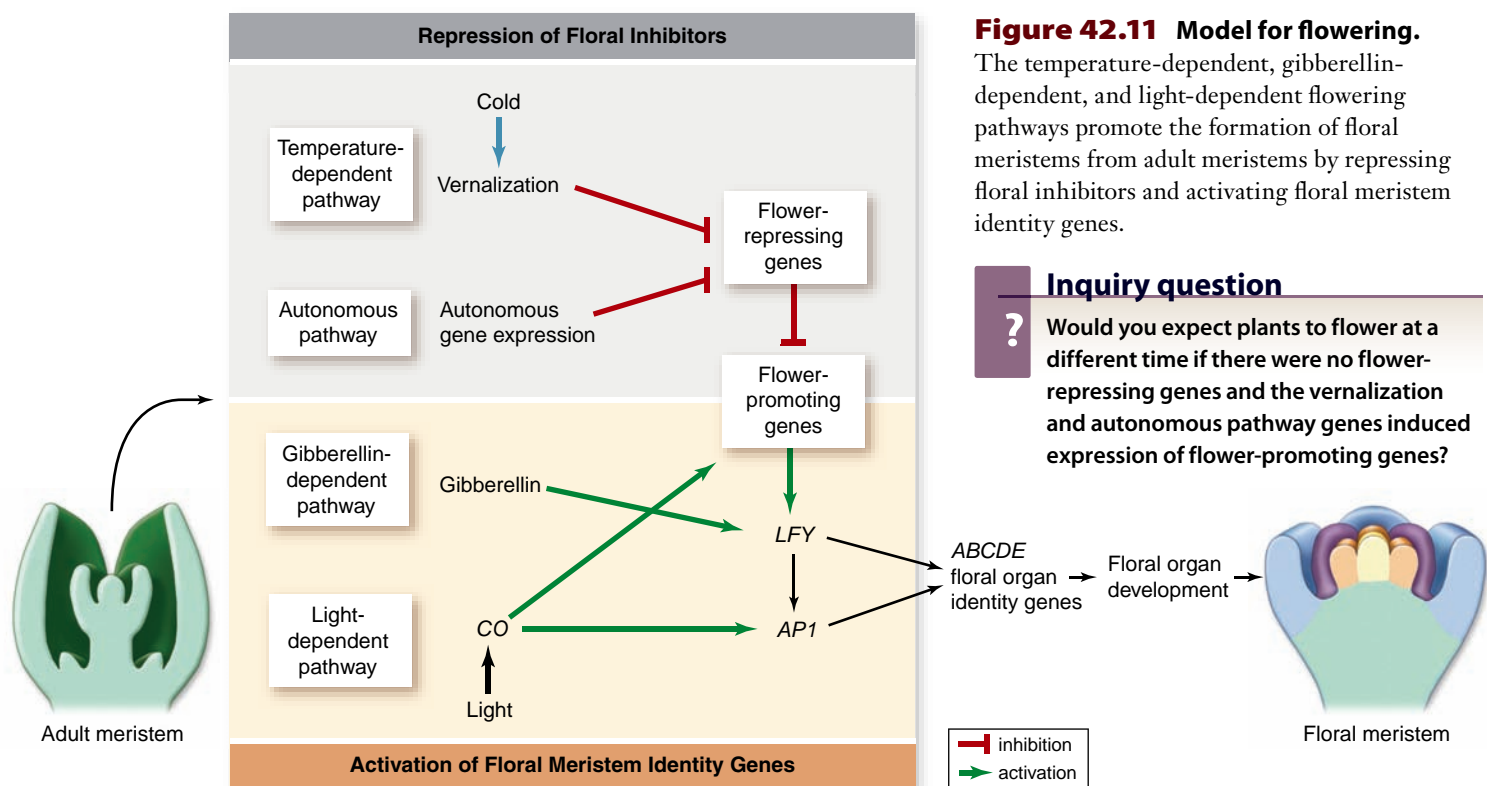

1. Class *A* genes alone specify the sepals.
2. Class *A* and class *B* genes together specify the petals.
3. Class *B* and class *C* genes together specify the stamens.
4. Class *C* genes alone specify the carpels.

The beauty of the ABC model is that it is entirely testable by making different combinations of floral organ identity mutants. Each class of genes is expressed in two whorls, yielding four different combinations of the gene products. When any one class is missing, aberrant floral organs occur in predictable positions.

### Modifications to the ABC model

As compelling as the ABC model is, it cannot fully explain specification of floral meristem identity. Class *D* genes that are essential for carpel formation have been identified, but even this discovery did not explain why a plant lacking *A*, *B*, and *C* gene function produced four whorls of sepals rather than four whorls of leaves. Floral parts are thought to have evolved from leaves; therefore, if the floral organ identity genes are removed, whorls of leaves, rather than sepals, would be predicted.

The answer to this puzzle is found in the more recently discovered class *E* genes, *SEPALATA1* (*SEP1*) through *SEPALATA4* (*SEP4*). The triple mutant *sep1 sep2 sep3* and the *sep4* mutant both produce four whorls of leaves. The proteins encoded by the *SEP* genes can interact with class *A*, *B*, and *C* proteins and possibly affect transcription of genes needed for the development of floral organs. Identification of the *SEP*

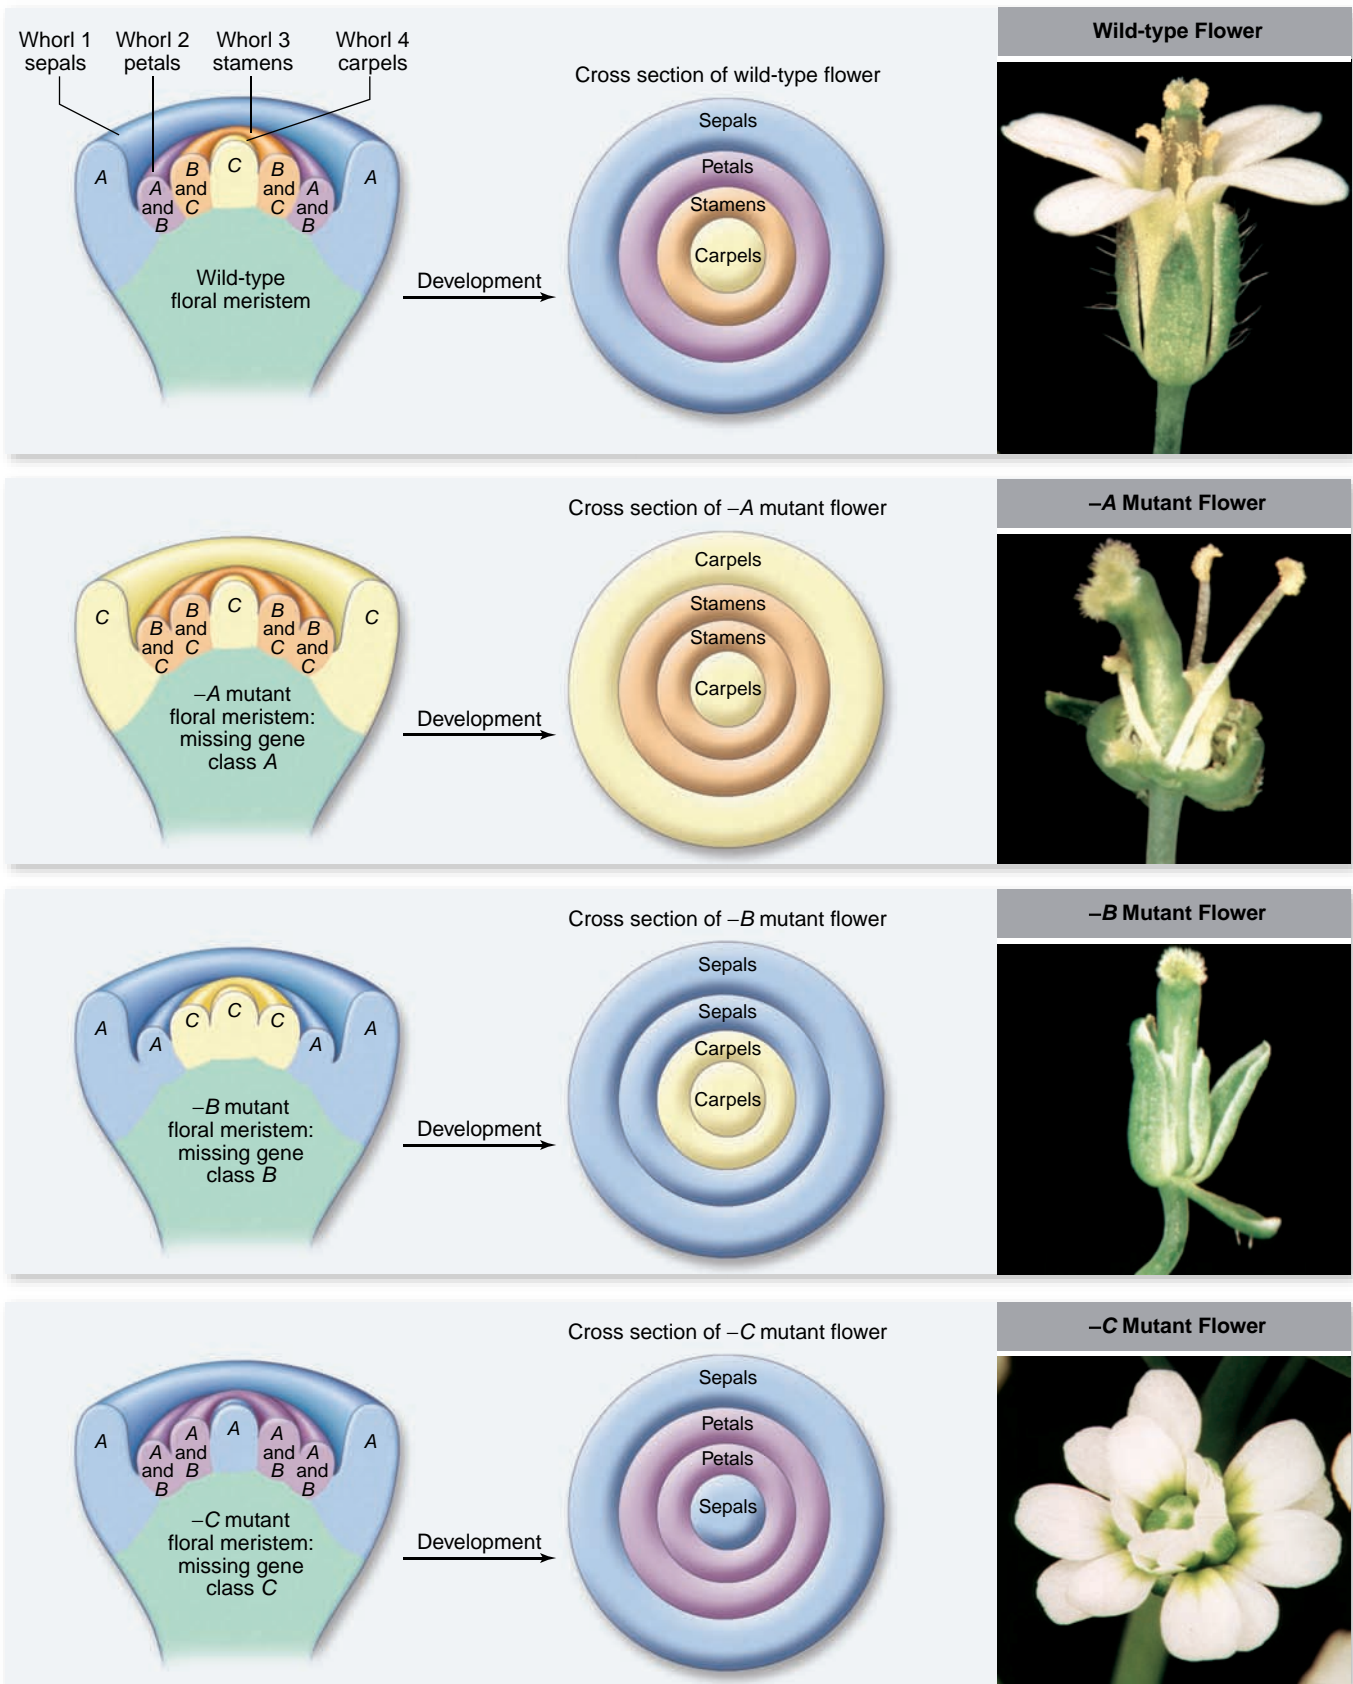

**Figure 42.11** Model for flowering.

The temperature-dependent, gibberellin-dependent, and light-dependent flowering pathways promote the formation of floral meristems from adult meristems by repressing floral inhibitors and activating floral meristem identity genes.

### Inquiry question

? Would you expect plants to flower at a different time if there were no flower-repressing genes and the vernalization and autonomous pathway genes induced expression of flower-promoting genes?

**Figure 42.12 ABC model for floral organ specification.** Letters labeling whorls indicate which gene classes are active. When *A* function is lost (*-A*), *C* expands to the first and second whorls. When *B* function is lost (*-B*), The outer two whorls have just *A* function, and both inner two whorls have just *C* function; none of the whorls have dual gene function. When *C* function is lost (*-C*), *A* expands into the inner two whorls. These new combinations of gene expression patterns alter which floral structures form in each whorl.

**Figure 42.13** Class *E* genes are needed to specify floral organ identity. When all three *SEP* genes are mutated, four whorls of leaves are produced.

genes lead to a new floral organ identity model that includes these class *E* genes (figure 42.13).

It is important to recognize that the *ABCDE* genes are actually only the beginning of the making of a flower. These organ identity genes are transcription factors that turn on many more genes that actually give rise to the three-dimensional flower. Other genes “paint” the petals—that is, complex biochemical pathways lead to the accumulation of anthocyanin pigments in petal cell vacuoles. These pigments can be orange, red, or purple, and the actual color is influenced by pH as well.

### Learning Outcomes Review 42.2

Four pathways have been identified that lead to flowering: light-dependent, temperature-dependent, gibberellin-dependent, and autonomous. Floral determination marks the point at which shoots become committed to making flowers. Floral meristem identity genes turn on floral organ identity genes, which control the development of flower parts.

- How would you test whether day length or night length determines flowering in plants with light-dependent flowering pathways?

## 42.3 Structure and Evolution of Flowers

### Learning Outcomes

1. List the parts of a typical angiosperm flower.
2. Distinguish between bilateral symmetry and radial symmetry.
3. Differentiate between microgametophytes and megagametophytes.

The complex and elegant process that gives rise to the reproductive structure called the flower is often compared with metamorphosis in animals. It is indeed a metamorphosis, but the subtle shift from mitosis to meiosis in the megaspore mother cell that leads to the development of a haploid, gamete-producing gametophyte is perhaps even more critical. The same can be said for pollen formation in the anther of the stamen.

The flower not only houses the haploid generations that will produce gametes, but it also functions to increase the probability that male and female gametes from different (or sometimes the same) plants will unite.

### Flowers evolved in the angiosperms

The evolution of the angiosperms is a focus of chapter 30. The diversity of angiosperms is partly due to the evolution of a great variety of floral phenotypes that may enhance the effectiveness of pollination. As mentioned previously, floral organs are thought to have evolved from leaves. In some early angiosperms, these organs maintain the spiral developmental pattern often found in leaves. The trend has been toward four distinct whorls of parts. A complete flower has four whorls (calyx, corolla, androecium, and gynoecium) (figure 42.14). An incomplete flower lacks one or more of the whorls.

### Flower morphology

In both complete and incomplete flowers, the **calyx** usually constitutes the outermost whorl; it consists of flattened appendages, called sepals, which protect the flower in the bud. The petals collectively make up the **corolla** and may be fused. Many petals function to attract pollinators. Although these two outer whorls of floral organs are not involved directly in gamete production or fertilization, they can enhance reproductive success.

**Male structures.** Androecium is a collective term for all the **stamens** (male structures) of a flower. Stamens are specialized

**Figure 42.14** A complete angiosperm flower.

structures that bear the angiosperm microsporangia. Similar structures bear the microsporangia in the pollen cones of gymnosperms. Most living angiosperms have stamens with filaments (“stalks”) that are slender and often threadlike; four microsporangia are evident at the apex in a swollen portion, the **anther**. Some of the more primitive angiosperms have stamens that are flattened and leaflike, with the sporangia produced from the upper or lower surface.

**Female structures.** The gynoecium is a collective term for all the female parts of a flower. In most flowers, the gynoecium, which is unique to angiosperms, consists of a single carpel or two or more fused carpels. Single or fused carpels are often referred to as simple or compound pistils, respectively. Most flowers with which we are familiar—for example, those of tomatoes and oranges—have a compound pistil. Other, less specialized flowers—for example, buttercups and stonecups—may have several to many separate, simple pistils, each formed from a single carpel.

Ovules (which develop into seeds) are produced in the pistil’s swollen lower portion, the **ovary**, which usually narrows at the top into a slender, necklike style with a pollen-receptive stigma at its apex. Sometimes the stigma is divided, with the number of stigma branches indicating how many carpels compose the particular pistil.

Carpels are essentially rolled floral leaves with ovules along the margins. It is possible that the first carpels were leaf blades that folded longitudinally; the leaf margins, which had hairs, did not actually fuse until the fruit developed, but the hairs interlocked and were receptive to pollen. In the course of evolution, evidence indicates that the hairs became localized into a stigma; a style was formed; and the fusing of the carpel margins ultimately resulted in a pistil. In many modern flowering plants, the carpels have become highly modified and are not visually distinguishable from one another unless the pistil is cut open.

### Trends of floral specialization

Two major evolutionary trends led to the wide diversity of modern flowering plants: (1) Separate floral parts have grouped together, or fused, and (2) floral parts have been lost or reduced (figure 42.15).

In the more advanced angiosperms, the number of parts in each whorl has often been reduced from many to few. The spiral patterns of attachment of all floral parts in primitive an-

### Figure 42.15

**Trends in floral specialization.** Wild geranium, *Geranium maculatum*, a typical eudicot. The petals are reduced to five each, the stamens to ten, compared with early angiosperms.

### Figure 42.16

**Bilateral symmetry in an orchid.**

Although more basal flowers are usually radially symmetrical, flowers of many derived groups, such as the orchid family (Orchidaceae), are bilaterally symmetrical.

giosperms have, in the course of evolution, given way to a single whorl at each level. The central axis of many flowers has shortened, and the whorls are close to one another. In some evolutionary lines, the members of one or more whorls have fused with one another, sometimes joining into a tube. In other kinds of flowering plants, different whorls may be fused together.

Whole whorls may even be lost from the flower, which may lack sepals, petals, stamens, carpels, or various combinations of these structures. Modifications often relate to pollination mechanisms, and in plants such as the grasses, wind has replaced animals for pollen dispersal.

### Trends in floral symmetry

Other trends in floral evolution have affected the symmetry of the flower. Primitive flowers such as those of buttercups are radially symmetrical; that is, one could draw a line anywhere through the center and have two roughly equal halves. Flowers of many advanced groups are bilaterally symmetrical; they are divisible into two equal parts along only a single plane. Examples of such flowers are snapdragons, mints, and orchids (figure 42.16). Bilaterally symmetrical flowers are also common among violets and peas. In these groups, they are often associated with advanced and highly precise pollination systems.

Bilateral symmetry has arisen independently many times. In snapdragons, the *CYCLOIDIA* gene regulates floral symmetry, and in its absence flowers are more radial (figure 42.17).

**Figure 42.17 Genetic regulation of asymmetry in flowers.** *a.* Snapdragon flowers normally have bilateral symmetry. *b.* The *CYCLOIDIA* gene regulates floral symmetry, and *cycloidia* mutant snapdragons have radially symmetrical flowers.

Here the experimental alteration of a single gene is sufficient to cause a dramatic change in morphology. Whether the same gene or functionally similar genes arose naturally in parallel in other species is an open question.

### The human influence on flower morphology

Although much floral diversity is the result of natural selection related to pollination, it is important to recognize the effect breeding (artificial selection) has on flower morphology. Humans have selected for practical or aesthetic traits that may have little adaptive value to species in the wild. For example, maize (corn) has been bred to satisfy the human palate. Human intervention ensures the reproductive success of each generation; however, in a natural setting, modern corn would not have the same protection from herbivores as its ancestors, and the fruit dispersal mechanism would be quite different.

### Gametes are produced in the gametophytes of flowers

Reproductive success depends on uniting the gametes (egg and sperm) found in the embryo sacs and pollen grains of flowers. As you learned in chapter 30, plant sexual life cycles are characterized by an *alternation of generations*, in which a diploid sporophyte generation gives rise to a haploid gametophyte generation. In angiosperms, the gametophyte generation is

very small and is completely enclosed within the tissues of the parent sporophyte. The male gametophytes, or microgametophytes, are **pollen grains**. The female gametophyte, or megagametophyte, is the **embryo sac**. Pollen grains and the embryo sac both are produced in separate, specialized structures of the angiosperm flower.

Like animals, angiosperms have separate structures for producing male and female gametes (figure 42.18), but the reproductive organs of angiosperms are different from those of animals in two ways. First, both male and female structures usually occur together in the same individual flower. Second, angiosperm reproductive structures are not permanent parts of the adult individual. Angiosperm flowers and reproductive organs develop seasonally, at times of the year most favorable for pollination. In some cases, reproductive structures are produced only once, and the parent plant dies. And, as you learned earlier in this chapter, the germ line in angiosperms is not set aside early on, but forms quite late during phase change.

### Pollen formation

Anthers contain four microsporangia, which produce microspore mother cells ( $2n$ ). Microspore mother cells produce microspores ( $n$ ) through meiotic cell division. The microspores, through mitosis and wall differentiation, become pollen. Inside each pollen grain is a generative cell; this cell later divides to produce two sperm cells.

**Figure 42.18 Formation of pollen grains and the embryo sac.** Diploid ( $2n$ ) microspore mother cells are housed in the anther and divide by meiosis to form four haploid ( $n$ ) microspores. Each microspore develops by mitosis into a pollen grain. The generative cell within the pollen grain later divides to form two sperm cells. Within the ovule, one diploid megaspore mother cell divides by meiosis to produce four haploid megaspores. Usually only one of the megaspores survives, and the other three degenerate. The surviving megaspore divides by mitosis to produce an embryo sac with eight nuclei.

**Figure 42.19** **Pollen grains.** *a.* In the Easter lily, *Lilium candidum*, the pollen tube emerges from the pollen grain through the groove or furrow that occurs on one side of the grain. *b.* In a plant of the sunflower family, *Hyoseris longiloba*, three pores are hidden among the ornamentation of the pollen grain. The pollen tube may grow out through any one of them.

Pollen grain shapes are specialized for specific flower species. As discussed in more detail later in this section, fertilization requires that the pollen grain grow a tube that penetrates the style until it encounters the ovary. Most pollen grains have a furrow or pore from which this pollen tube emerges; some grains have three furrows (figure 42.19).

### Embryo sac formation

Eggs develop in the ovules of the angiosperm flower. Within each ovule is a megaspore mother cell. Just as in pollen production, the megaspore mother cell undergoes meiosis to produce four haploid megaspores. In most plants, however, only one of these megaspores survives; the rest are absorbed by the ovule. The lone remaining megaspore enlarges and undergoes repeated mitotic divisions to produce eight haploid nuclei that are enclosed within a seven-celled embryo sac.

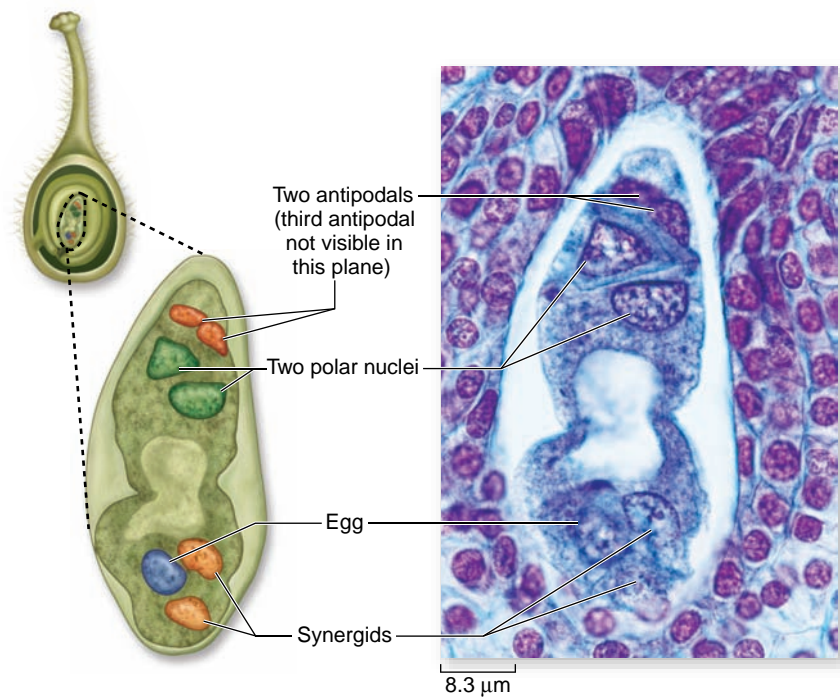

Within the embryo sac, the eight nuclei are arranged in precise positions. One nucleus is located near the opening of the embryo sac in the egg cell. Two others are located together in a single cell in the middle of the embryo sac; these are called *polar nuclei*. Two more nuclei are contained in individual cells called synergids that flank the egg cell; the other three nuclei reside in cells called the antipodals, located at the end of the sac, opposite the egg cell (figure 42.20).

The first step in uniting the two sperm cells in the pollen grain with the egg and polar nuclei is the germination of pollen on the stigma of the carpel and its growth toward the embryo sac.

### Learning Outcomes Review 42.3

An angiosperm flower consists of four concentric whorls: calyx, corolla, androecium, and gynoecium. Bilaterally symmetrical flowers are divisible into two equal parts along only a single plane; radially symmetrical flowers can be divided equally on any plane. The microspore mother cells in flowers undergo meiosis to produce microspores, which undergo mitosis to produce microgametophytes (pollen grains). Megaspore mother cells undergo a similar process to produce megaspores, which result in megagametophytes (embryo sacs).

- **What is the main evolutionary advantage of the flower?**

**Figure 42.20** **A mature embryo sac of a lily.** Eight nuclei are produced by mitotic divisions of the haploid megaspore. One is in the egg, two are polar nuclei, two occur in synergid cells, and three are in antipodal cells. The micrograph is falsely colored.

## 42.4 Pollination and Fertilization

### Learning Outcomes

1. **Discuss conditions under which self-pollination may be favored.**
2. **Describe three evolutionary strategies that promote outcrossing.**
3. **List the products of double fertilization.**

Pollination is the process by which pollen is placed on the stigma. Pollen may be carried to the flower by wind or by animals, or it may originate within the individual flower itself. When pollen from a flower's anther pollinates the same flower's stigma, the process is called *self-pollination*. When pollen from the anther of one flower pollinates the stigma of a different flower, the process is termed *cross-pollination*, or *outcrossing*.

As you just learned, pollination in angiosperms does not involve direct contact between the pollen grain and the ovule. When pollen reaches the stigma, it germinates, and a pollen tube grows down, carrying the sperm nuclei to the embryo sac. After double fertilization takes place, development of the embryo and endosperm begins. The seed matures within the ripening fruit; eventually, the germination of the seed initiates another life cycle.

Successful pollination in many angiosperms depends on the regular attraction of **pollinators**, such as insects, birds, and other animals, which transfer pollen between plants of the same

species. When animals disperse pollen, they perform the same function for flowering plants that they do for themselves when they actively search out mates.

The relationship between plant and pollinator can be quite intricate. Mutations in either partner can block reproduction. If a plant flowers at the “wrong” time, the pollinator may not be available. If the morphology of the flower or pollinator is altered, the result may be physical barriers to pollination. Clearly, floral morphology has coevolved with pollinators, and the result is a much more complex and diverse morphology, going beyond the simple initiation and development of four distinct whorls of organs.

## Early seed plants were wind-pollinated

Early seed plants were pollinated passively, by the action of the wind. As in present-day conifers, great quantities of pollen were shed and blown about, occasionally reaching the vicinity of the ovules of the same species.

Individual plants of any wind-pollinated species must grow relatively close to one another for such a system to operate efficiently. Otherwise, the chance that any pollen will arrive at an appropriate destination is very small. The vast majority of windblown pollen travels less than 100 m. This short distance is significant compared with the long distances pollen is routinely carried by certain insects, birds, and other animals.

## Flowers and animal pollinators have coevolved

The spreading of pollen from plant to plant by pollinators visiting flowers of an angiosperm species has played an important role in the evolutionary success of the group. It now seems clear that the earliest angiosperms, and perhaps their ancestors also, were insect-pollinated, and the coevolution of insects and plants has been important for both groups for over 100 million years. Such interactions have also been important in bringing about increased floral specialization. As flowers become increasingly specialized, so do their relationships with particular groups of insects and other animals.

### Bees

Among insect-pollinated angiosperms, the most numerous groups are those pollinated by bees (figure 42.21). Like most insects, bees initially locate sources of food by odor and then orient themselves on the flower or group of flowers by its shape, color, and texture.

Flowers that bees characteristically visit are often blue or yellow. Many have stripes or lines of dots that indicate the location of the nectaries, which often occur within the throats of specialized flowers. Some bees collect nectar, which is used as a source of food for adult bees and occasionally for larvae. Most of the approximately 20,000 species of bees visit flowers to obtain pollen, which is used to provide food in cells where bee larvae complete their development.

Except for a few hundred species of social and semisocial bees and about 1000 species that are parasitic in the nests of other bees, the great majority of bees—at least 18,000 species—are solitary. Solitary bees in temperate regions characteristically

**Figure 42.21** Pollination by a bumblebee. As this bumblebee, *Bombus* sp., collects nectar, pollen sticks to its body. The pollen will be distributed to the next plant the bee visits.

produce only a single generation in the course of a year. Often, they are active as adults for as little as a few weeks a year.

Solitary bees often use the flowers of a particular group of plants almost exclusively as sources of their larval food. The highly constant relationships of such bees with those flowers may lead to modifications, over time, in both the flowers and the bees. For example, the time of day when the flowers open may correlate with the time when the bees appear; the mouthparts of the bees may become elongated in relation to tubular flowers; or the bees' pollen-collecting apparatuses may be adapted to the anthers of the plants that they normally visit. When such relationships are established, they provide both an efficient mechanism of pollination for the flowers and a constant source of food for the bees that “specialize” on them.

### Insects other than bees

Among flower-visiting insects other than bees, a few groups are especially prominent. Flowers such as phlox, which are visited regularly by butterflies, often have flat “landing platforms” on which butterflies perch. They also tend to have long, slender floral tubes filled with nectar that is accessible to the long, coiled proboscis characteristic of Lepidoptera, the order of insects that includes butterflies and moths.

Flowers such as jimsonweed (*Datura stramonium*), evening primrose (*Oenothera biennis*), and others visited regularly by moths are often white, yellow, or some other pale color; they also tend to be heavily scented, making the flowers easy to locate at night (figure 42.22).

### Birds

Several interesting groups of plants are regularly visited and pollinated by birds, especially the hummingbirds of North and South America and the sunbirds of Africa (figure 42.23). Such plants must produce large amounts of nectar because birds will not continue to visit flowers if they do not find enough food to

## SCIENTIFIC THINKING

**Hypothesis:** Moths are more effective than bumblebees at moving pollen long distances.

**Prediction:** The pollen donors of seeds of wild plants are more widely distributed if moths carried the pollen than if bees carried it.

**Test:** Locate a large natural patch of the wild plant. Make sure that both moths and bees are abundant and that the plants are variable for a genetically controlled trait. In this case, assume the population contains some purple-flowered plants (a dominant trait) and some with white flowers (a recessive trait). Remove all the flowers from the purple-flowered plants except those at the edge of the population. Find a white-flowered plant at the center of the population to use as the test plant. Cover some flowers during the day and uncover them in the evening so moths, but not bees, can pollinate them. With other flowers, cover in the evening but not during the day, so bees, but not moths, can pollinate them. Collect seeds from each set of flowers and grow the plants. For each treatment, count the number of plants that produce purple flowers. These will have pollen donors that were a long distance from the test plant.

Cover some flowers during the day and others in the evening. Count the number of purple flowered plants obtained from each treatment.

**Result:** Seeds produced by bee pollination produced the same number of plants with purple flowers as those produced by moth pollination.

**Conclusion:** The hypothesis is not supported. Bees carry pollen as far as moths do.

**Further Experiments:** Growing plants from seed to check for flower color is very time-consuming. Propose another way to determine the source of the pollen in this experiment.

**Figure 42.22** Bees and moths as pollinators.

maintain themselves. But flowers producing large amounts of nectar have no advantage in being visited by insects, because an insect could obtain its energy requirements at a single flower and would not cross-pollinate the flower. How are these different selective forces balanced in flowers that are “specialized” for hummingbirds and sunbirds?

The answer involves the evolution of flower color. Ultraviolet light is highly visible to insects. Carotenoids, the yellow

**Figure 42.23** Hummingbirds and flowers. A long-tailed hermit hummingbird (*Phaethornis superciliosus*) extracts nectar from the flowers of *Heliconia imbricata* in the forests of Costa Rica. Note the pollen on the bird’s beak. Hummingbirds of this group obtain nectar primarily from long, curved flowers that more or less match the length and shape of their beaks.

or orange pigments we described in chapter 8 in the context of photosynthesis, are responsible for the colors of many flowers, including sunflowers and mustard. Carotenoids reflect both in the yellow range and in the ultraviolet range, the mixture resulting in a distinctive color called “bee’s purple.” Such yellow flowers may also be marked in distinctive ways normally invisible to us, but highly visible to bees and other insects (figure 42.24). These markings can be in the form of a bull’s-eye or a landing strip.

**Figure 42.24** How a bee sees a flower. *a.* The yellow flower of *Ludwigia peruviana* (Peruvian primrose) photographed in normal light and *(b)* with a filter that selectively transmits ultraviolet light. The outer sections of the petals reflect both yellow and ultraviolet, a mixture of colors called “bee’s purple”; the inner portions of the petals reflect yellow only and therefore appear dark in the photograph that emphasizes ultraviolet reflection. To a bee, this flower appears as if it has a conspicuous central bull’s-eye.

**Figure 42.25** Staminate and pistillate flowers of a birch, *Betula* sp. Birches are monoecious; their staminate flowers hang down in long, yellowish tassels, and their pistillate flowers mature into clusters of small, brownish, cone-like structures.

In contrast, red does not stand out as a distinct color to most insects, but it is a very conspicuous color to birds. To most insects, the red upper leaves of poinsettias look just like the other leaves of the plant. Consequently, even though the flowers produce abundant supplies of nectar and attract hummingbirds, insects tend to bypass them. Thus, the red color both signals to birds the presence of abundant nectar and makes that nectar as inconspicuous as possible to insects. Red is also seen again in fruits that are dispersed by birds (see chapter 37).

### Other animal pollinators

Other animals, including bats and small rodents, may aid in pollination. The signals here are also species-specific. As an example, the saguaro cactus (*Carnegieia gigantea*) of the Sonoran desert is pollinated by bats that feed on nectar at night, as well as by birds and insects.

These animals may also assist in dispersing the seeds and fruits that result from pollination. Monkeys are attracted to orange and yellow, and thus can be effective in dispersing fruits of this color in their habitats.

### Some flowering plants continue to use wind pollination

A number of groups of angiosperms are wind-pollinated—a characteristic of early seed plants. Among these groups are oaks, birches, cottonwoods, grasses, sedges, and nettles. The flowers of these plants are small, greenish, and odorless; their corollas are reduced or absent (figures 42.25 and 42.26). Such flowers often are grouped together in fairly large numbers

and may hang down in tassels that wave about in the wind and shed pollen freely.

Many wind-pollinated plants have stamen- and carpel-containing flowers separated between individuals or physically separated on a single individual. Maize is a good example, with pollen-producing tassels at the top of the plant and axillary shoots with female flowers lower down. Separation of pollen-producing and ovule-bearing flowers is a strategy that greatly promotes outcrossing, since pollen from one flower must land on a different flower for fertilization to have any chance of occurring. Some wind-pollinated plants, especially trees and shrubs, flower in the spring, before the development of their leaves can interfere with the wind-borne pollen. Wind-pollinated species do not depend on the presence of a pollinator for species survival, which may be another survival advantage.

### Self-pollination is favored in stable environments

Thus far we have considered examples of pollination that tend to lead to outcrossing, which is as highly advantageous for plants and for eukaryotic organisms generally. Nevertheless, self-pollination also occurs among angiosperms, particularly in temperate regions. Most self-pollinating plants have small, relatively inconspicuous flowers that shed pollen directly onto the stigma, sometimes even before the bud opens.

You might logically ask why many self-pollinated plant species have survived if outcrossing is as important genetically

**Figure 42.26** Wind-pollinated flowers. The large yellow anthers, dangling on very slender filaments, are hanging out, about to shed their pollen to the wind. Later, these flowers will become pistillate, with long, feathery stigmas—well suited for trapping windblown pollen—sticking far out of them. Many grasses, like this one, are therefore dichogamous.

for plants as it is for animals. Biologists propose two basic reasons for the frequent occurrence of self-pollinated angiosperms:

1. Self-pollination is ecologically advantageous under certain circumstances because self-pollinators do not need to be visited by animals to produce seed. As a result, self-pollinated plants expend less energy in producing pollinator attractants and can grow in areas where the kinds of insects or other animals that might visit them are absent or very scarce—as in the Arctic or at high elevations.
2. In genetic terms, self-pollination produces progenies that are more uniform than those that result from outcrossing. Remember that because meiosis is involved, recombination still takes place, as described in chapter 11—and therefore the offspring will not be identical to the parent. However, such progenies may contain high proportions of individuals well-adapted to particular habitats.

Self-pollination in normally outcrossing species tends to produce large numbers of ill-adapted individuals because it brings together deleterious recessive alleles—but some of these combinations may be highly advantageous in particular habitats. In these habitats, it may be advantageous for the plant to continue self-pollinating indefinitely.

### Several evolutionary strategies promote outcrossing

Outcrossing, as we have stressed, is critically important for the adaptation and evolution of all eukaryotic organisms, with a few exceptions. Often, flowers contain both stamens and pistils,

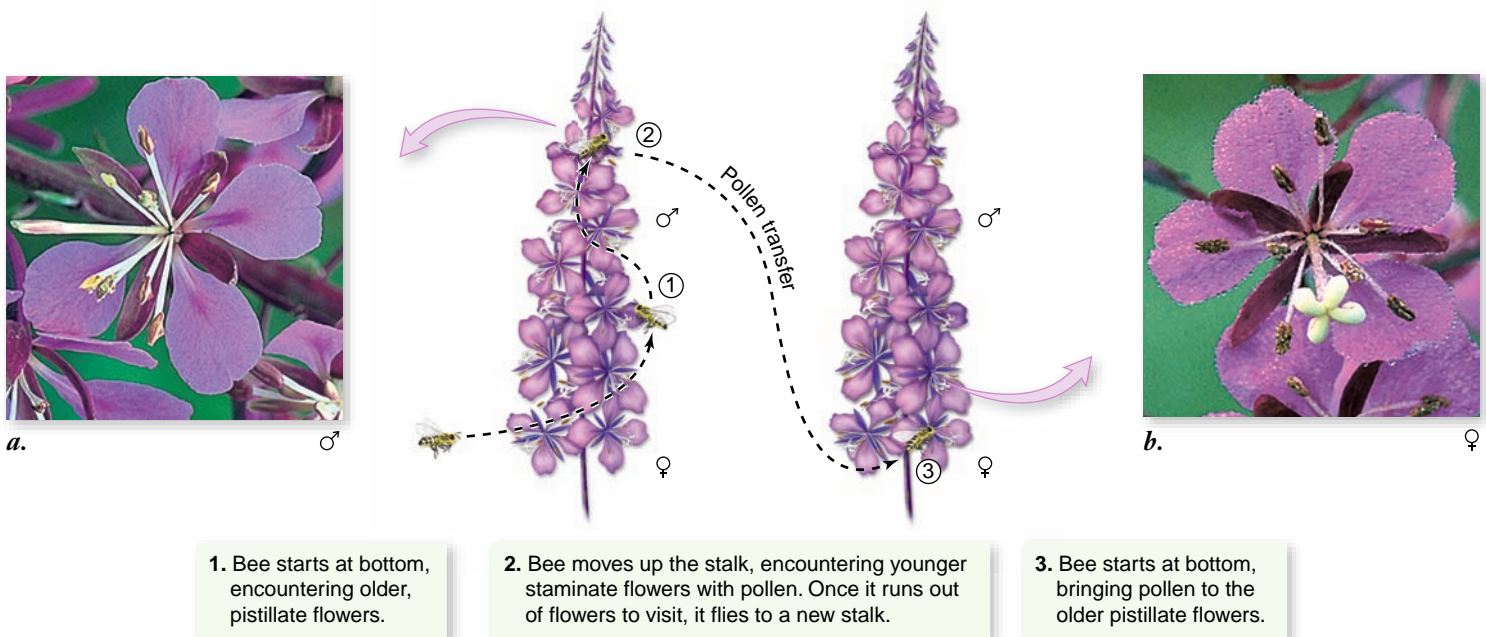

which increases the likelihood of self-pollination. One general strategy to promote outcrossing, therefore, is to separate stamens and pistils. Another strategy involves self-incompatibility that prevents self-fertilization.

### Separation of male and female structures in space or in time

In a number of species—for example, willows and some mulberries—staminate and pistillate flowers may occur on separate plants. Such plants, which produce only ovules or only pollen, are called dioecious, meaning “two houses.” These plants clearly cannot self-pollinate and must rely exclusively on outcrossing. In other kinds of plants, such as oaks, birches, corn (maize), and pumpkins, separate male and female flowers may both be produced on the same plant. Such plants are called **monoecious**, meaning “one house” (see figure 42.25). In monoecious plants, the separation of pistillate and staminate flowers, which may mature at different times, greatly enhances the probability of outcrossing.

Even if, as usually is the case, functional stamens and pistils are both present in each flower of a particular plant species, these organs may reach maturity at different times. Plants in which this occurs are called **dichogamous**. If the stamens mature first, shedding their pollen before the stigmas are receptive, the flower is effectively staminate at that time. Once the stamens have finished shedding pollen, the stigma or stigmas may become receptive, and the flower may become essentially pistillate (see figures 42.26 and 42.27). This separation in time has the same effect as if individuals were dioecious; the outcrossing rate is thereby significantly increased.

Many flowers are constructed such that the stamens and stigmas do not come in contact with each other. With this

1. Bee starts at bottom, encountering older, pistillate flowers.

2. Bee moves up the stalk, encountering younger staminate flowers with pollen. Once it runs out of flowers to visit, it flies to a new stalk.

3. Bee starts at bottom, bringing pollen to the older pistillate flowers.

**Figure 42.27** Dichogamy, as illustrated by the flowers of fireweed, *Epilobium angustifolium*. More than 200 years ago (in the 1790s) fireweed, which is outcrossing, was one of the first plant species to have its process of pollination described. First, the anthers shed pollen, and then the style elongates above the stamens while the four lobes of the stigma curl back and become receptive. Consequently, the flowers are functionally staminate at first, becoming pistillate about two days later. The flowers open progressively up the stem, so that the lowest are visited first, promoting outcrossing. Working up the stem, the bees encounter pollen-shedding, staminate-phase flowers and become covered with pollen, which they then carry to the lower, functionally pistillate flowers of another plant. Shown here are flowers in (a) the staminate phase and (b) the pistillate phase.

arrangement, the natural tendency is for the pollen to be transferred to the stigma of another flower, rather than to the stigma of its own flower, thereby promoting outcrossing.

### Self-incompatibility

Even when a flower's stamens and stigma mature at the same time, genetic self-incompatibility, which is widespread in flowering plants, increases outcrossing. Self-incompatibility results when the pollen and stigma recognize each other as being genetically related, and pollen tube growth is blocked (figure 42.28).

Self-incompatibility is controlled by the *S* (self-incompatibility) locus. Many alleles at the *S* locus regulate recognition responses between pollen and stigma. Researchers have identified two types of self-incompatibility. *Gametophytic self-incompatibility* depends on the haploid *S* locus of the pollen and the diploid *S* locus of the stigma. If either of the *S* alleles in the stigma matches the pollen's *S* allele, pollen tube growth stops before it reaches the embryo sac. Petunias exhibit gametophytic self-incompatibility.

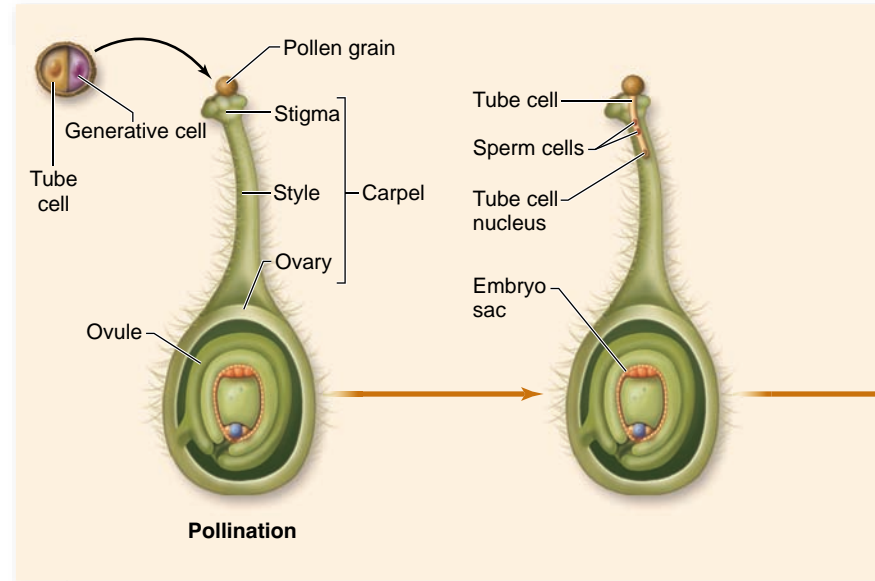

In *sporophytic self-incompatibility*, as occurs in broccoli, both *S* alleles of the pollen parent, not just the *S* allele of the pollen itself, are important. If the alleles in the stigma match either of the pollen parent's *S* alleles, the haploid pollen will not germinate.

Pollen-recognition mechanisms may have originated in a common ancestor of the gymnosperms. Fossils with pollen tubes from the Carboniferous period are consistent with the hypothesis that they had highly evolved pollen-recognition systems.

### Angiosperms undergo double fertilization

Fertilization in angiosperms is a complex, somewhat unusual process in which two sperm cells are utilized in a unique process called double fertilization. Double fertilization results in two key developments: (1) the fertilization of the egg, and (2) the formation of a nutrient substance called endosperm that nourishes the embryo.

Once a pollen grain has been spread by wind, by animals, or through self-pollination, it adheres to the sticky, sugary sub-

stance that covers the stigma and begins to grow a pollen tube that pierces the style (figure 42.29). The pollen tube, nourished by the sugary substance, grows until it reaches the ovule in the ovary. Meanwhile, the generative cell within the pollen tube cell divides to form two sperm cells.

The pollen tube eventually reaches the embryo sac in the ovule. At the entry to the embryo sac, one of the nuclei flanking the egg cell degenerates, and the pollen tube enters that cell. The tip of the pollen tube bursts and releases the two sperm cells. One of the sperm cells fertilizes the egg cell, forming a zygote. The other sperm cell fuses with the two polar nuclei located at the center of the embryo sac, forming the triploid ( $3n$ ) primary endosperm nucleus. The primary endosperm nucleus eventually develops into the endosperm (food supply).

Once fertilization is complete, the embryo develops as its cells divide numerous times. Meanwhile, protective tissues

**Figure 42.28 Genetic control can block self-pollination.** *a.* Gametophytic self-incompatibility is determined by the haploid pollen genotype. *b.* Sporophytic self-incompatibility recognizes the genotype of the diploid pollen parent, not just the haploid pollen genotype. The pollen contains proteins produced by the  $S_1S_2$  parent. In both cases, the recognition is based on the *S* locus, which has many different alleles. The subscript numbers indicate the *S* allele genotype. In gametophytic self-incompatibility, the block comes after pollen tube germination. In sporophytic self-incompatibility, the pollen tube fails to germinate.

**Figure 42.29 The formation of the pollen tube and double fertilization.** When pollen lands on the stigma of a flower, the pollen tube cell grows toward the embryo sac, forming a pollen tube. While the pollen tube is growing, the generative cell divides to form two sperm cells. When the pollen tube reaches the embryo sac, it enters one of the synergids and releases the sperm cells. In a process called double fertilization, one sperm cell nucleus fuses with the egg cell to form the diploid ( $2n$ ) zygote, and the other sperm cell nucleus fuses with the two polar nuclei to form the triploid ( $3n$ ) endosperm nucleus.

enclose the embryo, resulting in the formation of the seed. The seed, in turn, is enclosed in another structure, called the fruit. These typical angiosperm structures evolved in response to the need for seeds to be dispersed over long distances to ensure genetic variability.

### Learning Outcomes Review 42.4

Self-pollination may be favored when pollinators are absent or when plants are adapted to a stable environment, and therefore uniform offspring are advantageous. Mechanisms to promote outcrossing include the production of separate male and female flowers, maturation of male flowers at a different time than female flowers, and genetically controlled self-incompatibility. Double fertilization produces a diploid embryo and triploid endosperm that provides nutrition.

- Are all offspring of a self-pollinating plant identical?

## 42.5 Asexual Reproduction

### Learning Outcomes

1. Define apomixis.
2. List examples of plant parts involved in vegetative reproduction.
3. Outline the steps involved in protoplast regeneration.

Self-pollination reduces genetic variability, but asexual reproduction results in genetically identical individuals because only mitotic cell divisions occur. In the absence of meiosis, individuals that are highly adapted to a relatively unchanging environment persist for the same reasons that self-pollination is favored. Should conditions change dramatically, there will be less variation in the population for natural selection to act on, and the species may be less likely to survive.

Asexual reproduction is also used in agriculture and horticulture to propagate a particularly desirable plant with traits that would be altered by sexual reproduction or even by self-pollination. Most roses and potatoes, for example, are vegetatively (asexually) propagated.

### Apomixis involves development of diploid embryos

In certain plants, including some citruses, certain grasses (such as Kentucky bluegrass), and dandelions, the embryos in the seeds may be produced asexually from the parent plant. This kind of asexual reproduction is known as apomixis. Seeds produced in this way give rise to individuals that are genetically identical to their parents.

Although these plants reproduce by cloning diploid cells in the ovule, they also gain the advantage of seed dispersal, an adaptation usually associated with sexual reproduction. Asexual reproduction in plants is far more common in harsh or marginal environments, where there is little leeway for variation. For example, a greater proportion of asexual plants occur in the Arctic than in temperate regions.

**Figure 42.30 Vegetative reproduction.** Small plants arise from notches along the leaves of the house plant *Kalanchoë daigremontiana*. The plantlets can fall off and grow into new plants, an unusual form of vegetative reproduction.

### In vegetative reproduction, new plants arise from nonreproductive tissues

In a very common form of asexual reproduction called vegetative reproduction, new plant individuals are simply cloned from parts of adults (figure 42.30). The forms of vegetative reproduction in plants are many and varied.

**Runners or stolons.** Some plants reproduce by means of *runners* (also called *stolons*)—long, slender stems that grow along the surface of the soil. In the cultivated strawberry, for example, leaves, flowers, and roots are produced at every other node on the runner. Just beyond

each second node, the tip of the runner turns up and becomes thickened. This thickened portion first produces adventitious roots and then a new shoot that continues the runner.

**Rhizomes.** Underground horizontal stems, or *rhizomes*, are also important reproductive structures, particularly in grasses and sedges. Rhizomes invade areas near the parent plant, and each node can give rise to a new flowering shoot. The noxious character of many weeds results from this type of growth pattern, and many garden plants, such as irises, are propagated almost entirely from rhizomes. Corms and bulbs are vertical underground stems. Tubers are also stems specialized for storage and reproduction. Tubers are the terminal storage portion of a rhizome. Potatoes (*Solanum* spp.) are propagated artificially from tuber segments, each with one or more “eyes.” The eyes, or “seed pieces,” of a potato give rise to the new plant.

**Suckers.** The roots of some plants—for example, cherry, apple, raspberry, and blackberry—produce *suckers*, or sprouts, which give rise to new plants. Commercial varieties of banana do not produce seeds and are propagated by suckers that develop from buds on underground stems. When the root of a dandelion is broken, as it may be if one attempts to pull it from the ground, each root fragment may give rise to a new plant.

**Adventitious plantlets.** In a few plant species, even the leaves are reproductive. One example is the houseplant *Kalanchoë daigremontiana* (see figure 42.30), familiar to many people as the “maternity plant,” or “mother of thousands.” The common names of this plant are based on the fact that numerous plantlets arise from meristematic tissue located in notches along the leaves. The maternity plant is ordinarily propagated by means of these small plants, which, when they mature, drop to the soil and take root.

**Figure 42.31 Protoplast regeneration.** Different stages in the recovery of intact plants from single plant protoplasts of evening primrose. *a.* Individual plant protoplasts. *b.* Regeneration of the cell wall and the beginning of cell division. *c.* Production of somatic cell embryos from the callus. *d.* Recovery of a plantlet from the somatic cell embryo in culture. The plant can later be rooted in soil.

## Plants can be cloned from isolated cells in the laboratory

Whole plants can be cloned by regenerating plant cells or tissues on nutrient medium with growth hormones. This is another form of asexual reproduction. Cultured leaf, stem, and root tissues can undergo organogenesis in culture and form roots and shoots. In some cases, individual cells can also give rise to whole plants in culture.

Individual cells can be isolated from tissues with enzymes that break down cell walls, leaving behind the *protoplast*, a plant cell enclosed only by a plasma membrane. Plant cells have greater developmental plasticity than most vertebrate animal cells, and many, but not all, cell types in plants maintain the ability to generate organs or an entire organism in culture. Consider the limited number of adult stem cells in vertebrates and the challenges associated with cloning discussed in chapter 19.

When single plant cells are cultured, wall regeneration takes place. Cell division follows to form a *callus*, an undifferentiated mass of cells (figure 42.31). Once a callus is formed, whole plants can be produced in culture. Whole-plant development can go through an embryonic stage or can start with the formation of a shoot or root.

Tissue culture has many agricultural and horticultural applications. Virus-free raspberries and sugarcane can be propagated by culturing meristems, which are generally free of viruses, even in an infected plant. As with other forms of asexual reproduction, genetically identical individuals can be propagated.

### Learning Outcomes Review 42.5

In apomixis, embryos are produced by mitosis rather than fertilization; in contrast, asexual vegetative reproduction occurs from vegetative plant parts. Examples include runners, stolons, rhizomes, suckers, and adventitious plant parts. In the laboratory, protoplasts are produced by isolating cells and removing the cell walls. Inducing mitosis results in a cluster of undifferentiated cells called a callus, which can then be stimulated to differentiate into a plant.

- Under what conditions would vegetative reproduction benefit survival?

## 42.6 Plant Life Spans

### Learning Outcomes

1. Distinguish between herbaceous and woody perennials.
2. Define perennial and annual plants.
3. Describe the life cycle of a biennial plant.

Once established, plants live for highly variable periods of time, depending on the species. Life span may or may not correlate with reproductive strategy. Woody plants, which have extensive secondary growth, nearly always live longer than herbaceous plants, which have limited or no secondary growth. Bristlecone pine, for example, can live upward of 4000 years.

a.

b.

**Figure 42.32 Annual and perennial plants.** Plants live for very different lengths of time. *a.* Desert annuals complete their entire life span in a few weeks, flowering just once. *b.* Some trees, such as the giant redwood (*Sequoiadendron giganteum*), which occurs in scattered groves along the western slopes of the Sierra Nevada in California, live 2000 years or more, and flower year after year.

Some herbaceous plants send new stems above the ground every year, producing them from woody underground structures. Others germinate and grow, flowering just once before they die. Shorter-lived plants rarely become very woody because there is not enough time for secondary tissues to accumulate. Depending on the length of their life cycles, herbaceous plants may be annual, biennial, or perennial, whereas woody plants are generally perennial (figure 42.32).

Determining life span is even more complicated for clonally reproducing organisms. Aspen trees (*Populus tremuloides*) form huge clones from asexual reproduction of their roots. Collectively, an aspen clone may form the largest “organism” on Earth. Other asexually reproducing plants may cover less territory but live for thousands of years. Creosote bushes (*Larrea tridentata*) in the Mojave Desert have been identified that are up to 12,000 years old!

### Perennial plants live for many years

**Perennial plants** continue to grow year after year and may be herbaceous (as are many woodland, wetland, and prairie wildflowers), or woody (as are trees and shrubs). The majority of vascular plant species are perennials. Perennial plants in general are able to flower and produce seeds and fruit for an indefinite number of growing seasons.

Herbaceous perennials rarely experience any secondary growth in their stems; the stems die each year after a period of relatively rapid growth and food accumulation. Food is often stored in the plants’ roots or underground stems, which can

become quite large in comparison with their less substantial aboveground counterparts.

Trees and shrubs generally flower repeatedly, but there are exceptions. Bamboo lives for many seasons as a nonreproducing plant, but senesces and dies after flowering. The same is true for at least one tropical tree (*Tachigali versicolor*), which achieves great heights before flowering and senescing. Considering the tremendous amount of energy that goes into the growth of a tree, this particular reproductive strategy is quite curious.

Trees and shrubs are either *deciduous*, with all the leaves falling at one particular time of year and the plants remaining bare for a period, or *evergreen*, with the leaves dropping throughout the year and the plants never appearing completely bare. In northern temperate regions, conifers are the most familiar evergreens, but in tropical and subtropical regions, most angiosperms are evergreen, except where there is severe seasonal drought. In these areas, many angiosperms are deciduous, losing their leaves during the drought and thus conserving water.

## Annual plants grow, reproduce, and die in a single year

Annual plants grow, flower, and form fruits and seeds within one growing season and die when the process is complete. Many crop plants are annuals, including corn, wheat, and soybeans. Annuals generally grow rapidly under favorable conditions and in proportion to the availability of water or nutrients. The lateral meristems of some annuals, such as sunflowers or giant ragweed, do produce some secondary tissues for support, but most annuals are entirely herbaceous.

Annuals typically die after flowering once; the developing flowers or embryos use hormonal signaling to reallocate nutrients, so the parent plant literally starves to death. This can be demonstrated by comparing a population of bean plants in

which the beans are continually picked with a population in which the beans are left on the plant. The frequently picked population will continue to grow and yield beans much longer than the untouched population. The process that leads to the death of a plant is called **senescence**.

## Biennial plants follow a two-year life cycle

**Biennial plants**, which are much less common than annuals, have life cycles that take two years to complete. During the first year, biennials store the products of photosynthesis in underground storage organs. During the second year of growth, flowering stems are produced using energy stored in the underground parts of the plant. Certain crop plants, including carrots, cabbage, and beets, are biennials, but these plants generally are harvested for food during their first season, before they flower. They are grown for their leaves or roots, not for their fruits or seeds.

Wild biennials include evening primroses, Queen Anne's lace (*Daucus carota*), and mullein (*Verbascum thapsis*). Many plants that are considered biennials actually do not flower until they are three or more years of age, but all biennial plants flower only once before they die.

### Learning Outcomes Review 42.6

Woody perennials produce secondary growth, but herbaceous perennials typically do not. Perennial plants continue to grow year after year, whereas annual plants die after one growing season. During the first year of a biennial plant life cycle, food is produced and stored in underground storage organs. During the second year of growth, the stored energy is used to produce flowering stems.

- *What are the advantages and disadvantages of a biennial life cycle compared to an annual cycle?*

## Chapter Review

### 42.1 Reproductive Development

Plant life cycles are characterized by an alternation of generations.

**The transition to flowering competence is termed phase change.**

Phase change prepares a plant to respond to external and internal signals to begin flowering. External factors include light and temperature, and internal factors include hormone production.

**Mutations have clarified how phase change is controlled.**

In experiments with *Arabidopsis*, plants that flower earlier than normal result from mutations in phase change genes. The implication is that mechanisms have evolved to delay flowering.

### 42.2 Flower Production

Four genetically regulated pathways to flowering have been identified. The balance between floral-promoting and floral-inhibiting signals regulates flowering.

**The light-dependent pathway is geared to the photoperiod.**

The light-dependent pathway induces flowering based on the length of the dark period a plant experiences during 24 hr. Plants may be short-day, long-day, or day-neutral, depending on their flowering response.

**The temperature-dependent pathway is linked to cold.**

Some plants require vernalization, or exposure of seeds or plants to chilling in order to induce flowering.

**The gibberellin-dependent pathway requires an increased hormone level.**

Decreased levels of gibberellins delay flowering in plants with this pathway. Gibberellins likely affect phase-change gene expression.

**The autonomous pathway is independent of environmental cues.**

The autonomous pathway is typical of day-neutral plants. A balance between floral-promoting and floral-inhibiting signals controls flower development.

### **Floral meristem identity genes activate floral organ identity genes.**

Once floral organ identity genes are turned on, the four floral organs develop according to the ABC model. Class *A* genes alone specify sepals, classes *A* and *B* together specify petals, classes *B* and *C* specify stamens, and class *C* genes alone specify carpels.

## **42.3 Structure and Evolution of Flowers**

### **Flowers evolved in the angiosperms.**

Floral organs are believed to have evolved from leaves.

Complete flowers have four whorls corresponding to the four floral organs: the calyx, corolla, androecium, and gynoecium. Incomplete flowers lack one or more of the whorls.

Angiosperms may have radially or bilaterally symmetrical flowers.

### **Gametes are produced in the gametophytes of flowers.**

Meiosis in the anthers produces microspores, which undergo mitosis to produce pollen grains, which are the male gametophytes or microgametophytes.

Each pollen grain contains the generative cell that later divides to produce two sperm cells and a tube cell.

Meiosis in the ovules produces megaspores, which undergo mitosis to produce embryo sacs, which are the female gametophytes or megagametophytes.

The embryo sac contains seven cells, one of which is the egg cell and one of which contains two polar nuclei. The latter cell develops into triploid endosperm after fertilization.

## **42.4 Pollination and Fertilization**

### **Early seed plants were wind-pollinated.**

Wind-pollination is a passive process and does not carry pollen over long distances. Consequently, plants must be relatively close together to ensure that pollination occurs.

### **Flowers and animal pollinators have coevolved.**

Animal pollinators provide an efficient transfer of pollen that may cover long distances. Animal-pollinated flowers produce odors and visual cues to guide pollinators.

### **Some flowering plants continue to use wind pollination.**

Many wind-pollinated plant species have male and female flowers on separate individuals or on separate parts of each individual. The flowers are grouped in large numbers and exposed to the wind.

### **Self-pollination is favored in stable environments.**

Plants adapted to a stable environment benefit from having uniform progeny that are likely to be more successful than those arising from

cross-pollination. Offspring from self-pollination are not genetically identical, however.

Self-pollination is also favored where animal pollinators are scarce.

### **Several evolutionary strategies promote outcrossing.**

Outcrossing is promoted in plants in which male and female flowers are physically separated on the same plant or on different plants, or in which the two flowers mature on a different schedule.

Self-incompatibility prevents self-fertilization by preventing pollen tube growth.

### **Angiosperms undergo double fertilization.**

Double fertilization produces a diploid zygote and triploid endosperm that provides nourishment to the zygote.

## **42.5 Asexual Reproduction**

Asexual reproduction results in genetically identical individuals because progeny are produced by mitosis.

### **Apomixis involves development of diploid embryos.**

Apomixis is the production of embryos by mitosis rather than fertilization. These embryos develop in seeds.

### **In vegetative reproduction, new plants arise from nonreproductive tissues.**

Vegetative parts such as runners, rhizomes, suckers, and adventitious plantlets may give rise to new individual clones.

### **Plants can be cloned from isolated cells in the laboratory.**

Stripping away the cell wall produces a protoplast, which can then be induced to undergo mitosis to produce a callus. With the proper treatments, the callus can differentiate into a complete plant.

## **42.6 Plant Life Spans**

### **Perennial plants live for many years.**

Perennials live for years, although they may undergo dormancy.

### **Annual plants grow, reproduce, and die in a single year.**

Many crop plants are annuals and require replanting every year, such as corn, wheat, and soy beans.

### **Biennial plants follow a two-year life cycle.**

During the first year, biennials grow and store nutrients. In the second year, they produce flowers and seeds. Biennial crop plants are often harvested during the first year, such as carrots.

## **Review Questions**

### **UNDERSTAND**

- Morphogenesis is the development of
  - growth form.
  - reproductive structures.
  - a phase change.
  - meristems.
- Vernalization induces flowering following exposure to
  - water.
  - drought.
  - cold.
  - heat.
- Photoperiod is perceived by
  - phytochrome and cryptochrome.
  - phytochrome and chlorophyll.
  - cryptochrome and chlorophyll.
  - phytochrome, cryptochrome, and chlorophyll.
- Which of the following is not a component of a flower?
  - Sepal
  - Stamen
  - Carpel
  - Bract

5. Megaspores are produced in
    - a. anthers by mitosis.
    - b. anthers by meiosis.
    - c. ovules by mitosis.
    - d. ovules by meiosis.
  6. A stamen contains a
    - a. style.
    - b. stigma.
    - c. filament.
    - d. carpel.
  7. Unlike bee-pollinated flowers, bird-pollinated flowers
    - a. produce a strong fragrance.
    - b. contain a landing pad.
    - c. produce a bull's-eye pattern.
    - d. are red.
  8. Asexual reproduction is likely to be most common in which ecosystem?
    - a. Tropical rainforest
    - b. Temperate grassland
    - c. Arctic tundra
    - d. Deciduous forest
  9. Protoplasts are plant cells that lack
    - a. nuclei.
    - b. cell walls.
    - c. plasma membranes.
    - d. protoplasm.
  10. Perennial plants are
    - a. always herbaceous.
    - b. always woody.
    - c. either herbaceous or woody.
    - d. neither herbaceous nor woody.
  11. Senescence refers to
    - a. plant death.
    - b. reproductive growth.
    - c. pollination.
    - d. the accumulation of storage reserves.
4. Monoecious plants such as corn have either staminate or carpelate flowers. Knowing what you do about the molecular mechanisms of floral development, which of the following might explain the development of single-sex flowers?
    - a. Expression of *B*-type genes in the presumptive carpel whorl will generate staminate flowers.
    - b. Loss of *A*-type genes in the presumptive petal whorl will allow *C*-type and *B*-type genes to produce stamens instead of petals in that whorl.
    - c. Restricting *B*-type gene expression to the presumptive petal whorl will generate carpelate flowers.
    - d. All of these are correct.
  5. One of the most notable differences between gamete formation in most animals and gamete formation in plants is that
    - a. plants produce gametes in somatic tissue, whereas animals produce gametes in germ tissue.
    - b. plants produce gametes by mitosis, whereas animals produce gametes by meiosis.
    - c. plants produce only one of each gamete, but animals produce many gametes.
    - d. plants produce gametes that are diploid, but animals produce gametes that are haploid.

## APPLY

1. Under which of the following conditions would pollen from an  $S_2S_3$  plant successfully pollinate an  $S_1S_5$  flower?
  - a. Using pollen from a carpelate flower to fertilize a staminate flower would be successful.
  - b. If the plants used gametophytic self-incompatibility, half of the pollen would be successful.
  - c. If the plants used sporophytic self-incompatibility, half of the pollen would be successful.
  - d. Pollen from an  $S_2S_3$  plant can never pollinate an  $S_1S_5$  flower.
2. Your roommate is taking biology with you this semester and thinks he understands short- and long-day plants. He purchases one plant of each type and decides to see the difference himself by first trying to cause the short-day plant to flower. He places both plants under the same conditions and exposes each to a regimen of 10-hr days, expecting that the short-day plant will flower, and the long-day plant will not. You play a trick on your roommate and reverse the outcome. Specifically, what did you have to do?
  - a. Lengthen the time each is exposed to light
  - b. Shorten the time each is exposed to light
  - c. Quickly expose the plants to light during the middle of the night
  - d. None of the above
3. In Iowa, a company called Team Corn works to ensure that fields of seed corn outcross so that hybrid vigor can be maintained. They do this by removing the staminate (that is, pollen-producing) flowers from the corn plants. In an attempt to put Team Corn out of business, you would like to develop genetically engineered corn plants that
  - a. contain *Z* genes to prevent germination of pollen on the stigmatic surface.

## SYNTHESIZE

1. A commercial greenhouse in a remote location produces poinsettias. However, after a highway is built near the greenhouse, the poinsettias fail to flower. Explain what has happened.
2. If you live in a north temperate region, explain why it is advantageous to grow spinach for your salad in early spring rather than during the summer.
3. In wild columbine, flower morphology encourages cross-pollination. However, during the middle of the receptive period of the stigma, self-pollination can occur if the flower was not previously pollinated. If cross-pollination occurs after self-pollination, then that pollen reaches the base of the style before the self-pollen. Discuss the adaptive significance of this reproduction strategy.
4. In most parts of the world, commercial potato crops are produced asexually by planting tubers. However, in some regions of the world, such as Southeast Asia and the Andes, some potatoes are grown from true seeds. Discuss the advantages and disadvantages of growing potatoes from true seed.

# Chapter 43

## The Animal Body and Principles of Regulation

### Chapter Outline

- 43.1 Organization of the Vertebrate Body
- 43.2 Epithelial Tissue
- 43.3 Connective Tissue
- 43.4 Muscle Tissue
- 43.5 Nerve Tissue
- 43.6 Overview of Vertebrate Organ Systems
- 43.7 Homeostasis
- 43.8 Regulating Body Temperature

### Introduction

When people think of animals, they may think of pet dogs and cats, the animals in a zoo, on a farm, in an aquarium, or wild animals living outdoors. When thinking about the diversity of animals, people may picture the differences between the predatory lions and tigers and the herbivorous deer and antelope, or between a dangerous shark and a playful dolphin. Despite the differences among these animals, they are all vertebrates. All vertebrates share the same basic body plan, with similar tissues and organs that operate in much the same way. The micrograph shows a portion of the duodenum, part of the digestive system, which is made up of multiple types of tissues. In this chapter, we begin a detailed consideration of the biology of the vertebrates and the fascinating structure and function of their bodies. We conclude this chapter by exploring the principles involved in regulation and control of complex functional systems.

## 43.1 Organization of the Vertebrate Body

### Learning Outcomes

1. List the levels of organization in the vertebrate body.
2. Identify the tissue types found in vertebrates.
3. Describe how body cavities are organized.

The vertebrate body has four levels of organization: (1) cells, (2) tissues, (3) organs, and (4) organ systems. Like those of all animals, the bodies of vertebrates are composed of different cell types. Depending on the group, between 50 and several hundred different kinds of cells contribute to the adult vertebrate body. Humans have 210 different types of cells.

### Tissues are groups of cells of a single type and function

Groups of cells that are similar in structure and function are organized into *tissues*. Early in development, the cells of the growing embryo differentiate into the three fundamental embryonic tissues, called **germ layers**. From the innermost to the outermost layers, these are the *endoderm*, *mesoderm*, and *ectoderm*. Each germ layer, in turn, differentiates into the scores of different cell types and tissues that are characteristic of the vertebrate body.

In adult vertebrates, there are four principal kinds of tissues, or **primary tissues**: (1) **epithelial**, (2) **connective**, (3) **muscle**, and (4) **nerve tissue**. Each type is discussed in separate sections of this chapter.

### Organs and organ systems provide specialized functions

*Organs* are body structures composed of several different types of tissues that form a structural and functional unit (figure 43.1). One example is the heart, which contains cardiac muscle, connective tissue, and epithelial tissue. Nerve tissue connects the brain and spinal cord to the heart and helps regulate the heartbeat.

An **organ system** is a group of organs that cooperate to perform the major activities of the body. For example, the circulatory system is composed of the heart and blood vessels (arteries, capillaries, and veins) (see chapter 50). These organs cooperate in the transport of blood and help distribute substances about the body. The vertebrate body contains 11 principal organ systems.

### The general body plan of vertebrates is a tube within a tube, with internal support

The bodies of all vertebrates have the same general architecture. The body plan is essentially a tube suspended within a tube. The inner tube is the digestive tract, a long tube that travels from the mouth to the anus. An internal skeleton made of jointed bones or cartilage that grows as the body grows supports the outer tube, which forms the main vertebrate body. The outermost layer of the vertebrate body is the integument, or skin, and its many accessory organs and parts—hair, feathers, scales, and sweat glands.

### Vertebrates have both dorsal and ventral body cavities

Inside the main vertebrate body are two identifiable cavities. The *dorsal body cavity* forms within a bony skull and a column of bones, the vertebrae. The skull surrounds the brain, and within the stacked vertebrae is a channel that contains the spinal cord.

The *ventral body cavity* is much larger and extends anteriorly from the area bounded by the rib cage and vertebral column posteriorly to the area contained within the ventral body muscles (the abdominals) and the pelvic girdle. In mammals, a sheet of muscle, the diaphragm, breaks the ventral body cavity anteriorly into the *thoracic cavity*, which contains the heart and lungs, and posteriorly into the *abdominopelvic cavity*, which contains many organs, including the stomach, intestines, liver, kidneys, and urinary bladder (figure 43.2a).

Recall from the discussion of the animal body plan in chapter 32 that a coelom is a fluid-filled body cavity completely formed within the embryonic mesoderm layer of some animals

**Figure 43.1 Levels of organization within the body.** Similar cell types operate together and form tissues. Tissues functioning together form organs such as the heart, which is composed primarily of cardiac muscle with a lining of epithelial tissue. An organ system consists of several organs working together to carry out a function for the body. An example of an organ system is the circulatory system, which consists of the heart, blood vessels, and blood.

## 43.2 Epithelial Tissue

(vertebrates included). The coelom is present in vertebrates, but compared to invertebrates it is constricted, folded, and subdivided. The mesodermal layer that lines the coelom extends from the body wall to envelop and suspend several organs within the ventral body cavity (figure 43.2*b*). In the abdominopelvic cavity, the coelomic space is the *peritoneal cavity*.

In the thoracic cavity, the heart and lungs invade and greatly constrict the coelomic space. The thin space within mesodermal layers around the heart is the **pericardial cavity**, and the two thin spaces around the lungs are the **pleural cavities** (figure 43.2*b*).

### Learning Outcomes Review 43.1

The body's cells are organized into tissues, which in turn are organized into organs and organ systems. The main types of tissues in vertebrates are epithelial, connective, muscle, and nerve tissue. The bodies of humans and other mammals contain dorsal and ventral cavities. The ventral cavity is divided by the diaphragm into thoracic and abdominopelvic cavities. The adult coelom subdivides into the peritoneal, pericardial, and pleural cavities.

- Can an organ be made of more than one tissue?

### Learning Outcomes

1. Describe the structure and function of an epithelium.
2. Identify the cell types found in an epithelial membrane.
3. Explain the structure and function of different epithelia.

An epithelial membrane, or **epithelium** (plural, *epithelia*), covers every surface of the vertebrate body. Epithelial membranes can come from any of the three germ layers. For example, the epidermis, derived from ectoderm, constitutes the outer portion of the skin. An epithelium derived from endoderm lines the inner surface of the digestive tract, and the inner surfaces of blood vessels derive from mesoderm. Some epithelia change in the course of embryonic development into glands, which are specialized for secretion.

**Figure 43.2 Architecture of the vertebrate body.** *a.* All vertebrates have dorsal and ventral body cavities. The dorsal cavity divides into the cranial (contains the brain) and vertebral (contains the spinal cord) cavities. In mammals, a muscular diaphragm divides the ventral cavity into the thoracic and abdominopelvic cavities. *b.* Cross sections through three body regions show the relationships between body cavities, major organs, and coeloms (pericardial, pleural, and peritoneal cavities).

*a.*

*b.*

## Epithelium forms a barrier

Because epithelial membranes cover all body surfaces, a substance must pass through an epithelium in order to enter or leave the body. Epithelial membranes thus provide a barrier that can impede the passage of some substances while facilitating the passage of others. For land-dwelling vertebrates, the relative impermeability of the surface epithelium (the epidermis) to water offers essential protection from dehydration and from airborne pathogens. The epithelial lining of the digestive tract, in contrast, must allow selective entry of the products of digestion while providing a barrier to toxic substances. The epithelium of the lungs must allow for the rapid diffusion of gases into and out of the blood.

A characteristic of all epithelia is that the cells are tightly bound together, with very little space between them. Nutrients and oxygen must diffuse to the epithelial cells from blood vessels supplying underlying connective tissues. This places a limit on the thickness of epithelial membranes; most are only one or a few cell layers thick.

### Epithelial regeneration

Epithelium possesses remarkable regenerative powers, constantly replacing its cells throughout the life of the animal. For example, the liver, a gland formed from epithelial tissue, can readily regenerate, even after surgical removal of substantial portions. The epidermis renews every two weeks, and the epithelium inside the stomach is completely replaced every two to three days. This ability to regenerate is useful in a surface tissue because it constantly renews the surface and also allows quick replacement of the protective layer should damage or injury occur.

### Structure of epithelial tissues

Epithelial tissues attach to underlying connective tissues by a fibrous membrane. The secured side of the epithelium is called the *basal surface*, and the free side is the *apical surface*. This difference gives epithelial tissues an inherent polarity, which is often important in the function of the tissue. For example, proteins stud the basal surfaces of some epithelial tissues in the kidney tubules; these proteins actively transport  $\text{Na}^+$  into the intercellular spaces, creating an osmotic gradient that helps return water to the blood (see chapter 51).

## Epithelial types reflect their function

The two general classes of epithelial membranes are termed *simple* (single layer of cells) and *stratified* (multiple layers of cells). These classes are further subdivided into squamous, cuboidal, and columnar, based on the shape of the cells (table 43.1). *Squamous cells* are flat, *cuboidal cells* are about as wide as they are tall, and *columnar cells* are taller than they are wide.

### Simple epithelium

As mentioned, *simple epithelial membranes* are one cell thick. A simple squamous epithelium is composed of squamous epithelial cells that have a flattened shape when viewed in cross section. Examples of such membranes are those that line the lungs and blood capillaries, where the thin, delicate nature of these membranes permits the rapid movement of molecules (such as the diffusion of gases).

A simple cuboidal epithelium lines kidney tubules and several glands. In the case of glands, these cells are specialized for secretion.

A simple columnar epithelium lines the airways of the respiratory tract and the inside of most of the gastrointestinal tract, among other locations. Interspersed among the columnar epithelial cells of mucous membranes are numerous *goblet cells*, which are specialized to secrete mucus. The columnar epithelial cells of the respiratory airways contain cilia on their apical surface (the surface facing the lumen, or cavity), which move mucus and dust particles toward the throat. In the small intestine, the apical surface of the columnar epithelial cells forms fingerlike projections called *microvilli*, which increase the surface area for the absorption of food.

The expanded size of both cuboidal and columnar cells accommodates the added intracellular machinery needed for production of glandular secretions, active absorption of materials, or both. The glands of vertebrates form from invaginated epithelia. In **exocrine glands**, the connection between the gland and the epithelial membrane remains as a duct. The duct channels the product of the gland to the surface of the epithelial membrane, and thus to the external environment (or to an interior compartment that opens to the exterior, such as the digestive tract). A few examples of exocrine glands include sweat and sebaceous (oil) glands as well as the salivary glands. **Endocrine glands** are ductless glands; their connections with the epithelium from which they are derived has been lost during development. Therefore, their secretions (hormones) do not channel onto an epithelial membrane. Instead, hormones enter blood capillaries and circulate through the body. Endocrine glands are covered in more detail in chapter 46.

### Stratified epithelium

**Stratified epithelial membranes** are two to several cell layers thick and are named according to the features of their apical cell layers. For example, the epidermis is a *stratified squamous epithelium*; its properties are discussed in chapter 52. In terrestrial vertebrates, the epidermis is further characterized as a *keratinized epithelium* because its upper layer consists of dead squamous cells and is filled with a water-resistant protein called *keratin*.

The deposition of keratin in the skin increases in response to repeated abrasion, producing calluses. The water-resistant property of keratin is evident when comparing the skin of the face to the red portion of the lips, which can easily become dried and chapped. Lips are covered by a nonkeratinized, stratified squamous epithelium.

### Learning Outcomes Review 43.2

Epithelial tissues generally form barriers and include membranes that cover all body surfaces and glands. An epidermis has a basal surface that attaches to an underlying connective tissue and an apical surface that is free. Some epithelia are specialized for protection, whereas those that cover the surfaces of hollow organs may be specialized for transport and secretion. Simple epithelium has a single cell layer and may be classified as squamous, cuboidal, columnar, or pseudostratified; stratified epithelium is primarily squamous.

- How does the epithelium in a gland function differently from that in the lining of your gut?

**TABLE 43.1**

**Epithelial Tissue**

*S I M P L E E P I T H E L I U M*

**Squamous**

*Typical Location*

Lining of lungs, capillary walls, and blood vessels

*Function*

Cells form thin layer across which diffusion can readily occur

*Characteristic Cell Types*

Epithelial cells

**Cuboidal**

*Typical Location*

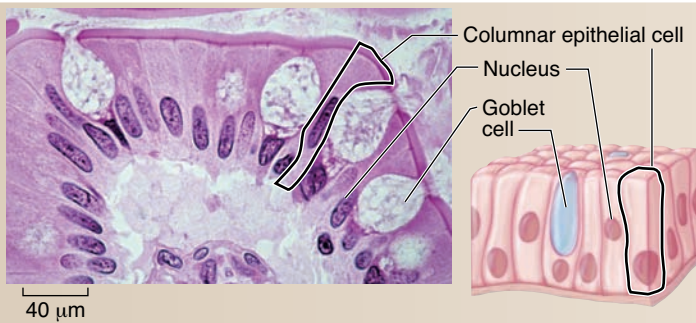

Lining of some glands and kidney tubules; covering of ovaries

*Function*

Cells rich in specific transport channels; functions in secretion and absorption

*Characteristic Cell Types*

Gland cells

**Columnar**

*Typical Location*

Surface lining of stomach, intestines, and parts of respiratory tract

*Function*

Thicker cell layer; provides protection and functions in secretion and absorption

*Characteristic Cell Types*

Epithelial cells

**Pseudostratified Columnar**

*Typical Location*

Lining of parts of the respiratory tract

*Function*

Secretes mucus; dense with cilia that aid in movement of mucus; provides protection

*Characteristic Cell Types*

Gland cells; ciliated epithelial cells

*S T R A T I F I E D E P I T H E L I U M*

**Squamous**

*Typical Location*

Outer layer of skin; lining of mouth

*Function*

Tough layer of cells; provides protection

*Characteristic Cell Types*

Epithelial cells

## 43.3 Connective Tissue

### Learning Outcomes

1. Describe the structure and function of connective tissue.
2. Identify the different kinds of connective tissue.
3. List the cells that make connective tissue.

Connective tissues derive from embryonic mesoderm and occur in many different forms (table 43.2). We divide these various forms into two major classes: *connective tissue proper*, which further divides into loose and dense connective tissues, and **special connective tissues**, which include cartilage, bone, and blood.

At first glance, it may seem odd that such diverse tissues are in the same category. Yet all connective tissues share a common structural feature: They all have abundant extracellular material because their cells are spaced widely apart. This extracellular material is called the **matrix** of the tissue. In bone, the matrix contains crystals that make the bones hard; in blood, the matrix is plasma, the fluid portion of the blood. The matrix itself consists of protein fibers and **ground substance**, the fluid material between cells and fibers containing a diverse array of proteins and polysaccharides.

### Connective tissue proper may be either loose or dense

During the development of both loose and dense connective tissues, cells called fibroblasts produce and secrete the extracellular matrix. Loose connective tissue contains other cells as well, including mast cells and macrophages—cells of the immune system.

#### Loose connective tissue

**Loose connective tissue** consists of cells scattered within a matrix that contains a large amount of ground substance. This gelatinous material is strengthened by a loose scattering of protein fibers such as collagen, which supports the tissue by forming a meshwork (figure 43.3), elastin, which makes the tissue elastic, and reticulin, which helps support the network of collagen. The flavored gelatin of certain desserts consists primarily of extracellular material extracted from the loose connective tissues of animals.

**Adipose cells**, more commonly termed fat cells, are important for nutrient storage, and they also occur in loose connective tissue. In certain areas of the body, including under the skin, in bone marrow, and around the kidneys, these cells can develop in large groups, forming **adipose tissue** (figure 43.4).

Each adipose cell contains a droplet of triglycerides within a storage vesicle. When needed for energy, the adipose cell hydrolyzes its stored triglyceride and secretes fatty acids into the blood for oxidation by the cells of the muscles, liver, and other organs. Adipose cells cannot divide; the number of adipose cells in an adult is generally fixed. When a person gains

**Figure 43.3 Collagen fibers.** These fibers, shown under an electron microscope, are composed of many individual collagen strands and can be very strong under tension.

weight, the cells become larger, and when weight is lost, the cells shrink.

#### Dense connective tissue

**Dense connective tissue**, with less ground substance, contains tightly packed collagen fibers, making it stronger than loose connective tissue. It consists of two types: regular and irregular. The collagen fibers of *dense regular connective tissue* line up in parallel, like the strands of a rope. This is the structure of tendons, which bind muscle to bone, and ligaments, which bind bone to bone.

In contrast, the collagen fibers of *dense irregular connective tissue* have many different orientations. This type of connective tissue produces the tough coverings that package organs, such as the capsules of the kidneys and adrenal glands. It also covers muscle, nerves, and bones.

### Special connective tissues have unique characteristics

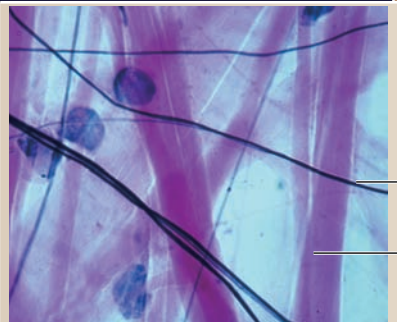

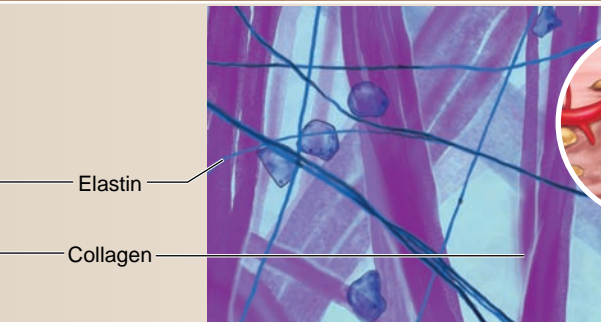

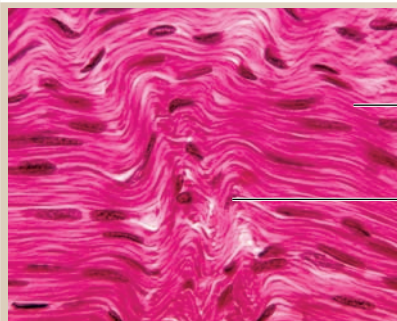

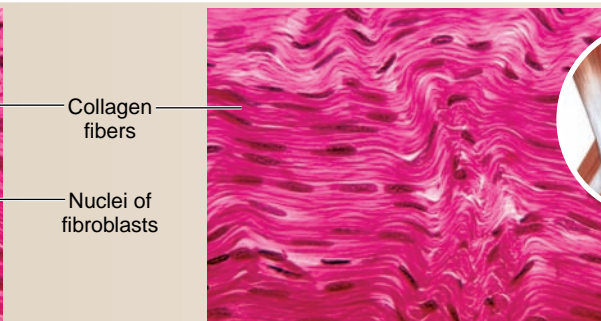

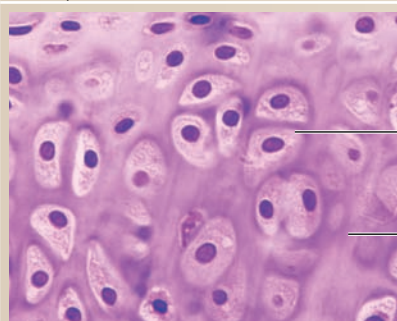

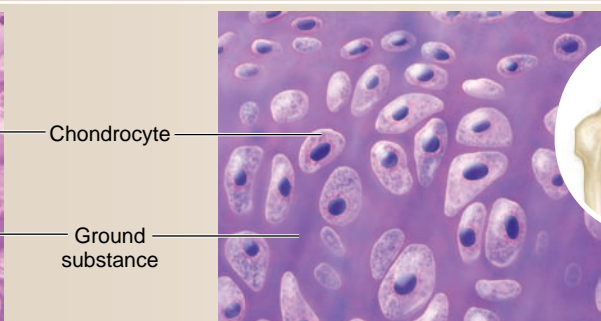

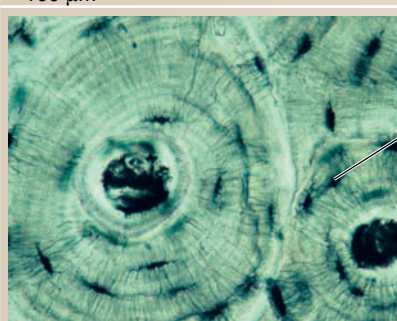

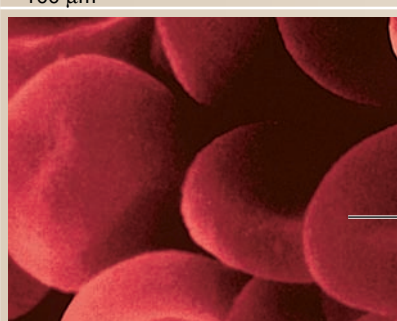

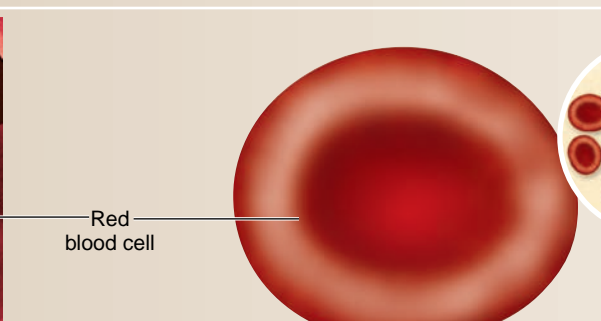

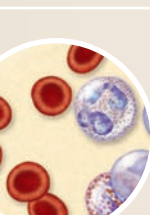

The special connective tissues—cartilage, bone, and blood—each have unique cells and matrices that allow them to perform their specialized functions.

**Figure 43.4 Adipose tissue.** Fat is stored in globules of adipose tissue, a type of loose connective tissue. As a person gains or loses weight, the size of the fat globules increases or decreases. A person cannot decrease the number of fat cells by losing weight.

## Cartilage

**Cartilage** (see table 43.2) is a specialized connective tissue in which the ground substance forms from a characteristic type of glycoprotein, called *chondroitin*, and collagen fibers laid down along lines of stress in long, parallel arrays. The result is a firm and flexible tissue that does not stretch, is far tougher than loose or dense connective tissue, and has great tensile strength.

Cartilage makes up the entire skeletal system of the modern agnathans and cartilaginous fishes (see chapter 35). In most adult vertebrates, however, cartilage is restricted to the joint surfaces of bones that form freely movable joints and certain other locations. In humans, for example, the tip of the nose, the outer ear, the intervertebral disks of the backbone, the larynx, and a few other structures are composed of cartilage.

*Chondrocytes*, the cells of cartilage, live within spaces called **lacunae** within the cartilage ground substance. These cells remain alive even though there are no blood vessels within the cartilage matrix; they receive oxygen and nutrients by diffusion through the cartilage ground substance from surrounding blood vessels. This diffusion can only occur because the cartilage matrix is well hydrated and not calcified, as is bone.

## Bone

Bone cells, or **osteocytes**, remain alive even though the extracellular matrix becomes hardened with crystals of calcium phosphate. Blood vessels travel through central canals into the bone, providing nutrients and removing wastes. Osteocytes extend cytoplasmic processes toward neighboring osteocytes through tiny canals, or *canaliculi*. Osteocytes communicate with the blood vessels in the central canal through this cytoplasmic network. Bone is described in more detail in chapter 47 along with muscle.

In the course of fetal development, the bones of vertebrate fins, arms, and legs, among other appendages, are first “modeled” in cartilage. The cartilage matrix then calcifies at particular locations, so that the chondrocytes are no longer able to obtain oxygen and nutrients by diffusion through the matrix. Living bone replaces the dying and degenerating cartilage.

## Blood

We classify *blood* as a connective tissue because it contains abundant extracellular material, the fluid plasma. The cells of blood are *erythrocytes*, or red blood cells, and *leukocytes*, or white blood cells. Blood also contains platelets, or *thrombocytes*, which are fragments of a type of bone marrow cell. We discuss blood more fully in chapter 50.

## All connective tissues have similarities

Although the descriptions of the types of connective tissue suggest numerous different functions for these tissues, they have some similarities. As mentioned, connective tissues originate as embryonic mesoderm, and they all contain abundant extracellular material called matrix; however, the extracellular matrix material is different in different types of connective tissue. Embedded within the extracellular matrix of each tissue type are varieties of cells, each with specialized functions.

### Learning Outcomes Review 43.3

Connective tissues are characterized by abundant extracellular materials forming a matrix between loosely organized cells. Connective tissue proper is classified as either loose or dense. Special connective tissues have unique extracellular matrices between cells. The matrix of cartilage is composed of organic materials, whereas that of bones is calcium crystals. The matrix of blood is a fluid, the plasma.

- *Why is blood considered connective tissue?*

## 43.4 Muscle Tissue

### Learning Outcomes

1. *Identify the unique features of muscle cells.*
2. *Describe the three kinds of muscle and muscle cells.*

Muscles are the motors of the vertebrate body. The characteristic that makes muscle cells unique is the relative abundance and organization of actin and myosin filaments within them. Although these filaments form a fine network in all eukaryotic cells, where they contribute to movement of materials within the cell, they are far more abundant and organized in muscle cells, which are specialized for contraction.

Vertebrates possess three kinds of muscle: *smooth*, *skeletal*, and *cardiac* (table 43.3). Skeletal and cardiac muscles are also known as *striated muscles* because their cells appear to have transverse stripes when viewed in longitudinal section under the microscope. The contraction of each skeletal muscle is under voluntary control, whereas the contraction of cardiac and smooth muscles is generally involuntary.

### Smooth muscle is found in most organs

**Smooth muscle** was the earliest form of muscle to evolve, and it is found throughout most of the animal kingdom. In vertebrates, smooth muscle occurs in the organs of the internal environment, or *viscera*, and is also called *visceral muscle*. Smooth muscle tissue is arranged into sheets of long, spindle-shaped cells, each cell containing a single nucleus. In some tissues, the cells contract only when a nerve stimulates them—and then all of the cells in the sheet contract as a unit.

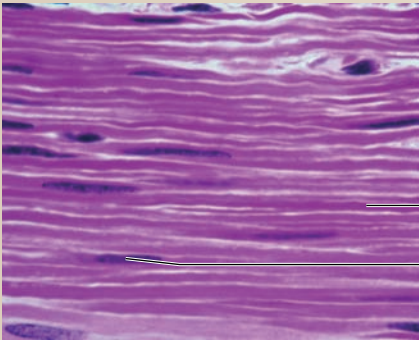

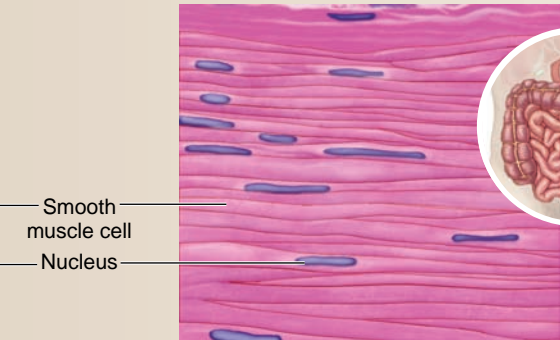

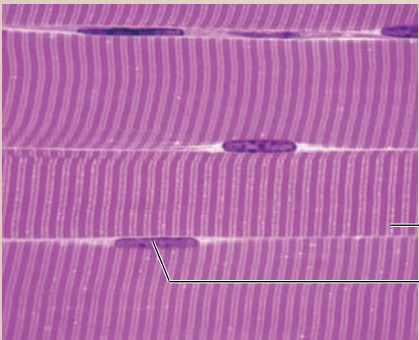

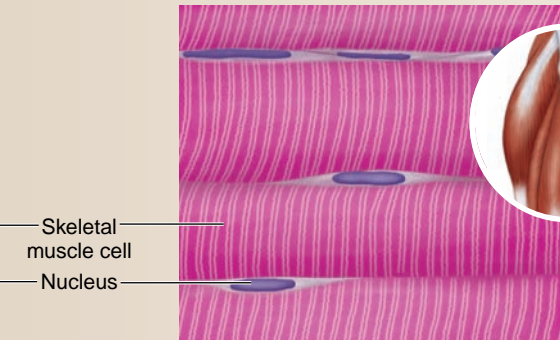

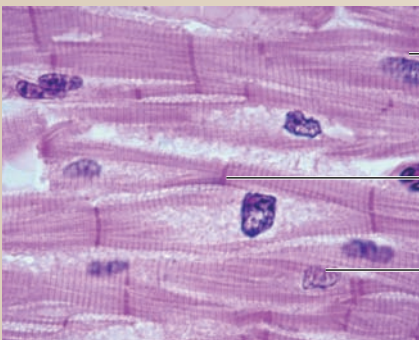

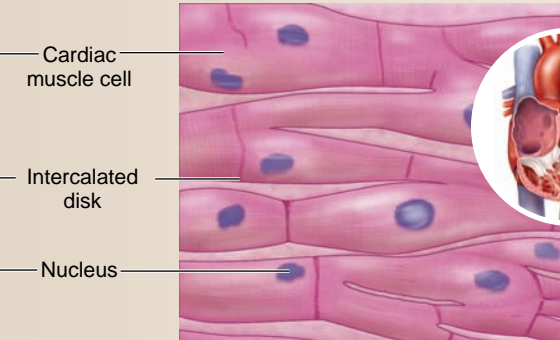

In vertebrates, muscles of this type line the walls of many blood vessels and make up the iris of the eye, which contracts in bright light. In other smooth muscle tissues, such as those in the wall of the digestive tract, the muscle cells themselves may spontaneously initiate electrical impulses, leading to a slow, steady contraction of the tissue. Here nerves regulate, rather than cause, the activity.

### Skeletal muscle moves the body

**Skeletal muscles** are usually attached to bones by tendons, so that their contraction causes the bones to move at their joints. A skeletal muscle is made up of numerous, very long muscle

TABLE 43.3

## Muscle Tissue

 <p>40 <math>\mu</math>m</p>	 <p>Smooth muscle cell Nucleus</p>	<p><b>Smooth Muscle</b> <i>Typical Location</i> Walls of blood vessels, stomach, and intestines <i>Function</i> Powers rhythmic, involuntary contractions commanded by the central nervous system <i>Characteristic Cell Types</i> Smooth muscle cells</p>
 <p>100 <math>\mu</math>m</p>	 <p>Skeletal muscle cell Nucleus</p>	<p><b>Skeletal Muscle</b> <i>Typical Location</i> Voluntary muscles <i>Function</i> Powers walking, lifting, talking, and all other voluntary movement <i>Characteristic Cell Types</i> Skeletal muscle cells</p>
 <p>40 <math>\mu</math>m</p>	 <p>Cardiac muscle cell Intercalated disk Nucleus</p>	<p><b>Cardiac Muscle</b> <i>Typical Location</i> Walls of heart <i>Function</i> Highly interconnected cells; promotes rapid spread of signal initiating contraction <i>Characteristic Cell Types</i> Cardiac muscle cells</p>

cells called **muscle fibers**, which have multiple nuclei. The fibers lie parallel to each other within the muscle and are connected to the tendons on the ends of the muscle. Each skeletal muscle fiber is stimulated to contract by a motor neuron.

The nervous system controls the overall strength of a skeletal muscle contraction by controlling the number of motor neurons that fire, and therefore the number of muscle fibers stimulated to contract. Each muscle fiber contracts by means of substructures called **myofibrils** containing highly ordered arrays of actin and myosin myofilaments. These filaments give the muscle fiber its striated appearance.

Skeletal muscle fibers are produced during development by the fusion of several cells, end to end. This embryological development explains why a mature muscle fiber contains many nuclei. The structure and function of skeletal muscle is explained in more detail in chapter 47.

### The heart is composed of cardiac muscle

The hearts of vertebrates are made up of striated muscle cells arranged very differently from the fibers of skeletal muscle. Instead of having very long, multinucleate cells running the length of the muscle, **cardiac muscle** consists of smaller, interconnected cells, each with a single nucleus. The interconnections between adjacent cells appear under the microscope as dark lines called **intercalated disks**. In reality, these lines are regions where gap junctions link adjacent cells. As noted in chapter 4, gap junctions have openings that permit the movement of small substances and ions from one cell to another. These interconnections enable the cardiac muscle cells to form a single functioning unit.

Certain specialized cardiac muscle cells can generate electrical impulses spontaneously, but the nervous system usually

## SCIENTIFIC THINKING

**Question:** Is the heartbeat a function of the nervous system, or does it originate in the heart itself?

**Hypothesis:** Cells in the heart are capable of generating an action potential without stimulation by the nervous system.

**Prediction:** If the heartbeat is produced by cells in the heart, then an isolated heart should continue to beat.

**Test:** Remove a frog's heart and keep in a bath of nutrient solution and oxygen.

**Result:** The heart continues to contract with no connection to the nervous system.

**Conclusion:** The heartbeat is intrinsic to the heart.

**Further Experiments:** How would you integrate the conclusions from this experiment with the one described in figure 44.12?

**Figure 43.5** The source of the heartbeat.

regulates the rate of impulse activity (figure 43.5). The impulses generated by the specialized cell groups spread across the gap junctions from cell to cell, synchronizing the heart's contraction. Chapter 50 describes this process more fully.

### Learning Outcomes Review 43.4

Muscles are the motors of the body; they are able to contract to change their length. Muscle tissue is of three types: smooth, skeletal, and cardiac. Smooth muscles provide a variety of visceral functions. Skeletal muscles enable the vertebrate body to move. Cardiac muscle forms a muscular pump, the heart.

- Why is it important that cardiac muscle cells have gap junctions?

## 43.5 Nerve Tissue

### Learning Outcomes

1. Describe the basic structure of neurons.
2. Distinguish between neurons and their supporting cells.
3. Identify the two divisions of the nervous system.

The fourth major class of vertebrate tissue is nerve tissue (table 43.4). Its cells include neurons and their supporting cells, called neuroglia. Neurons are specialized to produce and conduct electrochemical events, or impulses.

## Neurons sometimes extend long distances

Most **neurons** consist of three parts: a cell body, dendrites, and an axon. The *cell body* of a neuron contains the nucleus. *Dendrites* are thin, highly branched extensions that receive incoming stimulation and conduct electrical impulses to the cell body. The *axon* is a single extension of cytoplasm that conducts impulses away from the cell body. Axons and dendrites can be quite long. For example, the cell bodies of neurons that control the muscles in your feet lie in the spinal cord, and their axons may extend over a meter to your feet.

## Neuroglia provide support for neurons

**Neuroglia** do not conduct electrical impulses, but instead support and insulate neurons and eliminate foreign materials in and around neurons. In many neurons, neuroglia cells associate with the axons and form an insulating covering, a *myelin sheath*, produced by successive wrapping of the membrane around the axon. Gaps in the myelin sheath, known as *nodes of Ranvier*, serve as sites for accelerating an impulse (see chapter 44).

## Two divisions of the nervous system coordinate activity

The nervous system is divided into the **central nervous system (CNS)**, which includes the brain and spinal cord, and the **peripheral nervous system (PNS)**, which includes *nerves* and *ganglia*. Nerves consist of axons in the PNS that are bundled together in much the same way as wires are bundled together in a cable. Ganglia are collections of neuron cell bodies. The CNS generally has the role of integration and interpretation of input, such as input from the senses; the PNS communicates signals to and from the CNS to the rest of the body, such as to muscle cells or endocrine glands.

### Learning Outcomes Review 43.5

Nerve tissue is composed of neurons and neuroglia. Neurons are specialized to receive and conduct electrical signals; they generally have a cell body with a nucleus, dendrites that receive incoming signals, and axons that conduct impulses away from the cell body. Neuroglia have support functions, including providing insulation to axons. The central nervous system (CNS) and peripheral nervous system (PNS) both contain neurons and neuroglia.

- In chapter 4 you read that the surface-area-to-volume ratio limits cell size. How do neurons reach up to a meter in length in spite of this?

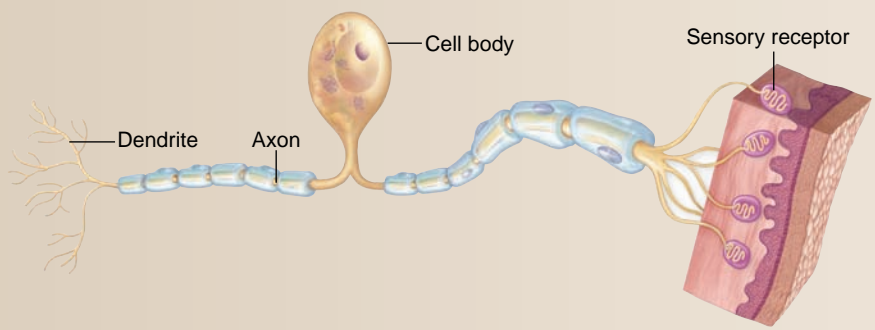

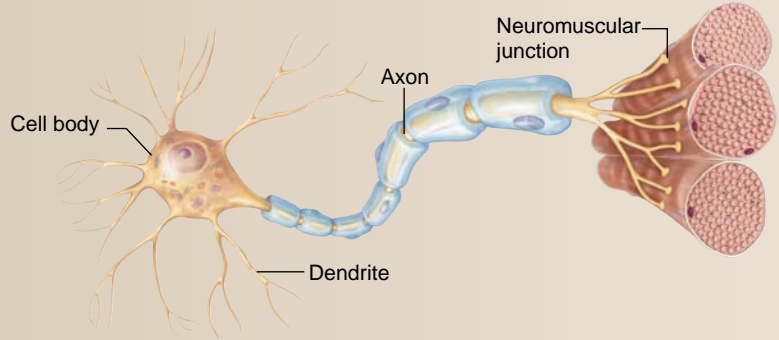

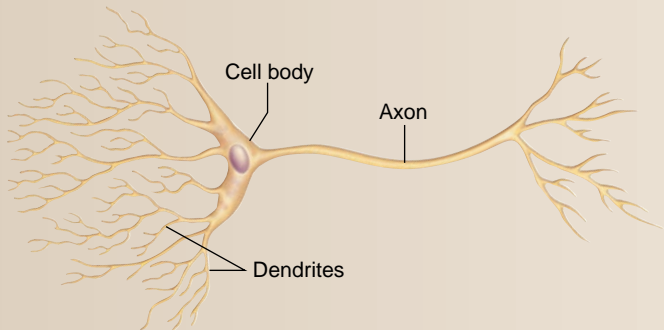

## 43.6 Overview of Vertebrate Organ Systems

### Learning Outcomes

1. Identify the different organ systems in vertebrates.
2. Explain the functional organization of these systems.

**TABLE 43.4**

**Nerve Tissue**

 <p>Labels: Cell body, Dendrite, Axon, Sensory receptor</p>	<p><b>Sensory Neurons</b>  <i>Typical Location</i>                      Eyes; ears; surface of skin  <i>Function</i>                      Receive information about the body's condition and external environment; send impulses from sensory receptors to central nervous system  <i>Characteristic Cell Types</i>                      Rods and cones; muscle stretch receptors</p>
 <p>Labels: Cell body, Dendrite, Axon, Neuromuscular junction</p>	<p><b>Motor Neurons</b>  <i>Typical Location</i>                      Brain and spinal cord  <i>Function</i>                      Stimulate muscles and glands; conduct impulses out of central nervous system toward muscles and glands  <i>Characteristic Cell Types</i>                      Motor neurons</p>
 <p>Labels: Cell body, Axon, Dendrites</p>	<p><b>Interneurons</b>  <i>Typical Location</i>                      Brain and spinal cord  <i>Function</i>                      Integrate information; conduct impulses between neurons within central nervous system  <i>Characteristic Cell Types</i>                      Interneurons</p>

In the chapters that follow, we look closely at the major organ systems of vertebrates (figure 43.6). In each chapter, you will be able to see the intimate relationship of structure and function. We approach the organ systems by placing them in the following functional groupings:

- Communication and integration
- Support and movement
- Regulation and maintenance
- Defense
- Reproduction and development

### Communication and integration sense and respond to the environment

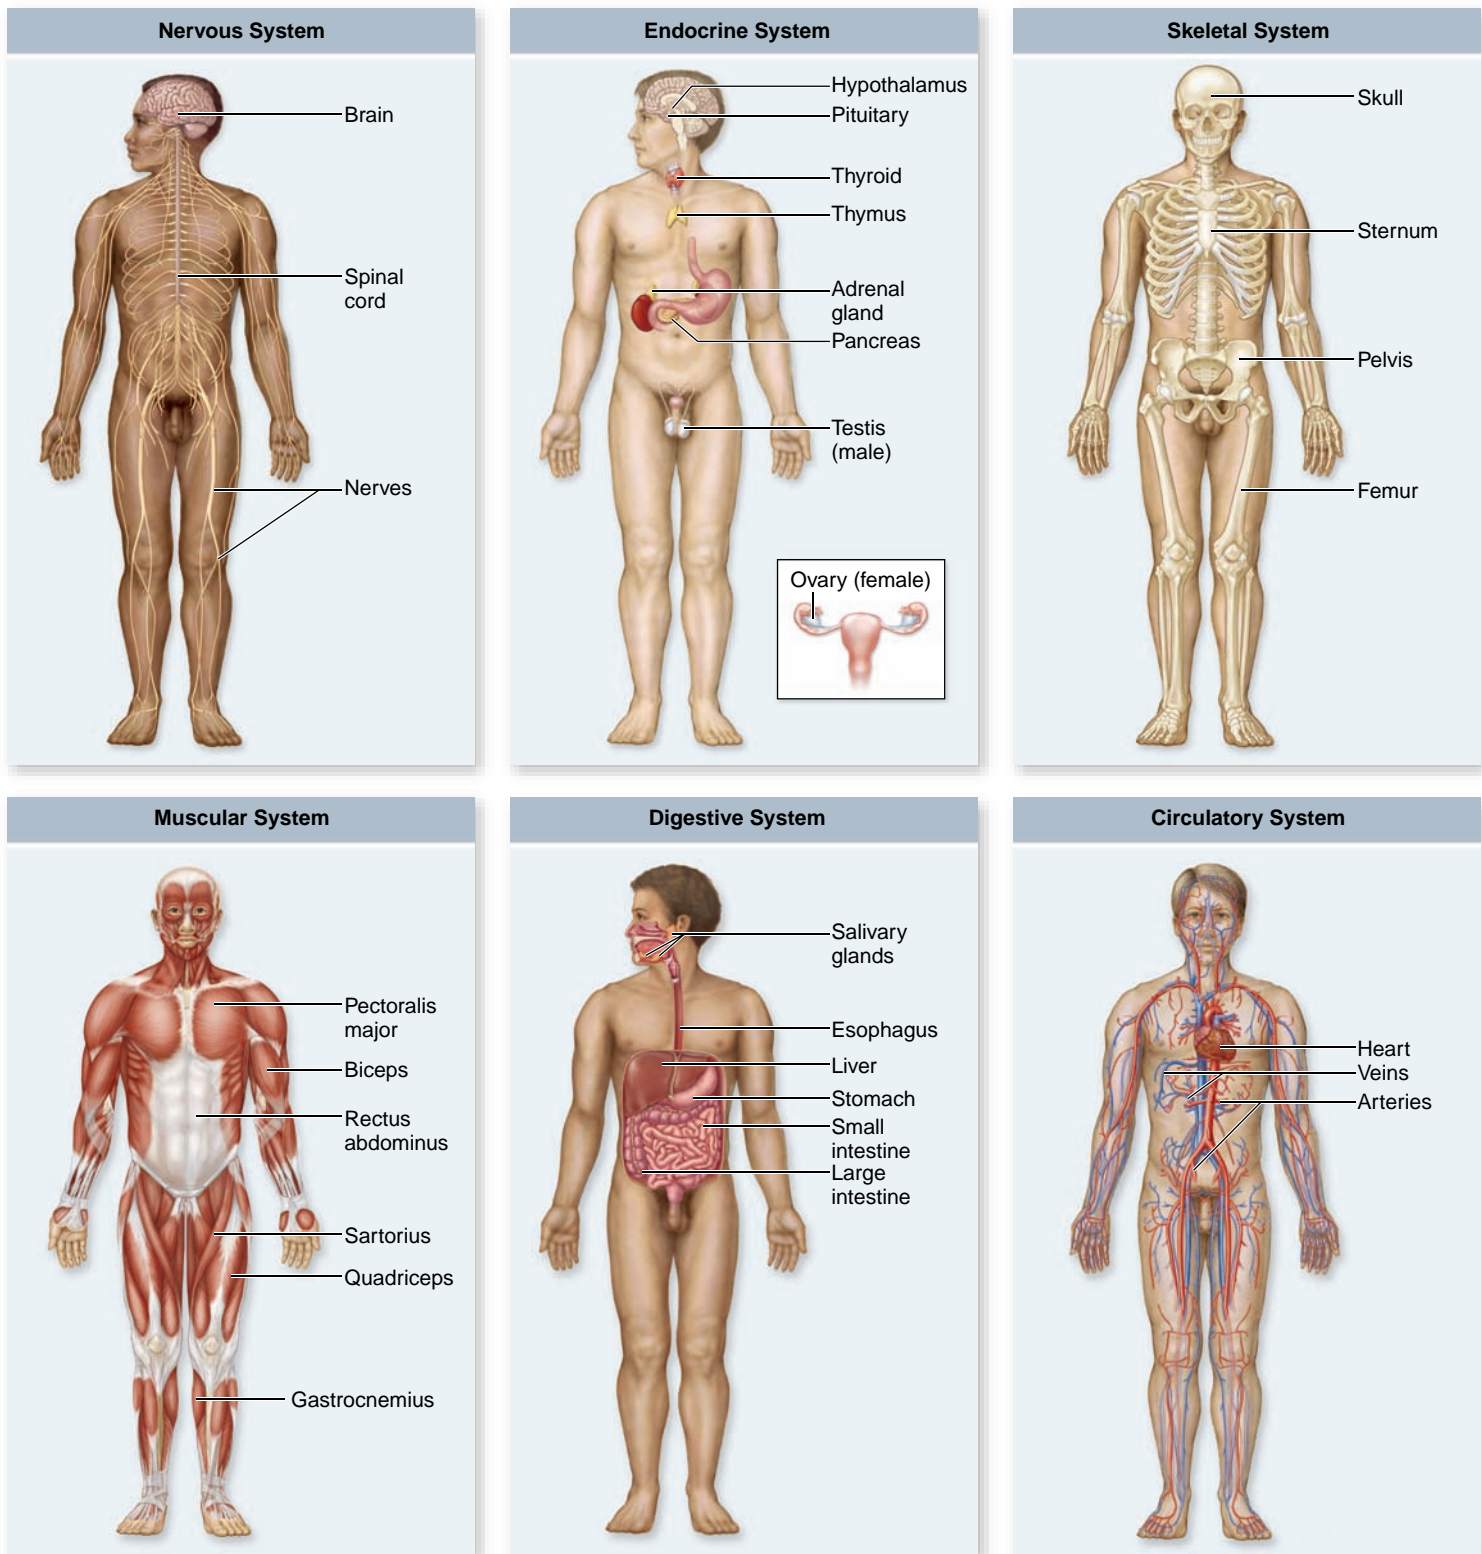

Two organ systems detect external and internal stimuli and coordinate the body's responses. The **nervous system**, which consists of the brain, spinal cord, nerves, and sensory organs, detects internal sensory feedback and external stimuli such as light, sound, and touch. This information is collected and integrated, and then the appropriate response is made.

The **sensory systems** are a subset of the nervous system we consider in a separate chapter. These include the organs and tissues that sense external stimuli, such as vision, hearing, smell, and so on.

Working in parallel with the nervous system, the **endocrine system** issues chemical signals that regulate and fine-tune the myriad chemical processes taking place in all other organ systems.

### Skeletal support and movement are vital to all animals

The **musculoskeletal system** consists of two interrelated organ systems. Muscles are most obviously responsible for movement, but without something to pull on, a muscle is useless. The skeletal system is the rigid framework against which most muscles pull. Vertebrates have internal skeletons, but many other animals exhibit external skeletons (such as insects) or hydrostatic skeletons (earthworms). Together, these two organ systems enable animals to exhibit a wide array of finely controlled movements.

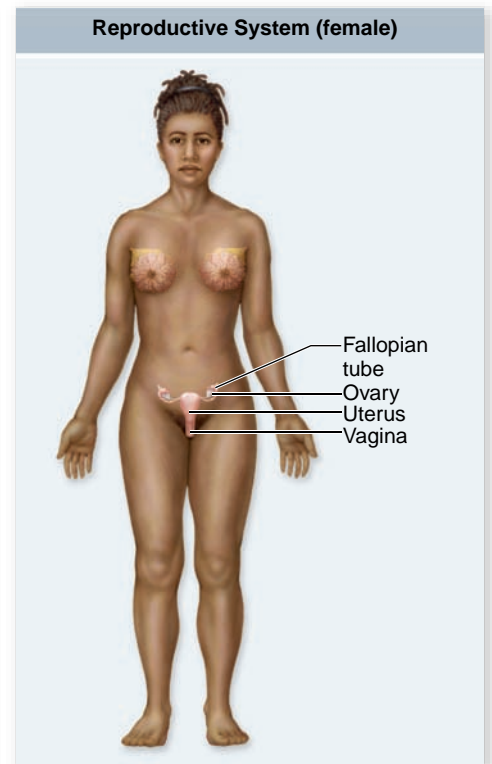

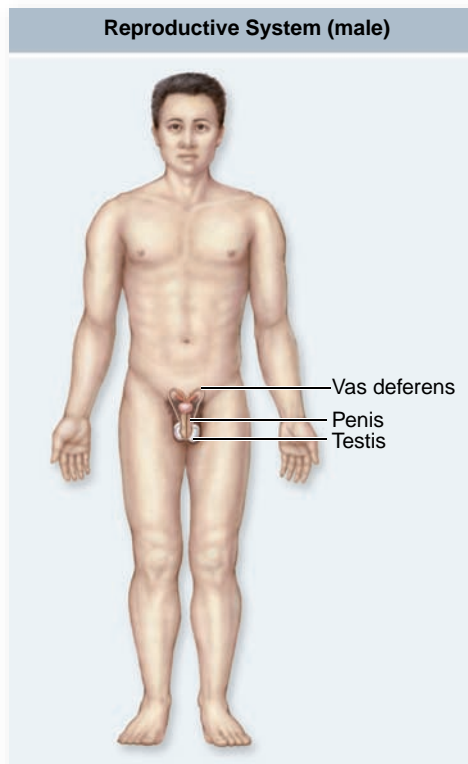

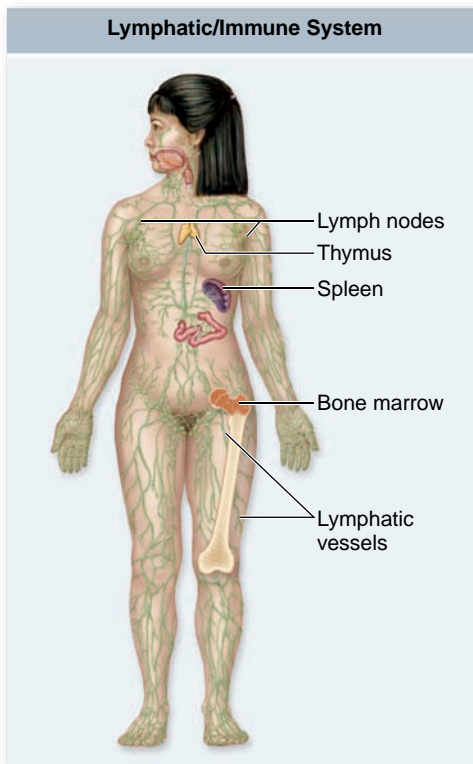

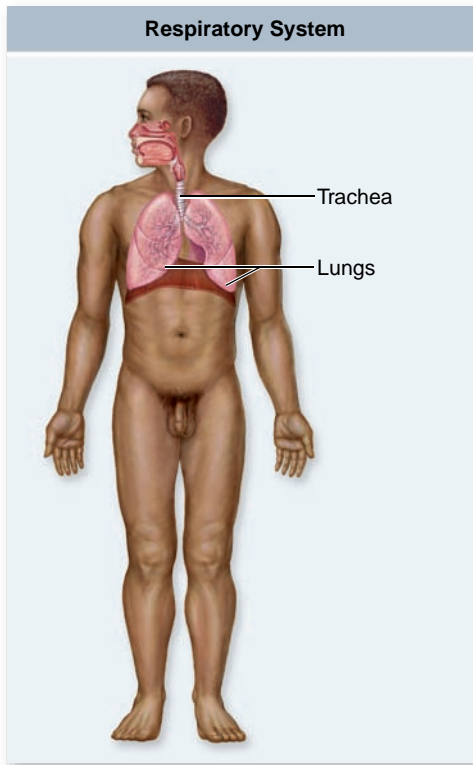

**Figure 43.6 Vertebrate organ systems.** Shown are the 11 principal organ systems of the human body, including both male and female reproductive systems.

### Regulation and maintenance of the body's chemistry ensures continued life

The organ systems grouped under regulation and maintenance participate in nutrient acquisition, waste disposal, material dis-

tribution, and maintenance of the internal environment. The chapter on the **digestive system** describes how we eat, absorb nutrients, and eliminate solid wastes. The heart and vessels of the **circulatory system** pump and distribute blood, carrying nutrients and other substances throughout the body. The

body acquires oxygen and expels carbon dioxide via the **respiratory system**.

Finally, vertebrates tightly regulate the concentration of their body fluids. We explore these processes in the chapter on osmoregulation, which is largely carried out by the **urinary system**.

## The body can defend itself from attackers and invaders

Every animal faces assault by bacteria, viruses, fungi, protozoists, and even other animals. The body's first line of defense

is the **integumentary system**—intact skin. Disease-causing agents that penetrate the first defense encounter a host of other protective **immune system** responses, including the production of antibodies and specialized cells that attack invading organisms.

## Reproduction and development ensure continuity of species

The biological continuity of vertebrates is the province of the **reproductive system**. Male and female reproductive systems consist of organs where male and female gametes develop, as well as glands and tubes that nurture gametes and allow gametes of complementary sexes to come into contact with one another. The female reproductive system in many vertebrates also has systems for nurturing the developing embryo and fetus.

After gametes have fused to form a *zygote*, an elaborate process of cell division and development takes place to change this beginning diploid cell into a multicellular adult. This process is explored in the animal development chapter.

### Learning Outcomes Review 43.6

Vertebrate organ systems include the nervous, endocrine, skeletal, muscular, digestive, circulatory, respiratory, urinary, integumentary, lymphatic/immune, and reproductive systems. These may be grouped functionally based on their roles in communication and integration, support and movement, regulation and maintenance, defense, and reproduction and development.

- *Is there any overlap between the different organ systems?*

## 43.7 Homeostasis

### Learning Outcomes

1. Explain homeostasis.
2. Illustrate how negative feedback can limit a response.
3. Illustrate how antagonistic effectors can maintain a system at a set point.

As animals have evolved, specialization of body structures has increased. Each cell is a sophisticated machine, finely tuned to carry out a precise role within the body. Such specialization of cell function is possible only when extracellular conditions stay within narrow limits. Temperature, pH, the concentrations of glucose and oxygen, and many other factors must remain relatively constant for cells to function efficiently and interact properly with one another. The dynamic constancy of the internal environment is called *homeostasis*. The term *dynamic* is used because conditions are never constant, but fluctuate continuously within narrow limits. Homeostasis is essential for life, and most of the regulatory mechanisms of the vertebrate body are involved with maintaining homeostasis (figure 43.7).

**Figure 43.7 Homeostatic mechanisms help maintain stable internal conditions.** Even though conditions outside of an animal's body may vary widely, the inside stays relatively constant due to many finely tuned control systems.

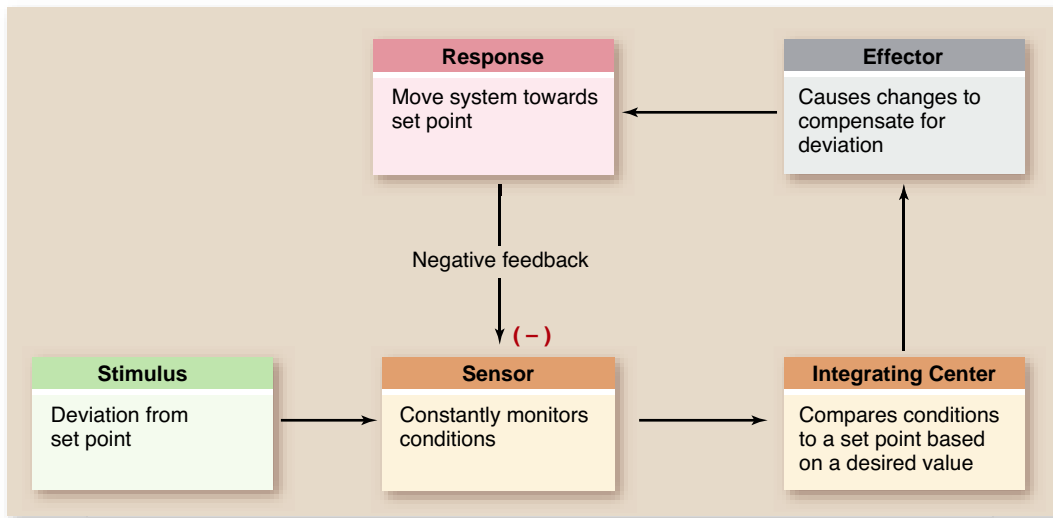

## Negative feedback mechanisms keep values within a range

To maintain internal constancy, the vertebrate body uses a type of control system known as a **negative feedback**. In negative feedback, conditions within the body as well as outside it are detected by specialized sensors, which may be cells or membrane receptors. If conditions deviate too far from a set point, biochemical reactions are initiated to change conditions back toward the set point.

This *set point* is analogous to the temperature setting on a space heater. When room temperature drops, the change is detected by a temperature-sensing device inside the heater controls—the **sensor**. The thermostat on which you have indicated the set point for the heater contains a **comparator**; when the sensor information drops below the set point, the comparator closes an electrical circuit. The flow of electricity through the heater then produces more heat. Conversely, when the room temperature increases, the change causes the circuit to open, and heat is no longer produced. Figure 43.8 summarizes the negative feedback loop.

In a similar manner, the human body has set points for body temperature, blood glucose concentration, electrolyte (ion) concentration, the tension on a tendon, and so on. The integrating center is often a particular region of the brain or spinal cord, but in some cases, it can also be cells of endocrine glands. When a deviation in a condition occurs, a message is sent to increase or decrease the activity of particular target organs, termed *effectors*. Effectors are generally muscles or glands, and their actions can change the value of the condition in question back toward the set point value.

Mammals and birds are *endothermic*; they can maintain relatively constant body temperatures independent of the environmental temperature. In humans, when the blood temperature exceeds 37°C (98.6°F), neurons in a part of the brain called the **hypothalamus** detect the temperature change. Acting through the control of motor neurons, the hypothalamus responds by promoting the dissipation of heat through sweating, dilation of blood vessels in the skin, and other mechanisms. These responses tend to counteract the rise in body temperature.

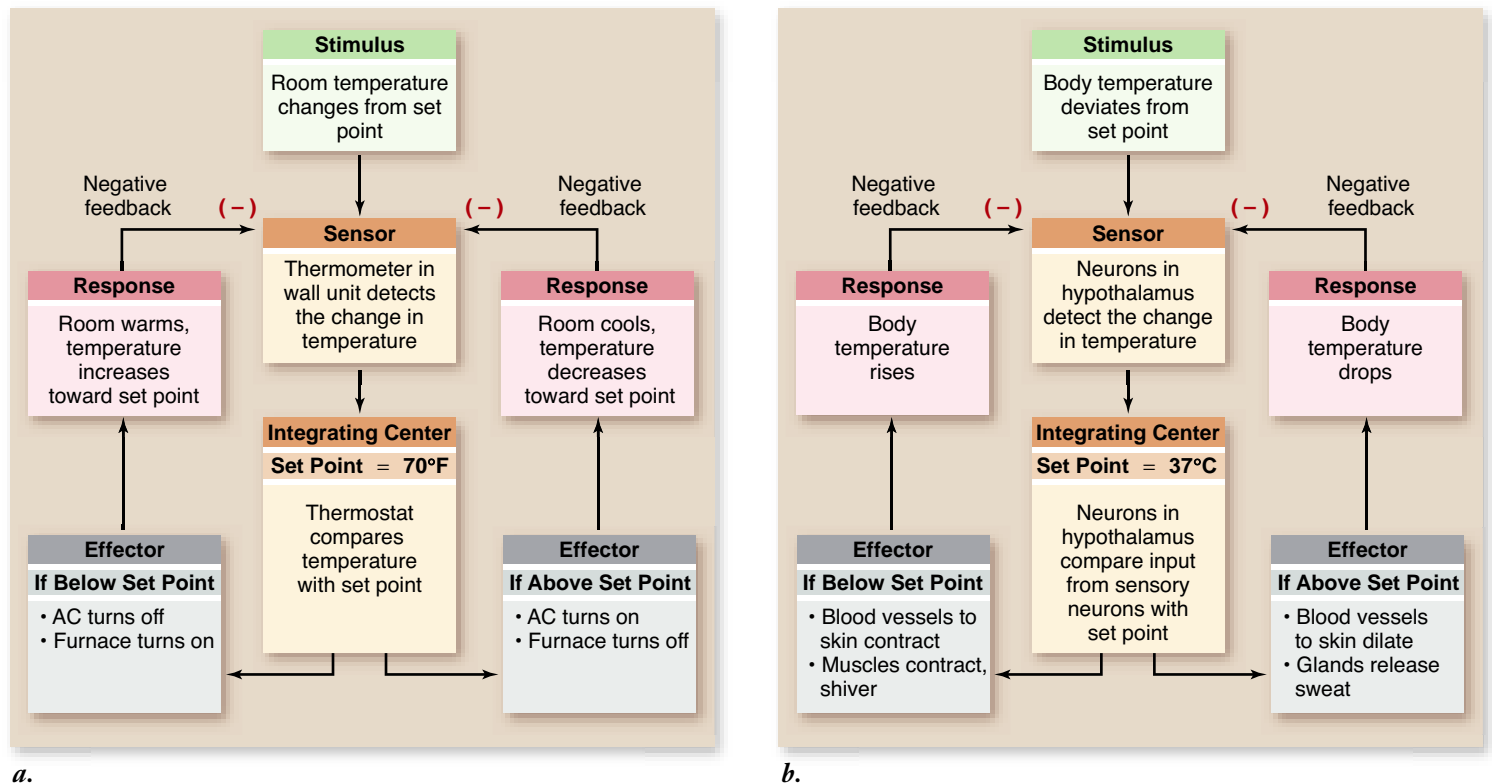

**Figure 43.8** Generalized diagram of a negative feedback loop. Negative feedback loops maintain a state of homeostasis, or dynamic constancy of the internal environment. Changing conditions are detected by sensors, which feed information to an integrating center that compares conditions to a set point. Deviations from the set point lead to a response to bring internal conditions back to the set point. Negative feedback to the sensor terminates the response.

### Antagonistic effectors act in opposite directions

The negative feedback mechanisms that maintain homeostasis often oppose each other to produce a finer degree of control. Most factors in the internal environment are controlled by several effectors, which often have antagonistic (opposing) actions. Control by antagonistic effectors is sometimes described as “push–pull,” in which the increasing activity of one effector is

accompanied by decreasing activity of an antagonistic effector. This affords a finer degree of control than could be achieved by simply switching one effector on and off.

To return to our earlier example, room temperature can be maintained by just turning the heater on and off, or turning an air conditioner on and off. A much more stable temperature is possible, however, if a thermostat controls both the air conditioner and heater. Then the heater turns on when the air conditioner shuts off, and vice versa (figure 43.9a).

**Figure 43.9** Room and body temperature are maintained by negative feedback and antagonistic effectors. *a.* If a thermostat senses a low temperature (as compared with a set point), the furnace turns on and the air conditioner turns off. If the temperature is too high, the air conditioner turns on and the furnace turns off. *b.* The hypothalamus of the brain detects an increase or decrease in body temperature. The comparator (also in the hypothalamus) then processes the information and activates effectors, such as surface blood vessels, sweat glands, and skeletal muscles. Negative feedback results in a reduction in the difference of the body’s temperature compared with the set point. Consequently, the stimulation of the effectors by the comparator is also reduced.

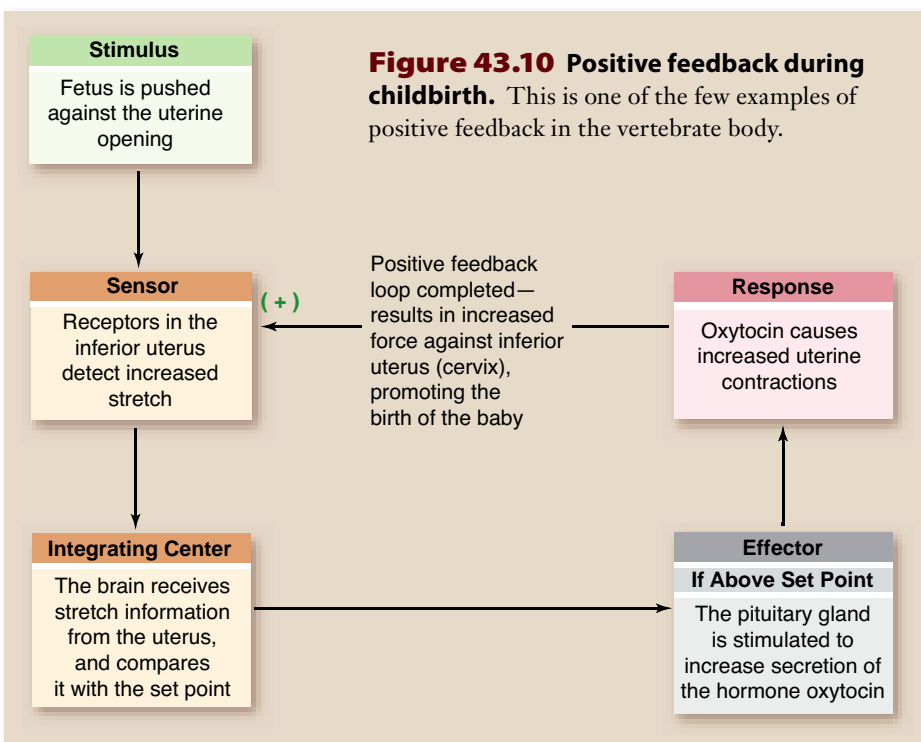

Antagonistic effectors are similarly involved in the control of body temperature. When body temperature falls, the hypothalamus coordinates a different set of responses, such as constriction of blood vessels in the skin and initiation of shivering, muscle contractions that help produce heat. These responses raise body temperature and correct the initial challenge to homeostasis (figure 43.9b).

## Positive feedback mechanisms enhance a change

In a few cases, the body uses *positive feedback* mechanisms, which push or accentuate a change further in the same direction. In a positive feedback loop, the effector drives the value of the controlled variable even farther from the set point. As a result, systems in which there is positive feedback are highly unstable, analogous to a spark that ignites an explosion. They do not help to maintain homeostasis.

Nevertheless, such systems are important components of some physiological mechanisms. For example, positive feedback occurs in blood clotting, in which one clotting factor activates another in a cascade that leads quickly to the formation of a clot. Positive feedback also plays a role in the contractions of the uterus during childbirth (figure 43.10). In this case, stretching of the uterus by the fetus stimulates contraction, and contraction causes further stretching; the cycle continues until the uterus expels the fetus.

In the body, most positive feedback systems act as part of some larger mechanism that maintains homeostasis. In the examples we have described, formation of a blood clot stops bleeding and therefore tends to keep blood volume constant, and expulsion of the fetus reduces the contractions of the uterus, stopping the cycle.

### Learning Outcomes Review 43.7

Homeostasis can be thought of as the dynamic constancy of an organism's internal environment. Negative feedback mechanisms correct deviations from a set point for different internal variables, such as temperature, pH, and many others, helping to keep body conditions within a normal range. Effectors that act antagonistically to each other are more effective than effectors that act alone. Positive feedback mechanisms that accentuate changes are less common and have specialized functions, such as blood clotting and giving birth.

- Do antagonistic effectors and negative feedback function together?

## 43.8 Regulating Body Temperature

### Learning Outcomes

1. Explain  $Q_{10}$  and its significance.
2. Define how organisms can be categorized with respect to temperature regulation.
3. Describe mechanisms for temperature homeostasis.

Temperature is one of the most important aspects of the environment that all organisms must contend with. This provides a good example to apply the principles of homeostatic regulation from the last section. As we will see, some organisms have a body temperature that conforms to the environment and others regulate their body temperature. First, let's consider why temperature is so important.

### $Q_{10}$ is a measure of temperature sensitivity

The rate of any chemical reaction is affected by temperature: The rate increases with increasing temperature, and it decreases with decreasing temperature. Reactions catalyzed by enzymes show the same kinetic effects, but the enzyme itself is also affected by temperature.

We can make this temperature dependence quantitative by examining the rate of a reaction at two different temperatures. The ratio between the rates of a reaction at two temperatures that differ by  $10^{\circ}\text{C}$  is called the  $Q_{10}$  for the enzyme:

$$Q_{10} = R_{T+10}/R_T$$

For most enzymes the  $Q_{10}$  value is around 2, which means for every  $10^{\circ}\text{C}$  increase in temperature, the rate of the reaction doubles. Obviously, this cannot continue forever since at high temperatures the enzyme's structure is affected and it can no longer be active.

The  $Q_{10}$  concept can also be applied to overall metabolism. The equation remains the same, but instead of the rate of a single reaction, the overall metabolic rate is used. When this has been measured, most organisms have a  $Q_{10}$  for metabolic rate around 2 to 3. This observation implies that the effect of temperature is mainly on the enzymes that make up metabolism.

In rare cases—for example, in some intertidal invertebrates—the  $Q_{10}$  is close to 1. Notice that this value means no change in metabolic rate with temperature. In the case of these intertidal invertebrates, they are exposed to large temperature fluctuations as they are alternately flooded with relatively cold water and exposed to direct sunlight and much higher air temperatures. These organisms have adapted to deal with these large temperature swings, probably through the evolution of different enzymes in a single metabolic pathway that have large differences in optimal temperature. This allows one enzyme to “make up” for others with decreased activity at a particular temperature.

## Temperature is determined by internal and external factors

Body temperature appears simple, yet a large number of variables influence it. These variables include both internal and external factors, as well as behavior. As you may recall from chapter 6, the second law of thermodynamics indicates that

no energy transaction is 100% efficient. Thus the reactions that make up metabolism are constantly producing heat as a result of this inefficiency. This heat must either be dissipated or can be used to raise body temperature.

Overall metabolic rate and body temperature are inter-related. Lower body temperatures do not allow high metabolic rates because of the temperature dependence of enzymes discussed earlier. Conversely, high metabolic rates may cause unacceptable heating of the body, requiring cooling.

Organisms therefore must deal with external and internal factors that relate body heat, metabolism, and the environment. The simplest model for temperature, more accurately body heat, is:

$$\text{body heat} = \text{heat produced} + (\text{heat gained} - \text{heat lost})$$

we can simplify this further to:

$$\text{body heat} = \text{heat produced} + \text{heat transferred}$$

Notice that the heat transferred can be either positive or negative, that is, it can be used for both heating and cooling.

We recognize four mechanisms of heat transfer that are relevant to biological systems: radiation, conduction, convection, and evaporation (figure 43.11).

- **Radiation.** The transfer of heat by electromagnetic radiation, such as from the Sun, does not require direct contact. Heat is transferred from hotter bodies to colder bodies by radiation.

**Figure 43.11 Methods of heat transfer.** Heat can be gained or lost by conduction, convection, and radiation. Heat can also be lost by evaporation of water on the surface of an animal.

- **Conduction.** The direct transfer of heat between two objects is called conduction. It is literally a direct transfer of kinetic energy between the molecules of the two objects in contact. Energy is transferred from hotter objects to colder ones.
- **Convection.** Convection is the transfer of heat brought about by the movement of a gas or liquid. This movement may be externally caused (wind) or may be due to density differences related to heating and cooling—for example, heated air is less dense and rises; the same is true for water.
- **Evaporation.** All substances have a heat of vaporization, that is, the amount of energy needed to change them from a liquid to a gas phase. Water, as you saw in chapter 2, has a high heat of vaporization, and many animals use this attribute of water as a source of cooling.

### Other factors

The overall rate of heat transfer by the methods just listed depends on a number of factors that influence these physical processes. These factors include surface area, temperature difference, and specific heat conduction. Taking these in order, the larger the surface area relative to overall mass, the greater the conduction of heat. Thus, small organisms have a relatively larger surface area for their mass, and they gain or lose heat more readily to the surroundings. This can be affected to a small extent by changing posture, and by extending or pulling in the limbs.

Temperature difference is also important; the greater the difference between ambient temperature and body temperature, the greater the heat transfer. The closer an animal's temperature is to the ambient temperature, the less heat is gained or lost.

Finally, an animal with high heat conductance tends to have a body temperature close to the ambient temperature. For animals that regulate temperature, surrounding the body with a substance with lower heat conductance has an advantage: It acts as insulation. Insulating substances include such features as feathers, fur, and blubber. For animals that regulate body temperature through behavior, a high heat conductance can maximize heat transfer.

### Organisms are classified based on heat source

For many years, physiologists classified animals according to whether they maintained a constant body temperature, or their body temperature fluctuated with environment. Animals that regulated their body temperature about a set point were called *homeotherms*, and those that allow their body temperature to conform to the environment were called *poikilotherms*.

Because homeotherms tended to maintain their body temperature above the ambient temperature, they were also colloquially called “warm-blooded”; poikilotherms were termed “cold-blooded.” The problem with this terminology is that a poikilotherm in an environment with a stable temperature (for example, many deep-sea fish species) has a more constant body temperature than some homeotherms.

These limitations to the dichotomy based on temperature regulation led to another view based on how body heat is generated. Animals that use metabolism to generate body heat and maintain their temperatures above the ambient temperature are called *endotherms*. Animals with a relatively low metabolic rate that do not use metabolism to produce heat and have a body temperature that conforms to the ambient temperature are called *ectotherms*. Endotherms tend to have a lower thermal conductivity due to insulating mechanisms, and ectotherms tend to have high thermal conductivity and lack insulation.

These two terms represent ideal end points of a spectrum of physiology and adaptations. Many animals fall in between these extremes and can be considered *heterotherms*. It is a matter of judgment how a particular animal is classified if it exhibits characteristics of each group.

### Ectotherms regulate temperature using behavior

Despite having low metabolic rates, ectotherms can regulate their temperature using behavior. Most invertebrates use behavior to adjust their temperature. Many butterflies, for example, must reach a certain body temperature before they can fly. In the cool of the morning, they orient their bodies so as to maximize their absorption of sunlight. Moths and many other insects use a shivering reflex to warm their thoracic flight muscles so that they may take flight (figure 43.12).

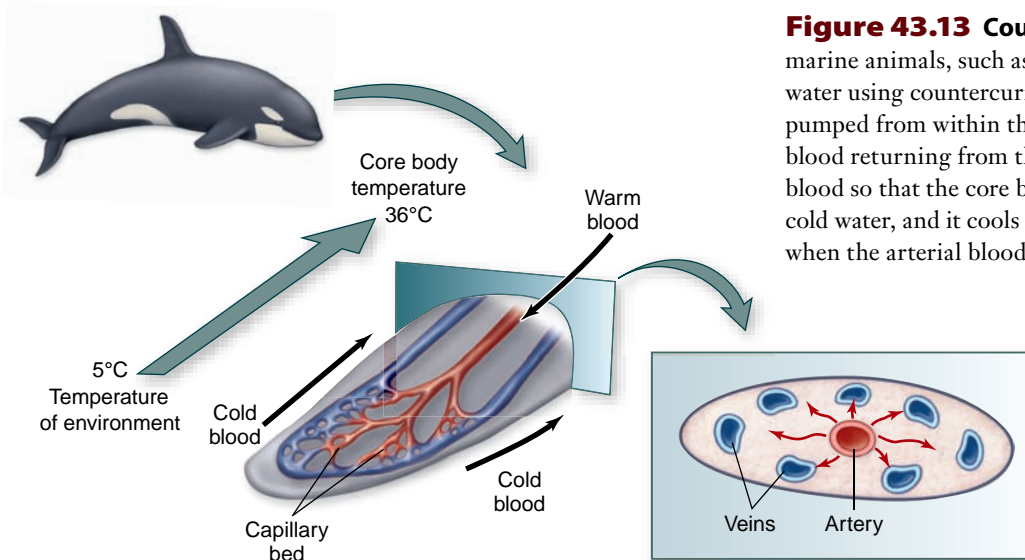

**Figure 43.12 Thermoregulation in insects.** Some insects, such as the sphinx moth, contract their thoracic muscles to warm up for flight.

### Inquiry question

Why does muscle temperature stop warming after 2 min?

**Figure 43.13 Countercurrent heat exchange.** Many marine animals, such as this killer whale, limit heat loss in cold water using countercurrent heat exchange. The warm blood pumped from within the body in arteries loses heat to the cooler blood returning from the skin in veins. This warms the venous blood so that the core body temperature can remain constant in cold water, and it cools the arterial blood so that less heat is lost when the arterial blood reaches the tip of the extremity.

Vertebrates other than mammals and birds are also ectothermic, and their body temperatures are more or less dependent on the environmental temperature. This does not mean that these animals cannot maintain high and relatively constant body temperatures, but they must use behavior to do this. Many ectothermic vertebrates are able to maintain temperature homeostasis, that is, are homeothermic ectotherms.

For example, certain large fish, including tuna, swordfish, and some sharks, can maintain parts of their body at a significantly higher temperature than that of the water. They do so using *countercurrent heat exchange*. This circulatory adaptation allows the cooler blood in the veins to be warmed through radiation of heat from the warmer blood in the arteries located close to the veins. The arteries carry warmer blood from the center of the body (figure 43.13).

Reptiles attempt to maintain a constant body temperature through behavioral means—by placing themselves in varying locations of sunlight and shade. That’s why you frequently see lizards basking in the sun. Some reptiles can maximize the effect of behavioral regulation by also controlling blood flow. The marine iguana can increase and decrease its heart rate and control the extent of dilation or contraction of blood vessels to regulate the amount of blood available for heat transfer by conduction. Increased heart rate and vasodilation allows them to maximize heating when on land, whereas decreased heart rate and vasoconstriction minimize cooling when diving for food.

In general, ectotherms have low metabolic rates, which has the advantage of correspondingly low intake of energy (food). It is estimated that a lizard (ectotherm) needs only 10% of the energy intake of a mouse (endotherm) of comparable size. The tradeoff is that ectotherms are not capable of sustained high-energy activity.

### Endotherms create internal metabolic heat for conservation or dissipation

For endotherms, the generation of internal heat via high metabolic rate can be used to warm the organism if it is cold, but

also represents a source of heat that must be dissipated at higher temperatures.

The simplest response that affects heat transfer is to control the amount of blood flow to the surface of the animal. Dilating blood vessels increases the amount of blood flowing to the surface, which in turn increases thermal heat exchange and dissipation of heat. In contrast, constriction of blood vessels decreases the amount of blood flowing to the surface and decreases thermal heat exchange, limiting the amount of heat lost due to conduction.

When ambient temperatures rise, many endotherms take advantage of evaporative cooling in the form of sweating or panting. Sweating is found in some mammals, including humans, and involves the active extrusion of water from sweat glands onto the surface of the body. As the water evaporates, it cools the skin, and this cooling can be transferred internally by capillaries near the surface of the skin. Panting is a similar adaptation used by some mammals and birds that takes advantage of respiratory surfaces for evaporative cooling. For evaporative cooling to be effective, the animal must be able to tolerate the loss of water.

The advantage of endothermy is that it allows sustained high-energy activity. The tradeoff for endotherms is that the high metabolic rate has a corresponding cost in requiring relatively constant and high rates of energy intake (food).

### Body size and insulation

Size is one important characteristic affecting animal physiology. Changes in body mass have a large effect on metabolic rate. Smaller animals consume much more energy per unit body mass than larger animals. This relationship is summarized in the “mouse to elephant” curve that shows the non-proportionality of metabolic rate versus size of mammals (figure 43.14).

For small animals with a high metabolic rate, surface area is also large relative to their volume. In a cold environment, this can be disastrous as they cannot produce enough internal heat to balance conductive loss through their large surface area.

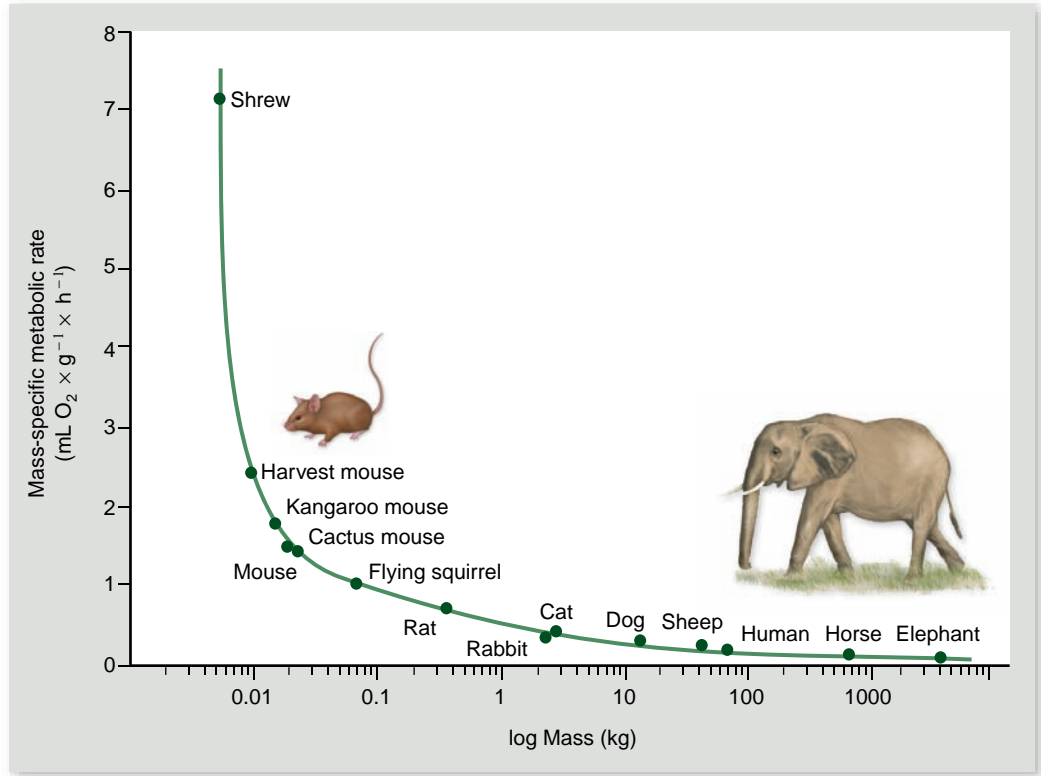

**Figure 43.14 Relationship between body mass and metabolic rate in mammals.**

Smaller animals have a much higher metabolic rate per unit body mass relative to larger animals. In the figure, mass-specific metabolic rate (expressed as O<sub>2</sub> consumption per unit mass) is plotted against body mass. Note that the body mass axis is a logarithmic scale.

?

**Inquiry question**

What does this graph predict about the different challenges faced by smaller versus larger mammals in hot and cold environments?

Thus, small endotherms in cold environments require significant insulation to maintain their body temperature. The amount of insulation can also vary seasonally and geographically with thicker coats in the north and in winter.

Conversely, large animals in hot environments have the opposite problem: Although their metabolic rate is relatively low, they still produce a large amount of heat with much less relative surface area to dissipate this heat by conduction. Thus large endotherms in hot environments usually have little insulation and will use behavior to lose heat, such as elephants flapping their ears to increase convective heat loss.

**Thermogenesis**

When temperatures fall below a critical lower threshold, normal endothermic responses are not sufficient to warm an animal. In this case, the animal resorts to **thermogenesis**, or the use of normal energy metabolism to produce heat. Thermogenesis takes two forms: shivering and nonshivering thermogenesis.

In nonshivering thermogenesis, fat metabolism is altered to produce heat instead of ATP. Nonshivering thermogenesis takes place throughout the body, but in some mammals, special stores of fat called brown fat are utilized specifically for this purpose. This brown fat is stored in small deposits in the neck and between the shoulders. This fat is highly vascularized, allowing efficient transfer of heat away from the site of production.

Shivering thermogenesis uses muscles to generate heat without producing useful work. It occurs in some insects, such as the earlier example of a butterfly warming its flight muscles, and in endothermic vertebrates. Shivering involves the use of

antagonistic muscles to produce little net generation of movement, but hydrolysis of ATP, generating heat.

**Mammalian thermoregulation is controlled by the hypothalamus**

Mammals that maintain a relatively constant core temperature need an overall control system (summarized in figure 43.15). The system functions much like the heating/cooling system in your house that has a thermostat connected to a furnace to produce heat and an air conditioner to remove heat. Such a system maintains the temperature of your house about a set point by alternately heating or cooling as necessary.

When the temperature of your blood exceeds 37°C (98.6°F), neurons in the hypothalamus detect the temperature change (see chapters 44 and 45). This leads to stimulation of the *heat-losing center* in the hypothalamus. Nerves from this area cause a dilation of peripheral blood vessels, bringing more blood to the surface to dissipate heat. Other nerves stimulate the production of sweat, leading to evaporative cooling. Production of hormones that stimulate metabolism is also inhibited.

When your temperature falls below 37°C, an antagonistic set of effects are produced by the hypothalamus. This is under control of the *heat-promoting center*, which has nerves that constrict blood vessels to reduce heat transfer, and inhibit sweating to prevent evaporative cooling. The adrenal medulla is stimulated to produce epinephrine, and the anterior pituitary to produce TSH, both of which stimulate metabolism. In the case of TSH, this is indirect as it stimulates the thyroid to produce thyroxine, which stimulates metabolism (see chapter 46). A

**Figure 43.15 The control of body temperature by the hypothalamus.** Central thermoreceptors in the brain and interior of the abdomen sense changes in core temperature. These thermoreceptors synapse with neurons on the hypothalamus, which acts as an integrating center. The hypothalamus then controls effectors such as blood vessels and sweat glands via sympathetic nerves. The hypothalamus also causes the release of hormones that stimulate the thyroid to produce thyroxin, which modulates metabolism.

combination of epinephrine and autonomic nerve stimulation of fat tissue can induce thermogenesis to produce more internal heat. Again, as temperature rises, negative feedback to the hypothalamus reduces the heat-producing response.

### Fever

Substances that cause a rise in temperature are called **pyrogens**, and they produce the state we call **fever**. Fever is a result of resetting the body's normal set point to a higher temperature. A number of gram-negative bacteria have components in their cell walls called endotoxins that act as pyrogens. Substances produced by circulating white blood cells act as pyrogens as well. Pyrogens act on the hypothalamus to increase the set point.

The adaptive value of fever seems to be that increased temperature can inhibit the growth of bacteria. Evidence for this comes from the observation that some ectotherms respond to pyrogens as well. When desert iguanas were injected with pyrogen-producing bacteria, they spent more time in the sun, producing an elevated temperature: They induced fever behaviorally!

These observations have led to a reevaluation of fever as a state that should be treated medically. Fever is a normal response to infection, and treatment to reduce fever may be working against this natural defense system. Extremely high fevers, however, can be dangerous, inducing symptoms ranging from seizures to delirium.

### Torpor

Endotherms can also reduce both metabolic rate and body temperature to produce a state of dormancy called *torpor*: Torpor allows an animal to reduce the need for food intake by reducing metabolism. Some birds, such as the hummingbird, allow their body temperature to drop as much as 25°C at night.

This strategy is found in smaller endotherms; larger mammals have too large a mass to allow rapid cooling.

*Hibernation* is an extreme state in which deep torpor lasts for several weeks or even several months. In this case, the animal's temperature may drop as much as 20°C below its normal set point for an extended period of time. The animals that practice hibernation seem to be in the midrange of size; smaller endotherms quickly consume more energy than they can easily store, even by reducing their metabolic rate.

Very large mammals do not appear to hibernate. It was long thought that bears hibernate, but in reality their temperature is reduced only a few degrees. They instead undergo a prolonged winter sleep. With their large thermal mass and low rate of heat loss, they do not seem to require the additional energy savings of hibernation.

### Learning Outcomes Review 43.8

The  $Q_{10}$  value of an enzyme indicates how its activity changes with a 10°C rise in temperature. The  $Q_{10}$  can also be applied to an organism's overall metabolism. Body heat is equal to heat produced plus heat transferred. Heat is transferred by conduction, convection, radiation, and evaporation. Organisms that generate heat and can maintain a temperature above ambient levels are called endotherms. Organisms that conform to their surroundings are called ectotherms. Both types can regulate temperature, but ectotherms mainly do so with behavior. Mammals maintain a consistent body temperature through regulation of metabolic rate by the hypothalamus. Two negative feedback loops act to raise or lower temperature as needed.

- Why are the terms "cold-blooded" and "warm-blooded" outmoded and inaccurate?

## Chapter Review

### 43.1 Organization of the Vertebrate Body (see figure 43.1)

**Tissues are groups of cells of a single type and function.**

Adult vertebrate primary tissues are epithelial, connective, muscle, and nerve tissues.

**Organs and organ systems provide specialized function.**

Organs consist of a group of different tissues that form a structural and functional unit. An organ system is a group of organs that collectively perform a function.

**The general body plan of vertebrates is a tube within a tube, with internal support (see figure 43.2).**

The tube of the digestive tract is surrounded by the skeleton and accessory organs and is enclosed in the integument.

**Vertebrates have both dorsal and ventral body cavities.**

The dorsal body cavity lies within the skull and vertebrae. The ventral body cavity, bounded by the rib cage and abdominal muscles, comprises the thoracic cavity and the abdominopelvic cavity.

The coelomic space of the abdominopelvic cavity is the peritoneal cavity; that surrounding the heart is the pericardial cavity; and those around the lungs are the pleural cavities.

### 43.2 Epithelial Tissue

**Epithelium forms a barrier.**

Epithelial cells are tightly bound together, forming a selective barrier. Epithelial cells are replaced constantly and can regenerate in wound healing. Epithelium has a basal surface attached to underlying connective tissues, and a free apical surface.

**Epithelial types reflect their function.**

Epithelium is divided into two general classes: simple (one cell layer) and stratified (multiple cells thick). These are further divided into squamous, cuboidal, and columnar based on the shape of cells (see table 43.1). Vertebrate glands form from invaginated epithelia.

### 43.3 Connective Tissue

**Connective tissue proper may be either loose or dense.**

Connective tissues contain various cells in an extracellular matrix of proteins and ground substance. Connective tissue proper is divided into loose connective tissue and dense connective tissue.

**Special connective tissues have unique characteristics.**

Special connective tissues, such as cartilage, rigid bone, and blood, have unique cells and matrices (see table 43.2). Cartilage is formed by chondrocytes and bone by osteocytes.

**All connective tissues have similarities.**

All connective tissues originate from mesoderm and contain a variety of cells within an extracellular matrix.

### 43.4 Muscle Tissue (see table 43.3)

**Smooth muscle is found in most organs.**

Involuntary smooth muscle occurs in the viscera and is composed of long, spindle-shaped cells with a single nucleus.

**Skeletal muscle moves the body.**

Voluntary skeletal or striated muscle is usually attached by tendons to bones, and the cells (fibers) have multiple nuclei and contain contractile myofibrils.

**The heart is composed of cardiac muscle.**

Cardiac muscle consists of striated muscle cells connected to each other by gap junctions that allow coordination.

### 43.5 Nerve Tissue (see table 43.4)

**Neurons sometimes extend long distances.**

Neurons have a cell body with a nucleus; dendrites, which receive impulses; and an axon, which transmits impulses away.

**Neuroglia provide support for neurons.**

Neuroglia help regulate the neuronal environment. Some types form the myelin sheaths that surround some axons.

**Two divisions of the nervous system coordinate activity.**

The central nervous system is the brain and spinal cord, and the peripheral nervous system contains nerves and ganglia.

### 43.6 Overview of Vertebrate Organ Systems (see figure 43.6)

**Communication and integration sense and respond to the environment.**

The three organ systems involved in communication and integration are the nervous, sensory, and endocrine systems.

**Skeletal support and movement are vital to all animals.**

The musculoskeletal system consists of muscles and the skeleton they act upon.

**Regulation and maintenance of the body's chemistry ensures continued life.**

The digestive, circulatory, respiratory, and urinary systems accomplish ingestion of nutrients and elimination of wastes.

**The body can defend itself from attackers and invaders.**

The integumentary system forms a barrier against attack; the immune system mounts a counterattack to foreign pathogens.

**Reproduction and development ensure continuity of species.**

All vertebrate species are capable of sexual reproduction.

### 43.7 Homeostasis

Homeostasis refers to the dynamic constancy of the internal environment and is essential for life.

**Negative feedback mechanisms keep values within a range.**

Negative feedback loops include a sensor, an integration center, and effectors that respond to deviations from a set point.

**Antagonistic effectors act in opposite directions.**

Negative feedback mechanisms often occur in antagonistic pairs that push and pull against each other.

**Positive feedback mechanisms enhance a change.**

In a positive feedback loop changes in one direction bring about further changes in the same direction.

### 43.8 Regulating Body Temperature

**$Q_{10}$  is a measure of temperature sensitivity.**

$Q_{10}$  is the ratio of reaction rates at two temperatures 10°C apart. For chemical reactions  $Q_{10}$  is about 2. Most organisms have a  $Q_{10}$  around 2 to 3, indicating temperature affects mainly enzymatic reactions.

**Temperature is determined by internal and external factors.**

Internal factors include metabolic rate; external factors affect heat transfer. Heat is transferred through radiation, conduction, convection, and evaporation (see figure 43.11).

**Organisms are classified based on heat source.**

Endotherms have high metabolic rates and generate heat internally. Ectotherms have low metabolic rates and conform to ambient temperature.

**Ectotherms regulate temperature using behavior.**

Ectotherms move around in an environment to alter their temperature (see figures 43.12 and 43.13).

**Endotherms create internal metabolic heat for conservation or dissipation.**

Endotherms regulate temperature by changes in metabolic rate, blood flow, and sweating or panting. Thermogenesis occurs when temperature falls below a critical level.

**Mammalian thermoregulation is controlled by the hypothalamus (see figure 43.15).**

The hypothalamus acts through a heat-losing and heat-promoting center to keep the blood temperature near a set point. Fever is an increase in body temperature; torpor is a lowered metabolic state associated with dormancy.

## Review Questions

### UNDERSTAND

- Which of the following cavities would contain your stomach?
  - Peritoneal
  - Pericardial
  - Pleural
  - Thoracic
- Epithelial tissues do all of the following except
  - form barriers or boundaries.
  - absorb nutrients in the digestive tract.
  - transmit information in the central nervous system.
  - allow exchange of gases in the lung.
- Ectotherms
  - cannot regulate their body temperatures.
  - regulate their internal temperature using metabolic energy.
  - can regulate temperature using behavior.
  - regulate temperature by dissipating but not generating heat.
- Connective tissues include a diverse group of cells, yet they all share
  - cuboidal shape.
  - the ability to produce hormones.
  - the ability to contract.
  - the presence of an extracellular matrix.
- Skeletal muscle cells differ from the “typical” mammalian cell in that they
  - contain multiple nuclei.
  - have mitochondria.
  - have no plasma membrane.
  - are not derived from embryonic tissue.
- Examples of smooth muscle sites include
  - the lining of blood vessels.
  - the iris of the eye.
  - the wall of the digestive tract.
  - all of these.
- The function of neuroglia is to
  - carry messages from the PNS to the CNS.
  - support and protect neurons.
  - stimulate muscle contraction.
  - store memories.
- Skeletal muscle cells are
  - large multinucleate cells that arise by growth.
  - large multinucleate cells that arise by fusion of smaller cells.
  - small cells connected by many gap junctions.
  - large cells with a single nucleus.

### APPLY

- Connective tissues, although quite diverse in structure and location, do share a common theme; the connection between other types of tissues. Although all of the following seem to fit that criterion, one of the tissues listed is not a type of connective tissue. Which one?
  - Blood
  - Muscle
  - Adipose
  - Cartilage
- What do all the organs of the body have in common?
  - Each contains the same kinds of cells.
  - Each is composed of several different kinds of tissue.
  - Each is derived from ectoderm.
  - Each can be considered part of the circulatory system.
- Rheumatoid arthritis is an autoimmune disease that attacks the linings of joints within the body. The cells that line these joints, and whose destruction causes the symptoms of arthritis, are known as
  - osteocytes.
  - erythrocytes.
  - chondrocytes.
  - thrombocytes.
- Suppose that an alien virus arrives on Earth. This virus causes damage to the nervous system by attacking the structures of neurons. Which of the following structures would be immune from attack?
  - Axon
  - Dendrite
  - Neuroglia
  - All of these would be attacked by the virus.
- Homeostasis
  - is a dynamic process.
  - describes the maintenance of the internal environment of the body.
  - is essential to life.
  - is all of these.

6. Which of the following scenarios correctly describes positive feedback?
  - a. If the temperature increases in your room, your furnace increases its output of warm air.
  - b. If you drink too much water, you produce more urine.
  - c. If the price of gasoline increases, drivers decrease the length of their trips.
  - d. If you feel cold, you start to shiver.
7. The three types of muscle all share
  - a. a structure that includes striations.
  - b. a membrane that is electrically excitable.
  - c. the ability to contract.
  - d. the characteristic of self-excitation.

## SYNTHESIZE

1. Suppose that you discover a new disease that affects nutrient absorption in the gut as well as causes problems with the skin. Is it possible that one disease could involve the same tissues? How could this occur?

2. Which organ systems are involved in regulation and maintenance? Why do you think they are linked in this way?
3. We have all experienced hunger pangs. Is hunger a positive or negative feedback stimulus? Describe the steps involved in the response to this stimulus.
4. Why is homeostasis described as a dynamic process? How does negative feedback function in this process? How can antagonistic effectors result in a constant level, and how does this relate to the idea of a dynamic process?

Chapter **44**

# The Nervous System

## Chapter Outline

---

- 44.1** Nervous System Organization
- 44.2** The Mechanism of Nerve Impulse Transmission
- 44.3** Synapses: Where Neurons Communicate with Other Cells
- 44.4** The Central Nervous System: Brain and Spinal Cord
- 44.5** The Peripheral Nervous System: Sensory and Motor Neurons

20  $\mu\text{m}$ 

## Introduction

---

All animals except sponges use a network of nerve cells to gather information about the body's condition and the external environment, to process and integrate that information, and to issue commands to the body's muscles and glands. As we saw in chapter 43, homeostasis of the animal's body is accomplished by negative feedback loops that maintain conditions within narrow limits. Negative feedback implies not only detection of appropriate stimuli but also communication of information to begin a response. The nervous system, composed of neurons, such as the one pictured here, is a fast communication system and a part of many feedback systems in the body.

## 44.1 Nervous System Organization

### Learning Outcomes

1. Distinguish the subdivisions of the vertebrate nervous system.
2. Identify the functional structure of neurons.
3. Name the different cell types in the nervous system.

An animal must be able to respond to environmental stimuli. A fly escapes a flyswatter; the antennae of a crayfish detect food and the crayfish moves toward it. To accomplish these actions, animals must have *sensory receptors* that can detect the stimulus and *motor effectors* that can respond to it. In most invertebrate phyla and in all vertebrate classes, sensory receptors and motor effectors are linked by way of the nervous system.

### The central nervous system is the “command center”

As described in chapter 43, the nervous system consists of neurons and supporting cells. Figure 44.1 shows the three types of

neurons. In vertebrates, **sensory neurons** (or afferent neurons) carry impulses from sensory receptors to the *central nervous system (CNS)*, which is composed of the brain and spinal cord. **Motor neurons** (or efferent neurons) carry impulses from the CNS to effectors—muscles and glands. A third type of neuron is present in the nervous systems of most invertebrates and all vertebrates: **interneurons** (or association neurons). Interneurons are located in the brain and spinal cord of vertebrates, where they help provide more complex reflexes and higher associative functions, including learning and memory.

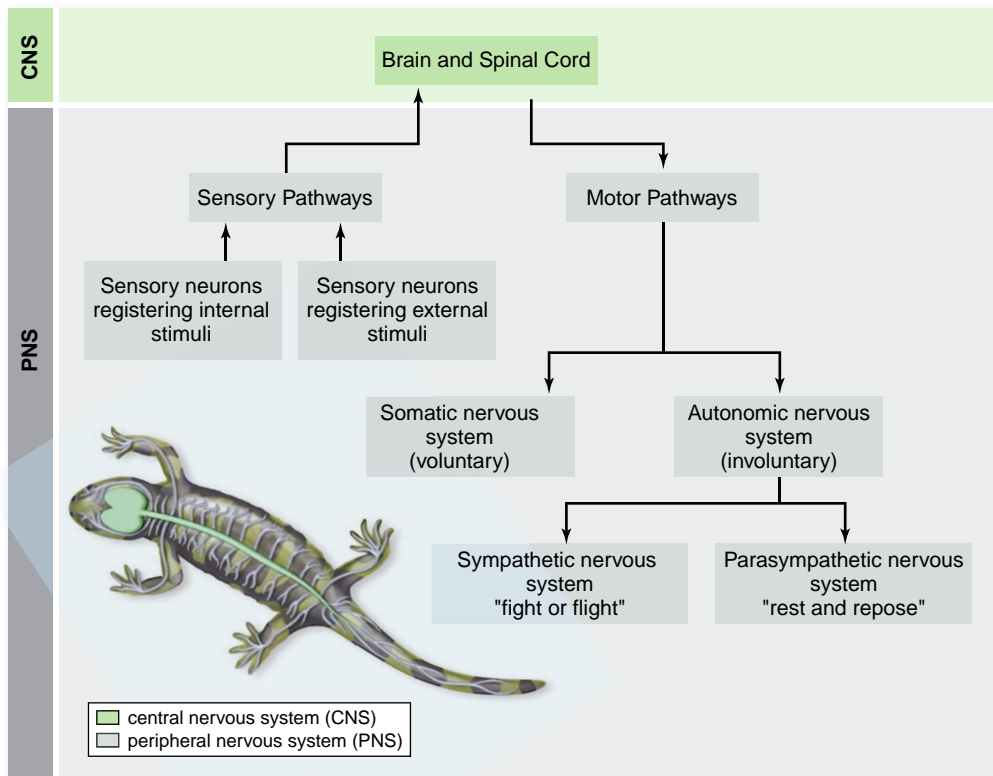

### The peripheral nervous system collects information and carries out responses

Together, sensory and motor neurons constitute the *peripheral nervous system (PNS)* in vertebrates. Motor neurons that stimulate skeletal muscles to contract make up the **somatic nervous system**; those that regulate the activity of the smooth muscles, cardiac muscle, and glands compose the **autonomic nervous system**.

The autonomic nervous system is further broken down into the *sympathetic* and *parasympathetic* divisions. These divisions counterbalance each other in the regulation of many organ systems. Figure 44.2 illustrates the relationships among the different parts of the vertebrate nervous system.

**Figure 44.1 Three types of neurons.** The brain and spinal cord form the central nervous system (CNS) of vertebrates, and sensory and motor neurons form the peripheral nervous system (PNS). Sensory neurons of the peripheral nervous system carry information about the environment to the CNS. Interneurons in the CNS provide links between sensory and motor neurons. Motor neurons of the PNS system carry impulses or “commands” to muscles and glands (effectors).

**Figure 44.2 Divisions of the vertebrate nervous system.** The major divisions are the central and peripheral nervous systems. The brain and spinal cord make up the central nervous system (CNS). The peripheral nervous system (PNS) includes everything outside the CNS and is divided into sensory and motor pathways. Sensory pathways can detect either external or internal stimuli. Motor pathways are divided into the somatic nervous system that activates voluntary muscles and the autonomic nervous system that activate involuntary muscles. The sympathetic and parasympathetic nervous systems are subsets of the autonomic nervous system that trigger opposing actions.

## The structure of neurons supports their function

Despite their varied appearances, most neurons have the same functional architecture (figure 44.3). The **cell body** is an enlarged region containing the nucleus. Extending from the cell body are one or more cytoplasmic extensions called **dendrites**. Motor and association neurons possess a profusion of highly branched dendrites, enabling those cells to receive information from many different sources simultaneously. Some neurons have extensions from the dendrites called *dendritic spines* that increase the surface area available to receive stimuli.

The surface of the cell body integrates the information arriving at its dendrites. If the resulting membrane excitation is sufficient, it triggers the conduction of impulses away from the cell body along an **axon**. Each neuron has a single axon leaving its cell body, although an axon may also branch to stimulate a number of cells. An axon can be quite long: The axons controlling the muscles in a person's feet can be more than a meter long, and the axons that extend from the skull to the pelvis in a giraffe are about 3 m long.

## Supporting cells include Schwann cells and oligodendrocytes

Neurons are supported both structurally and functionally by supporting cells, which are collectively called neuroglia. These cells are one-tenth as big and 10 times more numerous than neurons, and they serve a variety of functions, including supplying the neurons with nutrients, removing wastes from neurons, guiding axon migration, and providing immune functions.

**Figure 44.3 Structure of a typical vertebrate neuron.** Extending from the cell body are many dendrites, which receive information and carry it to the cell body. A single axon transmits impulses away from the cell body. Many axons are encased by a myelin sheath, with multiple membrane layers that insulate the axon. Small gaps, called nodes of Ranvier, interrupt the sheath at regular intervals. Schwann cells form myelin sheaths in the PNS (as shown for this motor neuron); extensions of oligodendrocytes form myelin sheaths in the CNS.

**Figure 44.4** The formation of the myelin sheath around a peripheral axon. The myelin sheath forms by successive wrappings of Schwann cell membranes around the axon.

Two of the most important kinds of neuroglia in vertebrates are **Schwann cells** and **oligodendrocytes**, which produce **myelin sheaths** that surround the axons of many neurons. Schwann cells produce myelin in the PNS, and oligodendrocytes produce myelin in the CNS. During development, these cells wrap themselves around each axon several times to form the myelin sheath—an insulating covering consisting of multiple layers of compacted membrane (figure 44.4).

Axons that have myelin sheaths are said to be myelinated, and those that don't are unmyelinated. In the CNS, myelinated axons form the *white matter*, and the unmyelinated dendrites and cell bodies form the *gray matter*. In the PNS, myelinated axons are bundled together, much like wires in a cable, to form nerves.

Small gaps, known as **nodes of Ranvier** (see figure 44.3), interrupt the myelin sheath at intervals of 1 to 2  $\mu\text{m}$ . We discuss the role of the myelin sheath in impulse conduction in the next section.

### Learning Outcomes Review 44.1

The vertebrate nervous system consists of the central nervous system (CNS) and peripheral nervous system (PNS). The PNS comprises the somatic nervous system and autonomic nervous system; the latter has sympathetic and parasympathetic divisions. A neuron consists of a cell body, dendrites that receive information, and a single axon that sends signals. Neurons carry out nervous system functions; they are supported by a variety of neuroglia.

- Which division of the PNS is under conscious control?

## 44.2 The Mechanism of Nerve Impulse Transmission

### Learning Outcomes

1. Identify the ions involved in nerve impulse transmission and their relative concentrations inside and outside the neuron.
2. Describe the production of the resting potential.
3. Explain how the action of voltage-gated channels produces an action potential.

Neuronal function depends on a changeable permeability to ions. Upon stimulation, electrical changes in the plasma membrane spread or propagate from one part of the cell to another. The architecture of the neuron provides the mechanisms for the generation and spread of these membrane electrical potentials.

The unique mechanisms of neurons primarily depend on the presence of specialized membrane transport proteins, where they are located, and how they are activated. First, we examine some of the basic electrical properties common to the plasma membranes of most animal cells, and then we look at how these properties operate in neurons.

### An electrical difference exists across the plasma membrane

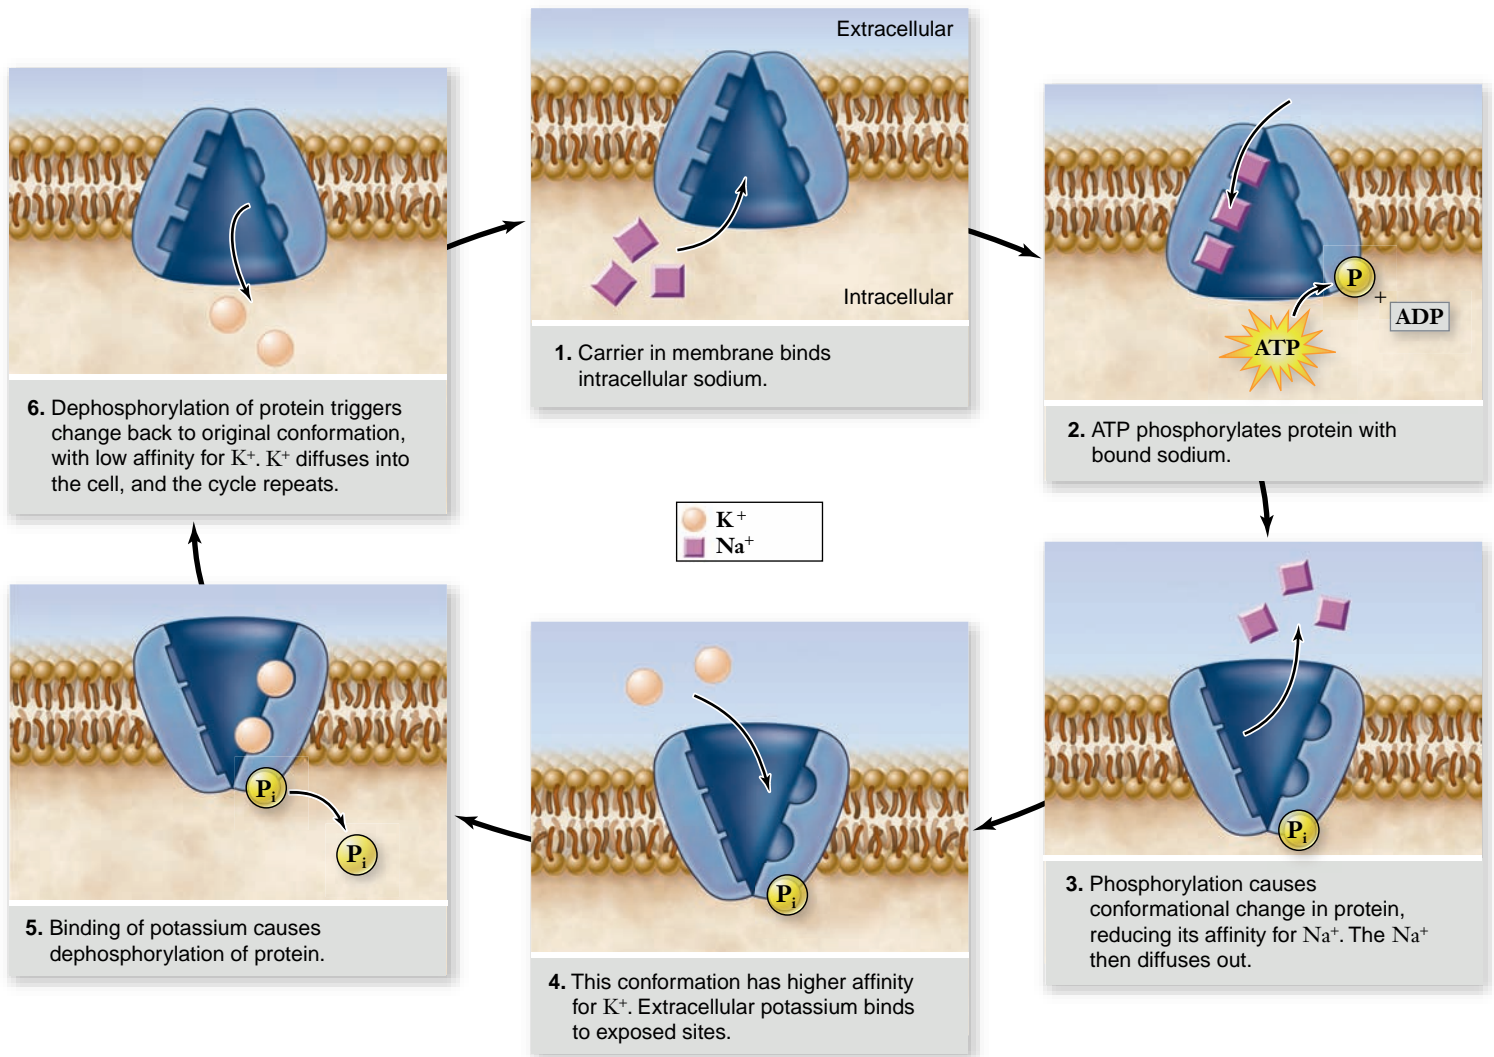

You first learned about membrane potential in chapter 5, where transport of ions across the cell membrane was discussed. Membrane potential is similar to the electrical potential difference that exists between the two poles of a flashlight or automobile battery. One pole is positive, and the other is negative. Similarly, a potential difference exists across every cell's plasma membrane. The side of the membrane exposed to the cytoplasm is the negative pole, and the side exposed to the extracellular fluid is the positive pole.

When a neuron is not being stimulated, it maintains a **resting potential**. A cell is very small, and so its membrane potential is very small. The resting membrane potential of many vertebrate neurons ranges from  $-40$  to  $-90$  millivolts (mV), or 0.04 to 0.09 volts (V). For the examples and figures in this chapter, we use an average resting membrane potential value of  $-70$  mV. The minus sign indicates that the inside of the cell is negative with respect to the outside.

### Contributors to membrane potential

The inside of the cell is more negatively charged in relation to the outside because of two factors:

1. The sodium–potassium pump, described in chapter 5, brings two potassium ions ( $\text{K}^+$ ) into the cell for every three sodium ions ( $\text{Na}^+$ ) it pumps out (figure 44.5). This helps establish and maintain concentration differences that result in high  $\text{K}^+$  and low  $\text{Na}^+$  concentrations inside the cell, and high  $\text{Na}^+$  and low  $\text{K}^+$  concentrations outside the cell.

**Figure 44.5 The sodium–potassium pump.** This pump transports three  $Na^+$  to the outside of the cell and simultaneously transports two  $K^+$  to the inside of the cell. This is an active transport carrier requiring the (phosphorylating) energy of ATP.

- Ion channels** in the cell membrane are more numerous for  $K^+$  than for  $Na^+$  making the membrane more permeable for  $K^+$ . Ion channels are membrane proteins that form pores through the membrane, allowing diffusion of specific ions across the membrane. Because there are more ion channels for  $K^+$ , the membrane is more permeable to  $K^+$  and it will diffuse out of the cell.

Two major forces act on ions in establishing the resting membrane potential: (1) The electrical potential produced by unequal distribution of charges across the membrane, and (2) the chemical force produced by unequal concentrations of ions across the membrane.

#### **The resting potential: Balance between two forces**

The resting potential arises due to the action of the sodium–potassium pump and the differential permeability of the membrane to  $Na^+$  and  $K^+$  due to ion channels. The pump moves three  $Na^+$  outside for every two  $K^+$  inside, which creates a small imbalance in cations outside the cell. This has only a minor effect; however, the concentration gradients created by the pump are

significant. The concentration of  $K^+$  is much higher inside the cell than outside, leading to diffusion of  $K^+$  through open  $K^+$  channels. Since the membrane is not permeable to the negative ions that could counterbalance this (mainly organic phosphates, amino acids, and proteins) it leads to a buildup of positive charge outside the membrane and negative charge inside the membrane. This electrical potential then is an attractive force pulling  $K^+$  ions back inside the cell. The balance between the diffusional force and the electrical force leads to the **equilibrium potential** (table 44.1). By relating the work done by each type of force, we can derive a quantitative expression for this equilibrium potential called the Nernst equation. This assumes the action of a single ion, and for a positive ion with charge equal to +1, the Nernst equation is:

$$E_K = 58 \text{ mV} \log\left(\frac{[K^+]_{\text{out}}}{[K^+]_{\text{in}}}\right)$$

The calculated equilibrium potential for  $K^+$  is  $-90 \text{ mV}$  (see table 44.1), close to the measured value of  $-70 \text{ mV}$ . The calculated value for  $Na^+$  is  $+60 \text{ mV}$ , clearly not at all close to the measured value, but the leakage of a small amount of  $Na^+$  back into the cell is responsible for lowering the equilibrium potential of  $K^+$  to the  $-70 \text{ mV}$  value observed. The resting membrane potential of a neuron

TABLE 44.1 The Ionic Composition of Cytoplasm and Extracellular Fluid (ECF)				
Ion	Concentration in ECF (mM)	Concentration in Cytoplasm (mM)	Ratio (ECF:cytoplasm)	Equilibrium Potential (mV)
Na <sup>+</sup>	150	15	10:1	+60
K <sup>+</sup>	5	150	1:30	-90
Cl <sup>-</sup>	110	7	15:1	-70

can be measured and viewed or graphed using a voltmeter and a pair of electrodes, one outside and one inside the cell (figure 44.6).

The uniqueness of neurons compared with other cells is not the production and maintenance of the resting membrane potential, but rather the sudden temporary disruptions to the resting membrane potential that occur in response to stimuli. Two types of changes can be observed: *graded potentials* and *action potentials*.

### Graded potentials are small changes that can reinforce or negate each other

**Graded potentials**, small transient changes in membrane potential, are caused by the activation of a class of channel proteins called **gated ion channels**. Introduced in chapter 9, gated channels behave like a door that can open or close, unlike ion leakage channels that are always open. The structure of gated ion channels is such that they have alternative conformations that can be open, allowing the passage of ions, or closed, not allowing the passage of ions. Each gated channel is selective, that is, when open they allow diffusion of only one type of ion. Most gated channels are closed in the normal resting cell.

### Chemically gated channels

In most neurons, gated ion channels in dendrites respond to the binding of signaling molecules (figure 44.7; see also figure 9.4a). These are referred to as *chemically gated*, or *ligand-gated*, channels. *Ligands* are chemical groups that attach to larger molecules to regulate or contribute to their function. When ligands temporarily bind to membrane receptor proteins or channels, they cause the shape of the protein to change, thus opening the ion channel. Hormones and neurotransmitters act as ligands, inducing opening of ligand-gated channels, and causing changes in plasma membrane permeability that lead to changes in membrane voltage.

### Depolarization and hyperpolarization

Permeability changes are measurable as depolarizations or hyperpolarizations of the membrane potential. A **depolarization** makes the membrane potential less negative (more positive), whereas a **hyperpolarization** makes the membrane potential more negative. For example, a change in potential from -70 mV to -65 mV is a depolarization; a change from -70 mV to -75 mV is a hyperpolarization.

**Figure 44.6 Establishment of the resting membrane potential.** A voltmeter placed with one electrode inside an axon and the other outside the membrane. The electric potential inside is -70 mV relative to the outside of the membrane. K<sup>+</sup> diffuses out of the cell through ion channels because its concentration is higher inside than outside. Negatively charged proteins and nucleic acids inside the cell cannot leave the cell and attract cations from outside the cell, such as K<sup>+</sup>. This balance of electrical and diffusional forces produces the resting potential. The sodium-potassium pump maintains cell equilibrium by counteracting the effects of Na<sup>+</sup> leakage into the cell and contributes to the resting potential by moving 3 Na<sup>+</sup> outside for every 2 K<sup>+</sup> moved inside.

**Figure 44.7 A chemically gated ion channel.** The acetylcholine (ACh) receptor is a chemically gated channel that can bind the neurotransmitter ACh. Binding of ACh causes the channel to open allowing  $\text{Na}^+$  ions to flow into the cell by diffusion.

These small changes in membrane potential result in *graded potentials* because their size depends on either the strength of the stimulus or the amount of ligand available to bind with their receptors. These potentials diminish in amplitude as they spread from their point of origin. Depolarizing or hyperpolarizing potentials can add together to amplify or reduce their effects, just as two waves can combine to make a bigger one when they meet in synchronization or can cancel each other out when a trough meets with a crest. The ability of graded potentials to combine is called **summation** (figure 44.8). We will return to this topic in the next section after we discuss the nature of action potentials.

**Figure 44.8 Graded potentials.** Graded potentials are the summation of subthreshold potentials produced by the opening of different chemically gated channels. (1) A weak excitatory stimulus,  $E_1$ , elicits a smaller depolarization than (2) a stronger stimulus,  $E_2$ . (3) An inhibitory stimulus,  $I$ , produces a hyperpolarization. (4) If all three stimuli occur very close together, the resulting polarity change will be the sum of the three individual changes.

## Action potentials result when depolarization reaches a threshold

When a particular level of depolarization is reached (about  $-55$  mV in some mammalian axons), a nerve impulse, or action potential, is produced in the region where the axon arises from the cell body. The level of depolarization needed to produce an action potential is called the **threshold potential**. Depolarizations bring a neuron closer to the threshold, and hyperpolarizations move the neuron further from the threshold.

The action potential is caused by another class of ion channels: **voltage-gated ion channels**. These channels open and close in response to changes in membrane potential; the flow of ions controlled by these channels creates the action potential. Voltage-gated channels are found in neurons and in muscle cells. Two different channels are used to create an action potential in neurons: **voltage-gated  $\text{Na}^+$  channels** and **voltage-gated  $\text{K}^+$  channels**.

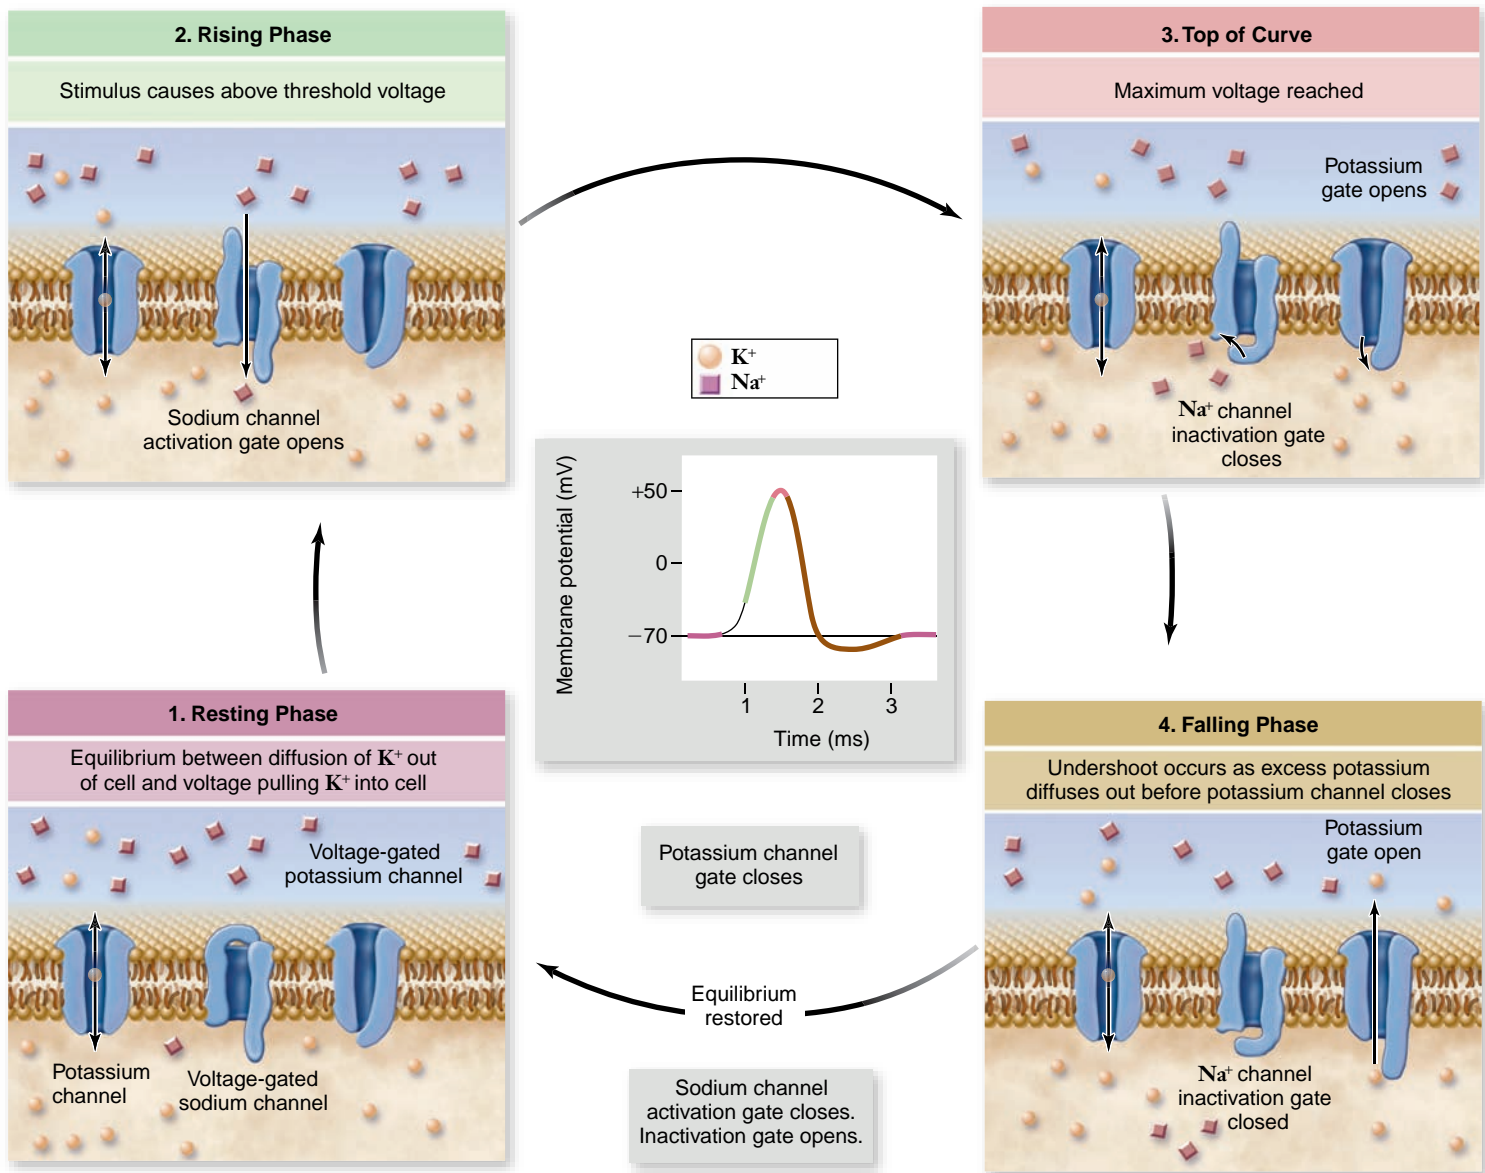

### Sodium and potassium voltage-gated channels

The behavior of the voltage-gated  $\text{Na}^+$  channel is more complex than that of the  $\text{K}^+$  channel, so we will consider it first. The channel has two gates: an activation gate and an inactivation gate. In its resting state the activation gate is closed and the inactivation gate is open. When the threshold voltage is reached, the activation gate opens rapidly, leading to an influx of  $\text{Na}^+$  ions due to both concentration and voltage gradients. After a short period the inactivation gate closes, stopping the influx of  $\text{Na}^+$  ions and leaving the channel in a temporarily inactivated state. The channel is returned to its resting state by the activation gate closing and the inactivation gate opening. The result of this is a transient influx of  $\text{Na}^+$  that depolarizes the membrane in response to a threshold voltage.

The  $\text{K}^+$  channel has a single activation gate that is closed in the resting state. In response to a threshold voltage, it opens slowly. With the high concentration of  $\text{K}^+$  inside the cell, and the membrane now far from the equilibrium potential, an efflux of  $\text{K}^+$  begins. The positive charge now leaving the cell counteracts the effect of the  $\text{Na}^+$  channel and repolarizes the membrane.

### Tracing an action potential's changes

Let us now put all of this together and see how the changing flux of ions leads to an action potential. The action potential has three phases: a *rising phase*, a *falling phase*, and an *undershoot phase* (figure 44.9). When a threshold potential is reached, the rapid opening of the  $\text{Na}^+$  channel causes an influx of  $\text{Na}^+$  that shifts the membrane potential toward the equilibrium potential for  $\text{Na}$  ( $+60$  mV). This appears as the rising phase on an oscilloscope. The membrane potential never quite reaches  $+60$  mV because the inactivation gate of the  $\text{Na}^+$  channel closes, terminating the rising phase. At the same time, the opening of the  $\text{K}^+$  channel leads to  $\text{K}^+$  diffusing out of the cell, repolarizing the membrane in the falling phase. The  $\text{K}^+$  channels remain open longer than necessary to restore the resting potential, resulting in a slight undershoot. This entire sequence of events for a single action potential takes about a millisecond.

**Figure 44.9 The action potential.** (1) At resting membrane potential, voltage-gated ion channels are closed, but there is some diffusion of  $K^+$ . In response to a stimulus, the cell begins to depolarize, and once the threshold level is reached, an action potential is produced. (2) Rapid depolarization occurs (the rising portion of the spike) because voltage-gated sodium channel activation gates open, allowing  $Na^+$  to diffuse into the axon. (3) At the top of the spike,  $Na^+$  channel inactivation gates close, and voltage-gated potassium channels that were previously closed begin to open. (4) With the  $K^+$  channels open, repolarization occurs because of the diffusion of  $K^+$  out of the axon. An undershoot occurs before the membrane returns to its original resting potential.

### The nature of action potentials

Action potentials are separate, all-or-none events. An action potential occurs if the threshold voltage is reached, but not while the membrane remains below threshold. Action potentials do not add together or interfere with one another, as graded potentials can. After  $Na^+$  channels “fire” they remain in an inactivated state until the inactivation gate reopens, preventing any summing of effects. This is called the absolute refractory period when the membrane cannot be stimulated. There is also a relative refractory period during which stimulation produces action potentials of reduced amplitude.

The production of an action potential results entirely from the passive diffusion of ions. However, at the end of each

action potential, the cytoplasm contains a little more  $Na^+$  and a little less  $K^+$  than it did at rest. Although the number of ions moved by a single action potential is tiny relative to the concentration gradients of  $Na^+$  and  $K^+$ , eventually this would have an effect. The constant activity of the sodium–potassium pump compensates for these changes. Thus, although active transport is not required to produce action potentials, it is needed to maintain the ion gradients.

### Action potentials are propagated along axons

The movement of an action potential through an axon is not generated by ions flowing from the base of the axon to the end.

**Figure 44.10 Propagation of an action potential in an unmyelinated axon.** When one region produces an action potential and undergoes a reversal of polarity, it serves as a depolarization stimulus for the next region of the axon. In this way, action potentials regenerate along each small region of the unmyelinated axon membrane.

Instead an action potential originates at the base of the axon, and is then recreated in adjacent stretches of membrane along the axon.

Each action potential, during its rising phase, reflects a reversal in membrane polarity. The positive charges due to

influx of  $\text{Na}^+$  can depolarize the adjacent region of membrane to threshold, so that the next region produces its own action potential (figure 44.10). Meanwhile, the previous region of membrane repolarizes back to the resting membrane potential. The signal does not back up because the  $\text{Na}^+$  channels that have just “fired” are still in an inactivated state and are refractory (resistant) to stimulation.

The propagation of an action potential is similar to people in a stadium performing the “wave”: Individuals stay in place as they stand up (depolarize), raise their hands (peak of the action potential), and sit down again (repolarize). The wave travels around the stadium, but the people stay in place.

## There are two ways to increase the velocity of nerve impulses

Action potentials are conducted without decreasing in amplitude, so the last action potential at the end of an axon is just as large as the first action potential. Animals have evolved two ways to increase the velocity of nerve impulses. The velocity of conduction is greater if the diameter of the axon is large or if the axon is myelinated (table 44.2).

Increasing the diameter of an axon increases the velocity of nerve impulses due to the electrical property of resistance. Electrical resistance is inversely proportional to cross-sectional area, which is a function of diameter, so larger diameter axons have less resistance to current flow. The positive charges carried by  $\text{Na}^+$  flows farther in a larger diameter axon, leading to a higher than threshold voltage farther from the origin of  $\text{Na}^+$  influx.

Larger diameter axons are found primarily in invertebrates. For example, in the squid, the escape response is controlled by a so-called giant axon. This large axon conducts nerve impulses faster than other smaller squid axons, allowing a rapid escape response. The squid giant axon was used by Alan Lloyd Hodgkin and Andrew Huxley in their pioneering studies of nerve transmission.

Myelinated axons conduct impulses more rapidly than unmyelinated axons because the action potentials in myelinated

TABLE 44.2		Conduction Velocities of Some Axons	
	Axon Diameter ( $\mu\text{m}$ )	Myelin	Conduction Velocity (m/s)
Squid giant axon	500	No	25
Large motor axon to human leg muscle	20	Yes	120
Axon from human skin pressure receptor	10	Yes	50
Axon from human skin temperature receptor	5	Yes	20
Motor axon to human internal organ	1	No	2

## 44.3 Synapses: Where Neurons Communicate with Other Cells

### Learning Outcomes

1. Distinguish between electrical and chemical synapses.
2. List the different chemical neurotransmitters.
3. Explain the effects of addictive drugs on the nervous system.

**Figure 44.11 Saltatory conduction in a myelinated axon.** Action potentials are only produced at the nodes of Ranvier in a myelinated axon. One node depolarizes the next node so that the action potentials can skip between nodes. As a result, saltatory (“jumping”) conduction in a myelinated axon is more rapid than conduction in an unmyelinated axon.

axons are only produced at the nodes of Ranvier. One action potential still serves as the depolarization stimulus for the next, but the depolarization at one node spreads quickly beneath the insulating myelin to trigger opening of voltage-gated channels at the next node. The impulses therefore seem to jump from node to node (figure 44.11) in a process called **saltatory conduction** (Latin *saltare*, “to jump”).

To see how saltatory conduction speeds impulse transmission, let’s return for a moment to the stadium wave analogy to describe propagation of an action potential. The wave moves across the seats of a crowded stadium as fans seeing the people in the adjacent section stand up are triggered to stand up in turn. Because the wave skips sections of empty bleachers, it actually progresses around the stadium even faster with more empty sections. The wave doesn’t have to “wait” for the missing people to stand, so it simply moves to the next populated section—just as the action potential jumps the nonconducting regions of myelin between exposed nodes.

### Learning Outcomes Review 44.2

Neurons maintain high  $K^+$  levels inside the cell, and high  $Na^+$  levels outside the cell. Diffusion of  $K^+$  to the outside leads to a resting potential of about  $-70$  mV. Opening of ligand-gated channels can depolarize or hyperpolarize the membrane, causing a graded potential. Action potentials are triggered when membrane potential exceeds a threshold value. Voltage-gated  $Na^+$  channels open, and depolarization occurs; subsequent opening of  $K^+$  channels leads to repolarization.

- How can only positive ions result in depolarization and repolarization of the membrane during an action potential?

An action potential passing down an axon eventually reaches the end of the axon and all of its branches. These branches may form junctions with the dendrites of other neurons, with muscle cells, or with gland cells. Such intercellular junctions are called **synapses**. The neuron whose axon transmits action potentials to the synapse is termed the *presynaptic cell*, and the cell receiving the signal on the other side of the synapse is the *postsynaptic cell*.

### The two types of synapses are electrical and chemical

The nervous systems of animals have two basic types of synapses: electrical and chemical. **Electrical synapses** involve direct cytoplasmic connections formed by gap junctions between the pre- and postsynaptic neurons (see chapter 4; figure 4.27). Membrane potential changes, including action potentials, pass directly and rapidly from one cell to the other through the gap junctions. Electrical synapses are common in invertebrate nervous systems, but are rare in vertebrates.

The vast majority of vertebrate synapses are *chemical synapses* (figure 44.12). When synapses are viewed under a light microscope, the presynaptic and postsynaptic cells appear to touch, but when viewed with an electron microscope most have a **synaptic cleft**, a narrow space that separates these two cells (figure 44.13).

The end of the presynaptic axon is swollen and contains numerous **synaptic vesicles**, each packed with chemicals called *neurotransmitters*. When action potentials arrive at the end of the axon, they stimulate the opening of voltage-gated calcium ( $Ca^{2+}$ ) channels, causing a rapid inward diffusion of  $Ca^{2+}$ . This influx of  $Ca^{2+}$  triggers a complex series of events that leads to the fusion of synaptic vesicles with the plasma membrane and the release of neurotransmitter by exocytosis (see chapter 5; figure 44.14).

The higher the frequency of action potentials in the presynaptic axon, the greater the number of vesicles that release their contents of neurotransmitters. The neurotransmitters diffuse to the other side of the cleft and bind to chemical- or ligand-gated receptor proteins in the membrane of the postsynaptic cell. The action of these receptors produces graded potentials in the postsynaptic membrane.

Neurotransmitters are chemical signals in an otherwise electrical system, requiring tight control over the duration of their action. Neurotransmitters must be rapidly removed from the synaptic cleft to allow new signals to be transmitted. This is accomplished by a variety of mechanisms, including enzymatic

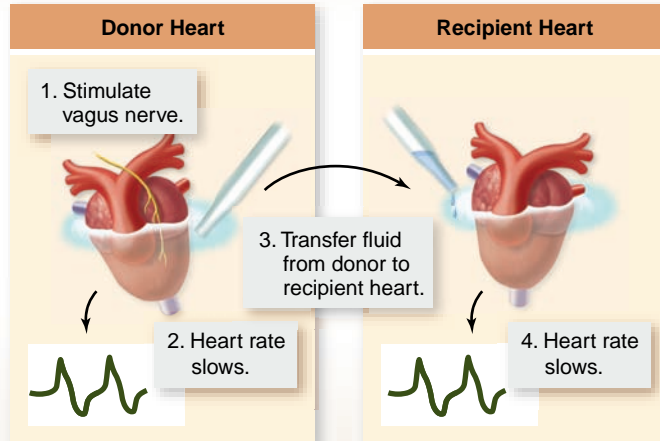

## SCIENTIFIC THINKING

**Question:** Is communication between neurons, and between neurons and muscle, chemical or electrical?

**Hypothesis:** Signaling between a neuron and heart muscle is chemical.

**Prediction:** Application of chemical solutes from one heart will affect the activity of another heart.

**Test:** Two frog hearts are placed in saline, one with vagus nerve attached, the other without. The vagus heart is stimulated, then fluid from around the vagus nerve is removed and applied to the other heart.

**Result:** Heart that was not stimulated by the vagus nerve slows as though it was stimulated.

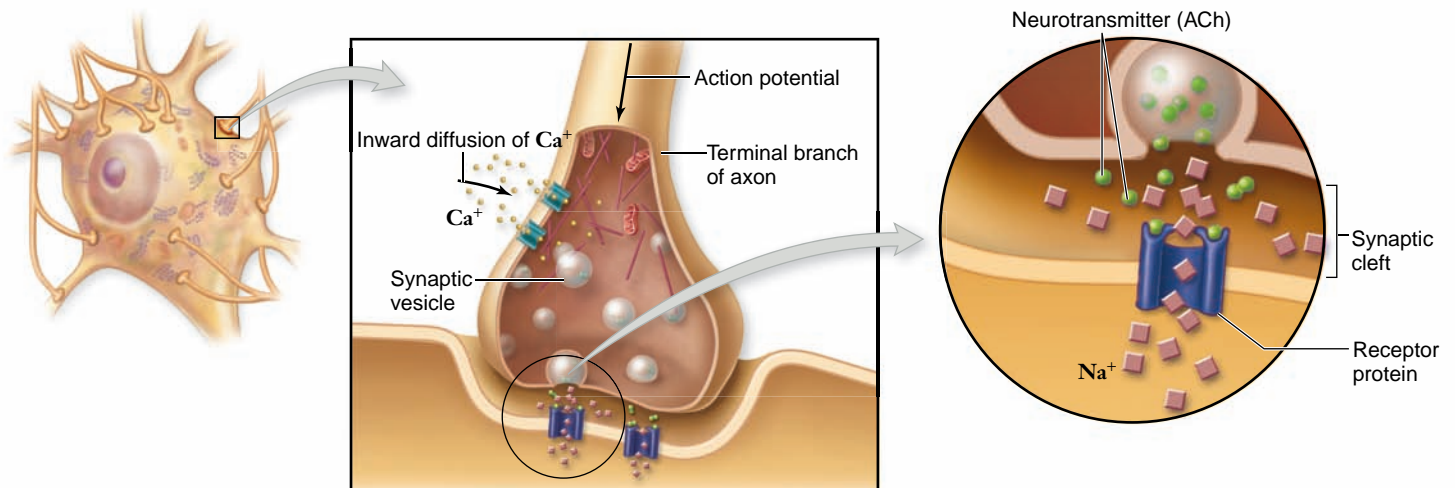

**Conclusion:** The nerve released a chemical signal that slowed heart rate.

**Further Experiments:** How does this conclusion extend the experiment described in Fig 43.5?

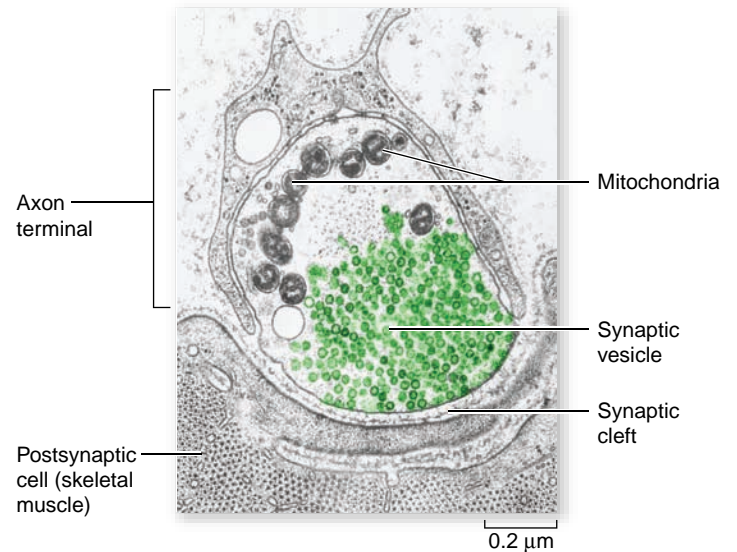

**Figure 44.12 Synaptic signaling.**

digestion in the synaptic cleft, reuptake of neurotransmitter molecules by the neuron, and uptake by glial cells.

Several different types of neurotransmitters have been identified, and they act in different ways. We next consider the action of a few of the important neurotransmitter chemicals.

**Figure 44.14 The release of neurotransmitter.** Action potentials arriving at the end of an axon trigger inward diffusion of Ca<sup>2+</sup>, which causes synaptic vesicles to fuse with the plasma membrane and release their neurotransmitters (acetylcholine [ACh] in this case). Neurotransmitter molecules diffuse across the synaptic gap and bind to ligand-gated receptors in the postsynaptic membrane.

**Figure 44.13 A synaptic cleft.** An electron micrograph showing a neuromuscular synapse. Synaptic vesicles have been colored green.

## Many different chemical compounds serve as neurotransmitters

No single chemical characteristic defines a neurotransmitter, although we can group certain types according to chemical similarities. Some, such as acetylcholine, have wide use in the nervous system, particularly where nerves connect with muscles. Other neurotransmitters are found only in very specific types of junctions, such as in the CNS.

### Acetylcholine

Acetylcholine (ACh) is the neurotransmitter that crosses the synapse between a motor neuron and a muscle fiber. This synapse is called a **neuromuscular junction** (figures 44.14, 44.15).

**Figure 44.15 Neuromuscular junctions.** A light micrograph shows axons branching to make contact with several individual muscle fibers.

Acetylcholine binds to its receptor proteins in the postsynaptic membrane and causes ligand-gated ion channels within these proteins to open (see figure 44.7). As a result, that site on the postsynaptic membrane produces a depolarization (figure 44.16a) called an *excitatory postsynaptic potential (EPSP)*. The EPSP, if large enough, can open the voltage-gated channels for  $\text{Na}^+$  and  $\text{K}^+$  that are responsible for action potentials. Because the postsynaptic cell in this case is a skeletal muscle fiber, the action potentials it produces stimulate muscle contraction through mechanisms discussed in chapter 47.

For the muscle to relax, ACh must be eliminated from the synaptic cleft. *Acetylcholinesterase (AChE)*, an enzyme in the postsynaptic membrane, eliminates ACh. This enzyme, one of the fastest known, cleaves ACh into inactive fragments. Nerve gas and the agricultural insecticide parathion are potent inhibitors of AChE; in humans, they can produce severe spastic paralysis and even death if paralysis affects the respiratory muscles. Although ACh acts as a neurotransmitter between motor neurons and skeletal muscle cells, many neurons also use ACh as a neurotransmitter at their synapses with the dendrites or cell bodies of other neurons.

### Amino acids

Glutamate is the major excitatory neurotransmitter in the vertebrate CNS. Excitatory neurotransmitters act to stimulate action potentials by producing EPSPs. Some neurons in the brains of people suffering from Huntington disease undergo changes that render them hypersensitive to glutamate, leading to neurodegeneration.

Glycine and  $\gamma$ -aminobutyric acid (GABA) are inhibitory neurotransmitters. These neurotransmitters cause the opening of ligand-gated channels for the chloride ion ( $\text{Cl}^-$ ), which has a concentration gradient favoring its diffusion into the neuron. Because  $\text{Cl}^-$  is negatively charged, it makes the inside of the membrane

a.

b.

**Figure 44.16 Different neurotransmitters can have different effects.** a. An excitatory neurotransmitter promotes a depolarization, or excitatory postsynaptic potential (EPSP). b. An inhibitory neurotransmitter promotes a hyperpolarization, or inhibitory postsynaptic potential (IPSP).

even more negative than it is at rest—for example, from  $-70$  mV to  $-85$  mV (see figure 44.16b). This hyperpolarization is called an *inhibitory postsynaptic potential (IPSP)*, and it is very important for neural control of body movements and other brain functions. The drug diazepam (Valium) causes its sedative and other effects by enhancing the binding of GABA to its receptors, thereby increasing the effectiveness of GABA at the synapse.

### Biogenic amines

The **biogenic amines** include the hormone epinephrine (adrenaline), together with the neurotransmitters dopamine, norepinephrine, and serotonin. Epinephrine, norepinephrine, and dopamine are derived from the amino acid tyrosine and are included in the subcategory of *catecholamines*. Serotonin is a biogenic amine derived from a different amino acid, tryptophan.

**Epinephrine** is released into the blood as a hormonal secretion, while **norepinephrine** is released at synapses of neurons in the sympathetic nervous system (discussed in detail later on). The effects of these neurotransmitters on target receptors are responsible for the “fight or flight” response—faster and stronger heartbeat, increased blood glucose concentration, and diversion of blood flow into the muscles and heart.

**Dopamine** is a very important neurotransmitter used in some areas of the brain controlling body movements and other functions. Degeneration of particular dopamine-releasing neurons produces the resting muscle tremors of Parkinson disease, and people with this condition are treated with L-dopa (an acronym for L-3,4-dihydroxyphenylalanine), a precursor from which dopamine can be produced. Additionally, studies suggest that excessive activity of dopamine-releasing neurons in other areas of the brain is associated with schizophrenia. As a result, drugs that block the production of dopamine, such as the dopamine antagonist chlorpromazine (Thorazine), sometimes help patients with schizophrenia.

**Serotonin** is a neurotransmitter involved in the regulation of sleep, and it is also implicated in various emotional states. Insufficient activity of neurons that release serotonin may be one cause of clinical depression. Antidepressant drugs, such as fluoxetine (Prozac), block the elimination of serotonin from the synaptic cleft; these drugs are termed *selective serotonin reuptake inhibitors*, or SSRIs.

### Other neurotransmitters

Axons also release various polypeptides, called **neuropeptides**, at synapses. These neuropeptides may have a typical neurotransmitter function, or they may have more subtle, long-term action on the postsynaptic neurons. In the latter case, they are often called **neuromodulators**. A given axon generally releases only one kind of neurotransmitter, but many can release both a neurotransmitter and a neuromodulator.

**Substance P** is an important neuropeptide released at synapses in the CNS by sensory neurons activated by painful stimuli. The perception of pain, however, can vary depending on circumstances. An injured football player may not feel the full extent of his trauma, for example, until he is out of the game.

The intensity with which pain is perceived partly depends on the effects of neuropeptides called *enkephalins* and *endorphins*. **Enkephalins**, released by axons descending from the brain into the spinal cord, inhibit the passage of pain informa-

tion back up to the brain. **Endorphins**, released by neurons in the brain stem, also block the perception of pain. Opium and its derivatives, morphine and heroin, have an analgesic (pain-reducing) effect because they are similar enough in chemical structure to bind to the receptors normally used by enkephalins and endorphins. For this reason, the enkephalins and the endorphins are referred to as *endogenous opiates*.

Nitric oxide (NO) is the first gas known to act as a regulatory molecule in the body. Because NO is a gas, it diffuses through membranes, so it cannot be stored in vesicles. It is produced as needed from the amino acid arginine. Nitric oxide diffuses out of the presynaptic axon and into neighboring cells by simply passing through the lipid portions of the plasma membranes.

In the PNS, nitric oxide is released by some neurons that innervate the gastrointestinal tract, penis, respiratory passages, and cerebral blood vessels. These autonomic neurons cause smooth-muscle relaxation in their target organs. This relaxation can produce the engorgement of the spongy tissue of the penis with blood, causing an erection. The drug sildenafil (Viagra) increases the release of NO in the penis, thus enabling and prolonging an erection. The brain releases nitric oxide as a neurotransmitter, where it appears to participate in the processes of learning and memory.

## A postsynaptic neuron must integrate input from many synapses

Different types of input from a number of presynaptic neurons influence the activity of a postsynaptic neuron in the brain and spinal cord of vertebrates. For example, a single motor neuron in the spinal cord can have in excess of 50,000 synapses from presynaptic axons.

Each postsynaptic neuron may receive both excitatory and inhibitory synapses (figure 44.17). The EPSPs (depolarizations)

**Figure 44.17** Integration of EPSPs and IPSPs takes place on the neuronal cell body. *a.* The synapses made by some axons are excitatory (green); the synapses made by other axons are inhibitory (red). The summed influence of all of these inputs determines whether the axonal membrane of the postsynaptic cell will be sufficiently depolarized to produce an action potential. *b.* Micrograph of a neuronal cell body with numerous synapses.

and IPSPs (hyperpolarizations) from these synapses interact with each other when they reach the cell body of the neuron. Small EPSPs add together to bring the membrane potential closer to the threshold, and IPSPs subtract from the depolarizing effect of the EPSPs, deterring the membrane potential from reaching threshold. This process is called *synaptic integration*.

Because of the all-or-none characteristic of an action potential, a postsynaptic neuron is like a switch that is either turned on or remains off. Information may be encoded in the pattern of firing over time, but each neuron can only fire or not fire when it receives a signal.

The events that determine whether a neuron fires may be extremely complex and involve many presynaptic neurons. There are two ways the membrane can reach the threshold voltage: by many different dendrites producing EPSPs that sum to the threshold voltage, or by one dendrite producing repeated EPSPs that sum to the threshold voltage. We call the first **spatial summation** and the second **temporal summation**.

In spatial summation, graded potentials due to dendrites from different presynaptic neurons that occur at the same time add together to produce an above-threshold voltage. All of this input does not need to be in the form of EPSPs, just so the potential produced by summing all of the EPSPs and IPSPs is greater than the threshold voltage. When the membrane at the base of the axon is depolarized above the threshold, it produces an action potential and a nerve impulse is sent down the axon.

In temporal summation, a single dendrite can produce sufficient depolarization to produce an action potential if it produces EPSPs that are close enough in time to sum to a depolarization that is greater than threshold. A typical EPSP can last for 15 ms, so for temporal summation to occur, the next impulse must arrive in less time. If enough EPSPs are produced to raise the membrane at the base of the axon above threshold, then an impulse will be sent.

The distinction between these two methods of summation is like filling a hole in the ground with soil: you can have many shovels that add soil to the hole until it is filled, or a single shovel that adds soil at a faster rate to fill the hole. When the hole is filled, the axon will fire.

## Neurotransmitters play a role in drug addiction

When certain cells of the nervous system are exposed to a constant stimulus that produces a chemically mediated signal for a prolonged period, the cells may lose their ability to respond to that stimulus, a process called **habituation**. You are familiar with this loss of sensitivity—when you sit in a chair, for example, your awareness of the chair diminishes after a certain length of time.

Some nerve cells are particularly prone to this loss of sensitivity. If receptor proteins within synapses are exposed to high levels of neurotransmitter molecules for prolonged periods, the postsynaptic cell often responds by decreasing the number of receptor proteins in its membrane. This feedback is a normal function in all neurons, one of several mechanisms that have evolved to make the cell more efficient. In this case, the cell adjusts the number of receptors downward because plenty of stimulating neurotransmitter is available. In the case of artificial neurotrans-

mitter effects produced by drugs, long-term drug use means that more of the drug is needed to obtain the same effect.

### Cocaine

The drug cocaine causes abnormally large amounts of neurotransmitter to remain in the synapses for long periods. Cocaine affects neurons in the brain's "pleasure pathways" (the *limbic system*, described later). These cells use the neurotransmitter dopamine. Cocaine binds tightly to the transporter proteins on presynaptic membranes that normally remove dopamine from the synaptic cleft. Eventually the dopamine stays in the cleft, firing the receptors repeatedly. New signals add more and more dopamine, firing the pleasure pathway more and more often (figure 44.18).

### Nicotine

Nicotine has been found to have no affinity for proteins on the presynaptic membrane, as cocaine does; instead, it binds directly to a specific receptor on postsynaptic neurons of the brain. Because nicotine does not normally occur in the brain, why should it have a receptor there?

Researchers have found that "nicotine receptors" are a class of receptors that normally bind the neurotransmitter acetylcholine. Nicotine evolved in tobacco plants as a secondary compound—it affects the CNS of herbivorous insects, and therefore helps to protect the plant. It is an "accident of nature" that nicotine is also able to bind to some human ACh receptors.

**Figure 44.18** How cocaine alters events at the synapse.

When cocaine binds to the dopamine transporters, it prevents reuptake of dopamine so the neurotransmitter survives longer in the synapse and continues to stimulate the postsynaptic cell. Cocaine thus acts to intensify pleasurable sensations.

When neurobiologists compare the nerve cells in the brains of smokers with those of nonsmokers, they find changes in both the number of nicotine receptors and the levels of RNA used to make the receptors. The brain adjusts to prolonged, chronic exposure to nicotine by “turning down the volume” in two ways: (1) by making fewer receptor proteins to which nicotine can bind; and (2) by altering the pattern of activation of the nicotine receptors—that is, their sensitivity to stimulation by neurotransmitters.

Having summarized the physiology and chemistry of neurons and synapses, we turn now to the structure of the vertebrate nervous system, beginning with the CNS and then the PNS.

### Learning Outcomes Review 44.3

Electrical synapses involve direct cytoplasmic connections between two neurons; chemical synapses involve chemicals that cross the synaptic cleft, which separates neurons. Neurotransmitters include acetylcholine, epinephrine, glycine, GABA, biogenic amines, substance P, and nitric oxide. Many addictive drugs bind to sites that normally bind neurotransmitters or to membrane transport proteins in synapses.

- *Why is tobacco use such a difficult habit to overcome?*

## 44.4 The Central Nervous System: Brain and Spinal Cord

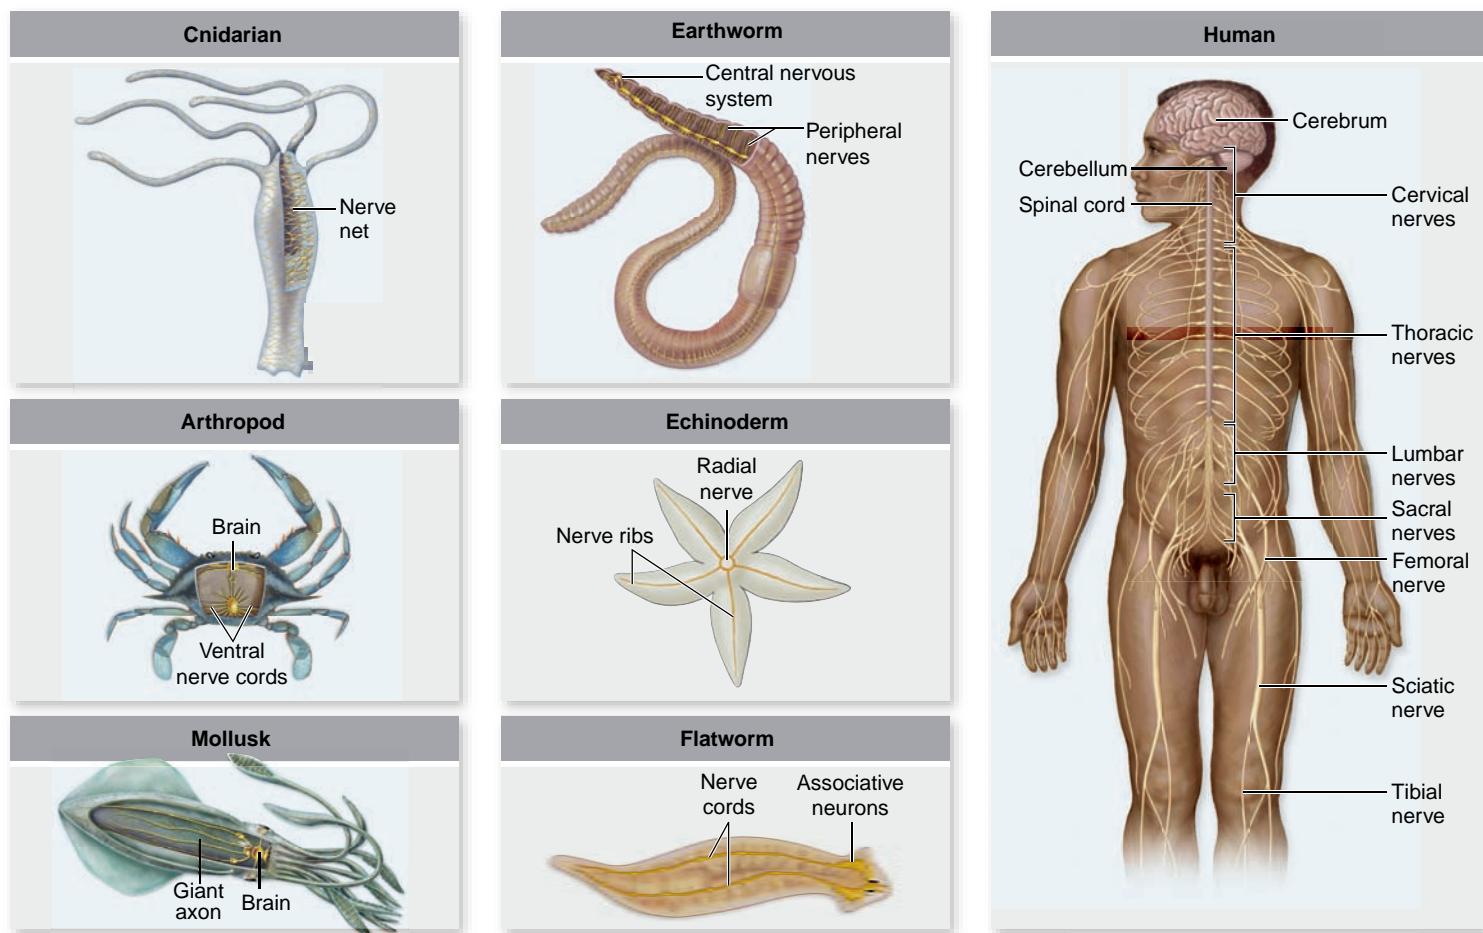

### Learning Outcomes

1. Describe the organization of the brain in vertebrates.
2. Describe characteristics of the human cerebrum.
3. Explain how a simple reflex works.

The complex nervous system of vertebrate animals has a long evolutionary history. In this section we describe the structures making up the CNS, namely the brain and the spinal cord. First, it is helpful to review the origin and development of the vertebrate nervous system.

### As animals became more complex, so did their nervous systems

Among the noncoelomate invertebrates (see chapter 33), sponges are the only major phylum that lack nerves. The simplest nervous systems occur among cnidarians (figure 44.19),

**Figure 44.19 Diversity of nervous systems.** Nervous systems in animals range from simple nerve nets to paired nerve cords with primitive brains to elaborate brains and sensory systems. Bilateral symmetry is correlated with the concentration of nervous tissue and sensory structures in the front end of the nerve cord. This evolutionary process is referred to as cephalization.

in which all neurons are similar and linked to one another in a web, or **nerve net**. There is no associative activity, no control of complex actions, and little coordination.

The simplest animals with associative activity in the nervous system are the free-living flatworms, phylum Platyhelminthes. Running down the bodies of these flatworms are two nerve cords, from which peripheral nerves extend outward to the muscles of the body. The two nerve cords converge at the front end of the body, forming an enlarged mass of nervous tissue that also contains interneurons with synapses connecting neurons to one another. This primitive “brain” is a rudimentary central nervous system and permits a far more complex control of muscular responses than is possible in cnidarians.

All of the subsequent evolutionary changes in nervous systems can be viewed as a series of elaborations on the characteristics already present in flatworms. For example, among coelomate invertebrates (see chapter 34), earthworms exhibit a central nervous system that is connected to all other parts of the body by peripheral nerves. And in arthropods, the central coordination of complex responses is increasingly localized in the front end of the nerve cord. As this region evolved, it came to contain a progressively larger number of interneurons and to develop tracts, which are major information highways within the brain.

**Figure 44.20** The basic organization of the vertebrate brain can be seen in the brains of primitive fishes.

The brain is divided into three regions that are found in differing proportions in all vertebrates: the hindbrain, which is the largest portion of the brain in fishes; the midbrain, which in fishes is devoted primarily to processing visual information; and the forebrain, which is concerned mainly with olfaction (the sense of smell) in fishes. In terrestrial vertebrates, the forebrain plays a far more dominant role in neural processing than it does in fishes.

## Vertebrate brains have three basic divisions

Casts of the interior braincases of fossil agnathans, fishes that swam 500 MYA (see chapter 35), have revealed much about the early evolutionary stages of the vertebrate brain. Although small, these brains already had the three divisions that characterize the brains of all contemporary vertebrates:

1. the *hindbrain*, or rhombencephalon;
2. the *midbrain*, or mesencephalon; and
3. the *forebrain*, or prosencephalon (figure 44.20 and table 44.3).

### The hindbrain in fishes

The hindbrain was the major component of these early brains, as it still is in fishes today. Composed of the **cerebellum**, **pons**, and **medulla oblongata**, the hindbrain may be considered an extension of the spinal cord devoted primarily to coordinating motor reflexes. Tracts containing large numbers of axons run like cables up and down the spinal cord to the hindbrain. The hindbrain, in turn, integrates the many sensory signals coming from the muscles and coordinates the pattern of motor responses.

Much of this coordination is carried on within a small extension of the hindbrain called the cerebellum (“little cerebrum”). In more advanced vertebrates, the cerebellum plays an increasingly important role as a coordinating center for movement and it is correspondingly larger than it is in the fishes. In all vertebrates, the cerebellum processes data on the current position and movement of each limb, the state of relaxation or contraction of the muscles involved, and the general position of the body and its relation to the outside world.

TABLE 44.3		Subdivisions of the Central Nervous System
Major Subdivision	Function	
SPINAL CORD	Spinal reflexes; relays sensory and motor information	
BRAIN		
Hindbrain (Rhombencephalon)		
Medulla oblongata	Sensory nuclei; reticular-activating system; autonomic functions	
Pons	Reticular-activating system; autonomic functions	
Cerebellum	Coordination of movements; balance	
Midbrain (Mesencephalon)	Reflexes involving eyes and ears	
Forebrain (Prosencephalon)		
Diencephalon		
Thalamus	Relay station for ascending sensory and descending motor tracts; autonomic functions	
Hypothalamus	Autonomic functions; neuroendocrine control	
Telencephalon (cerebrum)		
Basal ganglia	Motor control	
Corpus callosum	Connects and relays information between the two hemispheres	
Hippocampus (limbic system)	Memory; emotion	
Cerebral cortex	Higher cognitive functions; integrates and interprets sensory information; organizes motor output	

**Figure 44.21 Evolution of the vertebrate brain.** The relative sizes of different brain regions have changed as vertebrates have evolved. In sharks and other fishes, the hindbrain is predominant, and the rest of the brain serves primarily to process sensory information. In amphibians and reptiles, the forebrain is far larger, and it contains a larger cerebrum devoted to associative activity. In birds, which evolved from reptiles, the cerebrum is even more pronounced. In mammals, the cerebrum covers the optic tectum and is the largest portion of the brain. The dominance of the cerebrum is greatest in humans, in whom it envelops much of the rest of the brain.

### The midbrain and forebrain of fishes

In fishes, the remainder of the brain is devoted to the reception and processing of sensory information. The midbrain is composed primarily of the *optic tectum*, which receives and processes visual information, whereas the forebrain is devoted to the processing of olfactory (smell) information.

The brains of fishes continue growing throughout their lives. This continued growth is in marked contrast to the brains of other classes of vertebrates, which generally complete their development by infancy. The human brain continues to develop through early childhood, but few new neurons are produced once development has ceased. One exception is the hippocampus, which has control over which experiences are filed away into long-term memory and which are forgotten. The extent of neurogenesis (production of new neurons) in adult brains is controversial, and one area of active current research.

### The dominant forebrain in more recent vertebrates

Starting with the amphibians and continuing more prominently in the reptiles, processing of sensory information is increasingly centered in the forebrain. This pattern was the dominant evolutionary trend in the further development of the vertebrate brain (figure 44.21).

The forebrain in reptiles, amphibians, birds, and mammals is composed of two elements that have distinct functions. The *diencephalon* consists of the thalamus and hypothalamus. The **thalamus** is an integration and relay center between incoming sensory information and the cerebrum. The hypothalamus participates in basic drives and emotions and controls the secretions of the pituitary gland. The **telencephalon**, or “end brain,” is located at the front of the forebrain and is devoted largely to associative activity. In mammals, the tel-

encephalon is called the cerebrum. The telencephalon also includes structures we discuss later on when describing the human brain.

### The expansion of the cerebrum

In examining the relationship between brain mass and body mass among the vertebrates, a remarkable difference is observed between fishes and reptiles on the one hand, and birds and mammals on the other. Mammals have brains that are particularly large relative to their body mass. This is especially true of porpoises and humans.

The increase in brain size in mammals largely reflects the great enlargement of the cerebrum, the dominant part of the mammalian brain. The **cerebrum** is the center for correlation, association, and learning in the mammalian brain. It receives sensory data from the thalamus and issues motor commands to the spinal cord via descending tracts of axons.

In vertebrates, the central nervous system is composed of the brain and the spinal cord (see table 44.3). These two structures are responsible for most of the information processing within the nervous system and they consist primarily of interneurons and neuroglia. Ascending tracts carry sensory information to the brain. Descending tracts carry impulses from the brain to the motor neurons and interneurons in the spinal cord that control the muscles of the body.

### The human forebrain exhibits exceptional information-processing ability

The human cerebrum is so large that it appears to envelop the rest of the brain. It is split into right and left **cerebral hemispheres**, which are connected by a tract called the **corpus**

**Figure 44.22** A section through the human brain. In this sagittal section showing one cerebral hemisphere, the corpus callosum, a fiber tract connecting the two cerebral hemispheres, can be clearly seen.

**callosum** (figure 44.22). The hemispheres are further divided into the *frontal*, *parietal*, *temporal*, and *occipital lobes*.

Each hemisphere primarily receives sensory input from the opposite, or contralateral, side of the body and exerts motor control primarily over that side. Therefore, a touch on the right hand is relayed primarily to the left hemisphere, which may then initiate movement of the right hand in response to the touch. Damage to one hemisphere due to a stroke often results in a loss of sensation and paralysis on the contralateral side of the body.

### The cerebral cortex

Much of the neural activity of the cerebrum occurs within a layer of gray matter only a few millimeters thick on its outer surface. This layer, called the **cerebral cortex**, is densely packed with nerve cells. In humans, it contains over 10 billion nerve cells, amounting to roughly 10% of all the neurons in the brain. The surface of the cerebral cortex is highly convoluted; this is particularly true in the human brain, where the convolutions increase the surface area of the cortex threefold.

The activities of the cerebral cortex fall into one of three general categories: motor, sensory, and associative. Each of its regions correlates with a specific function (figure 44.23). The **primary motor cortex** lies along the *gyrus* (convolution) on the posterior border of the frontal lobe, just in front of the *central sulcus* (crease). Each point on the surface of the motor cortex is associated with the movement of a different part of the body (figure 44.24, right).

Just behind the central sulcus, on the anterior edge of the parietal lobe, lies the **primary somatosensory cortex**. Each point in this area receives input from sensory neurons serving skin and muscle senses in a particular part of the body (figure 44.24, left). Large areas of the primary motor cortex and primary somatosensory cortex are devoted to the fingers,

**Figure 44.23** The cerebrum. This diagram shows the lobes of the cerebrum and indicates some of the known regions of specialization.

lips, and tongue because of the need for manual dexterity and speech. The auditory cortex lies within the temporal lobe, and different regions of this cortex deal with different sound frequencies. The visual cortex lies on the occipital lobe, with different sites processing information from different positions on the retina, equivalent to particular points in the visual fields of the eyes.

The portion of the cerebral cortex that is not occupied by these motor and sensory cortices is referred to as the **association cortex**. The site of higher mental activities, the association cortex reaches its greatest extent in primates, especially humans, where it makes up 95% of the surface of the cerebral cortex.

### Basal ganglia

Buried deep within the white matter of the cerebrum are several collections of cell bodies and dendrites that produce islands of gray matter. These aggregates of neuron cell bodies, which are collectively termed the *basal ganglia*, receive sensory information from ascending nerve tracts and motor commands from the cerebral cortex and cerebellum.

Outputs from the basal ganglia are sent down the spinal cord, where they participate in the control of body movements. Damage to specific regions of the basal ganglia can produce the resting tremor of muscles that is characteristic of Parkinson disease.

### Thalamus and hypothalamus

The thalamus is a primary site of sensory integration in the brain. Visual, auditory, and somatosensory information is sent to the thalamus, where the sensory tracts synapse with association neurons. The sensory information is then relayed via the thalamus to the occipital, temporal, and parietal lobes of the cerebral cortex, respectively. The transfer of each of these types

**Figure 44.24** The primary somatosensory cortex (left) and the primary motor cortex (right). Each of these regions of the cerebral cortex is associated with a different region of the body, as indicated in this stylized map. The areas of the body are drawn in relative proportion to the amount of cortex dedicated to their sensation or control. For example, the hands have large areas of sensory and motor control, and the pharynx has a considerable area of motor control but little area devoted to the sensations of the pharynx.

of sensory information is handled by specific aggregations of neuron cell bodies within the thalamus.

The hypothalamus integrates the visceral activities. It helps regulate body temperature, hunger and satiety, thirst, and—along with the limbic system—various emotional states. The hypothalamus also controls the pituitary gland, which in turn regulates many of the other endocrine glands of the body. By means of its interconnections with the cerebral cortex and with control centers in the *brainstem* (a term used to refer collectively to the midbrain, pons, and medulla oblongata), the hypothalamus helps coordinate the neural and hormonal responses to many internal stimuli and emotions.

The *hippocampus* and *amygdala*, along with the hypothalamus, are the major components of the **limbic system**—an evolutionarily ancient group of linked structures deep within the cerebrum that are responsible for emotional responses, as described earlier. The hippocampus is also believed to be important in the formation and recall of memories.

## Complex functions of the human brain may be controlled in specific areas

Although studying brain function is difficult, it has long fascinated researchers. The distinction between sleep and waking, the use and acquisition of language, spatial recognition, and memory are all areas of active research. Although far from understood, one generalization that emerged was the regionalization of function.

### Sleep and arousal

The brainstem contains a diffuse collection of neurons referred to as the *reticular formation*. One part of this formation, the *reticular-activating system*, controls consciousness and alertness. All of the sensory pathways feed into this system, which moni-

tors the information coming into the brain and identifies important stimuli. When the reticular-activating system has been stimulated to arousal, it increases the level of activity in many parts of the brain. Neural pathways from the reticular formation to the cortex and other brain regions are depressed by anesthetics and barbiturates.

The reticular-activating system controls both sleep and the waking state. It is easier to sleep in a dark room than in a lighted one because there are fewer visual stimuli to stimulate the reticular-activating system. In addition, activity in this system is reduced by serotonin, a neurotransmitter discussed earlier. Serotonin causes the level of brain activity to fall, bringing on sleep.

Brain state can be monitored by means of an electroencephalogram (EEG), a recording of electrical activity. Awake but relaxed individuals with eyes closed exhibit a brain pattern of large, slow waves termed *alpha waves*. In an alert individual with eyes open, the waves are more rapid (*beta waves*) and more desynchronized as sensory input is being received. *Theta waves* and *delta waves* are very slow waves seen during sleep. When an individual is in REM sleep—characterized by rapid eye movements with the eyes closed—the EEG is more like that of an awake, relaxed individual.

### Language

Although the two cerebral hemispheres seem structurally similar, they are responsible for different activities. The most thoroughly investigated example of this lateralization of function is language.

The left hemisphere is the “dominant” hemisphere for language in 90% of right-handed people and nearly two-thirds of left-handed people. (By *dominant*, we mean it is the hemisphere in which most neural processing related to language is performed.) Different brain regions control language in the

**Figure 44.25 Different brain regions control various language activities.** This illustration shows how the brain reacts in human subjects asked to listen to a spoken word, to read that same word silently, to repeat the word out loud, and then to speak a word related to the first. Regions of white, red, and yellow show the greatest activity. Compare this with figure 44.24 to see how regions of the brain are mapped.

dominant hemisphere (figure 44.25). Wernicke's area, located in the parietal lobe between the primary auditory and visual areas, is important for language comprehension and the formulation of thoughts into speech (see figure 44.23). Broca's area, found near the part of the motor cortex controlling the face, is responsible for the generation of motor output needed for language communication.

Damage to these brain areas can cause language disorders known as *aphasias*. For example, if Wernicke's area is damaged, the person's speech is rapid and fluid but lacks meaning; words are tossed together as in a "word salad."

### Spatial recognition

Whereas the dominant hemisphere for language is adept at sequential reasoning, like that needed to formulate a sentence, the nondominant hemisphere (the right hemisphere in most people) is adept at spatial reasoning, the type of reasoning needed to assemble a puzzle or draw a picture. It is also the hemisphere primarily involved in musical ability—a person with damage to Broca's speech area in the left hemisphere may not be able to speak but may retain the ability to sing.

Damage to the nondominant hemisphere may lead to an inability to appreciate spatial relationships and may impair musical activities such as singing. Even more specifically, damage to the inferior temporal cortex in that hemisphere eliminates the capacity to recall faces, a condition known as prosopagnosia. Reading, writing, and oral comprehension remain normal, and patients with this disability can still recognize acquaintances by their voices. The nondominant hemisphere is also important for the consolidation of memories of nonverbal experiences.

### Memory and learning

One of the great mysteries of the brain is the basis of memory and learning. Memory appears dispersed across the brain. Specific cortical sites cannot be identified for particular memories because relatively extensive cortical damage does not selectively remove memories. Although memory is impaired if portions of the brain, particularly the temporal lobes, are removed, it is not lost entirely. Many memories persist in spite of the damage, and the ability to access them is gradually recovered with time.

Fundamental differences appear to exist between short-term and long-term memory. Short-term memory is transient, lasting only a few moments. Such memories can readily be erased by the application of an electrical shock, leaving previously stored long-term memories intact. This result suggests that short-term memories are stored in the form of a transient neural excitation. Long-term memory, in contrast, appears to involve structural changes in certain neural connections within the brain.

Two parts of the temporal lobes, the hippocampus and the amygdala, are involved in both short-term memory and its consolidation into long-term memory. Damage to these structures impairs the ability to process recent events into long-term memories.

### Synaptic plasticity

Part of the basis of learning and memory are changes to the function of a synapse over time. Two examples of this synaptic plasticity are long-term potentiation (LTP), and long-term depression (LTD). The mechanism of LTP is complex and not completely understood. One well-studied form involves synapses that release the neurotransmitter glutamate, and have *N*-methyl-D-aspartic acid (NMDA) type of receptors. When either the same synapse is stimulated repeatedly, or neighboring synapses are stimulated, the postsynaptic membrane becomes significantly depolarized. This releases a block of the NMDA receptor by  $Mg^{2+}$  such that glutamate binding causes an influx of  $Ca^{2+}$  that stimulates a signal transduction pathway involving calcium/calmodulin-dependent protein kinase II. This pathway leads to the insertion of another receptor type, the  $\alpha$ -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) receptor, into the postsynaptic membrane, making the synapse more sensitive to future stimulation (figure 44.26).

If the stimulation of an NMDA receptor is less, and the postsynaptic membrane is less depolarized, LTD can result. In this case, a different  $Ca^{2+}$ -dependent signaling pathway results in the loss of AMPA receptors from the membrane. Taken together, these two mechanisms can make a synapse more or less sensitive to future stimulation.

### Alzheimer disease: Degeneration of brain neurons

In the past, little was known about *Alzheimer disease*, a condition in which the memory and thought processes of the brain become dysfunctional. Scientists disagree about the biological nature of the disease and its cause. Two hypotheses have been proposed: One suggests that nerve cells in the brain are killed from the outside in, and the other that the cells are killed from the inside out.

**Figure 44.26 LTP and LTD modulate synaptic function.** *a.* When the postsynaptic membrane is significantly depolarized, when GABA binds to the *N*-methyl-D-aspartic acid receptor (NMDAR), the influx of Ca<sup>2+</sup> leads to the insertion of  $\alpha$ -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate receptors (AMPA). This potentiates the synapse for future stimulation. *b.* When the postsynaptic membrane does not have as large a depolarization, or there is less GABA, then GABA binding to NMDA receptor triggers a different pathway that results in removal of AMPA receptors. This depresses the synapse for future stimulation. CaMKII, calmodulin-dependent protein kinase 2.

In the first hypothesis, external proteins called  $\beta$ -amyloid exist in an abnormal form, which then forms aggregates, or plaques. The plaques begin to fill in the brain and then damage and kill nerve cells. However, these amyloid plaques have been found in autopsies of people who did not exhibit Alzheimer disease.

The second hypothesis maintains that the nerve cells are killed by an abnormal form of an internal protein called tau ( $\tau$ ), which normally functions to maintain protein transport microtubules. Abnormal forms of  $\tau$ -protein assemble into helical segments that form tangles, which interfere with the normal functioning of the nerve cells. At this point, the association of tangles with actual neuronal death is stronger.

## The spinal cord conveys messages and controls some responses directly

The spinal cord is a cable of neurons extending from the brain down through the backbone (figure 44.27). It is enclosed and protected by the vertebral column and layers of membranes called *meninges*, which also cover the brain. Inside the spinal cord are two zones.

The inner zone is gray matter and primarily consists of the cell bodies of interneurons, motor neurons, and neuroglia. The outer zone is white matter and contains cables of sensory axons in the dorsal columns and motor axons in the

ventral columns. These nerve tracts may also contain the dendrites of other nerve cells. Messages from the body and the brain run up and down the spinal cord, the body's "information highway."

In addition to relaying messages, the spinal cord also functions in **reflexes**, the sudden, involuntary movement of muscles. A reflex produces a rapid motor response to a stimulus because the sensory neuron passes its information to a motor

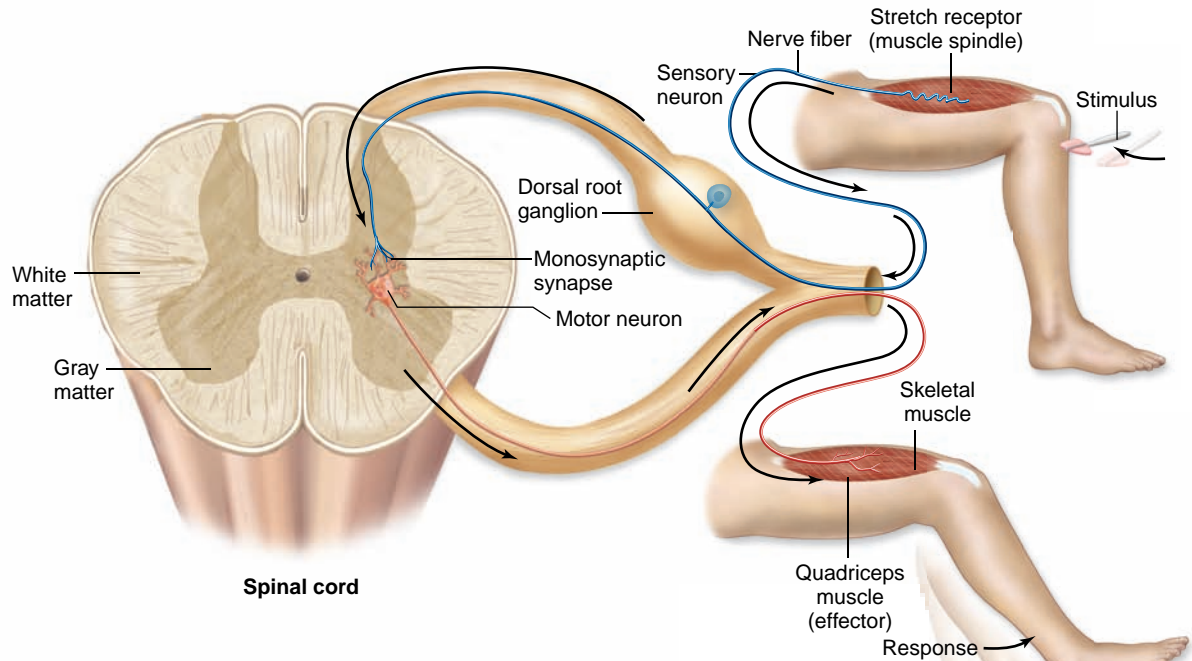

**Figure 44.27 A view down the human spinal cord.** Pairs of spinal nerves can be seen extending from the spinal cord. Along these nerves, as well as the cranial nerves that arise from the brain, the central nervous system communicates with the rest of the body.

### Figure 44.28

#### The knee-jerk reflex.

This is the simplest reflex, involving only sensory and motor neurons.

neuron in the spinal cord, without higher level processing. One of the most frequently used reflexes in your body is blinking, a reflex that protects your eyes. If an object such as an insect or a cloud of dust approaches your eye, the eyelid blinks before you realize what has happened. The reflex occurs before the cerebrum is aware the eye is in danger.

Because they pass information along only a few neurons, reflexes are very fast. A few reflexes, such as the knee-jerk reflex (figure 44.28), are monosynaptic reflex arcs. In these, the sensory nerve cell makes synaptic contact directly with a motor neuron in the spinal cord whose axon travels directly back to the muscle.

Most reflexes in vertebrates, however, involve a single connecting interneuron between the sensory neuron and the motor neuron (figure 44.29). The withdrawal of a hand from a hot stove or the blinking of an eye in response to a puff of air involves a relay of information from a sensory neuron through one or more interneurons to a motor neuron. The motor neuron then stimulates the appropriate muscle to contract. Notice that the sensory neuron may also connect to other interneurons to send signals to the brain. Although you jerked your hand away from the stove, you will still feel pain.

### Figure 44.29

#### A cutaneous spinal reflex.

This reflex is more complex than a knee-jerk reflex because it requires interneurons as well as sensory and motor neurons. Interneurons connect a sensory neuron with a motor neuron to cause muscle contraction as shown. Other interneurons inhibit motor neurons, allowing antagonistic muscles to relax.

### Spinal cord regeneration

In the past, scientists tried to repair severed spinal cords by installing nerves from another part of the body to bridge the gap and act as guides for the spinal cord to regenerate. But most of these experiments failed. Although axons may regenerate through the implanted nerves, they cannot penetrate the spinal cord tissue once they leave the implant. Also, a factor that inhibits nerve growth is present in the spinal cord.

After discovering that fibroblast growth factor stimulates nerve growth, neurobiologists working with rats tried “gluing” the nerves on, from the implant to the spinal cord, with fibrin that had been mixed with the fibroblast growth factor. Three months later, rats with the nerve bridges began to show movement in their lower bodies. Dye tests indicated that the spinal cord nerves had regrown from both sides of the gap.

Many scientists are encouraged by the potential to use a similar treatment in human medicine. But most spinal cord injuries in humans do not involve a completely severed spinal cord; often, nerves are crushed, which results in different tissue damage. Also, even though the rats with nerve bridges did regain some ability to move, tests indicated that they were barely able to walk or stand.

#### Learning Outcomes Review 44.4

The vertebrate brain has three primary regions: the hindbrain, midbrain, and forebrain. The cerebrum, part of the forebrain, is composed of two cerebral hemispheres in which gray matter of the cerebral cortex overlays white matter and islands of gray matter (nuclei) called the basal ganglia. The spinal cord relays messages to and from the brain; a reflex occurs when the spinal cord processes sensory information directly and initiates a motor response.

- What is the advantage of having reflexes?

## 44.5 The Peripheral Nervous System: Sensory and Motor Neurons

### Learning Outcomes

1. Describe the organization of the peripheral nervous system.
2. Explain the actions of sensory and somatic neurons.
3. Distinguish between the somatic and autonomic nervous systems.
4. Describe differences between the sympathetic and parasympathetic divisions of the autonomic nervous system.

The PNS consists of nerves, the cablelike collections of axons (figure 44.30), and **ganglia** (singular, *ganglion*), aggregations of neuron cell bodies located outside the CNS. To review, the

**Figure 44.30** Nerves in the peripheral nervous system. Photomicrograph showing a cross section of a bullfrog nerve. The nerve is a bundle of axons bound together by connective tissue. Many myelinated axons are visible, each looking somewhat like a doughnut.

function of the PNS is to receive information from the environment, convey it to the CNS, and to carry responses to effectors such as muscle cells.

### The PNS has somatic and autonomic systems

At the spinal cord, a spinal nerve separates into sensory and motor components. The axons of sensory neurons enter the dorsal surface of the spinal cord and form the **dorsal root** of the spinal nerve, whereas motor axons leave from the ventral surface of the spinal cord and form the **ventral root** of the spinal nerve. The cell bodies of sensory neurons are grouped together outside each level of the spinal cord in the **dorsal root ganglia**. The cell bodies of somatic motor neurons, on the other hand, are located within the spinal cord and so are not located in ganglia.

As mentioned earlier, somatic motor neurons stimulate skeletal muscles to contract, and autonomic motor neurons innervate involuntary effectors—smooth muscles, cardiac muscle, and glands. A comparison of the somatic and autonomic nervous systems is provided in table 44.4; we discuss each system in turn.

TABLE 44.4		Comparison of the Somatic and Autonomic Nervous Systems	
Characteristic	Somatic	Autonomic	
Effectors	Skeletal muscle	Cardiac muscle	Smooth muscle Gastrointestinal tract Blood vessels Airways
Effect on motor nerves	Excitation	Excitation or inhibition	
Innervation of effector cells	Always single	Typically dual	
Number of sequential neurons in path to effector	One	Two	
Neurotransmitter	Acetylcholine	Acetylcholine, norepinephrine	

## The somatic nervous system

### controls movements

Somatic motor neurons stimulate the skeletal muscles of the body to contract in response to conscious commands and as part of reflexes that do not require conscious control. Voluntary control of skeletal muscles is achieved by activation of tracts of axons that descend from the cerebrum to the appropriate level of the spinal cord. Some of these descending axons stimulate spinal cord motor neurons directly, and others activate interneurons that in turn stimulate the spinal motor neurons.

When a particular muscle is stimulated to contract, however, its antagonist must be inhibited. In order to flex the arm, for example, the flexor muscles must be stimulated while the antagonistic extensor muscle is inhibited (see chapter 47). Descending motor axons produce this necessary inhibition by causing hyperpolarizations (IPSPs) of the spinal motor neurons that innervate the antagonistic muscles.

## The autonomic nervous system controls involuntary functions through two divisions

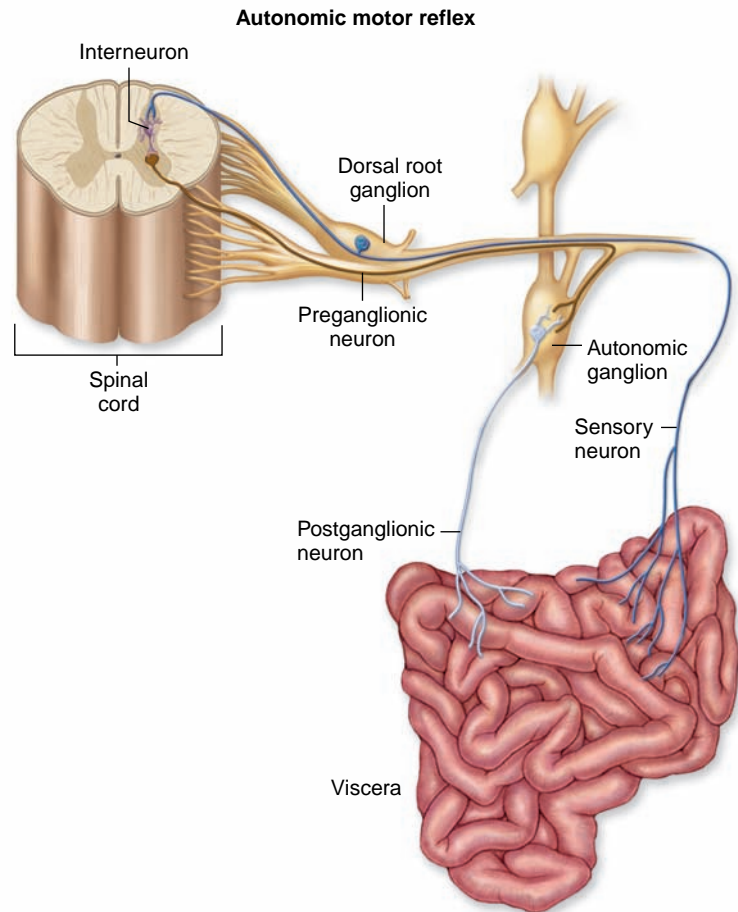

The autonomic nervous system is composed of the *sympathetic* and *parasympathetic* divisions plus the medulla oblongata of the hindbrain, which coordinates this system. Although they differ, the sympathetic and parasympathetic divisions share several features. In both, the efferent motor pathway involves two neurons: The first has its cell body in the CNS and sends an axon to an autonomic ganglion; it is called *preganglionic neuron*. These neurons release acetylcholine at their synapses.

The second neuron has its cell body in the autonomic ganglion and sends its axon to synapse with a smooth muscle, cardiac muscle, or gland cell (figure 44.31). This second neuron is termed the *postganglionic neuron*. Those in the parasympathetic division release ACh, and those in the sympathetic division release norepinephrine.

### The sympathetic division

In the sympathetic division, the preganglionic neurons originate in the thoracic and lumbar regions of the spinal cord (figure 44.32, left). Most of the axons from these neurons synapse in two parallel chains of ganglia immediately outside the spinal cord. These structures are usually called the *sympathetic chain* of ganglia. The sympathetic chain contains the cell bodies of postganglionic neurons, and it is the axons from these neurons that innervate the different visceral organs.

There are some exceptions to this general pattern, however. The axons of some preganglionic sympathetic neurons pass through the sympathetic chain without synapsing and, instead, terminate within the medulla of the adrenal gland (see chapter 46). In response to action potentials, the adrenal medulla cells secrete the hormone epinephrine (adrenaline). At the same time, norepinephrine is released at the synapses of the postganglionic neurons. As described earlier, both of these neurotransmitters prepare the body for action by heightening metabolism and blood flow.

**Figure 44.31 An autonomic neural path.** There are two motor neurons in the efferent pathway. The first, or preganglionic neuron, exits the CNS and synapses at an autonomic ganglion. The second, or postganglionic neuron, exits the ganglion and regulates the visceral effectors (smooth muscle, cardiac muscle, or glands).

### The parasympathetic division

The actions of the sympathetic division are antagonized by the parasympathetic division. Preganglionic parasympathetic neurons originate in the brain and sacral regions of the spinal cord (see figure 44.32, right). Because of this origin, there cannot be a chain of parasympathetic ganglia analogous to the sympathetic chain. Instead, the preganglionic axons, many of which travel in the vagus (tenth cranial) nerve, terminate in ganglia located near or even within the internal organs. The postganglionic neurons then regulate the internal organs by releasing ACh at their synapses. Parasympathetic nerve effects include a slowing of the heart, increased secretions and activities of digestive organs, and so on. Table 44.5 compares the actions of the sympathetic and parasympathetic divisions.

## G proteins mediate cell responses to autonomic signals

You might wonder how release of ACh can slow the heart rate—an inhibitory effect—when it has excitatory effects elsewhere.

**Figure 44.32** The sympathetic and parasympathetic divisions of the autonomic nervous system. The preganglionic neurons of the sympathetic division exit the thoracic and lumbar regions of the spinal cord, and those of the parasympathetic division exit the brain and sacral region of the spinal cord. The ganglia of the sympathetic division are located near the spinal cord; and those of the parasympathetic division are located near the organs they innervate. Most of the internal organs are innervated by both divisions.

TABLE 44.5		Autonomic Innervation of Target Tissues	
Target Tissue	Sympathetic Stimulation	Parasympathetic Stimulation	
Pupil of eye	Dilation	Constriction	
<b>Glands</b>			
Salivary	Vasoconstriction; slight secretion	Vasodilation; copious secretion	
Gastric	Inhibition of secretion	Stimulation of gastric activity	
Liver	Stimulation of glucose secretion	Inhibition of glucose secretion	
Sweat	Sweating	None	
<b>Gastrointestinal tract</b>			
Sphincters	Increased tone	Decreased tone	
Wall	Decreased tone	Increased motility

In skin	Constriction	None	
In viscera	Constriction	Dilation	

**Figure 44.33 The parasympathetic effects of ACh require the action of G proteins.** The binding of ACh to its receptor causes dissociation of a G protein complex, releasing some components of this complex to move within the membrane and bind to other proteins that form ion channels. Shown here are the effects of ACh on the heart, where the G protein components cause the opening of K<sup>+</sup> channels. This leads to outward diffusion of potassium and hyperpolarization, slowing the heart rate.

The answer is simple, the cells involved in each case have different receptors for ACh that produce different effects. In the neuromuscular junction, the receptor for ACh is a ligand-gated Na<sup>+</sup> channel that when open allows an influx of Na<sup>+</sup> that depolarizes the membrane. In the case of the heart, the inhibitory effect on the pacemaker cells is produced because binding of ACh to a different receptor leads to K<sup>+</sup> channels opening, resulting in the outward diffusion of K<sup>+</sup>, hyperpolarizing the membrane. The ACh receptor in the heart is a member of the class of receptors called G protein-coupled receptors.

In chapter 9, you learned that G protein-coupled receptors consist of a membrane receptor and effector protein that are coupled by the action of a G protein. The receptor is activated by binding to its ligand, in this case ACh, and the receptor activates a G protein that in turn activates an effector protein, in this case a K<sup>+</sup> channel (figure 44.33).

This kind of system can also lead to excitation in other organs if the G protein acts on different effector proteins. For example, the parasympathetic nerves that innervate the stomach can cause increased gastric secretions and contractions.

The sympathetic nerve effects also are mediated by the action of G protein-coupled receptors. Stimulation by norepinephrine from sympathetic nerve endings and epinephrine from the adrenal medulla requires G proteins to activate the target cells. We describe these interactions in more detail, together with hormone action, in chapter 46.

### Learning Outcomes Review 44.5

The PNS comprises the somatic (voluntary) and autonomic (involuntary) nervous systems. A spinal nerve contains sensory neurons, which carry information from sense organs to the CNS, and motor neurons, which carry directives from the CNS to targets such as muscle cells. The sympathetic division of the autonomic nervous system activates the body for fight-or-flight responses; the parasympathetic division generally promotes relaxation and digestion.

- **Why would having the sympathetic and parasympathetic divisions be more advantageous than having a single system?**

## Chapter Review

### 44.1 Nervous System Organization

The three types of neurons in vertebrates are sensory neurons, motor neurons, and interneurons (see figure 44.1).

**The central nervous system is the “command center.”**

The CNS consists of the brain and the spinal cord, where sensory input is integrated and responses originate.

**The peripheral nervous system collects information and carries out responses.**

The PNS comprises sensory neurons that carry impulses to the CNS and motor neurons that carry impulses from the CNS to effectors.

The somatic nervous system primarily acts on skeletal muscles; the autonomic nervous system is involuntary and consists of the antagonistic sympathetic and parasympathetic divisions.

**The structure of neurons supports their function.**

Neurons have a cell body, dendrites that receive information, and a long axon that conducts impulses away from the cell.

**Supporting cells include Schwann cells and oligodendrocytes.**

Neuroglia are supporting cells of the nervous system. Schwann cells (PNS) and oligodendrocytes (CNS) produce myelin sheaths that surround and insulate axons (see figure 44.3).

### 44.2 The Mechanism of Nerve Impulse Transmission

**An electrical difference exists across the plasma membrane.**

The sodium-potassium pump moves Na<sup>+</sup> outside the cell and K<sup>+</sup> into the cell. Leakage of K<sup>+</sup> also moves positive charge outside the cell. The membrane resting potential is typically -70 mV.

**Graded potentials are small changes that can reinforce or negate each other.**

Ligand-gated ion channels are responsible for graded potentials. Graded potentials can combine in an additive way (summation).

**Action potentials result when depolarization reaches a threshold.**

Action potentials are all-or-nothing events resulting from the rapid and sequential opening of voltage-gated ion channels (see figure 44.9).

**Action potentials are propagated along axons.**

Influx of  $\text{Na}^+$  during an action potential causes the adjacent region to depolarize, producing its own action potential (see figure 44.10).

**There are two ways to increase the velocity of nerve impulses.**

The speed of nerve impulses increases as the diameter of the axon increases. Saltatory conduction, in which impulses jump from node to node, also increases speed (see figure 44.11).

### 44.3 Synapses: Where Neurons Communicate with Other Cells

An action potential terminates at the end of the axon at the synapse—a gap between the axon and another cell.

**The two types of synapses are electrical and chemical.**

Electrical synapses consist of gap junctions; chemical synapses release neurotransmitters to cross the synapse (see figure 44.14).

**Many different chemical compounds serve as neurotransmitters.**

Neurotransmitter molecules include acetylcholine, amino acids, biogenic amines, neuropeptides, and a gas—nitric oxide.

**A postsynaptic neuron must integrate input from many synapses.**

Excitatory postsynaptic potentials (EPSPs) depolarize the membrane; inhibitory postsynaptic potentials (IPSPs) hyperpolarize it. The additive effect may or may not produce an action potential.

**Neurotransmitters play a role in drug addiction.**

Addictive drugs often act by mimicking a neurotransmitter or by interfering with neurotransmitter reuptake.

### 44.4 The Central Nervous System: Brain and Spinal Cord

**As animals became more complex, so did their nervous systems.**

The nervous system has evolved from a nerve net composed of linked nerves, to nerve cords with association nerves, and to the development of coordination centers (see figure 44.19).

**Vertebrate brains have three basic divisions.**

The vertebrate brain is divided into hindbrain, midbrain, and forebrain (see figure 44.20). The forebrain is divided further into

the diencephalon and telencephalon. The telencephalon, called the cerebrum in mammals, is the center for association and learning.

**The human forebrain exhibits exceptional information-processing ability.**

The cerebrum is divided into right and left hemispheres (see figure 44.22), which are subdivided into frontal, parietal, temporal, and occipital lobes (see figure 44.23). The cerebrum contains the primary motor and somatosensory cortexes as well as the basal ganglia.

The limbic system consists of the hypothalamus, hippocampus, and amygdala, and it is responsible for emotional states.

**Complex functions of the human brain may be controlled in specific areas.**

The reticular activating system in the brainstem controls consciousness and alertness. Short-term memory may be stored as transient neural excitation; long-term memory involves changes in neural connections.

**The spinal cord conveys messages and controls some responses directly.**

Reflexes are the sudden, involuntary movement of muscles in response to a stimulus (see figures 44.28 and 44.29).

### 44.5 The Peripheral Nervous System: Sensory and Motor Neurons

**The PNS has somatic and autonomic systems.**

Sensory axons (inbound) form the dorsal root of the spinal nerve. The cell bodies are in the dorsal root ganglia.

Motor axons (outbound) form the ventral root of the spinal nerve. Cell bodies are located in the spinal cord.

**The somatic nervous system controls movements.**

Somatic motor neurons stimulate skeletal muscles in response to conscious commands and involuntary reflexes.

**The autonomic nervous system controls involuntary functions through two divisions.**

Sympathetic neurons originate in the thoracic and lumbar regions of the spinal cord and synapse at an autonomic ganglion outside the spinal cord (see figure 44.31). Parasympathetic neurons originate in the brain and in sacral regions of the spinal cord and terminate in ganglia near or within internal organs (see figure 44.32 and table 44.5).

**G proteins mediate cell responses to autonomic signals.**

The binding of ACh activates a G protein that in turn activates a  $\text{K}^+$  channel, allowing outflow of  $\text{K}^+$  and hyperpolarization of the membrane and slowing heart rate.

## Review Questions

### UNDERSTAND

- Which of the following best describes the electrical state of a neuron at rest?
  - The inside of a neuron is more negatively charged than the outside.
  - The outside of a neuron is more negatively charged than the inside.
  - The inside and the outside of a neuron have the same electrical charge.
  - Potassium ions leak into a neuron at rest.
- The \_\_\_\_ cannot be controlled by conscious thought.
  - motor neurons
  - somatic nervous system
  - autonomic nervous system
  - skeletal muscles

3. A fight-or-flight response in the body is controlled by the
  - a. sympathetic division of the nervous system.
  - b. parasympathetic division of the nervous system.
  - c. release of acetylcholine from postganglionic neurons.
  - d. somatic nervous system.
4. Inhibitory neurotransmitters
  - a. hyperpolarize postsynaptic membranes.
  - b. hyperpolarize presynaptic membranes.
  - c. depolarize postsynaptic membranes.
  - d. depolarize presynaptic membranes.
5. White matter is\_\_\_\_, and gray matter is\_\_\_\_.
  - a. comprised of axons; comprised of cell bodies and dendrites
  - b. myelinated; unmyelinated
  - c. found in the CNS; also found in the CNS
  - d. all of these are correct
6. During an action potential
  - a. the rising phase is due to an influx of  $\text{Na}^+$ .
  - b. the falling phase is due to an influx of  $\text{K}^+$ .
  - c. the falling phase is due to an efflux of  $\text{K}^+$ .
  - d. both a and c occur.
7. A functional reflex requires
  - a. only a sensory neuron and a motor neuron.
  - b. a sensory neuron, the thalamus, and a motor neuron.
  - c. the cerebral cortex and a motor neuron.
  - d. only the cerebral cortex and the thalamus.
4. The following is a list of the components of a chemical synapse. A mutation in the structure of which of these would affect only the reception of the message, not its release or the response?
  - a. Membrane proteins in the postsynaptic cell
  - b. Proteins in the presynaptic cell
  - c. Cytoplasmic proteins in the postsynaptic cell
  - d. Both a and b
5. Suppose that you stick your finger with a sharp pin. The area affected is very small and only one pain receptor fires. However, it fires repeatedly at a rapid rate (it hurts!). This is an example of
  - a. temporal summation.
  - b. spatial summation.
  - c. habituation.
  - d. repolarization.
6. As you sit quietly reading this sentence, the part of the nervous system that is most active is the
  - a. somatic nervous system.
  - b. sympathetic nervous system.
  - c. parasympathetic nervous system.
  - d. none of these choices is correct.
7. G protein-coupled receptors are involved in the nervous system by
  - a. controlling the release of neurotransmitters.
  - b. controlling the opening and closing of  $\text{Na}^+$  channels during an action potential.
  - c. controlling the opening and closing of  $\text{K}^+$  channels during an action potential.
  - d. acting as receptors for neurotransmitters on postsynaptic cells.

## APPLY

1. Imagine that you are doing an experiment on the movement of ions across neural membranes. Which of the following plays a role in determining the equilibrium concentration of ions across these membranes?
  - a. Ion concentration gradients
  - b. Ion pH gradients
  - c. Ion electrical gradients
  - d. Both a and c
2. The  $\text{Na}^+/\text{K}^+$  ATPase pump is
  - a. not required for action potential firing.
  - b. important for long-term maintenance of resting potential.
  - c. important only at the synapse.
  - d. used to stimulate graded potentials.
3. Botox, a derivative of the botulinum toxin that causes food poisoning, inhibits the release of acetylcholine at the neuromuscular junction. How could this strange-sounding treatment produce desired cosmetic effects?
  - a. By inhibiting the parasympathetic branch of the autonomic nervous system
  - b. By inhibiting the sympathetic branch of the autonomic nervous system
  - c. By causing paralysis of facial muscles, which decreases wrinkles in the face
  - d. By causing facial muscles to contract, whereby the skin is stretched tighter, thereby reducing wrinkles

## SYNTHESIZE

1. Tetraethylammonium (TEA) is a drug that blocks voltage-gated  $\text{K}^+$  channels. What effect would TEA have on the action potentials produced by a neuron? If TEA could be applied selectively to a presynaptic neuron that releases an excitatory neurotransmitter, how would it alter the synaptic effect of that neurotransmitter on the postsynaptic cell?
2. Describe the status of the  $\text{Na}^+$  and  $\text{K}^+$  channels at each of the following stages: rising, falling, and undershoot.
3. Describe the steps required to produce an excitatory postsynaptic potential (EPSP). How would these differ at an inhibitory synapse?
4. Your friend Karen loves caffeine. However, lately she has been complaining that she needs to drink more caffeinated beverages in order to get the same effect she used to. Excellent student of biology that you are, you tell her that this is to be expected. Why?

# Sensory Systems

## Chapter Outline

- 45.1** Overview of Sensory Receptors
- 45.2** Mechanoreceptors: Touch and Pressure
- 45.3** Hearing, Vibration, and Detection of Body Position
- 45.4** Chemoreceptors: Taste, Smell, and pH
- 45.5** Vision
- 45.6** The Diversity of Sensory Experiences

## Introduction

All input from sensory neurons to the central nervous system (CNS) arrives in the same form, as electrical signals. Sensory neurons receive input from a variety of different kinds of sense receptor cells, such as the rod and cone cells found in the vertebrate eye shown in the micrograph. Different sensory neurons lead to different brain regions and so are associated with the different senses. The intensity of the sensation depends on the frequency of action potentials conducted by the sensory neuron. The brain distinguishes a sunset, a symphony, and searing pain only in terms of the identity of the sensory neuron carrying the action potentials and the frequency of these impulses. Thus, if the auditory nerve is artificially stimulated, the brain perceives the stimulation as sound. But if the optic nerve is artificially stimulated in exactly the same manner and degree, the brain perceives a flash of light.

In this chapter, we examine sensory systems, primarily in vertebrates. We also compare some of these systems with their counterparts in invertebrates.

## 45.1 Overview of Sensory Receptors

### Learning Outcomes

1. List the three categories of vertebrate sensory receptors.
2. Explain how sensory information is conveyed from sensory neurons to the CNS.
3. Describe how gated ion channels work.

When we think of sensory receptors, the senses of vision, hearing, taste, smell, and touch come to mind—the senses that provide information about our environment. Certainly this external information is crucial to the survival and success of animals, but sensory receptors also provide information about internal states, such as stretching of muscles, position of the body, and blood pressure. In this section, we take a general look at types of receptors and how they work.

### Sensory receptors detect both external and internal stimuli

**Exteroceptors** are receptors that sense stimuli that arise in the external environment. Almost all of a vertebrate's exterior senses evolved in water before the invasion of land. Consequently, many senses of terrestrial vertebrates emphasize stimuli that travel well in water, using receptors that have been retained in the transition from sea to land. Mammalian hearing, for example, converts an airborne stimulus into a waterborne one, using receptors similar to those that originally evolved in the water.

A few vertebrate sensory systems that function well in the water, such as the electrical organs of fish, cannot function in the air and are not found among terrestrial vertebrates. In contrast, some land-dwellers have sensory systems that could not function in water, such as infrared heat detectors.

**Interoceptors** sense stimuli that arise from within the body. These internal receptors detect stimuli related to muscle length and tension, limb position, pain, blood chemistry, blood volume and pressure, and body temperature. Many of these receptors are simpler than those that monitor the external environment and are believed to bear a closer resemblance to primitive sensory receptors. In the rest of this chapter, we consider the different types of exteroceptors and interoceptors according to the kind of stimulus each is specialized to detect.

### Receptors can be grouped into three categories

Sensory receptors differ with respect to the nature of the environmental stimulus that best activates their sensory dendrites. Broadly speaking, we can recognize three classes of receptors:

1. **Mechanoreceptors** are stimulated by mechanical forces such as pressure. These include receptors for touch, hearing, and balance.

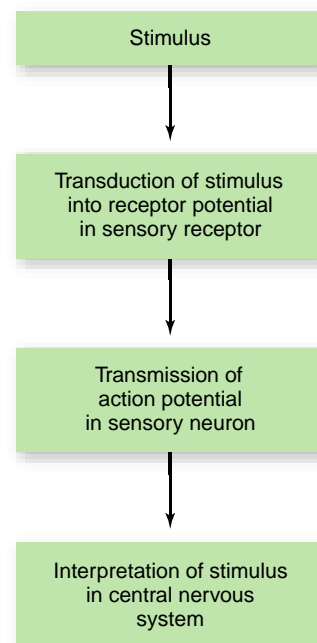

2. **Chemoreceptors** detect chemicals or chemical changes. The senses of smell and taste rely on chemoreceptors.
3. **Electromagnetic receptors** react to heat and light energy. The photoreceptors of the eyes that detect light are an example, as are the thermal receptors found in some reptiles.

The simplest sensory receptors are free nerve endings that respond to bending or stretching of the sensory neuron's membrane to changes in temperature or to chemicals such as oxygen in the extracellular fluid. Other sensory receptors are more complex, involving the association of the sensory neurons with specialized epithelial cells.

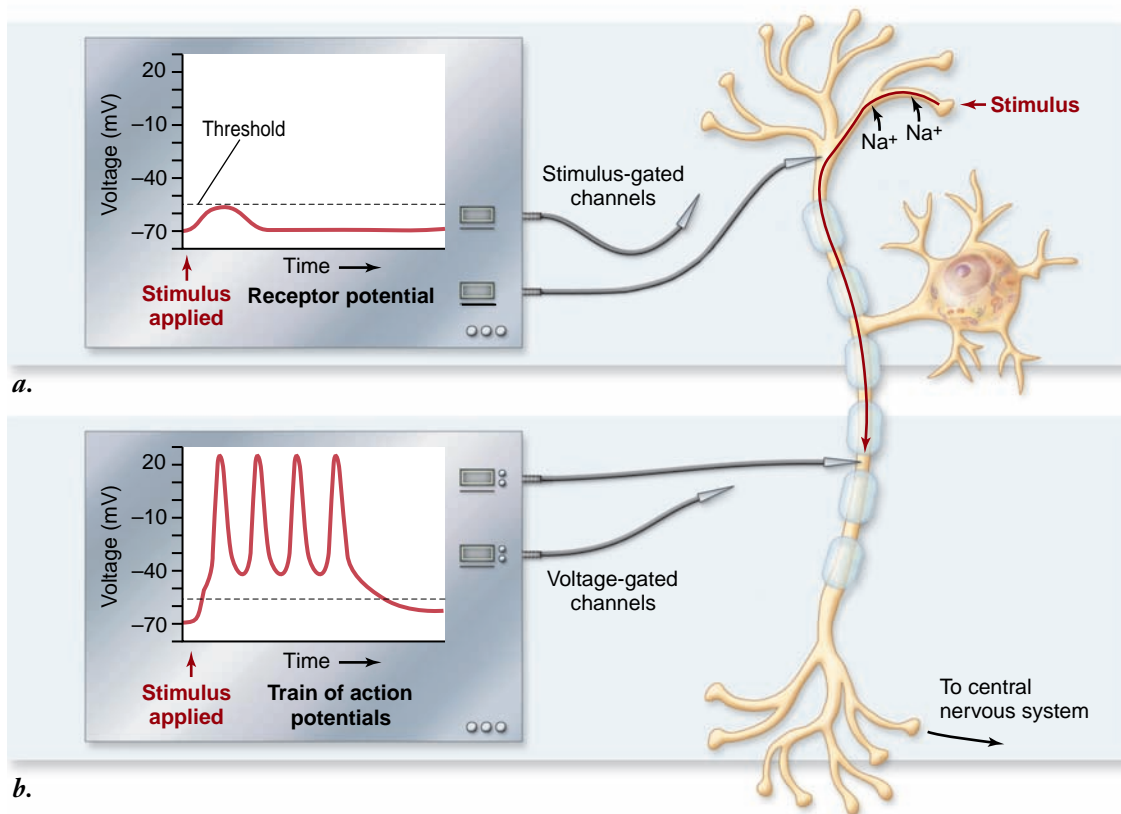

### Sensory information is conveyed in a four-step process

Sensory information picked up by sensory neurons is conveyed to the CNS, where the impulses are perceived in a four-step process (figure 45.1):

1. **Stimulation.** A physical stimulus impinges on a sensory neuron or an associated, but separate, sensory receptor.
2. **Transduction.** The stimulus energy is transformed into graded potentials in the dendrites of the sensory neuron.
3. **Transmission.** Action potentials develop in the axon of the sensory neuron and are conducted to the CNS along an afferent nerve pathway.
4. **Interpretation.** The brain creates a sensory perception from the electrochemical events produced by afferent stimulation. We actually perceive the five senses with our brains, not with our sense organs.

**Figure 45.1** The path of sensory information. Sensory stimuli are transduced into receptor potentials, which can trigger sensory neuron action potentials that are conducted to the brain for interpretation.

**Figure 45.2** Events in sensory transduction.

*a.* Depolarization of a free nerve ending leads to a receptor potential that spreads by local current flow to the axon. *b.* Action potentials are produced in the axon in response to a sufficiently large receptor potential.

## Sensory transduction involves gated ion channels

Sensory cells respond to stimuli because they possess **stimulus-gated ion channels** in their membranes. The sensory stimulus causes these ion channels to open or close, depending on the sensory system involved. In most cases, the sensory stimulus produces a depolarization of the receptor cell, analogous to the excitatory postsynaptic potential (EPSP, described in chapter 44) produced in a postsynaptic cell in response to a neurotransmitter. A depolarization that occurs in a sensory receptor on stimulation is referred to as a *receptor potential* (figure 45.2*a*).

Like an EPSP, a receptor potential is a graded potential: The larger the sensory stimulus, the greater the degree of depolarization. Receptor potentials also decrease in size with distance from their source. This prevents small, irrelevant stimuli from reaching the cell body of the sensory neuron. If the receptor potential or the summation of receptor potentials is great enough to generate a threshold level of depolarization, an action potential is produced that propagates along the sensory axon into the CNS (figure 45.2*b*).

The greater the sensory stimulus, the greater the depolarization of the receptor potential and the higher the frequency of action potentials. (Remember that frequency of action potentials, not their summation, is responsible for conveying the intensity of the stimulus.)

Generally, a logarithmic relationship exists between stimulus intensity and action potential frequency—for example, a particular sensory stimulus that is 10 times greater than another sensory stimulus produces action potentials at twice the frequency of the other stimulus. This relationship allows the CNS to interpret the strength of a sensory stimulus based on the frequency of incoming signals.

### Learning Outcomes Review 45.1

Sensory receptors include mechanoreceptors, chemoreceptors, and electromagnetic energy-detecting receptors. The four steps by which information is conveyed to the CNS are stimulation, transduction, transmission, and interpretation in the CNS. Gated ion channels open or close in response to stimuli, altering membrane potential; if this change exceeds a threshold, an action potential is generated.

- Why is the relationship between intensity of stimulus and frequency of action potentials said to be logarithmic?

## 45.2 Mechanoreceptors: Touch and Pressure

### Learning Outcomes

1. Explain how mechanoreceptors detect touch.
2. Distinguish between nociceptors, thermoreceptors, proprioceptors, and baroreceptors.

Although the receptors of the skin, called the cutaneous receptors, are classified as interoceptors, they in fact respond to stimuli at the border between the external and internal environments. These receptors serve as good examples of the specialization of receptor structure and function, responding to pain, heat, cold, touch, and pressure.

## Pain receptors alert the body to damage or potential damage

A stimulus that causes or is about to cause tissue damage is perceived as pain. The receptors that transmit impulses perceived as pain are called **nociceptors**, so named because they can be sensitive to noxious substances as well as tissue damage. Although specific nociceptors exist, many hyperstimulated sensory receptors can also produce the perception of pain in the brain.

Most nociceptors consist of free nerve endings located throughout the body, especially near surfaces where damage is most likely to occur. Different nociceptors may respond to extremes in temperature, very intense mechanical stimulation such as a hard impact, or specific chemicals in the extracellular fluid, including some that are released by injured cells. The thresholds of these sensory cells vary; some nociceptors are sensitive only to actual tissue damage, but others respond before damage has occurred.

### Transient receptor potential ion channels

One kind of tissue damage can be due to extremes of temperature, and in this case the molecular details of how a noxious stimulus can result in the sensation of pain are becoming clear. A class of ion channel protein found in nociceptors, the transient receptor potential (TRP) ion channel, can be stimulated by temperature to produce an inward flow of cations, primarily  $\text{Na}^+$  and  $\text{Ca}^{2+}$ . This depolarizing current causes the sensory neuron to fire, leading to the release of glutamate and an EPSP in neurons in the spinal cord, ultimately producing the pain response.

TRP channels that respond to both hot and cold have been found. Differences have also been found in the sensitivity of TRP channels to the degree of temperature change, with some responding only to temperature changes that damage tissues and others that respond to milder changes. Thus, we can respond to the feelings of hot and cold as well as feel pain associated with extremes of hot and cold.

The first such TRP channel identified responds to the chemical capsaicin, found in chili peppers, as well as to heat. This explains the sensation of heat we feel when we eat chili peppers, as well as the associated pain! A cold-responsive TRP receptor also responds to the chemical menthol, explaining how this substance is perceived as “cold.” Chemical stimulation of TRP channels can reduce the body’s pain response by desensitizing the sensory neuron. This analgesic response is why menthol is found in cough drops.

## Thermoreceptors detect changes in heat energy

The skin contains two populations of **thermoreceptors**, which are naked dendritic endings of sensory neurons that are sensitive to changes in temperature. (Nociceptors are similar in that they consist of free nerve endings.) These thermoreceptors contain TRP ion channels that are responsive to hot and cold.

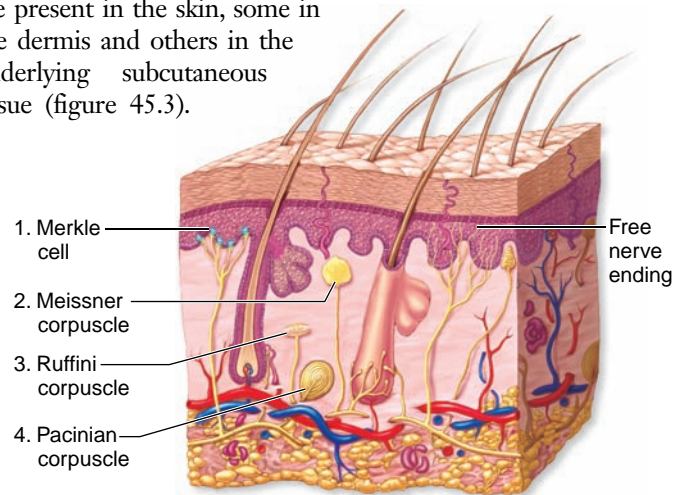

Cold receptors are stimulated by a fall in temperature and are inhibited by warming, whereas warm receptors are stimulated by a rise in temperature and inhibited by cooling. Cold receptors are located immediately below the epidermis; they are three to four times more numerous than are warm receptors. Warm receptors are typically located slightly deeper, in the dermis.

Thermoreceptors are also found within the hypothalamus of the brain, where they monitor the temperature of the circulat-

ing blood and thus provide the CNS with information on the body’s internal (core) temperature. Information from the hypothalamic thermoreceptors alter metabolism and stimulate other responses to increase or decrease core temperature as needed.

## Different receptors detect touch, depending on intensity

Several types of mechanoreceptors are present in the skin, some in the dermis and others in the underlying subcutaneous tissue (figure 45.3).

1. Merkel Cell

Tonic receptors located near the surface of the skin that are sensitive to touch pressure and duration.

2. Meissner Corpuscle

Phasic receptors sensitive to fine touch, concentrated in hairless skin.

3. Ruffini Corpuscle

Tonic receptors located near the surface of the skin that are sensitive to touch pressure and duration.

4. Pacinian Corpuscle

Pressure-sensitive phasic receptors deep below the skin in the subcutaneous tissue.

**Figure 45.3** Sensory receptors in human skin.

Cutaneous receptors may be free nerve endings or sensory dendrites in association with other supporting structures.

These receptors contain sensory cells with ion channels that open in response to mechanical distortion of the membrane. They detect various forms of physical contact, known as the sense of touch.

Morphologically specialized receptors that respond to fine touch are most concentrated on areas such as the fingertips and face. They are used to localize cutaneous stimuli very precisely. These receptors can be either phasic (intermittently activated) or tonic (continuously activated). The phasic receptors include hair follicle receptors and Meissner corpuscles, which are present on surfaces that do not contain hair, such as the fingers, palms, and nipples.

The tonic receptors consist of Ruffini corpuscles in the dermis and touch dome endings (Merkel's disks) located near the surface of the skin. These receptors monitor the duration of a touch and the extent to which it is applied.

Deep below the skin in the subcutaneous tissue lie phasic, pressure-sensitive receptors called Pacinian corpuscles. Each of these receptors consists of the end of an afferent axon surrounded by a capsule of alternating layers of connective tissue cells and extracellular fluid. When sustained pressure is applied to the corpuscle, the elastic capsule absorbs much of the pressure, and the axon ceases to produce impulses. Pacinian corpuscles thus monitor only the onset and removal of pressure, as may occur repeatedly when something that vibrates is placed against the skin.

## Muscle length and tension are monitored by proprioceptors

Buried within the skeletal muscles of all vertebrates except the bony fishes are **muscle spindles**, sensory stretch receptors that lie in parallel with the rest of the fibers in the muscle (figure 45.4). Each spindle consists of several thin muscle fibers wrapped together and innervated by a sensory neuron, which becomes activated when the muscle, and therefore the spindle, is stretched.

Muscle spindles, together with other receptors in tendons and joints, are known as **proprioceptors**. These sensory receptors provide information about the relative position or movement of the animal's body parts. The sensory neurons conduct action potentials into the spinal cord, where they synapse with somatic motor neurons that innervate the muscle. This pathway constitutes the muscle stretch reflex, including the knee-jerk reflex mentioned in chapter 44. When the muscle is briefly stretched by tapping the patellar ligament with a rubber mallet, the muscle spindle apparatus is also stretched. The spindle apparatus is embedded within the muscle, and, like the muscle fibers outside the spindle, is stretched along with the muscle. The result is the action potential that activates the somatic motor neurons and causes the leg to jerk.

When a muscle contracts, it exerts tension on the tendons attached to it. The **Golgi tendon organs**, another type of proprioceptor, monitor this tension. If it becomes too high, they elicit a reflex that inhibits the motor neurons innervating the muscle. This reflex helps ensure that muscles do not contract so strongly that they damage the tendons to which they are attached.

## Baroreceptors detect blood pressure

Blood pressure is monitored at two main sites in the body. One is the carotid sinus, an enlargement of the left and right internal

**Figure 45.4** How a muscle spindle works. A muscle spindle is a stretch receptor embedded within skeletal muscle. Stretching of the muscle elongates the spindle fibers and stimulates the sensory dendritic endings wrapped around them. This causes the sensory neurons to send impulses to the CNS, where they synapse with interneurons and, in some cases, motor neurons.

carotid arteries that supply blood to the brain. The other is the aortic arch, the portion of the aorta very close to its emergence from the heart. The walls of the blood vessels at both sites contain a highly branched network of afferent neurons called baroreceptors, which detect tension or stretch in the walls.

When the blood pressure decreases, the frequency of impulses produced by the baroreceptors decreases. The CNS responds to this reduced input by stimulating the sympathetic division of the autonomic nervous system, causing an increase in heart rate and vasoconstriction. Both effects help raise the blood pressure, thus maintaining homeostasis. A rise in blood pressure increases baroreceptor impulses, which conversely reduces sympathetic activity and stimulates the parasympathetic division, slowing the heart and lowering the blood pressure.

### Learning Outcomes Review 45.2

Mechanical distortion of the plasma membrane of mechanoreceptors produces nerve impulses. Nociceptors detect damage or potential damage to tissues and cause pain; thermoreceptors sense changes in heat energy; proprioceptors monitor muscle length; and baroreceptors monitor blood pressure within arteries.

- Why is it important to detect stretching of muscles?

## 45.3 Hearing, Vibration, and Detection of Body Position

### Learning Outcomes

1. Explain how sound waves in the environment lead to production of action potentials in the inner ear.
2. Describe how hearing differs between aquatic and terrestrial animals.
3. Describe how body position and movement are detected by hearing-associated structures.

Hearing, the detection of sound waves, actually works better in water than in air because water transmits pressure waves more efficiently. Despite this limitation, hearing is widely used by terrestrial vertebrates to monitor their environments, communicate with other members of their species, and detect possible sources of danger.

Sound is a result of vibration, or waves, traveling through a medium, such as water or air. Detection of sound waves is possible through the action of specialized mechanoreceptors that first evolved in aquatic organisms. The cells that are involved in the detection of sound are also evolutionarily related to the gravity-sensing systems discussed in the end of this section.

### The lateral line system in fish detects low-frequency vibrations

In addition to hearing, the lateral line system in fish provides a sense of “distant touch,” enabling them to sense objects that reflect pressure waves and low-frequency vibrations. This enables a fish to detect prey, for example, and to swim in synchrony with the rest of its school. It also enables a blind cave fish to sense its environment by monitoring changes in the patterns of water flow past the lateral line receptors.

The lateral line system is found in amphibian larvae, but is lost at metamorphosis and is not present in any terrestrial

vertebrate. The sense provided by the lateral line system supplements the fish’s sense of hearing, which is performed by the sensory structures in their ears.

The lateral line system consists of hair cells within a longitudinal canal in the fish’s skin that extends along each side of the body and within several canals in the head (figure 45.5*a*). The hair cells’ surface processes project into a gelatinous membrane called a cupula. The hair cells are innervated by sensory neurons that transmit impulses to the brain.

Hair cells have several hairlike processes, called stereocilia, and one longer process called a **kinocilium** (figure 45.5*b*). The stereocilia are actually microvilli containing actin fibers, and the kinocilium is a true cilium that contains microtubules. Vibrations carried through the fish’s environment produce movements of the cupula, which cause the processes to bend. When the stereocilia bend in the direction of the kinocilium, the associated sensory neurons are stimulated and generate a receptor potential. As a result, the frequency of action potentials produced by the sensory neuron is increased. In contrast, if the stereocilia are bent in the opposite direction, then the activity of the sensory neuron is inhibited.

### Ear structure is specialized to detect vibration

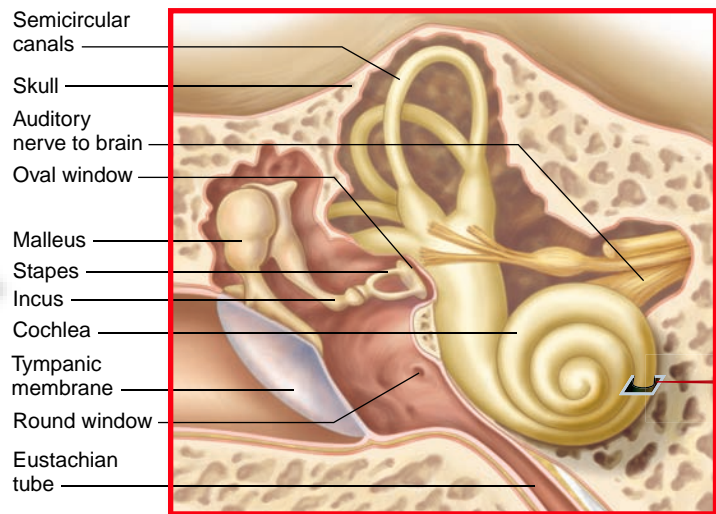

The structure of the ear allows pressure waves to be transduced into nerve impulses based on mechanosensory cells like those in the lateral line system. We will first consider the structure of the ear in fish, which is related to the lateral line system that senses pressure waves in water. Then we will consider how the structure of the ear of terrestrial vertebrates allows the sensing of pressure waves in air.

### Hearing structures in fish

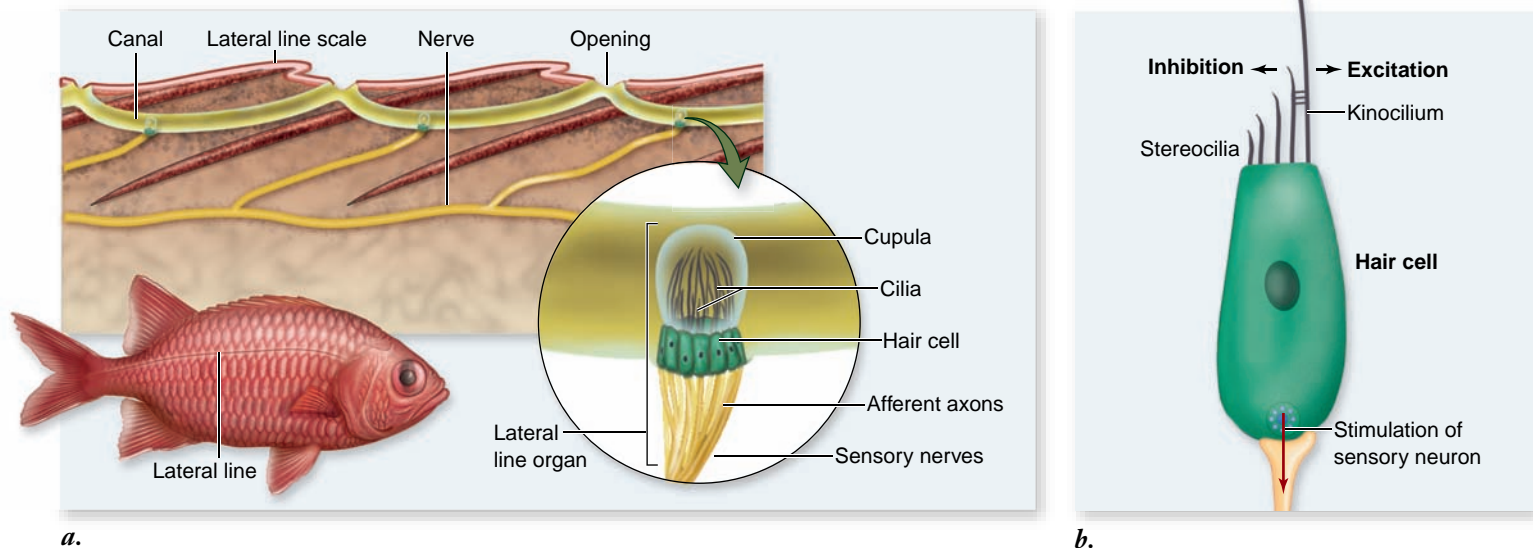

Sound waves travel through the body of a fish as easily as through the surrounding water because the fish’s body is composed primarily of water. For sound to be detected, therefore, an object of different density is needed. In many fish, this function is served by the **otoliths**, literally “ear rocks,” composed of calcium carbonate crystals. Otoliths are contained in the otolith organs of the membranous **labyrinth**, a system of fluid-filled chambers and tubes also present in other vertebrates. When

a.

b.

**Figure 45.5 The lateral line system.** *a.* This system consists of canals running the length of the fish's body beneath the surface of the skin. Within these canals are sensory structures containing hair cells with cilia that project into a gelatinous cupula. Pressure waves traveling through the water in the canals deflect the cilia and depolarize the sensory neurons associated with the hair cells. *b.* Hair cells are mechanoreceptors with hairlike cilia that project into a gelatinous membrane. The hair cells of the lateral line system (and the membranous labyrinth of the vertebrate inner ear) have a number of smaller cilia called stereocilia and one larger kinocilium. When the cilia bend in the direction of the kinocilium, the hair cell releases a chemical transmitter that depolarizes the associated sensory neuron. Bending of the cilia in the opposite direction has an inhibitory effect.

### Inquiry question

? How would the lateral line system of a shark detect an injured and thrashing fish?

otoliths in fish vibrate against hair cells in the otolith organ, action potentials are produced. Hair cells are so-called because of the stereocilia that project from their surface.

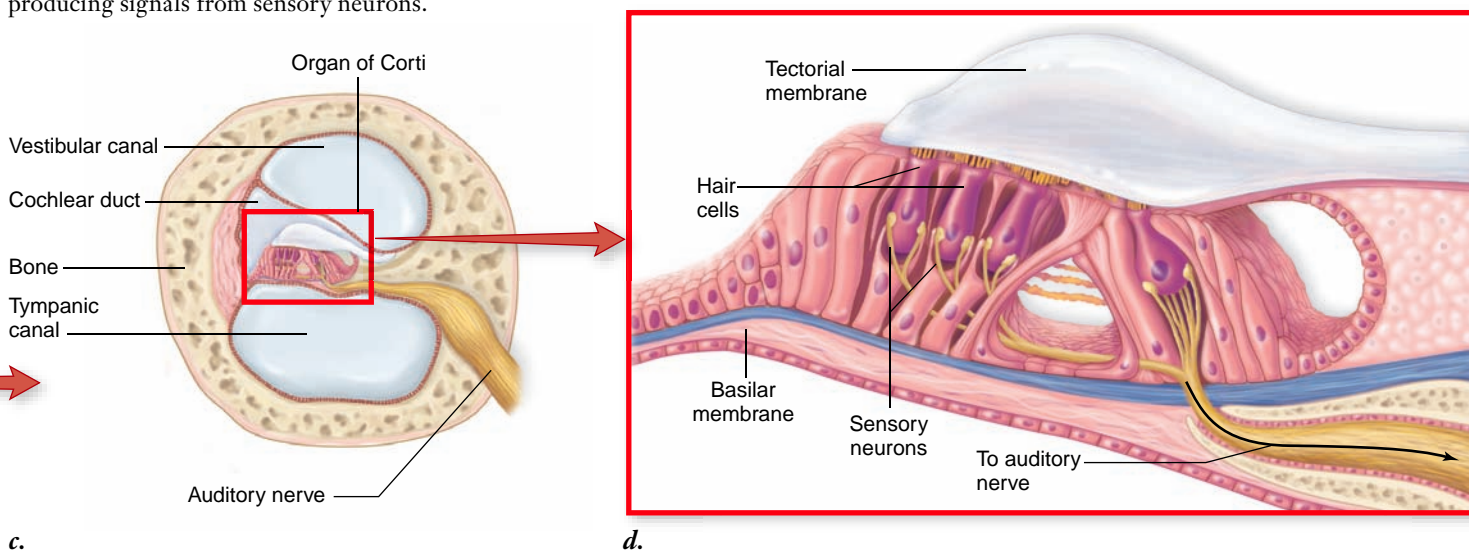

### Hearing structures of terrestrial vertebrates

In the ears of terrestrial vertebrates, vibrations in air may be channeled through an ear canal to the eardrum, or tympanic membrane.

These structures are part of the **outer ear**. Vibrations of the tympanic membrane cause movement of one or more small bones that are located in a bony cavity known as the **middle ear**.

Amphibians and reptiles have a single middle ear bone, the **stapes** (stirrup), but mammals have two others: the **malleus** (hammer) and **incus** (anvil) (figure 45.6*a, b*). Where did these two additional bones come from?

**Figure 45.6 Structure and function of the human ear.** The structure of the human ear is shown in successive enlargements illustrating functional parts (*a* to *d*). Sound waves passing through the ear canal produce vibrations of the tympanic membrane, which causes movement of the middle-ear ossicles (the malleus, incus, and stapes) against an inner membrane (the oval window). This vibration creates pressure waves in the fluid in the vestibular and tympanic canals of the cochlea. These pressure waves cause cilia in hair cells to bend, producing signals from sensory neurons.

The fossil record makes clear that the malleus and incus of modern mammals is derived from the two bones in the lower jaws of synapsid reptiles (figure 45.7). Through evolutionary time, these bones became progressively smaller and came to lie closer to the stapes. Eventually, in modern mammals, they became completely disconnected from the jawbone and moved within the middle ear itself.

The middle ear is connected to the throat by the Eustachian tube, also known as the auditory tube, which equalizes the air pressure between the middle ear and the external environment. The “ear popping” you may have experienced when flying in an airplane or driving on a mountain is caused by pressure equalization between the two sides of the eardrum.

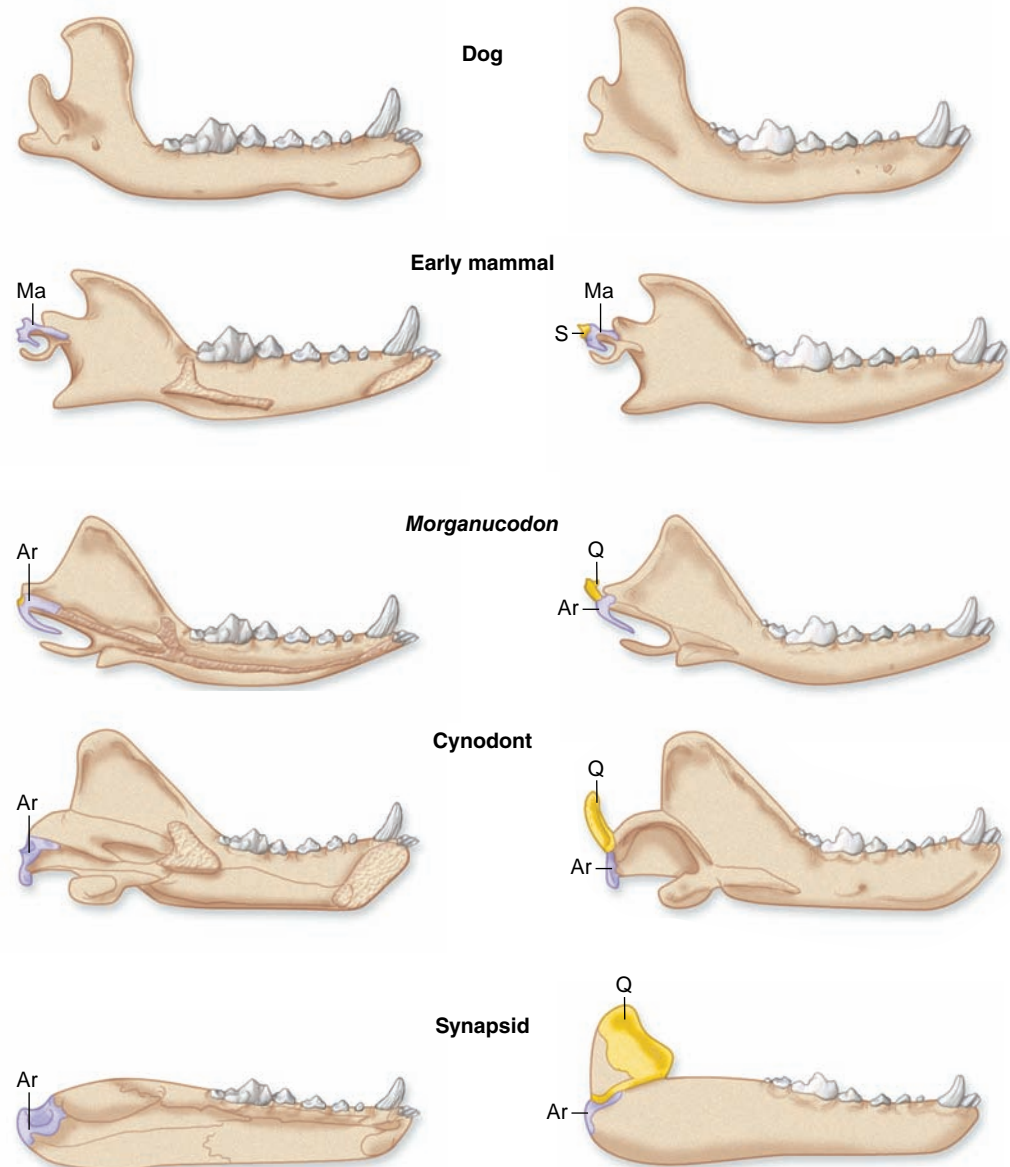

The stapes vibrates against a flexible membrane, the oval window, which leads into the **inner ear**. Because the oval window is smaller in diameter than the tympanic membrane, vibrations against it produce more force per unit area, transmitted into the inner ear. The inner ear consists of the **cochlea**, a bony structure containing part of the membranous labyrinth called the cochlear duct. The cochlear duct is located in the center of

the cochlea; the area above the cochlear duct is the vestibular canal, and the area below is the tympanic canal (figure 45.6c). All three chambers are filled with fluid. The oval window opens to the upper vestibular canal, so that when the stapes causes it to vibrate, it produces pressure waves of fluid. These pressure waves travel down to the tympanic canal, pushing another flexible membrane, the round window, that transmits the pressure back into the middle ear cavity.

### Transduction occurs in the cochlea

As pressure waves are transmitted through the cochlea to the round window, they cause the cochlear duct to vibrate. The bottom of the cochlear duct, called the basilar membrane, is quite flexible and vibrates in response to these pressure waves. The surface of the basilar membrane contains sensory hair cells. The stereocilia from the hair cells project into an overhanging gelatinous membrane, the tectorial membrane. This sensory apparatus, consisting of the basilar membrane, hair cells with associated sensory neurons, and tectorial membrane, is known as the organ of Corti (figure 45.6d).

**Figure 45.7 Evolution of the mammalian inner ear.** Two of the bones in the inner ear of modern mammals, the stapes and malleus, are derived from the quadrate and articular bones, respectively, of their reptilian ancestors. The transition from an early ancestor of mammals, a synapsid, through several transition forms, to a modern dog is illustrated. Note how the bones become smaller and change position, ultimately disappearing from the lower jaw entirely in modern mammals (represented by the dog) and becoming parts of the inner ear. During embryology in modern mammals, these bones develop in association with the lower jaw bone before moving inward to the inner ear, providing further evidence of their evolutionary origin.

As the basilar membrane vibrates, the cilia of the hair cells bend in response to the movement of the basilar membrane relative to the tectorial membrane. The bending of these stereocilia in one direction depolarizes the hair cells. Bending in the opposite direction repolarizes or even hyperpolarizes the membrane. The hair cells, in turn, stimulate the production of action potentials in sensory neurons that project to the brain, where they are interpreted as sound.

### Frequency localization in the cochlea

The basilar membrane of the cochlea consists of elastic fibers of varying length and stiffness, like the strings of a musical instrument, embedded in a gelatinous material. At the base of the cochlea (near the oval window), the fibers of the basilar membrane are short and stiff. At the far end of the cochlea (the apex), the fibers are 5 times longer and 100 times more flexible. Therefore, the resonant frequency of the basilar membrane is higher at the base than at the apex; the base responds to higher pitches, the apex to lower pitches.

When a wave of sound energy enters the cochlea from the oval window, it initiates an up-and-down motion that travels the length of the basilar membrane. However, this wave imparts most of its energy to that part of the basilar membrane with a resonant frequency near the frequency of the sound wave, resulting in a maximum deflection of the basilar membrane at that point (figure 45.8). As a result, the hair cell depolarization is greatest in that region, and the afferent axons from that region are stimulated more than those

of other regions. When these action potentials arrive in the brain, they are interpreted as representing a sound of a particular frequency, or pitch.

### The range of terrestrial vertebrate hearing

The flexibility of the basilar membrane limits the frequency range of human hearing to between approximately 20 and 20,000 cycles per second (hertz, Hz) in children. Our ability to hear high-pitched sounds decays progressively throughout middle age. Other vertebrates can detect sounds at frequencies lower than 20 Hz and much higher than 20,000 Hz. Dogs, for example, can detect sounds at 40,000 Hz, enabling them to hear high-pitched dog whistles that seem silent to a human listener.

Hair cells are also innervated by efferent axons from the brain, and impulses in those axons can make hair cells less sensitive. This central control of receptor sensitivity can increase an individual's ability to concentrate on a particular auditory signal (for example, a single voice) in the midst of background noise, which is effectively "tuned out" by the efferent axons.

### Some vertebrates have the ability to navigate by sound

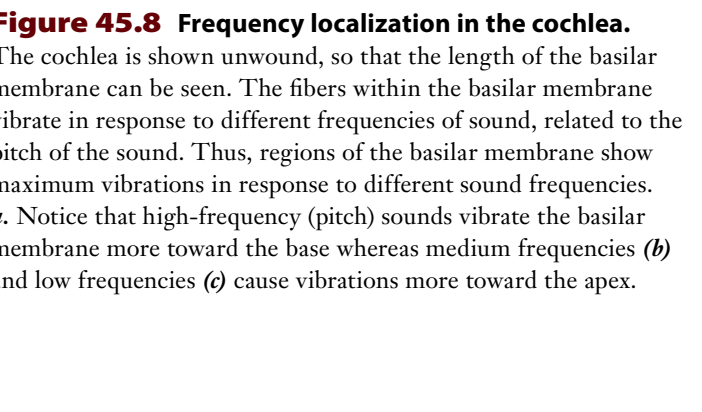

Because terrestrial vertebrates have two ears located on opposite sides of the head, the information provided by hearing can be used to determine the direction of a sound source with some precision. Sound sources vary in strength, however, and sounds are weakened and reflected to varying degrees by the presence

a.

b.

c.

**Figure 45.8** Frequency localization in the cochlea.

The cochlea is shown unwound, so that the length of the basilar membrane can be seen. The fibers within the basilar membrane vibrate in response to different frequencies of sound, related to the pitch of the sound. Thus, regions of the basilar membrane show maximum vibrations in response to different sound frequencies. *a.* Notice that high-frequency (pitch) sounds vibrate the basilar membrane more toward the base whereas medium frequencies (*b*) and low frequencies (*c*) cause vibrations more toward the apex.

of objects in the environment. For these reasons, auditory sensors do not provide a reliable measure of distance.

A few groups of mammals that live and obtain their food in dark environments have circumvented the limitations of darkness. A bat flying in a completely dark room easily avoids objects placed in its path—even a wire less than a millimeter in diameter. Shrews use a similar form of “lightless vision” beneath the ground, as do whales and dolphins beneath the sea. All of these mammals are able to perceive presence and distance of objects by sound.

These mammals emit sounds and then determine the time it takes these sounds to reach an object and return to the animal. This process is called **echolocation**. A bat, for example, produces clicks that last 2 to 3 ms and are repeated several hundred times per second. By calculating the time each click takes to hit an object and return, bats can calculate the location, direction of movement, and speed of objects in their environment. The human inventions sonar and radar are based on the same principles of echolocation.

The three-dimensional imaging achieved with such an auditory sonar system is quite sophisticated. Bats can track and intercept rapidly maneuvering aerial prey and can distinguish one type of insect from another.

## Body position and movement are detected by systems associated with hearing systems

The evolutionary strategy of using internal calcium carbonate crystals as a way to detect vibration has also allowed the devel-

opment of sensory organs that detect body position in space and movements such as acceleration.

Most invertebrates can orient themselves with respect to gravity due to a sensory structure called a **statocyst**. Statocysts generally consist of ciliated hair cells with the cilia embedded in a gelatinous membrane containing crystals of calcium carbonate. These stones, or statoliths, increase the mass of the gelatinous membrane so that it can bend the cilia when the animal's position changes. If the animal tilts to the right, for example, the statolith membrane bends the cilia on the right side and activates associated sensory neurons.

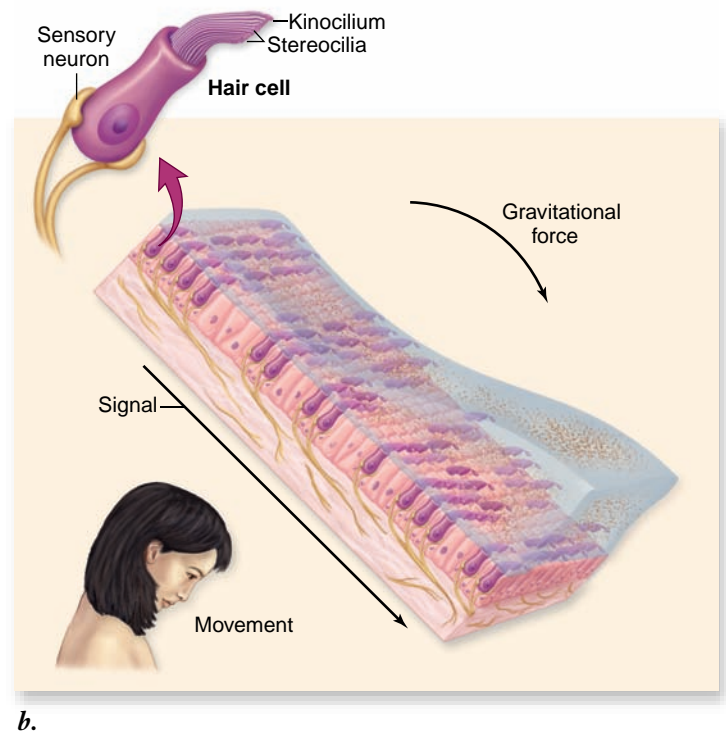

A similar structure is found in the membranous labyrinth of the inner ear of vertebrates. This labyrinth is surrounded by bone and perilymph, which is similar in ionic content to interstitial fluid. Inside, the chambers and tubes are filled with endolymph fluid, which is similar in ionic content to intracellular fluid. Though intricate, the entire structure is very small; in a human, it is about the size of a pea.

### Structure of the labyrinth and semicircular canals

The receptors for gravity in most vertebrates consist of two chambers of the membranous labyrinth called the **utricle** and **sacculus** (figure 45.9). Within these structures are hair cells with stereocilia and a kinocilium, similar to those in the lateral line system of fish. The hairlike processes are embedded within a gelatinous membrane, the otolith membrane, containing calcium carbonate crystals. Because the otolith organ is oriented differently in the utricle and saccule, the utricle is more sensitive to

*b.* When your head bends forward, gravity distorts the matrix in the direction of movement. This causes the stereocilia in hair cells to bend, stimulating sensory neurons.

horizontal acceleration (as in a moving car) and the saccule to vertical acceleration (as in an elevator). In both cases, the acceleration causes the stereocilia to bend, and consequently produces action potentials in an associated sensory neuron.

The membranous labyrinth of the utricle and saccule is continuous with three **semicircular canals**, oriented in different planes so that angular acceleration in any direction can be detected (figure 45.10). At the ends of the canals are swollen chambers called ampullae, into which protrude the cilia of another group of hair cells. The tips of the cilia are embedded within a sail-like wedge of gelatinous material called a cupula (similar to the cupula of the fish lateral line system) that protrudes into the endolymph fluid of each semicircular canal.

### Action of the vestibular apparatus

When the head rotates, the fluid inside the semicircular canals pushes against the cupula and causes the cilia to bend. This bending either depolarizes or hyperpolarizes the hair cells, depending on the direction in which the cilia are bent. This is similar to the way the lateral line system works in a fish: If the stereocilia are bent in the direction of the kinocilium, a receptor potential is produced, which stimulates the production of action potentials in associated sensory neurons.

The saccule, utricle, and semicircular canals are collectively referred to as the **vestibular apparatus**. The saccule and utricle provide a sense of linear acceleration, and the semicircular canals provide a sense of angular acceleration. The brain uses information that comes from the vestibular apparatus about the body's position to maintain balance and equilibrium.

### Learning Outcomes Review 45.3

Sound waves cause middle-ear ossicles to vibrate; fluid in the inner ear is vibrated in turn, bending hair cells and causing action potentials. In terrestrial animals, sound waves in air must transition to the fluid in the inner ear. Hair cells in the vestibular apparatus of terrestrial vertebrates provide a sense of acceleration and balance.

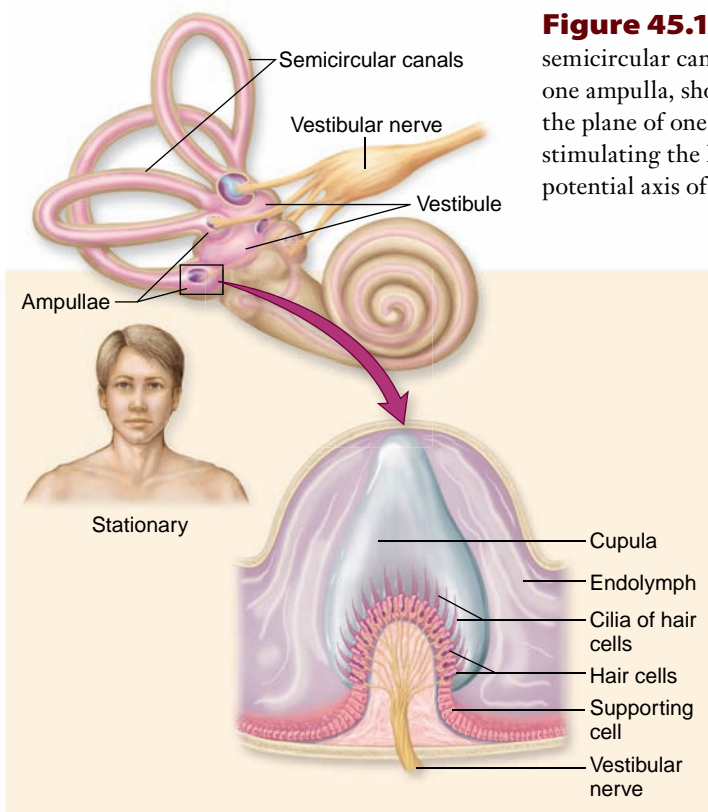

- Why is a lateral line system not useful to adult amphibians?

## 45.4 Chemoreceptors: Taste, Smell, and pH

### Learning Outcomes

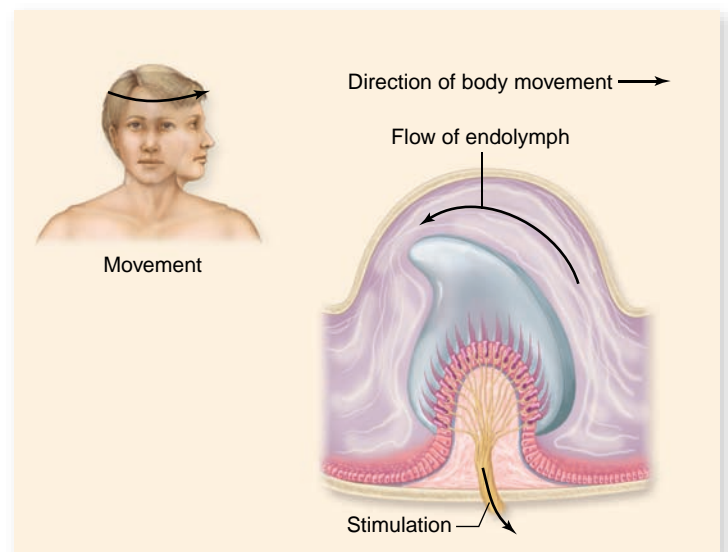

1. List the five taste categories.
2. Describe how taste buds and olfactory neurons function.

Some sensory cells, called chemoreceptors, contain membrane proteins that can bind to particular chemicals or ligands in the extracellular fluid. In response to this chemical interaction, the membrane of the sensory neuron becomes depolarized and produces action potentials. Chemoreceptors are used in the senses of taste and smell and are also important in monitoring the chemical composition of the blood and cerebrospinal fluid.

a.

**Figure 45.10** The structure of the semicircular canals. The position of the semicircular canals in relation to the rest of the inner ear. *a.* Enlargement of a section of one ampulla, showing how hair cell cilia insert into the cupula. *b.* Angular acceleration in the plane of one of the semicircular canals causes bending of the cupula, thereby stimulating the hair cells. Each inner ear contains three semicircular canals, one for each potential axis of rotation.

b.

## Taste detects and analyzes potential food

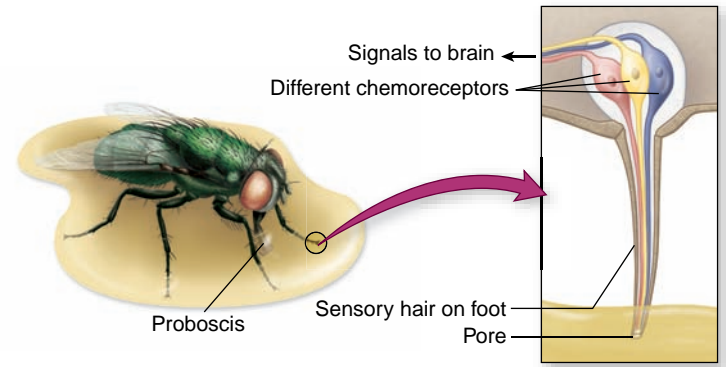

The perception of taste (gustation), like the perception of color, is a combination of physical and psychological factors. This is commonly broken down into five categories: sweet, sour, salty, bitter, and umami (perception of glutamate and other amino acids that give a hearty taste to many protein-rich foods such as meat, cheese, and broths). Taste buds—collections of chemosensitive epithelial cells associated with afferent neurons—mediate the sense of taste in vertebrates. In a fish, the taste buds are scattered over the surface of the body. These are the most sensitive vertebrate chemoreceptors known. They are particularly sensitive to amino acids; a catfish, for example, can distinguish between two different amino acids at a concentration of less than 100 parts per billion (1 g in 10,000 L of water)! The ability to taste the surrounding water is very important to bottom-feeding fish, enabling them to sense the presence of food in an often murky environment.

The taste buds of all terrestrial vertebrates occur in the epithelium of the tongue and oral cavity, within raised areas called papillae (figure 45.11). Taste buds are onion-shaped structures of between 50 and 100 taste cells; each cell has fingerlike projections called microvilli that poke through the top of the taste bud, called the taste pore (figure 45.11c). Chemicals from food dissolve in saliva and contact the taste cells through the taste pore.

Within a taste bud, the chemicals that produce salty and sour tastes act directly through ion channels. The prototypical salty taste is due to  $\text{Na}^+$  ions, which diffuse through  $\text{Na}^+$  channels into cells in receptor cells in the taste bud. This  $\text{Na}^+$  influx depolarizes the membrane, causing the receptor cell to release neurotransmitter and activate a sensory neuron that sends an impulse to the brain. The cells that detect sour taste act in a similar fashion except that the ion detected is  $\text{H}^+$ . Sour tastes are associated with increased concentration of protons that can also depolarize the membrane when they diffuse through ion channels.

The mechanism of detection of sweet, bitter, and umami are indirect. In this case substances that fall into these categories can bind to G protein-coupled receptors (see chapter 9) specific for each category. The nature and distribution of these receptors is an area of active investigation, but recent data indicate that individual receptor cells in the taste bud express only

**Figure 45.11 Taste.** *a.* Human tongues have projections called papillae that bear taste buds. Different sorts of taste buds are located on different regions of the tongue. *b.* Groups of taste buds are embedded within a papilla. *c.* Individual taste buds are bulb-shaped collections of chemosensitive receptors that open out into the mouth through a pore. *d.* Photomicrograph of taste buds in papillae.

**Figure 45.12 Many insects taste with their feet.** In the blowfly shown here, chemoreceptors extend into the sensory hairs on the foot. Different chemoreceptors detect different types of food molecules. When the fly steps in a food substance, it can taste the different food molecules and extend its proboscis for feeding.

one type of receptor. This leads to cells that have receptors for sweet, for bitter or for umami tastes. Activation of any of these G protein-coupled receptors then stimulates a single signaling pathway that leads the release of neurotransmitter from receptor cells to activate a sensory neuron and send an impulse to the brain. There they interact with other sensory neurons carrying information related to smell, described next. In this model, the different tastes are encoded to the brain based on which receptor cells are activated.

Like vertebrates, many arthropods also have taste chemoreceptors. For example, flies, because of their mode of searching for food, have taste receptors in sensory hairs located on their feet. The sensory hairs contain a variety of chemoreceptors that are able to detect sugars, salts, and other tastes by the integration of stimuli from these chemoreceptors (figure 45.12). If they step on potential food, their proboscis (the tubular feeding apparatus) extends to feed.

## Smell can identify a vast number of complex molecules

In terrestrial vertebrates, the sense of smell (olfaction) involves chemoreceptors located in the upper portion of the

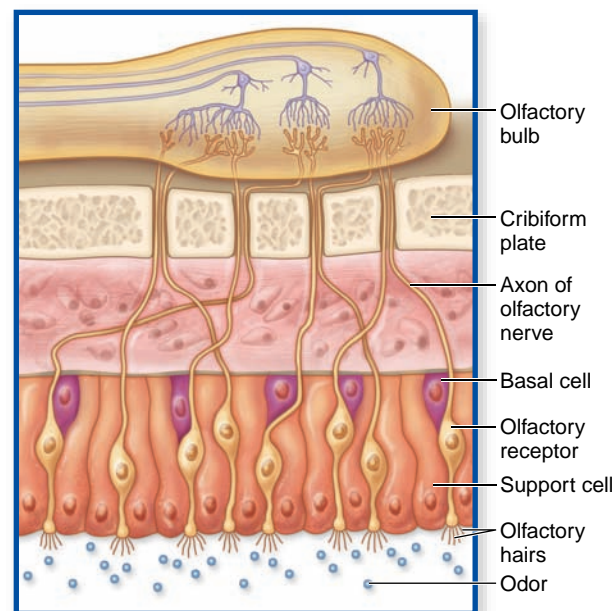

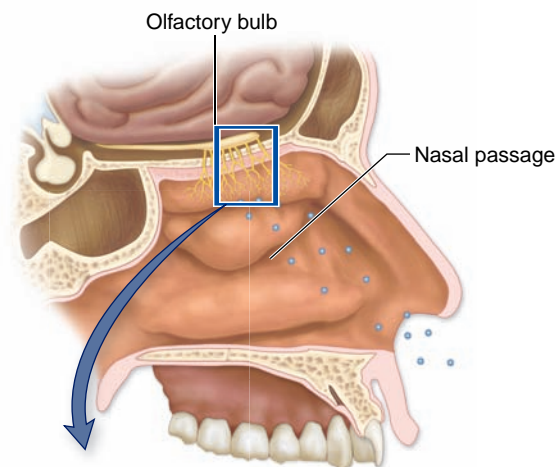

nasal passages (figure 45.13). These receptors, whose dendrites end in tassels of cilia, project into the nasal mucosa, and their axons project directly into the cerebral cortex. A terrestrial vertebrate uses its sense of smell in much the same way that a fish uses its sense of taste—to sample the chemical environment around it.

Because terrestrial vertebrates are surrounded by air, their sense of smell has become specialized to detect airborne particles—but these particles must first dissolve in extracellular fluid before they can activate the olfactory receptors. The sense of smell can be extremely acute in many mammals, so much so that a single odorant molecule may be all that is needed to excite a given receptor.

Although humans can detect only five modalities of taste, they can discern thousands of different smells. New research suggests that as many as a thousand different genes may code for different receptor proteins for smell. The particular set of olfactory neurons that respond to a given odor might serve as a “fingerprint” the brain can use to identify the odor.

### Internal chemoreceptors detect pH and other characteristics

Sensory receptors within the body detect a variety of chemical characteristics of the blood or fluids derived from the blood, including cerebrospinal fluid. Included among these receptors are the **peripheral chemoreceptors** of the aortic and carotid bodies, which are sensitive primarily to plasma pH, and the **central chemoreceptors** in the medulla oblongata of the brain, which are sensitive to the pH of cerebrospinal fluid. When the breathing rate is too low, the concentration of plasma  $\text{CO}_2$  increases, producing more carbonic acid and causing a fall in the blood pH. The carbon dioxide can also enter the cerebrospinal fluid and lower the pH, thereby stimulating the central chemoreceptors. This stimulation indirectly affects the respiratory control center of the brainstem, which increases the breathing rate. The aortic bodies can also respond to a lowering of blood oxygen concentrations, but this effect is normally not significant unless a person goes to a high altitude where the partial pressure of oxygen is lower.

**Figure 45.13 Smell.** Humans detect smells by means of olfactory neurons (receptor cells) located in the lining of the nasal passages. The axons of these neurons transmit impulses directly to the brain via the olfactory nerve. Basal cells regenerate new olfactory neurons to replace dead or damaged cells. Olfactory neurons typically live about a month.

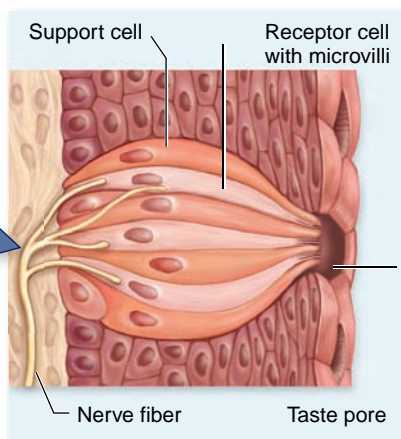

### Inquiry question

? In what ways do the senses of taste and smell share similarities? How are they different?

### Learning Outcomes Review 45.4

The five tastes humans perceive are sweet, sour, salty, bitter, and umami (amino acids). Taste and smell chemoreceptors detect chemicals from outside the body; olfactory receptors can identify thousands of different odors. Internal chemoreceptors monitor acid–base balance within the body and help regulate breathing.

- What are the advantages of insects' having taste receptors on their feet?

c.

d.

## 45.5 Vision

### Learning Outcomes

1. Compare invertebrate and vertebrate eyes.
2. Explain how a vertebrate eye focuses an image.
3. Describe how photoreceptors function.

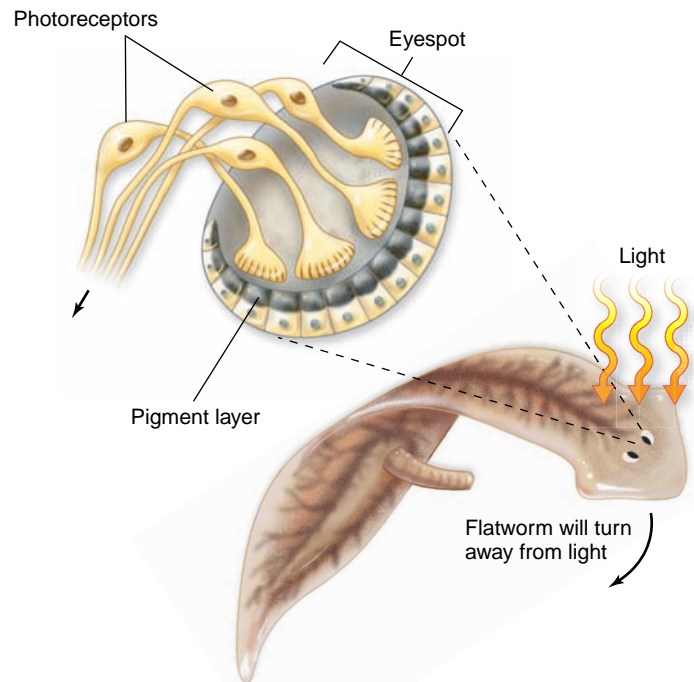

The ability to perceive objects at a distance is important to most animals. Predators locate their prey, and prey avoid their predators, based on the three long-distance senses of hearing, smell, and vision. Of these, vision can act most distantly; with the naked eye, humans can see stars thousands of light years away—and a single photon is sufficient to stimulate a cell of the retina to send an action potential.

### Vision senses light and light changes at a distance

Vision begins with the capture of light energy by **photoreceptors**. Because light travels in a straight line and arrives virtually instantaneously regardless of distance, visual information can be used to determine both the direction and the distance of an object. Other stimuli, which spread out as they travel and move more slowly, provide much less precise information.

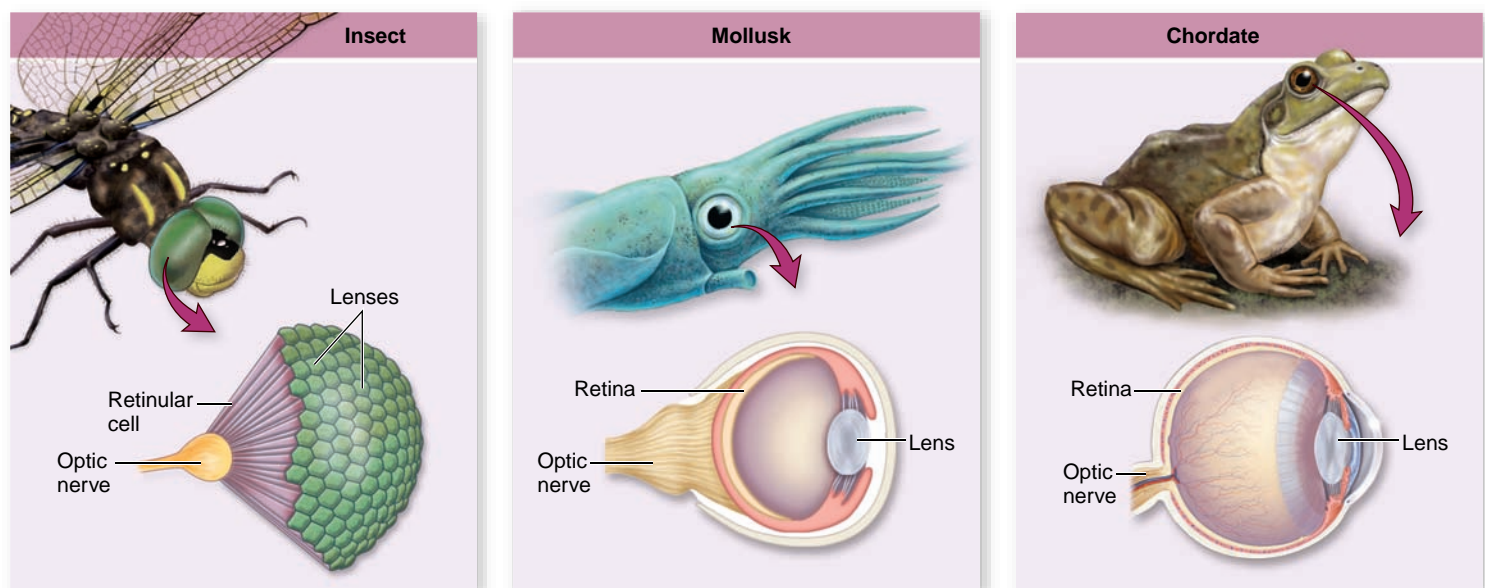

#### Invertebrate eyes

Many invertebrates have simple visual systems with photoreceptors clustered in an eyespot. Simple eyespots can be made sensitive to the direction of a light source by the addition of a pigment layer that shades one side of the eye. Flatworms have a screening pigmented layer on the inner and

**Figure 45.14 Simple eyespots in the flatworm.** Eyespots can detect the direction of light because a pigmented layer on one side of the eyespot screens out light coming from the back of the animal. Light is thus detected more readily coming from the front of the animal; flatworms respond by turning away from the light.

back sides of both eyespots, allowing stimulation of the photoreceptor cells only by light from the front of the animal (figure 45.14). The flatworm will turn and swim in the direction in which the photoreceptor cells are the least stimulated. Although an eyespot can perceive the direction of light, it cannot be used to construct a visual image.

**Figure 45.15 Eyes in three phyla of animals.** Although they are superficially similar, these eyes differ greatly in structure from one another (see also figure 21.16 for a detailed comparison of mollusk and chordate eye structure). Each has evolved separately and, despite the apparent structural complexity, has done so from simpler structures.

**Figure 45.16 Structure of the human eye.** The transparent cornea and lens focus light onto the retina at the back of the eye, which contains the photoreceptors (rods and cones). The center of each eye’s visual field is focused on the fovea. Focusing is accomplished by contraction and relaxation of the ciliary muscle, which adjusts the curvature of the lens.

### Inquiry question

? How does the human eye differ from the eye of a mollusk, and how do these differences create a blind spot?

The members of four phyla—annelids, mollusks, arthropods, and chordates—have evolved well-developed, image-forming eyes. True image-forming eyes in these phyla, although strikingly similar in structure, are believed to have evolved independently, an example of convergent evolution (figure 45.15). Interestingly, the photoreceptors in all of these image-forming eyes use the same light-capturing molecule, suggesting that not many alternative molecules are able to play this role.

### Structure of the vertebrate eye

The human eye is typical of the vertebrate eye (figure 45.16). The “white of the eye” is the **sclera**, formed of tough connective tissue. Light enters the eye through a transparent **cornea**, which begins to focus the light. Focusing occurs because light is refracted (bent) when it travels into a medium of different density. The colored portion of the eye is the **iris**; contraction of the iris muscles in bright light decreases the size of its opening, the pupil. Light passes through the pupil to the **lens**, a transparent structure that completes the focusing of the light onto the retina at the back of the eye. The lens is attached by the suspensory ligament to the ciliary muscles.

The shape of the lens is influenced by the amount of tension in the suspensory ligament, which surrounds the lens and attaches it to the circular ciliary muscle. When the ciliary muscle contracts, it puts slack in the suspensory ligament, and the lens becomes more rounded and bends light more strongly. This rounding is required for close vision. In distance vision, the ciliary muscles relax, moving away from the lens and tightening the suspensory ligament. The lens thus becomes more flattened and bends light less, keeping the image focused on the retina. People who are nearsighted or farsighted do not properly focus the image on the retina (figure 45.17). Interestingly,

**Figure 45.17 Focusing the human eye.** *a.* In people with normal vision, the image remains focused on the retina in both near and far vision because of changes produced in the curvature of the lens. When a person with normal vision stands 20 feet or more from an object, the lens is in its least convex form, and the image is focused on the retina. *b.* In nearsighted people, the image comes to a focus in front of the retina, and the image thus appears blurred. *c.* In farsighted people, the focus of the image would be behind the retina because the distance from the lens to the retina is too short. Corrective lenses adjust the angle of the light as it enters the eye, focusing it on the retina.

the lens of an amphibian or a fish does not change shape; these animals instead focus images by moving their lens in and out, just as you would do to focus a camera.

## Vertebrate photoreceptors are rod cells and cone cells

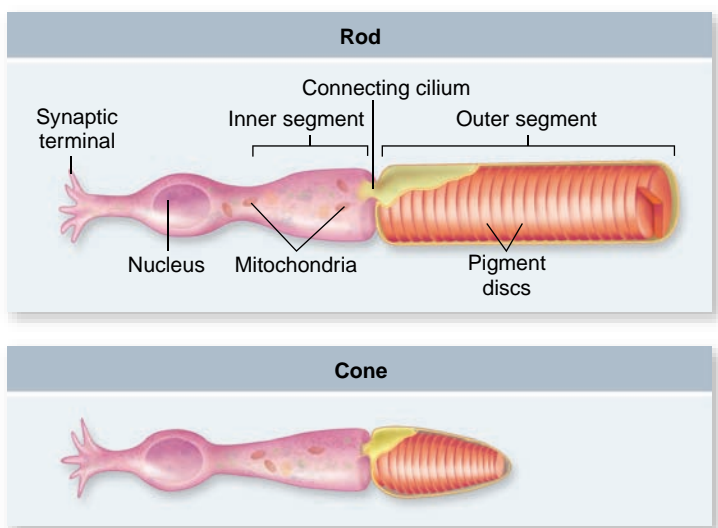

The vertebrate retina contains two kinds of photoreceptor cells, called rods and cones (figure 45.18). **Rods**, which get their name from the shape of their outer segment, are responsible for black-and-white vision when the illumination is dim. In contrast, **cones** are responsible for high visual acuity (sharpness) and color vision; cones have a cone-shaped outer segment. Humans have about 100 million rods and 3 million cones in each retina. Most of the cones are located in the central region of the retina known as the **fovea**, where the eye forms its sharpest image. Rods are almost completely absent from the fovea.

### Structure of rods and cones

Rods and cones have the same basic cellular structure. An inner segment rich in mitochondria contains numerous vesicles filled with neurotransmitter molecules. It is connected by a narrow stalk to the outer segment, which is packed with hundreds of flattened disks stacked on top of one another. The light-capturing molecules, or photopigments, are located on the membranes of these disks (see figure 45.18).

In rods, the photopigment is called **rhodopsin**. It consists of the protein opsin bound to a molecule of *cis*-retinal, which is produced from vitamin A. Vitamin A is derived from carotene, a photosynthetic pigment in plants.

The photopigments of cones, called **photopsins**, are structurally very similar to rhodopsin. Humans have three kinds of cones, each of which possesses a photopsin consisting of *cis*-retinal bound to a protein with a slightly different amino acid sequence. These differences shift the absorption maximum, the

**Figure 45.18 Rods and cones.** The pigment-containing outer segment in each of these cells is separated from the rest of the cell by a partition through which there is only a narrow passage, the connecting cilium.

**Figure 45.19 Color vision.** The absorption maximum of *cis*-retinal in the rhodopsin of rods is 500 nm. However, the “blue cones” have their maximum light absorption at 420 nm; the “green cones” at 530 nm; and the “red cones” at 560 nm. The brain perceives all other colors from the combined activities of these three cones’ systems.

region of the electromagnetic spectrum that is best absorbed by the pigment (figure 45.19). The absorption maximum of the *cis*-retinal in rhodopsin is 500 nanometers (nm); in contrast, the absorption maxima of the three kinds of cone photopsins are 420 nm (blue-absorbing), 530 nm (green-absorbing), and 560 nm (red-absorbing). These differences in the light-absorbing properties of the photopsins are responsible for the different color sensitivities of the three kinds of cones, which are often referred to as simply blue, green, and red cones.

The **retina**, the inside surface of the eye, is made up of three layers of cells (figure 45.20): The layer closest to the external surface of the eyeball consists of the rods and cones; the next layer contains **bipolar cells**; and the layer closest to the cavity of the eye is composed of **ganglion cells**. Thus, light must first pass through the ganglion cells and bipolar cells in order to reach the photoreceptors. The rods and cones synapse with the bipolar cells, and the bipolar cells synapse with the ganglion cells, which transmit impulses to the brain via the optic nerve. Ganglion cells are the only neurons of the retina capable of sending action potentials to the brain. The flow of sensory information in the retina is therefore opposite to the path of light through the retina.

Because the ganglion cells lie in the inner cavity of the eye, the optic nerve must intrude through the retina (see figure 45.16), creating a blind spot. You can see this blind spot yourself by holding a finger up in front of your face. Put a colored object on the finger tip, and then, with your left eye closed, focus on a point next to, but beyond, the fingertip. Now slowly move your finger to the right while keeping your eye focused on the distant point. At some point, you’ll notice that you can no longer see the colored spot on your finger. The structure of the eye of mollusks avoids this problem by having the sensory neurons attach behind, rather than in front of, the retina (see figure 45.15).

**Figure 45.20 Structure of the retina.** Note that the rods and cones are at the rear of the retina, not the front. Light passes through four other types of cells (ganglion, amacrine, bipolar, and horizontal) in the retina before it reaches the rods and cones. Once the photoreceptors are activated, they stimulate bipolar cells, which in turn stimulate ganglion cells. The flow of sensory information in the retina is thus opposite to the direction of light.

The retina contains two additional types of neurons called horizontal cells and amacrine cells. Stimulation of horizontal cells by photoreceptors at the center of a spot of light on the retina can inhibit the response of photoreceptors peripheral to the center. This lateral inhibition enhances contrast and sharpens the image.

Most vertebrates, particularly those that are diurnal (active during the day), have color vision, as do many insects and some other invertebrates. Indeed, honeybees—as well as some birds, lizards, and other vertebrates (figure 45.21)—can see light in the near-ultraviolet range, which is invisible to the human eye. Color vision requires the presence of more than one photopigment in different receptor cells, but not all animals with color vision have the three-cone system characteristic of humans and other primates. Fish, turtles, and birds, for example, have four or five kinds of cones; the “extra” cones enable these animals to see near-ultraviolet light and to distinguish shades of colors that we cannot detect. On the other hand, many mammals, for example, squirrels and dogs, have only two types of cones and thus have more limited ability to distinguish different colors.

### Sensory transduction in photoreceptors

The transduction of light energy into nerve impulses follows a sequence that is the opposite of the usual way that sensory stimuli are detected. In the dark, the photoreceptor cells release an inhibitory neurotransmitter that hyperpolarizes the bipolar neurons. This prevents the bipolar neurons from releasing excitatory neurotransmitter to the ganglion cells that signal to the brain. In the presence of light, the photoreceptor cells stop releasing their inhibitory neurotransmitter, in effect, stimulating bipolar cells. The bipolar cells in turn stimulate the ganglion cells, which transmit action potentials to the brain.

The production of inhibitory neurotransmitter by photoreceptor cells is due to the presence of ligand-gated  $\text{Na}^+$  chan-

## SCIENTIFIC THINKING

**Hypothesis:** Birds can see light in the ultraviolet range.

**Prediction:** Birds will respond to individuals differently depending on how much ultraviolet is detected in their feathers.

**Test:** Zebra finch feathers reflect a moderate amount of ultraviolet light. Female zebra finches were exposed to different males, some of which were behind a filter that screened out UV light, whereas others were behind a control filter that let the UV pass through.

**Result and Conclusion:** Females preferred to spend time near the UV-positive males. Not only can female zebra finches see light in the UV range, but they prefer males with UV in the feathers.

**Further Experiments:** What are two hypotheses about why females prefer UV-positive males? How would you test these hypotheses?

**Figure 45.21 Ultraviolet vision in birds.** Humans cannot distinguish colors in the near ultraviolet range, whereas many animals can. This photograph was taken with a special film that shows ultraviolet patterns on a zebra finch (*Taeniopygia guttata*) that are not detectable by humans.

nels. In the dark, many of these channels are open, allowing an influx of  $\text{Na}^+$ . This flow of  $\text{Na}^+$  in the absence of light, called the dark current, depolarizes the membrane of photoreceptor cells. In this state, the cells produce inhibitory neurotransmitter that hyperpolarizes the membrane of bipolar cells. In the light, the  $\text{Na}^+$  channels in the photoreceptor cell rapidly close, reducing the dark current and causing the photoreceptor to hyperpolarize. In this state, they no longer produce inhibitory neurotransmitter. In the absence of inhibition, the membrane of the bipolar cells is depolarized, causing them to release excitatory neurotransmitter to the ganglion cells.

The control of the dark current depends on the ligand for the  $\text{Na}^+$  channels in the photoreceptor cells: the nucleotide cyclic guanosine monophosphate (cGMP). In the dark, the level of cGMP is high, and the channels are open. The system is made sensitive to light by the nature and structure of the photopigments. Photopigments in the eye are actually G protein-coupled receptor proteins that are activated by absorbing light. When a photopigment absorbs light, *cis*-retinal isomerizes and dissociates from the receptor protein, opsin, in what is known as the bleaching reaction. As a result of this dissociation, the opsin receptor protein changes shape, activating its associated G protein. The activated G protein then activates its effector protein, the enzyme phosphodiesterase, which cleaves cGMP to GMP. The loss of cGMP causes the cGMP-gated  $\text{Na}^+$

**Figure 45.22 Signal transduction in the vertebrate eye.**

In the absence of light, cGMP keeps Na<sup>+</sup> channels open causing a Na<sup>+</sup> influx that leads to the release of inhibitory neurotransmitter. Light is absorbed by the retinal in rhodopsin, changing its structure. This causes rhodopsin to associate with a G protein. The activated G protein stimulates phosphodiesterase, which converts cGMP to GMP. Loss of cGMP closes Na<sup>+</sup> channels and prevents release of inhibitory neurotransmitter, which causes bipolar cells to stimulate ganglion cells.

channels to close, reducing the dark current (figure 45.22). Each opsin is associated with over 100 regulatory G proteins, which, when activated, release subunits that activate hundreds of molecules of the phosphodiesterase enzyme. Each enzyme molecule can convert thousands of cGMP to GMP, closing the Na<sup>+</sup> channels at a rate of about 1000 per second and inhibiting the dark current.

The absorption of a single photon of light can block the entry of more than a million Na<sup>+</sup>, without changing K<sup>+</sup> permeability—the photoreceptor becomes hyperpolarized and releases less inhibitory neurotransmitter. Freed from inhibition, the bipolar cells activate the ganglion cells, which send impulses to the brain (figure 45.23).

**Visual processing takes place in the cerebral cortex**

Action potentials propagated along the axons of ganglion cells are relayed through structures called the **lateral geniculate nuclei** of the thalamus and projected to the occipital lobe of the cerebral cortex (see figure 45.23). There the brain interprets this information as light in a specific region of the eye's receptive field. The pattern of activity among the ganglion cells across the retina encodes a point-to-point map of the receptive field, allowing the retina and brain to image objects in visual space.

The frequency of impulses in each ganglion cell provides information about the light intensity at each point. At the same time,

**Figure 45.23 The pathway of visual information.** Action potentials in the optic nerves are relayed from the retina to the lateral geniculate nuclei, and from there to the visual cortex of the occipital lobes. Note that half the optic nerves (the medial fibers arising from the inner portion of the retinas) cross to the other side at the optic chiasm, so that each hemisphere of the cerebrum receives input from both eyes.

the relative activity of ganglion cells connected (through bipolar cells) with the three types of cones provides color information.

### Visual acuity

The relationship between receptors, bipolar cells, and ganglion cells varies in different parts of the retina. In the fovea, each cone makes a one-to-one connection with a bipolar cell, and each bipolar cell synapses with one ganglion cell. This point-to-point relationship is responsible for the high acuity of foveal vision.

Outside the fovea, many rods can converge on a single bipolar cell, and many bipolar cells can converge on a single ganglion cell. This convergence permits the summation of neural activity, making the area of the retina outside the fovea more sensitive to dim light than the fovea, but at the expense of acuity and color vision. This is why dim objects, such as faint stars at night, are best seen when you don't look directly at them. It has been said that we use the periphery of the eye as a detector, and the fovea as an inspector.

**Color blindness** can result from an inherited lack of one or more types of cones. People with normal color vision are trichromats; that is they have all three cones. Those with only two types of cones are dichromats. For example, people with red-green color blindness may lack red cones and have difficulty distinguishing red from green. Color blindness resulting from absence of one type of cone is a sex-linked recessive trait (see chapter 13), and therefore it is most often exhibited in

males. Red-green color blindness can also result from a shift in the sensitivity curve of the absorption spectrum for one type of cone, resulting in the different cone types being stimulated by the same electromagnetic wavelengths and causing the individual to be unable to distinguish between red and green.

### Binocular vision

Primates (including humans) and most predators have two eyes, one located on each side of the face. When both eyes are trained on the same object, the image that each eye sees is slightly different because the views have a slightly different angle. This slight displacement of the images (an effect called parallax) permits **binocular vision**, the ability to perceive three-dimensional images and to sense depth. Having eyes facing forward maximizes the field of overlap in which this stereoscopic vision occurs.

In contrast, prey animals generally have eyes located to the sides of the head, preventing binocular vision but enlarging the overall receptive field. It seems that natural selection has favored the detection of potential predators over depth perception in many prey species. The eyes of the American woodcock (*Scolopax minor*), for example, are located at exactly opposite sides of the bird's skull so that it has a 360° field of view without turning its head.

Most birds have laterally placed eyes and, as an adaptation, have two foveas in each retina. One fovea provides sharp frontal vision, like the single fovea in the retina of mammals, and the other fovea provides sharper lateral vision.

### Learning Outcomes Review 45.5

Many invertebrate groups have eyespots that detect light without forming images. Annelids, mollusks, arthropods, and chordates have independently evolved image-forming eyes. The vertebrate eye admits light through a pupil and then focuses it with an adjustable lens onto the retina, which contains photoreceptors. Photoreceptor rods and cones contain the photopigment *cis*-retinal, which indirectly activates bipolar neurons and then ganglion cells. The latter then transmit action potentials that ultimately reach the occipital lobe of the brain.

- Can an individual with red-green color blindness learn to distinguish these two colors? Why or why not?

## 45.6 The Diversity of Sensory Experiences

### Learning Outcomes

1. List examples of uncommon special senses.
2. Explain how ampullae of Lorenzini work.

Vision is the primary sense used by all vertebrates that live in a light-filled environment, but visible light is by no means the only part of the electromagnetic spectrum that vertebrates use to sense their environment.

## Some snakes have receptors capable of sensing infrared radiation

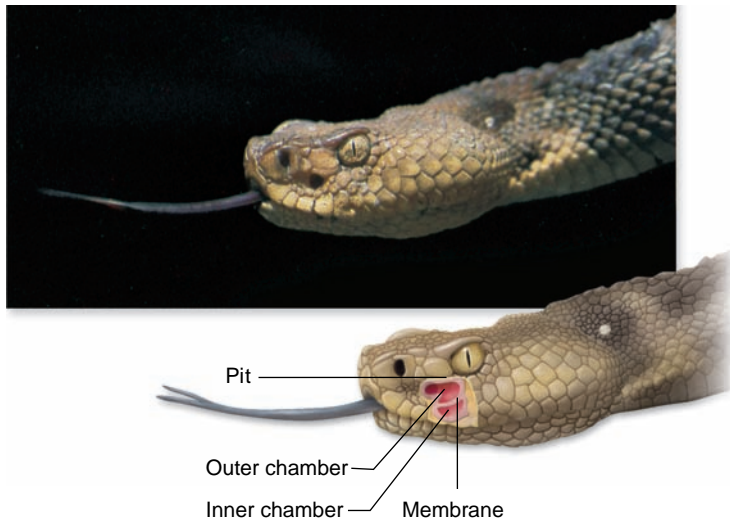

Electromagnetic radiation with wavelengths longer than those of visible light is too low in energy to be detected by photoreceptors. Radiation from this infrared portion of the spectrum is what we normally think of as radiant heat.

Heat is an extremely poor environmental stimulus in water because water readily absorbs heat. Air, in contrast, has a low thermal capacity, so heat in air is a potentially useful stimulus. The only vertebrates known to have the ability to sense infrared radiation, however, are several types of snakes.

One type, the pit vipers, possess a pair of heat-detecting **pit organs** located on either side of the head between the eye and the nostril (figure 45.24). Each pit organ is composed of two chambers separated by a membrane. The infrared radiation falls on the membrane and warms it. Thermal receptors on the membrane are stimulated. The nature of these receptors is not known; they probably consist of temperature-sensitive neurons innervating the two chambers.

The paired pit organs appear to provide stereoscopic information, in much the same way that two eyes do. In fact, the nerves from the pits are connected to the optic tectum, the same part of the brain that controls vision; recent research suggests that information from the pits and from the eyes are overlain on each other, allowing snakes to combine visual and infrared thermal data. In fact, the pits are designed like a pinhole camera, and to some extent can focus a thermal image!

As a result, these exteroceptors are extraordinarily sensitive. Blind pit vipers can strike as accurately as a normal snake, and snakes deprived of their senses of sight and smell can accurately strike a target only 0.2° warmer than the background. Many pit vipers hunt endothermic prey at night, so the value of these capabilities is obvious.

**Figure 45.24** “Seeing” heat. The depression between the nostril and the eye of this rattlesnake opens into the pit organ. In the cutaway portion of the diagram, you can see that the organ is composed of two chambers separated by a membrane. Snakes known as pit vipers have the ability to sense infrared radiation (heat).

## Some vertebrates can sense electrical currents

Although air does not readily conduct an electrical current, water is a good conductor. All aquatic animals generate electrical currents from contractions of their muscles. A number of different groups of fishes can detect these electrical currents. The so-called electrical fish even have the ability to produce electrical discharges from specialized electrical organs. Electrical fish use these weak discharges to locate their prey and mates and to construct a three-dimensional image of their environment, even in murky water.

The elasmobranchs (sharks, rays, and skates) have electroreceptors called the **ampullae of Lorenzini**. The receptor cells are located in sacs that open through jelly-filled canals to pores on the body surface. The jelly is a very good conductor, so a negative charge in the opening of the canal can depolarize the receptor at the base, causing the release of neurotransmitter and increased activity of sensory neurons. This allows sharks, for example, to detect the electrical fields generated by the muscle contractions of their prey. Although the ampullae of Lorenzini were lost in the evolution of teleost fish (most of the bony fish), electroreception reappeared in some groups of teleost fish that developed analogous sensory structures. Electroreceptors evolved yet another time, independently, in the duck-billed platypus, an egg-laying mammal. The receptors in its bill can detect the electrical currents created by the contracting muscles of shrimp and fish, enabling the mammal to detect its prey at night and in muddy water.

## Some organisms detect magnetic fields

Eels, sharks, bees, and many birds appear to navigate along the magnetic field lines of the Earth. Even some bacteria use such forces to orient themselves.

Birds kept in dark cages, with no visual cues to guide them, peck and attempt to move in the direction in which they would normally migrate at the appropriate time of the year. They do not do so, however, if the cage is shielded from magnetic fields by steel. In addition, if the magnetic field of a blind cage is deflected 120° clockwise by an artificial magnet, a bird that normally orients to the north will orient toward the east-southeast. The nature of magnetic receptors in these vertebrates is the subject of much speculation, but the mechanism remains very poorly understood.

### Learning Outcomes Review 45.6

Pit vipers can detect infrared radiation (heat). Many aquatic vertebrates can locate prey and perceive environmental contours by means of electroreceptors. The ampullae of Lorenzini, electroreceptors found in sharks and their relatives, contain a highly conductive jelly that triggers sensory neurons. Magnetic receptors may aid in bird migration.

- **Would a heat-sensing organ be useful for hunting ectothermic prey?**

## Chapter Review

### 45.1 Overview of Sensory Receptors

**Sensory receptors detect both external and internal stimuli.**

Exteroreceptors sense stimuli from the external environment, whereas interoreceptors sense stimuli from the internal environment.

**Receptors can be grouped into three categories.**

Receptors differ with respect to the environmental stimulus to which they respond: mechanoreceptors, chemoreceptors, and energy-detecting receptors.

**Sensory information is conveyed in a four-step process.**

Once detected, sensory information is conveyed in four steps: stimulation, transduction, transmission, and interpretation.

**Sensory transduction involves gated ion channels.**

Sensory transduction produces a graded receptor potential. A single potential or a sum of potentials may exceed a threshold to produce an action potential (see figure 45.2). A logarithmic relationship exists between stimulus intensity and action potential frequency.

### 45.2 Mechanoreceptors: Touch and Pressure

**Pain receptors alert the body to damage or potential damage.**

Nociceptors are free nerve endings located in the skin that respond to damaging stimuli, which is perceived as pain. Extreme temperatures can affect transient receptor potential (TRP) ion channels and cause depolarization by inflow of  $\text{Na}^+$  and  $\text{Ca}^{2+}$ .

**Thermoreceptors detect changes in heat energy.**

Thermoreceptors are naked dendritic endings of sensory neurons that also contain TRP ion channels and respond to cold or heat.

**Different receptors detect touch, depending on intensity.**

Various receptors in the skin respond to mechanical distortion of the membrane to convey touch (see figure 45.3).

**Muscle length and tension are monitored by proprioceptors.**

Proprioceptors provide information about the relative position or movement of body parts and the degree of muscle stretching.

**Baroreceptors detect blood pressure.**

### 45.3 Hearing, Vibration, and Detection of Body Position

Hearing, the detection of sound or pressure waves, works best in water and provides directional information.

**The lateral line system in fish detects low-frequency vibrations (see figure 45.5).**

**Ear structure is specialized to detect vibration.**

The outer ear of terrestrial vertebrates channels sound to the eardrum (tympanic membrane) (see figure 45.6). Vibrations are transferred through middle ear bones to the oval window and into the cochlea, where the organ of Corti transduces them.

**Transduction occurs in the cochlea.**

The basilar membrane of the cochlea consists of fibers that respond to different frequencies of sound (see figure 45.8).

**Some vertebrates have the ability to navigate by sound.**

Echolocation allows bats, whales, and other species to navigate by sound.

**Body position and movement are detected by systems associated with hearing systems.**

Body position is detected by statocysts, ciliated hair cells embedded in a gelatinous matrix containing statoliths (see figure 45.9). Body movement is detected by hair cells located in the saccule and utricle (see figure 45.10).

### 45.4 Chemoreceptors: Taste, Smell, and pH

**Taste detects and analyzes potential food.**

Taste buds are collections of chemosensitive epithelial cells located on papillae (see figure 45.11). Tastes are broken down into five categories: sweet, sour, salty, bitter, and umami.

**Smell can identify a vast number of complex molecules.**

Smell, or olfaction, involves chemoreceptors located in the upper portion of the nasal passages (see figure 45.13). Their axons connect directly to the cerebral cortex.

**Internal chemoreceptors detect pH and other characteristics.**

Internal chemoreceptors of the aorta detect changes in blood pH, and central chemoreceptors in the medulla oblongata are sensitive to the pH of the cerebrospinal fluid.

### 45.5 Vision

**Vision senses light and light changes at a distance.**

Four phyla—annelids, mollusks, arthropods, and chordates—have independently evolved image-forming eyes (see figure 45.15).

In the vertebrate eye, light enters through the pupil, with intensity controlled by the iris. The lens, controlled by the ciliary muscle, focuses the light on the retina (see figure 45.16).

**Vertebrate photoreceptors are rod cells and cone cells.**

Rods detect black and white; cones are necessary for visual acuity and color vision (see figure 45.18).

In the retina, photoreceptors synapse with bipolar cells, which in turn synapse with ganglion cells; the ganglion cells send action potentials to the brain (see figure 45.20).

**Visual processing takes place in the cerebral cortex (see figure 45.23).**

In the fovea, a region of the retina responsible for high acuity, each cone cell is connected to a single bipolar cell/ganglion cell, unlike in areas outside the fovea.

Primates and most predators have binocular vision—images from each eye overlap to produce a three-dimensional image.

### 45.6 The Diversity of Sensory Experiences

**Some snakes have receptors capable of sensing infrared radiation.**

The pit organ of pit vipers detects heat.

**Some vertebrates can sense electrical currents.**

Electroreceptors in elasmobranchs and the duck-billed platypuses can detect electrical currents.

**Some organisms detect magnetic fields.**

Many organisms appear to navigate along magnetic field lines, but the mechanisms remains poorly understood.

## Review Questions

### UNDERSTAND

- Which of these is not a method by which sensory receptors receive information about the internal or external environment?
  - Changes in pressure
  - Light or heat changes
  - Changes in molecular concentration
  - All of these are used by sensory receptors.
- Which of the following correctly lists the steps of perception?
  - Interpretation, stimulation, transduction, transmission
  - Stimulation, transduction, transmission, interpretation
  - Interpretation, transduction, stimulation, transmission
  - Transduction, interpretation, stimulation, transmission
- All sensory receptors are able to initiate nerve impulses by opening or closing
  - voltage-gated ion channels.
  - exteroceptors.
  - interoceptors.
  - stimulus-gated ion channels.
- In the fairy tale, Sleeping Beauty fell asleep after pricking her finger. What kind of receptor responds to that kind of painful stimulus?
  - Mechanoreceptor
  - Nociceptor
  - Thermoreceptor
  - Touch receptor
- The ear detects sound by the movement of
  - the basilar membrane.
  - the tectorial membrane.
  - the Eustachian tube.
  - fluid in the semicircular canals.
- Hair cells in the vestibular apparatus of terrestrial vertebrates
  - measure temperature changes within the body.
  - sense sound in very low range of hearing.
  - provide a sense of acceleration and balance.
  - measure changes in blood pressure.
- \_\_\_\_\_ is the photopigment contained within both rods and cones of the eye.
  - Carotene
  - Cis*-retinal
  - Photochrome
  - Chlorophyll
- Which of the following is not a method used by vertebrates to gather information about their environment?
  - Infrared radiation
  - Magnetic fields
  - Electrical currents
  - All of these are methods used for sensory reception.
- The lobe of the brain that recognizes and interprets visual information is the
  - occipital lobe.
  - frontal lobe.
  - parietal lobe.
  - temporal lobe.

### APPLY

- What do the sensory systems of annelids, mollusks, arthropods, and chordates have in common?
  - They all use the same stimuli for taste.
  - They all use neurons to detect vibration.

- They all have image-forming eyes that evolved independently.
  - They all use chemoreceptors in their skin to detect food.
- Animals can more easily tell the direction of a visual signal than an auditory signal because
  - light travels in straight lines.
  - the wind provides too much background noise.
  - sound travels faster underwater.
  - eyes are more sensitive than ears.
- The difference in the structure of the vertebrate and mollusk eyes
  - results because mollusks live in water, causing images to be upside down.
  - indicates that vertebrates have better vision than mollusks.
  - reveals a disadvantage of vertebrate eye structure.
  - makes color vision more efficient in vertebrates.
- The ability of some insects, birds, and lizards to see ultraviolet light is
  - a result of a common diet eaten by those species.
  - an example of convergent evolution in cone cell sensitivity.
  - the ancestral state inherited from flatworms.
  - an adaptation for nocturnal activity.

### SYNTHESIZE

- When blood pH falls too low, a potentially fatal condition known as acidosis results. Among the variety of responses to this condition, the body changes the breathing rate. How does the body sense this change? How does the breathing rate change? How does this increase pH?
- The function of the vertebrate eye is unusual compared with other processes found within the body. For example, the direction in which sensory information flows is actually opposite to path that light takes through the retina. Explain the sequence of events involved in the movement of light and information through the structures of the eye, and explain why they move in opposite directions. Consider, also, how this sequence of events compares to the functioning of the mollusk eye.
- How would the otolith organs of an astronaut respond to zero gravity? Would the astronaut still have a subjective impression of motion? Would the semicircular canals detect angular acceleration equally well at zero gravity?

# The Endocrine System

## Chapter Outline

- 46.1** Regulation of Body Processes by Chemical Messengers
- 46.2** Actions of Lipophilic Versus Hydrophilic Hormones
- 46.3** The Pituitary and Hypothalamus: The Body's Control Centers
- 46.4** The Major Peripheral Endocrine Glands
- 46.5** Other Hormones and Their Effects

## Introduction

*Diabetes is a disease in which well-fed people appear to starve to death. The disease was known to Roman and Greek physicians, who described a “melting away of flesh” coupled with excessive urine production “like the opening of aqueducts.” Until 1922, the diagnosis of diabetes in children was effectively a death sentence. In that year, Frederick Banting and Charles Best extracted the molecule insulin from the pancreas. Injections of insulin into the bloodstream dramatically reversed the symptoms of the disease. This served as an impressive confirmation of a new concept: that certain internal organs produced powerful regulatory chemicals that were distributed via the blood.*

*We now know that the tissues and organs of the vertebrate body cooperate to maintain homeostasis through the actions of many regulatory mechanisms. Two systems, however, are devoted exclusively to the regulation of the body organs: the nervous system and the endocrine system. Both release regulatory molecules that control the body organs by binding to receptor proteins on or in the cells of those organs. In this chapter, we examine the regulatory molecules of the endocrine system, the cells and glands that produce them, and how they function to regulate the body's activities.*

## 46.1 Regulation of Body Processes by Chemical Messengers

### Learning Outcomes

1. Describe the role of hormones in regulating body processes.
2. Identify the different types of hormones.
3. Differentiate between lipophilic and hydrophilic hormones.

There are four mechanisms of cell communication: direct contact, synaptic signaling, endocrine signaling, and paracrine signaling. Here we are concerned with signaling methods of communication; we begin with the three signaling mechanisms.

As discussed in chapter 44, the axons of neurons secrete chemical messengers called neurotransmitters into the synaptic cleft. These chemicals diffuse only a short distance to the postsynaptic membrane, where they bind to their receptor proteins and stimulate the postsynaptic cell. Synaptic transmission generally affects only the postsynaptic cell that receives the neurotransmitter.

A *hormone*, in contrast, is a regulatory chemical that is secreted into extracellular fluid and carried by the blood and can therefore act at a distance from its source. Organs that are specialized to secrete hormones are called *endocrine glands*, but some organs, such as the liver and the kidney, can produce hormones in addition to performing other functions. The organs and tissues that produce hormones are collectively called the **endocrine system**.

The blood carries hormones to every cell in the body, but only target cells with the appropriate receptor for a given hormone can respond to it. Hormone receptor proteins function in a similar manner to neurotransmitter receptors. The receptor proteins specifically bind the hormone and activate signal transduction pathways that produce a response to the hormone. The highly specific interaction between hormones and their receptors enable hormones to be active at remarkably small concentrations. It is not unusual to find hormones circulating in the blood at concentrations of  $10^{-8}$  to  $10^{-10}$  M. In addition to the chemical messengers released as neurotransmitters and as hormones, other molecules are released and act within an organ on nearby cells as local regulators. These chemicals are termed **paracrine regulators**. They act in a way similar to endocrine hormones, but they do not travel through the blood to reach their target. This allows cells of an organ to regulate one another.

Cells can also release signaling molecules that affect their own behavior, or autocrine signaling. This is common in the immune system, and is also seen in cancer cells that may release growth factors that stimulate their own growth.

Chemical communication is not limited to cells within an organism. *Pheromones* are chemicals released into the environment to communicate among individuals of a single species. These aid in communication between animals

and may alter the behavior or physiology of the receiver, but are not involved in the normal metabolic regulation of an animal.

Figure 46.1 compares the different types of chemical messengers used for internal regulation.

### Some molecules act as both circulating hormones and neurotransmitters

Blood delivery of hormones enables endocrine glands to coordinate the activity of large numbers of target cells distributed throughout the body, but that may not be the only role for these molecules. A molecule produced by an endocrine gland and used as a hormone may also be produced and used as a neurotransmitter by neurons. The hormone norepinephrine, for example, is secreted into the blood by the adrenal glands, but it is also released as a neurotransmitter by sympathetic nerve endings. Norepinephrine acts as a hormone to coordinate the activity of the heart, liver, and blood vessels during response to stress.

Neurons can also secrete a class of hormones called **neurohormones** that are carried by blood. The neurohormone antidiuretic hormone, for example, is secreted by neurons in the brain. Some specialized regions of the brain contain not only neurotransmitting neurons, but also clusters of neurons

**Figure 46.1** Different types of chemical messengers.

The functions of organs are influenced by neural, paracrine, and endocrine regulators. Each type of chemical regulator binds to specific receptor proteins on the surface or within the cells of target organs.

producing neurohormones. In this way, neurons can deliver chemical messages beyond the nervous system itself.

The secretory activity of many endocrine glands is controlled by the nervous system. As you will see, the hypothalamus controls the hormonal secretions of the anterior-pituitary gland, and produces the hormones of the posterior pituitary.

The secretion of a number of hormones, however, can be independent of neural control. For example, the release of insulin by the pancreas and aldosterone by the adrenal cortex is stimulated by increases in the blood concentrations of glucose and potassium ( $K^+$ ), respectively.

## Endocrine glands produce three chemical classes of hormones

The endocrine system (figure 46.2) includes all of the organs that secrete hormones—the thyroid gland, pituitary gland, ad-

**Figure 46.2** The human endocrine system. The major endocrine glands are shown, but many other organs secrete hormones in addition to their primary functions.

renal glands, and so on (table 46.1). Cells in these organs secrete hormones into extracellular fluid, where it diffuses into surrounding blood capillaries. For this reason, hormones are referred to as endocrine secretions. In contrast, cells of some glands excrete their products into a duct to outside the body, or into the gut. For example, the pancreas excretes hydrolytic enzymes into the lumen of the small intestine. These glands are termed exocrine glands.

Molecules that function as hormones must exhibit two basic characteristics. First, they must be sufficiently complex to convey regulatory information to their targets. Simple molecules such as carbon dioxide, or ions such as  $Ca^{2+}$ , do not function as hormones. Second, hormones must be adequately stable to resist destruction prior to reaching their target cells. Three primary chemical categories of molecules meet these requirements.

1. **Peptides and proteins** are composed of chains of amino acids. Some important examples of peptide hormones include antidiuretic hormone (9 amino acids), insulin (51 amino acids), and growth hormone (191 amino acids). These hormones are encoded in DNA and produced by the same cellular machinery responsible for transcription and translation of other peptide molecules. The most complex are glycoproteins composed of two peptide chains with attached carbohydrates. Examples include thyroid-stimulating hormone and luteinizing hormone.
2. **Amino acid derivatives** are hormones manufactured by enzymatic modification of specific amino acids; this group comprises the biogenic amines discussed in chapter 44. They include hormones secreted by the adrenal medulla (the inner portion of the adrenal gland), thyroid, and pineal glands. Those secreted by the adrenal medulla are derived from tyrosine. Known as **catecholamines**, they include epinephrine (adrenaline) and norepinephrine (noradrenaline). Other hormones derived from tyrosine are the **thyroid hormones**, secreted by the thyroid gland. The pineal gland secretes a different amine hormone, **melatonin**, derived from tryptophan.
3. **Steroids** are lipids manufactured by enzymatic modifications of cholesterol. They include the hormones testosterone, estradiol, progesterone, aldosterone, and cortisol. Steroid hormones can be subdivided into sex steroids, secreted by the testes, ovaries, placenta, and adrenal cortex, and corticosteroids (mineralocorticoids and cortisol), secreted only by the adrenal cortex.

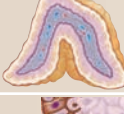

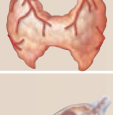

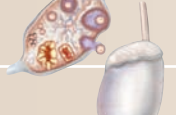

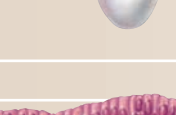

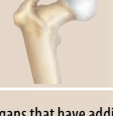

## Hormones can be categorized as lipophilic or hydrophilic

The manner in which hormones are transported and interact with their targets differs depending on their chemical nature. Hormones may be categorized as lipophilic (non-polar), which are fat-soluble, or hydrophilic (polar), which are water-soluble. The lipophilic hormones include the steroid hormones and thyroid hormones. Most other hormones are hydrophilic.

This distinction is important in understanding how these hormones regulate their target cells. Hydrophilic hormones are freely soluble in blood, but cannot pass through the membrane of

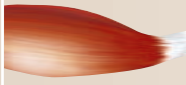

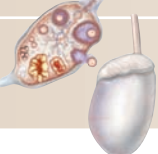

**TABLE 46.1**
**Principal Mammalian Endocrine Glands and Their Hormones\***

Endocrine Gland and Hormone	Target Tissue		Principal Actions	Chemical Nature
<b>Hypothalamus</b>				
Releasing hormones	Adenohypophysis		Activate release of adenohypophyseal hormones	Peptides
Inhibiting hormones	Adenohypophysis		Inhibit release of adenohypophyseal hormones	Peptides (except prolactin-inhibiting factor, which is dopamine)
<b>Neurohypophysis (Posterior-pituitary gland)</b>				
Antidiuretic hormone (ADH)	Kidneys		Conserves water by stimulating its reabsorption from urine	Peptide (9 amino acids)
Oxytocin (OT)	Uterus		Stimulates contraction	Peptide (9 amino acids)
	Mammary glands		Stimulates milk ejection	
<b>Adenohypophysis (Anterior-pituitary gland)</b>				
Adrenocorticotrophic hormone (ACTH)	Adrenal cortex		Stimulates secretion of adrenal cortical hormones such as cortisol	Peptide (39 amino acids)
Melanocyte-stimulating hormone (MSH)	Skin		Stimulates color change in reptiles and amphibians; various functions in mammals	Peptide (two forms; 13 and 22 amino acids)
Growth hormone (GH)	Many organs		Stimulates growth by promoting bone growth, protein synthesis, and fat breakdown	Protein
Prolactin (PRL)	Mammary glands		Stimulates milk production	Protein
Thyroid-stimulating hormone (TSH)	Thyroid gland		Stimulates thyroxine secretion	Glycoprotein
Luteinizing hormone (LH)	Gonads		Stimulates ovulation and corpus luteum formation in females; stimulates secretion of testosterone in males	Glycoprotein
Follicle-stimulating hormone (FSH)	Gonads		Stimulates spermatogenesis in males; stimulates development of ovarian follicles in females	Glycoprotein
<b>Thyroid Gland</b>				
Thyroid hormones (thyroxine and triiodothyronine)	Most cells		Stimulates metabolic rate; essential to normal growth and development	Amino acid derivative (iodinated)
Calcitonin	Bone		Inhibits loss of calcium from bone	Peptide (32 amino acids)

\*These are hormones released from endocrine glands. Hormones are released from organs that have additional, nonendocrine functions, such as the liver, kidney, and intestine.

**TABLE 46.1**
**Principal Mammalian Endocrine Glands and Their Hormones, *continued***

Endocrine Gland and Hormone	Target Tissue		Principal Actions	Chemical Nature
<b>Parathyroid Glands</b>				
Parathyroid hormone (PTH)	Bone, kidneys, digestive tract		Raises blood calcium level by stimulating bone breakdown; stimulates calcium reabsorption in kidneys; activates vitamin D	Peptide (34 amino acids)
<b>Adrenal Medulla</b>				
Epinephrine (adrenaline) and norepinephrine (noradrenaline)	Smooth muscle, cardiac muscle, blood vessels		Initiates stress responses; raises heart rate, blood pressure, metabolic rate; dilates blood vessels; mobilizes fat; raises blood glucose level	Amino acid derivatives
<b>Adrenal Cortex</b>				
Glucocorticoids (e.g., cortisol)	Many organs		Adaptation to long-term stress; raises blood glucose level; mobilizes fat	Steroid
Mineralocorticoids (e.g., aldosterone)	Kidney tubules		Maintains proper balance of Na <sup>+</sup> and K <sup>+</sup> in blood	Steroid
<b>Pancreas</b>				
Insulin	Liver, skeletal muscles, adipose tissue		Lowers blood glucose level; stimulates glycogen, fat, protein synthesis	Peptide (51 amino acids)
Glucagon	Liver, adipose tissue		Raises blood glucose level; stimulates breakdown of glycogen in liver	Peptide (29 amino acids)
<b>Ovary</b>				
Estradiol	General		Stimulates development of female secondary sex characteristics	Steroid
	Female reproductive structures		Stimulates growth of sex organs at puberty and monthly preparation of uterus for pregnancy	
Progesterone	Uterus		Completes preparation for pregnancy	Steroid
	Mammary glands		Stimulates development	
<b>Testis</b>				
Testosterone	Many organs		Stimulates development of secondary sex characteristics in males and growth spurt at puberty	Steroid
	Male reproductive structures		Stimulates development of sex organs; stimulates spermatogenesis	
<b>Pineal Gland</b>				
Melatonin	Gonads, brain, pigment cells		Regulates biological rhythms	Amino acid derivative

### Figure 46.3 The life of hormones.

Endocrine glands produce both hydrophilic and lipophilic hormones, which are transported to targets through the blood. Lipophilic hormones bind to transport proteins that make them soluble in blood. Target cells have membrane receptors for hydrophilic hormones, and intracellular receptors for lipophilic hormones. Hormones are eventually destroyed by their target cells or cleared from the blood by the liver or the kidney.

target cells. They must therefore activate their receptors from outside the cell membrane. In contrast, lipophilic hormones travel in the blood attached to transport proteins (figure 46.3). Their lipid solubility enables them to cross cell membranes and bind to intracellular receptors.

Both types of hormones are eventually destroyed or otherwise deactivated after their use, eventually being excreted in bile or urine. However, hydrophilic hormones are deactivated more rapidly than lipophilic hormones. Hydrophilic hormones tend to act over relatively brief periods of time (minutes to hours), whereas lipophilic hormones generally are active over prolonged periods, such as days to weeks.

### Paracrine regulators exert powerful effects within tissues

Paracrine regulation occurs in most organs and among the cells of the immune system. **Growth factors**, proteins that promote growth and cell division in specific organs, are among the most important paracrine regulators. Growth factors play a critical role in regulating mitosis throughout life (see chapter 10). For example, *epidermal growth factor* activates mitosis of skin and development of

connective tissue cells, whereas *nerve growth factor* stimulates the growth and survival of neurons. *Insulin-like growth factor* stimulates cell division in developing bone as well as protein synthesis in many other tissues. **Cytokines** (described in chapter 52) are growth factors specialized to control cell division and differentiation in the immune system, whereas **neurotrophins** are growth factors that regulate the nervous system.

The importance of growth factor function is underscored by the observation that damage to the genes coding for growth factors or their receptors can lead to the unregulated cell division and development of tumors.

### Paracrine regulation of blood vessels

The gas nitric oxide (NO), which can function as a neurotransmitter (see chapter 44), is also produced by the endothelium of blood vessels. In this context, it is a paracrine regulator because it diffuses to the smooth muscle layer of the blood vessel and promotes vasodilation. One of its major roles involves the control of blood pressure by dilating arteries. The endothelium of blood vessels is a rich source of paracrine regulators, including *endothelin*, which stimulates vasoconstriction, and *bradykinin*, which promotes vasodilation. Paracrine regulation supplements the regulation of blood vessels

by autonomic nerves, enabling vessels to respond to local conditions, such as increased pressure or reduced oxygen.

### Prostaglandins

A particularly diverse group of paracrine regulators are the **prostaglandins**. A prostaglandin is a 20-carbon-long fatty acid that contains a five-membered carbon ring. This molecule is derived from the precursor molecule *arachidonic acid*, released from phospholipids in the cell membrane under hormonal or other stimulation. Prostaglandins are produced in almost every organ and participate in a variety of regulatory functions. Some prostaglandins are active in promoting smooth muscle contraction. Through this action, they regulate reproductive functions such as gamete transport, labor, and possibly ovulation. Excessive prostaglandin production may be involved in premature labor, endometriosis, or dysmenorrhea (painful menstrual cramps). They also participate in lung and kidney regulation through effects on smooth muscle.

In fish, prostaglandins have been found to function as both a hormone and a paracrine regulator. Prostaglandins produced in the fish's ovary during ovulation can travel to the brain to synchronize associated spawning behavior.

Prostaglandins are produced at locations of tissue damage, where they promote many aspects of inflammation, including swelling, pain, and fever. This effect of prostaglandins has been well studied. Drugs that inhibit prostaglandin synthesis, such as aspirin, help alleviate these symptoms.

Aspirin is the most widely used of the *nonsteroidal anti-inflammatory drugs (NSAIDs)*, a class of drugs that also includes indomethacin and ibuprofen. These drugs act to inhibit two related enzymes: cyclooxygenase-1 and 2 (COX-1 and COX-2). The anti-inflammatory effects are due to the inhibition of COX-2, which is necessary for the production of prostaglandins from arachidonic acid. This reduces inflammation and associated pain from the action of prostaglandins. Unfortunately, the inhibition of COX-1 produces unwanted side effects, including gastric bleeding and prolonged clotting time.

More recently developed pain relievers, called *COX-2 inhibitors*, selectively inhibit COX-2 but not COX-1. COX-2 inhibitors may be of potentially great benefit to arthritis sufferers and others who must use pain relievers regularly, but concerns have been raised that they may also affect other aspects of prostaglandin function in the cardiovascular system. Some COX-2 inhibitors were removed from the market when

a greater risk of heart attack and stroke was detected. Some have remained in use, however, and others may be reintroduced upon FDA approval. Aside from the possibly lessened gastrointestinal side effects, COX-2 inhibitors are not more effective for pain than the older NSAIDs.

### Learning Outcomes Review 46.1

Hormones coordinate the activity of specific target cells. The three chemical classes of endocrine hormones are peptides and proteins, amino acid derivatives, and steroids. Lipophilic hormones such as steroids can cross membranes, but need carriers in the blood; hydrophilic hormones move readily in the blood, but cannot cross membranes. Paracrine regulators act within the organ in which they are produced.

■ How do hormones and neurotransmitters differ?

## 46.2 Actions of Lipophilic Versus Hydrophilic Hormones

### Learning Outcomes

1. Explain how steroid hormone receptors activate transcription.
2. Explain how the signal carried by peptide hormones crosses the membrane.
3. Describe the different types of membrane receptors.

As mentioned previously, hormones can be divided into the lipophilic (lipid-soluble) and the hydrophilic (water-soluble). The receptors and actions of these two broad categories have notable differences, which we explore in this section.

### Lipophilic hormones activate intracellular receptors

The lipophilic hormones include all of the steroid hormones and thyroid hormones (figure 46.4) as well as other lipophilic regulatory molecules including the retinoids, or vitamin A.

**Figure 46.4 Chemical structures of lipophilic hormones.** Steroid hormones are derived from cholesterol. The two steroid hormones shown, cortisol and testosterone, differ slightly in chemical structure yet have widely different effects on the body. The thyroid hormone, thyroxine, is formed by coupling iodine to the amino acid tyrosine.

**Figure 46.5 The mechanism of lipophilic hormone action.** Lipophilic hormones diffuse through the plasma membrane of cells and bind to intracellular receptor proteins. The hormone-receptor complex then binds to specific regions of the DNA (hormone response elements), regulating the production of messenger RNA (mRNA). Most receptors for these hormones reside in the nucleus; if the hormone is one that binds to a receptor in the cytoplasm, the hormone-receptor complex moves together into the nucleus.

Lipophilic hormones can enter cells because the lipid portion of the plasma membrane does not present a barrier. Once inside the cell the lipophilic regulatory molecules all have a similar mechanism of action.

### Transport and receptor binding

These hormones circulate bound to transport proteins (see figure 46.3), which make them soluble and prolong their survival in the blood. When the hormones arrive at their target cells, they dissociate from their transport proteins and pass through the plasma membrane of the cell (figure 46.5). The hormone then binds to an intracellular receptor protein.

Some steroid hormones bind to their receptors in the cytoplasm, and then move as a hormone-receptor complex into the nucleus. Other steroids and the thyroid hormones travel directly into the nucleus before encountering their receptor proteins. Whether the hormone finds its receptor in the nucleus or translocates with its receptor into the nucleus from the cytoplasm, the rest of the story is similar.

### Activation of transcription in the nucleus

The hormone receptor, activated by binding to the hormone, is now also able to bind to specific regions of the DNA. These DNA regions, located in the promoters of specific genes, are known as **hormone response elements**. The binding of the hormone-receptor complex has a direct effect on the level of transcription at that site by activating, or in some cases deactivating, gene transcription. Receptors therefore function as *hormone-activated transcription factors* (see chapters 9 and 16).

The proteins that result from activation of these transcription factors often have activity that changes the metabolism of the target cell in a specific fashion; this change constitutes the cell's response to hormone stimulation. When estrogen binds to its receptor in liver cells of chickens, for example, it activates the cell to produce the protein vitellogenin, which is then transported to the ovary to form the yolk of eggs. In contrast, when thyroid hormone binds to its receptor in the anterior pituitary of humans, it inhibits the expression of the gene for thyrotropin, a mechanism of negative feedback (described later).

Because this activation and transcription process requires alterations in gene expression, it often takes several hours before the response to lipophilic hormone stimulation is apparent in target cells.

## Hydrophilic hormones activate receptors on target cell membranes

Hormones that are too large or too polar to cross the plasma membranes of their target cells include all of the peptide, protein, and glycoprotein hormones, as well as the catecholamine hormones. These hormones bind to receptor proteins located on the outer surface of the plasma membrane. This binding must then activate the hormone response inside the cell, initiating the process of signal transduction. The cellular response is most often achieved through receptor-dependent activation of the powerful intracellular enzymes called *protein kinases*. As described in chapter 9, protein kinases are critical regulatory enzymes that activate or deactivate intracellular proteins by phosphorylation. By regulating protein kinases, hydrophilic hormone receptors exert a powerful influence over the broad range of intracellular functions.

## Receptor kinases

For some hormones, such as insulin, the receptor itself is a kinase (figure 46.6), and it can directly phosphorylate intracellular proteins that alter cellular activity. In the case of insulin, this action results in the placement in the plasma membrane of glucose transport proteins that enable glucose to enter cells. Other peptide hormones, such as growth hormone, work through similar mechanisms, although the receptor itself is not a kinase. Instead, the hormone-bound receptor recruits and activates intracellular kinases, which then initiate the cellular response.

## Second-messenger systems

Many hydrophilic hormones, such as epinephrine, work through second-messenger systems. A number of different molecules in the cell can serve as second messengers, as you saw in chapter 9. The interaction between the hormone and its receptor activates mechanisms in the plasma membrane that increase the concentration of the second messengers within the target cell cytoplasm.

In the early 1960s, Earl Sutherland showed that activation of the epinephrine receptor on liver cells increases intracellular cyclic adenosine monophosphate, or cyclic AMP (cAMP), which then serves as an intracellular second messenger. The

**Figure 46.6** The action of hydrophilic hormones. Hydrophilic hormones cannot enter cells and must therefore work extracellularly via activation of transmembrane receptor proteins. (1) These receptors can function as kinase enzymes, activating phosphorylation of other proteins inside cells. (2) Alternatively, acting through intermediary G proteins, the hormone-bound receptor activates production of a second messenger. The second messenger activates protein kinases that phosphorylate and thereby activate other proteins. GPCR, G protein–coupled receptor.

cAMP second-messenger system was the first such system to be described. Since that time, another hormonally regulated second-messenger system has been described that generates two lipid messengers: **inositol triphosphate (IP<sub>3</sub>)** and diacyl glycerol (DAG). These systems were described in chapter 9.

### The action of G proteins

Receptors that activate second messengers do not manufacture the second messenger themselves. Rather, they are linked to a second-messenger-generating enzyme via membrane proteins called *G proteins* [that is, they are G protein-coupled receptors (GPCR); see chapter 9]. The binding of the hormone to its receptor causes the G protein to shuttle within the plasma membrane from the receptor to the second-messenger-generating enzyme (see figure 46.6). When the G protein activates the enzyme, the result is an increase in second-messenger molecules inside the cell.

In the case of epinephrine, the G protein activates an enzyme called *adenylyl cyclase*, which catalyzes the formation of the second messenger cAMP from ATP. The second messenger formed at the inner surface of the plasma membrane then diffuses within the cytoplasm, where it binds to and activates protein kinases.

The identities of the proteins that are subsequently phosphorylated by the protein kinases vary from one cell type to the next and include enzymes, membrane transport proteins, and transcription factors. This diversity provides hormones with distinct actions in different tissues. In liver cells, for example, cAMP-dependent protein kinases activate enzymes that convert glycogen into glucose. In contrast, cardiac muscle cells express a different set of cellular proteins such that a cAMP increase activates an increase in the rate and force of cardiac muscle contraction.

### Activation versus inhibition

The cellular response to a hormone depends on the type of G protein activated by the hormone's receptor. Some receptors are linked to G proteins that activate second-messenger-producing enzymes, whereas other receptors are linked to G proteins that inhibit their second-messenger-generating enzyme. As a result, some hormones stimulate protein kinases in their target cells, and others inhibit their targets. Furthermore, a single hormone can have distinct actions in two different cell types if the receptors in those cells are linked to different G proteins.

Epinephrine receptors in the liver, for example, produce cAMP through the enzyme adenylyl cyclase, mentioned earlier. The cAMP they generate activates protein kinases that promote the production of glucose from glycogen. In smooth muscle, by contrast, epinephrine receptors can be linked through a different stimulatory G protein to the IP<sub>3</sub>-generating enzyme phospholipase C. As a result, epinephrine stimulation of smooth muscle results in IP<sub>3</sub>-regulated release of intracellular calcium, causing muscle contraction.

### Duration of hydrophilic hormone effects

The binding of a hydrophilic hormone to its receptor is reversible and usually very brief; hormones soon dissociate from receptors or are rapidly deactivated by their target cells after binding. Additionally, target cells contain specific enzymes that rapidly deactivate second messengers and protein kinases. As a result, hydrophilic hormones are capable of stimulating immediate responses within cells, but often have a brief duration of action (minutes to hours).

## Learning Outcomes Review 46.2

Steroids, which are lipophilic, pass through a target cell's membrane and bind to intracellular receptor proteins. The hormone-receptor complex then binds to the hormone response element of the promoter region of the target gene. Hydrophilic hormones such as peptides bind externally to membrane receptors that activate protein kinases directly or that operate through second-messenger systems such as cAMP or IP<sub>3</sub>/DAG.

- How can a single hormone, such as epinephrine, have different effects in different tissues?

## 46.3 The Pituitary and Hypothalamus: The Body's Control Centers

### Learning Outcomes

1. Explain why the pituitary is considered a compound gland.
2. Describe the connections between the hypothalamus, posterior pituitary, and anterior pituitary.
3. Describe the roles of releasing and inhibiting hormones.

The **pituitary gland**, also known as the **hypophysis**, hangs by a stalk from the hypothalamus at the base of the brain posterior to the optic chiasm. The hypothalamus is a part of the central nervous system (CNS) that has a major role in regulating body processes. Both these structures were described in chapter 44; here we discuss in detail how they work together to bring about homeostasis and changes in body processes.

### The pituitary is a compound endocrine gland

A microscopic view reveals that the gland consists of two parts, one of which appears glandular and is called the **anterior pituitary**, or **adenohypophysis**. The other portion appears fibrous and is called the **posterior pituitary**, or **neurohypophysis**. These two portions of the pituitary gland have different embryonic origins, secrete different hormones, and are regulated by different control systems. These two regions are conserved in all vertebrate animals, suggesting an ancient and important function of each.

### The posterior pituitary stores and releases two neurohormones

The posterior pituitary appears fibrous because it contains axons that originate in cell bodies within the hypothalamus and that extend along the stalk of the pituitary as a tract of fibers. This anatomical relationship results from the way the posterior pituitary is formed in embryonic development. As the floor of the third ventricle of the brain forms the hypothalamus, part of this neural tissue grows downward

to produce the posterior pituitary. The hypothalamus and posterior pituitary thus remain directly interconnected by a tract of axons.

### Antidiuretic hormone

The endocrine role of the posterior pituitary first became evident in 1912, when a remarkable medical case was reported: A man who had been shot in the head developed the need to urinate every 30 minutes or so, 24 hours a day. The bullet had lodged in his posterior pituitary. Subsequent research demonstrated that removal of this portion of the pituitary produces the same symptoms.

In the early 1950s investigators isolated a peptide from the posterior pituitary, **antidiuretic hormone (ADH)**. ADH stimulates water reabsorption by the kidneys (figure 46.7), and in doing so inhibits diuresis (urine production). When ADH is missing, as it was in the shooting victim, the kidneys do not reabsorb as much water, and excessive quantities of urine are produced. This is why the consumption of alcohol, which inhibits ADH secretion, leads to frequent urination. The role of ADH in kidney function is covered in chapter 51.

### Oxytocin

The posterior pituitary also secretes **oxytocin**, a second peptide neurohormone that, like ADH, is composed of nine amino acids. In mammals, oxytocin stimulates the milk ejection reflex. During suckling, sensory receptors in the nipples send impulses to the hypothalamus, which triggers the release of oxytocin.

Oxytocin is also needed to stimulate uterine contractions in women during childbirth.

Oxytocin secretion continues after childbirth in a woman who is breast-feeding; as a result, the uterus of a nursing mother contracts and returns to its normal size after pregnancy more quickly than the uterus of a mother who does not breast-feed.

A related posterior pituitary neurohormone, *arginine vasotocin*, exerts similar effects in nonmammalian species. For example, in chickens and sea turtles, arginine vasotocin activates oviduct contraction during egg laying.

More recently, oxytocin has been identified as an important regulator of reproductive behavior. In both men and women, it is thought to be involved in promoting pair bonding (leading to its being called the “cuddle hormone”) as well as regulating sexual responses, including arousal and orgasm. For these effects, it most likely functions in a paracrine fashion inside the CNS, much like a neurotransmitter.

### Hypothalamic production of the neurohormones

ADH and oxytocin are actually produced by neuron cell bodies located in the hypothalamus. These two neurohormones are transported along the axon tract that runs from the hypothalamus to the posterior pituitary, where they are stored. In response to the appropriate stimulation—increased blood plasma osmolality in the case of ADH, the suckling of a baby in the case of oxytocin—the neurohormones are released by the posterior pituitary into the blood.

Because this reflex control involves both the nervous and the endocrine systems, ADH and oxytocin are said to be secreted by a **neuroendocrine reflex**.

**Figure 46.7** The effects of antidiuretic hormone (ADH).

Dehydration increases the osmotic concentration of the blood and lowers blood pressure, stimulating the neurohypophysis to secrete ADH. ADH increases reabsorption of water by the kidneys and causes vasoconstriction, increasing blood pressure. Decreased blood osmolarity and increased blood pressure complete negative feedback loops to maintain homeostasis.

## The anterior pituitary produces seven hormones

The anterior pituitary, unlike the posterior pituitary, does not develop from growth of the brain; instead, it develops from a pouch of epithelial tissue that pinches off from the roof of the embryo’s mouth. In spite of its proximity to the brain, it is not part of the nervous system.

Because it forms from epithelial tissue, the anterior pituitary is an independent endocrine gland. It produces at least seven essential hormones, many of which stimulate growth of their target organs, as well as production and secretion of other hormones from additional endocrine glands. Therefore, several hormones of the anterior pituitary are collectively termed *tropic hormones*, or *tropins*. Tropic hormones act on other endocrine glands to stimulate secretion of hormones produced by the target gland.

The hormones produced and secreted by different cell types in the anterior pituitary can be categorized into three structurally similar families: the *peptide hormones*, the *protein hormones*, and the *glycoprotein hormones*.

### Peptide hormones

The **peptide hormones** of the anterior pituitary are cleaved from a single precursor protein, and therefore they share some common sequence. They are fewer than 40 amino acids in size.

1. **Adrenocorticotropic hormone (ACTH, or corticotropin)** stimulates the adrenal cortex to produce corticosteroid hormones, including cortisol (in humans)

and corticosterone (in many other vertebrates). These hormones regulate glucose homeostasis and are important in the response to stress.

2. **Melanocyte-stimulating hormone (MSH)** stimulates the synthesis and dispersion of melanin pigment, which darkens the epidermis of some fish, amphibians, and reptiles, and can control hair pigment color in mammals.

### Protein hormones

The **protein hormones** each comprise a single chain of approximately 200 amino acids, and they share significant structural similarities.

1. **Growth hormone (GH, or *somatotropin*)** stimulates the growth of muscle, bone (indirectly), and other tissues, and it is also essential for proper metabolic regulation.
2. **Prolactin (PRL)** is best known for stimulating the mammary glands to produce milk in mammals; however, it has diverse effects on many other targets, including regulation of ion and water transport across epithelia, stimulation of a variety of organs that nourish young, and activation of parental behaviors.

### Glycoprotein hormones

The largest and most complex hormones known, the *glycoprotein hormones* are dimers, containing alpha ( $\alpha$ ) and beta ( $\beta$ ) subunits, each around 100 amino acids in size, with covalently linked sugar residues. The  $\alpha$  subunit is common to all three hormones. The  $\beta$  subunit differs, endowing each hormone with a different target specificity.

1. **Thyroid-stimulating hormone (TSH, or *thyrotropin*)** stimulates the thyroid gland to produce the hormone thyroxine, which in turn regulates development and metabolism by acting on nuclear receptors.
2. **Luteinizing hormone (LH)** stimulates the production of estrogen and progesterone by the ovaries and is needed for ovulation in female reproductive cycles (see chapter 53). In males, it stimulates the testes to produce testosterone, which is needed for sperm production and for the development of male secondary sexual characteristics.
3. **Follicle-stimulating hormone (FSH)** is required for the development of ovarian follicles in females. In males, it is required for the development of sperm. FSH stimulates the conversion of testosterone into estrogen in females, and into dihydroxytestosterone in males. FSH and LH are collectively referred to as *gonadotropins*.

## Hypothalamic neurohormones regulate the anterior pituitary

The anterior pituitary, unlike the posterior pituitary, is not derived from the brain and does not receive an axon tract from the hypothalamus. Nevertheless, the hypothalamus controls the production and secretion of its hormones. This control is itself exerted hormonally rather than by means of nerve axons.

Neurons in the hypothalamus secrete two types of neurohormones, **releasing hormones** and **inhibiting hormones**,

**Figure 46.8** Hormonal control of the adenohypophysis by the hypothalamus. Neurons in the hypothalamus secrete hormones that are carried by portal blood vessels directly to the adenohypophysis, where they either stimulate or inhibit the secretion of hormones from the adenohypophysis.

that diffuse into blood capillaries at the base of the hypothalamus (figure 46.8). These capillaries drain into small veins that run within the stalk of the pituitary to a second bed of capillaries in the anterior pituitary. This unusual system of vessels is known as the *hypothalamohypophyseal portal system*. In a portal system, two capillary beds are linked by veins. In this case, the hormone enters the first capillary bed, and the vein delivers this to the second capillary bed where the hormone exits and enters the anterior pituitary.

### Releasers

Each neurohormone released by the hypothalamus into the portal system regulates the secretion of a specific hormone in

the anterior pituitary. Releasing hormones are peptide neurohormones that stimulate release of other hormones; specifically, *thyrotropin-releasing hormone* (TRH) stimulates the release of TSH; *corticotropin-releasing hormone* (CRH) stimulates the release of ACTH; and *gonadotropin-releasing hormone* (GnRH) stimulates the release of FSH and LH. A releasing hormone for growth hormone, called *growth hormone-releasing hormone* (GHRH), has also been discovered, and TRH, oxytocin and vasoactive intestinal peptide all appear to act as releasing hormones for prolactin.

### Inhibitors

The hypothalamus also secretes neurohormones that inhibit the release of certain anterior-pituitary hormones. To date, three such neurohormones have been discovered: *Somatostatin*, or *growth hormone-inhibiting hormone* (GHIH), which inhibits the secretion of GH; *prolactin-inhibiting factor* (PIF), which inhibits the secretion of prolactin and has been found to be the neurotransmitter dopamine; and *MSH-inhibiting hormone* (MIH), which inhibits the secretion of MSH.

### Feedback from peripheral endocrine glands regulates anterior-pituitary hormones

Because hypothalamic hormones control the secretions of the anterior pituitary, and because the hormones of the anterior pituitary in turn control the secretions of other endocrine glands, it may seem that the hypothalamus is in charge of hormonal secretion for the whole body. This however, ignores a crucial aspect of endocrine control: The hypothalamus and the anterior pituitary are themselves partially con-

**Figure 46.9 Negative feedback inhibition.** The hormones secreted by some endocrine glands feed back to inhibit the secretion of hypothalamic releasing hormones and adenohypophysis tropic hormones. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone

trolled by the very hormones whose secretion they stimulate. In most cases, this control is inhibitory (figure 46.9). This type of control system is called *negative feedback*, and it acts to maintain relatively constant levels of the target cell hormone.

### An example of negative feedback: Thyroid gland control

To illustrate how important the negative feedback mechanism is, let's consider the hormonal control of the thyroid gland. The hypothalamus secretes TRH into the hypothalamohypophyseal portal system, which stimulates the anterior pituitary to secrete TSH. TSH in turn causes the thyroid gland to release **thyroxine**. Thyroxine and other thyroid hormones affect metabolic rate, as described in the following section.

Among thyroxine's many target organs are the hypothalamus and the anterior pituitary themselves. Thyroxine acts on these organs to inhibit their secretion of TRH and TSH, respectively. This negative feedback inhibition is essential for homeostasis because it keeps the thyroxine levels fairly constant.

The hormone thyroxine contains the element iodine; without iodine, the thyroid gland cannot produce thyroxine. Individuals living in iodine-poor areas (such as central prairies distant from seacoasts and the fish that are the natural source of iodine) lack sufficient iodine to manufacture thyroxine, so the hypothalamus and anterior pituitary receive far less negative feedback inhibition than is normal. This reduced inhibition results in elevated secretion of TRH and TSH.

High levels of TSH stimulate the thyroid gland, whose cells enlarge in a futile attempt to manufacture more thyroxine. Because they cannot without iodine, the thyroid gland keeps getting bigger and bigger—a condition known as a goiter (figure 46.10). Goiter size can be reduced by providing iodine in the diet. In most countries, goiter is prevented through the addition of iodine to table salt.

**Figure 46.10 A woman with a goiter.** This condition is caused by a lack of iodine in the diet. As a result, thyroxine secretion is low, so there is less negative feedback inhibition of TSH. The elevated TSH secretion, in turn, stimulates the thyroid to enlarge in an effort to produce additional thyroxine.

### An example of positive feedback: Ovulation

Positive feedback in the control of the hypothalamus and anterior pituitary by the target glands is uncommon because positive feedback causes deviations from homeostasis. Positive feedback accentuates change, driving the change in the same direction. One example is the control of **ovulation**, the explosive release of a mature egg (an oocyte) from the ovary.

As the oocyte grows, follicle cells surrounding it produce increasing levels of the steroid hormone estrogen, resulting in a progressive rise in estrogen in the blood. Peak estrogen levels signal the hypothalamus that the oocyte is ready to be ovulated. Estrogen then exerts positive feedback on the hypothalamus and pituitary, resulting in a surge of LH from the anterior pituitary. This LH surge causes the follicle cells to rupture and release the oocyte to the oviduct, where it can potentially be fertilized. The positive feedback cycle is then terminated because the tissue remaining of the ovarian follicle forms the corpus luteum, which secretes progesterone and estrogen that feed back to inhibit secretion of FSH and LH. This process is discussed in more detail in chapter 53.

### Hormones of the anterior pituitary work directly and indirectly

Early in the 20th century, experimental techniques were developed for surgical removal of the pituitary gland (a procedure called *hypophysectomy*). Hypophysectomized animals exhibited a number of deficits, including reduced growth and development, diminished metabolism, and failure of reproduction. These powerful and diverse effects earned the pituitary a reputation as the “master gland.” Indeed, many of these are *direct effects*, resulting from anterior-pituitary hormones activating receptors in nonendocrine targets, such as liver, muscle, and bone. The tropic hormones produced by the anterior pituitary have *indirect effects*, however, through their ability to activate other endocrine glands, such as the thyroid, adrenal glands, and gonads. Of the seven anterior-pituitary hormones, growth hormone, prolactin, and MSH work primarily through direct effects, whereas the tropic hormones ACTH, TSH, LH, and FSH have endocrine glands as their exclusive targets.

#### Effects of growth hormone

The importance of the anterior pituitary is illustrated by a condition known as *gigantism*, characterized by excessive growth of the entire body or any of its parts. The tallest human being ever recorded, Robert Wadlow, had gigantism (figure 46.11). Born in 1928, he stood 8 feet 11 inches tall, weighed 485 pounds, and was still growing before he died from an infection at the age of 22.

We now know that gigantism is caused by the excessive secretion of GH in a growing child. By contrast, a deficiency in GH secretion during childhood results in **pituitary dwarfism**—a failure to achieve normal stature.

GH stimulates protein synthesis and growth of muscles and connective tissues; it also indirectly promotes the elongation of bones by stimulating cell division in the cartilaginous epiphyseal growth plates of bones (see chapter 47). Researchers found that this stimulation does not occur in the absence of blood plasma, suggesting that GH must work in concert with another hormone

**Figure 46.11 The Alton giant.** This photograph of Robert Wadlow of Alton, Illinois, taken on his 21st birthday, shows him at home with his father and mother and four siblings. Born normal size, he developed a growth-hormone-secreting pituitary tumor as a young child and never stopped growing during his 22 years of life, reaching a height of 8 ft 11 in.

to exert its effects on bone. We now know that GH stimulates the production of **insulin-like growth factors**, which liver and bone produce in response to stimulation by GH. The insulin-like growth factors then stimulate cell division in the epiphyseal growth plates, and thus the elongation of the bones.

Although GH exhibits its most dramatic effects on juvenile growth, it also functions in adults to regulate protein, lipid, and carbohydrate metabolism. Recently a peptide hormone named **ghrelin**, produced by the stomach between meals, was identified as a potent stimulator of GH release, establishing an important linkage between nutrient intake and GH production.

Because human skeletal growth plates transform from cartilage into bone at puberty, GH can no longer cause an increase in height in adults. Excessive GH secretion in an adult results in a form of gigantism called **acromegaly**, characterized by bone and soft tissue deformities such as a protruding jaw, elongated fingers, and thickening of skin and facial features. Our knowledge of the regulation of GH has led to the development of drugs that can control its secretion, for example through activation of somatostatin, or by mimicking ghrelin. As a result, gigantism is much less common today.

Animals that have been genetically engineered to express additional copies of the GH gene grow to larger than normal

## 46.4 The Major Peripheral Endocrine Glands

size (see figure 17.16), making agricultural applications of GH manipulation an active area of investigation. Among other actions, GH has been found to increase milk yield in cows, promote weight gain in pigs, and increase the length of fish. The growth-promoting actions of GH thus appear to have been conserved throughout the vertebrates.

### Other hormones of the anterior pituitary

Like growth hormone, prolactin acts on organs that are not endocrine glands. In contrast to GH, however, the actions of prolactin appear to be very diverse. In addition to stimulating production of milk in mammals, prolactin has been implicated in the regulation of tissues important in birds for the nourishment and incubation of young, such as the crop (which produces “crop milk,” a nutritional fluid fed to chicks by regurgitation) and the brood patch (a vascular area on the abdomen of birds used to warm eggs).

In amphibians, prolactin promotes transformation of salamanders from terrestrial forms to aquatic breeding adults. Associated with these reproductive actions is an ability of prolactin to activate associated behaviors, such as parental care in mammals, broodiness in birds, and “water drive” in amphibians.

Prolactin also has varied effects on electrolyte balance through actions on the kidneys of mammals, the gills of fish, and the salt glands of marine birds. This variation suggests that although prolactin may have an ancient function in the regulation of salt and water movement across membranes, its actions have diversified with the appearance of new vertebrate species. The field of comparative endocrinology studies questions about hormone action across diverse species, with the objective of understanding the mechanisms of hormone evolution.

Unlike growth hormone and prolactin, the other adeno-hypophyseal hormones act on relatively few targets. TSH stimulates the thyroid gland, and ACTH stimulates the adrenal cortex. The gonadotropins, FSH and LH, act on the gonads. Although both FSH and LH act on the gonads, they each target different cells in the gonads of both females and males (see chapter 53). These hormones all share the common characteristic of activating target endocrine glands.

The final pituitary hormone, MSH regulates the activity of cells called melanophores, which contain the black pigment **melanin**. In response to MSH, melanin is dispersed throughout these cells, darkening the skin of reptiles, amphibians, or fish. In mammals, which lack melanophores but have similar cells called melanocytes, MSH can darken hair by increasing melanin deposition in the developing hair shaft.

### Learning Outcomes Review 46.3

The posterior pituitary develops from neural tissue; the anterior pituitary develops from epithelial tissue. Axons from the hypothalamus extend into the posterior pituitary and produce neurohormones; these neurons also secrete factors that release or inhibit hormones of the anterior pituitary. Releasers stimulate secretion of hormones; TRH causes TSH release. Inhibitors suppress secretion; GHIH inhibits GH release.

- **Could someone with a pituitary tumor causing gigantism be treated with GHIH? What outcome would you predict?**

### Learning Outcomes

1. **Identify the major peripheral endocrine glands.**
2. **Describe the components of  $\text{Ca}^{2+}$  homeostasis.**
3. **Explain the action of pancreatic hormones on blood glucose.**

Although the pituitary produces an impressive array of hormones, many endocrine glands are found in other locations. Some of these may be controlled by tropic hormones of the pituitary, but others, such as the adrenal medulla and the pancreas, are independent of pituitary control. Several endocrine glands develop from derivatives of the primitive pharynx, which is the most anterior segment of the digestive tract (see chapter 48). These glands, which include the *thyroid* and *parathyroid* glands, produce hormones that regulate processes associated with nutrient uptake, such as carbohydrate, lipid, protein, and mineral metabolism.

### The thyroid gland regulates basal metabolism and development

The thyroid gland varies in shape in different vertebrate species, but is always found in the neck area, anterior to the heart. In humans it is shaped like a bow tie and lies just below the Adam's apple in the front of the neck.

The thyroid gland secretes three hormones: primarily thyroxine, smaller amounts of triiodothyronine (collectively referred to as thyroid hormones), and calcitonin. As described earlier, thyroid hormones are unique in being the only molecules in the body containing iodine (thyroxine contains four iodine atoms, triiodothyronine contains three).

### Thyroid-related disorders

Thyroid hormones work by binding to nuclear receptors located in most cells in the body, influencing the production and activity of a large number of cellular proteins. The importance of thyroid hormones first became apparent from studies of human thyroid disorders. Adults with hypothyroidism have low metabolism due to underproduction of thyroxine, including a reduced ability to utilize carbohydrates and fats. As a result, they are often fatigued, overweight, and feel cold. Hypothyroidism is particularly concerning in infants and children, where it impairs growth, brain development, and reproductive maturity. Fortunately, because thyroid hormones are small, simple molecules, people with hypothyroidism can take thyroxine orally as a pill.

People with hyperthyroidism, by contrast, often exhibit opposite symptoms: weight loss, nervousness, high metabolism, and overheating because of overproduction of thyroxine. Drugs are available that block thyroid hormone synthesis in the thyroid gland, but in some cases portions of the thyroid gland must be removed surgically or by radiation treatment.

## Actions of thyroid hormones

Thyroid hormones regulate enzymes controlling carbohydrate and lipid metabolism in most cells, promoting the appropriate use of these fuels for maintaining the body's basal metabolic rate. Thyroid hormones often function cooperatively, or *synergistically*, with other hormones, promoting the activity of growth hormone, epinephrine, and reproductive steroids. Through these actions, thyroid hormones function to ensure that adequate cellular energy is available to support metabolically demanding activities.

In humans, which exhibit a relatively high metabolic rate at all times, thyroid hormones are maintained in the blood at constantly elevated levels. In contrast, in reptiles, amphibians, and fish, which undergo seasonal cycles of activity, thyroid hormone levels in the blood increase during periods of metabolic activation (such as growth, reproductive development, migration, or breeding) and diminish during periods of inactivity in cold months.

Some of the most dramatic effects of thyroid hormones are observed in their regulation of growth and development. In developing humans, for example, thyroid hormones promote growth of neurons and stimulate maturation of the CNS. Children born with hypothyroidism are stunted in their growth and suffer severe mental retardation, a condition called *cretinism*. Early detection through measurement of thyroid hormone levels allows this condition to be treated with thyroid hormone administration.

The most impressive demonstration of the importance of thyroid hormones in development is displayed in amphibians. Thyroid hormones direct the metamorphosis of tadpoles into frogs, a process that requires the transformation of an aquatic, herbivorous larva into a terrestrial, carnivorous juvenile (figure 46.12). If the thyroid gland is removed from a tadpole, it will not change into a frog. Conversely, if an immature tadpole is fed pieces of a thyroid gland, it will undergo premature metamorphosis and become a miniature frog. This illustrates the powerful actions thyroid hormones can elicit by regulating the expression of multiple genes.

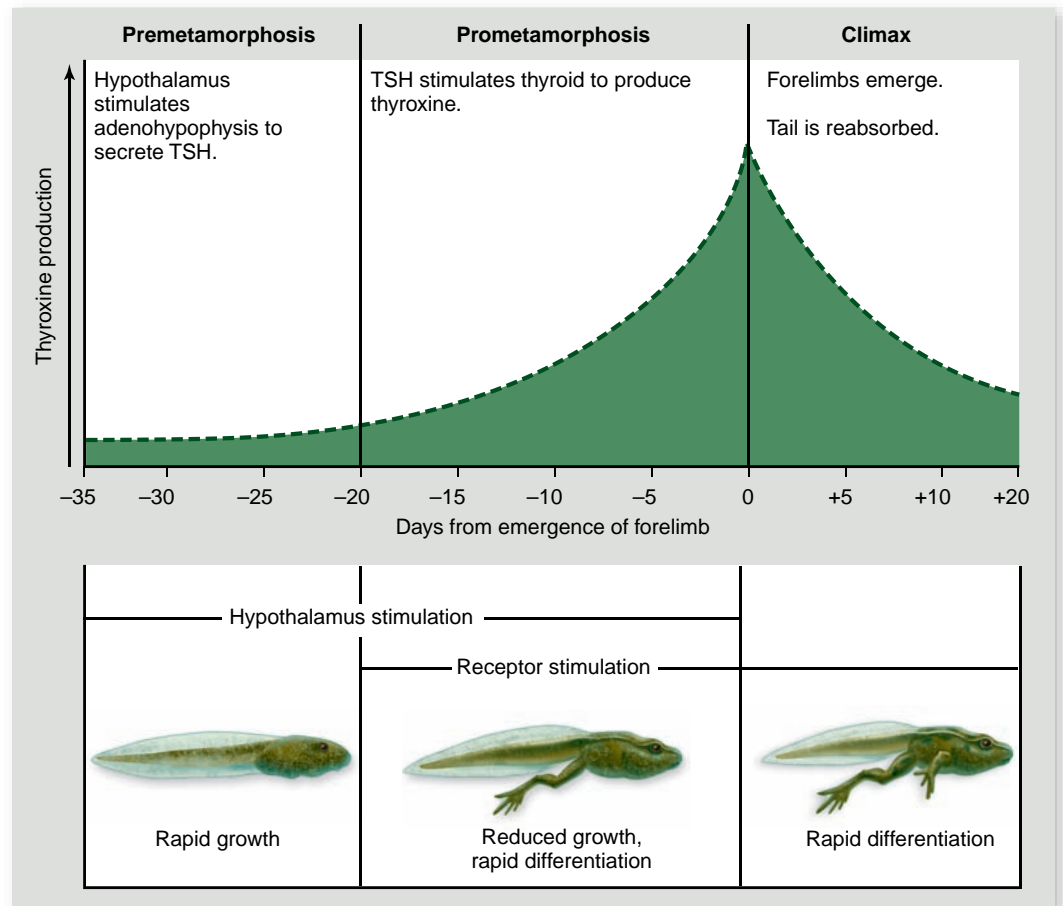

## Calcium homeostasis is regulated by several hormones

Calcium is a vital component of the vertebrate body both because of its being a structural component of bones and because of its role in ion-mediated processes such as muscle contraction. The thyroid and parathyroid glands act with vitamin D to regulate calcium homeostasis.

### Calcitonin secretion by the thyroid

In addition to the thyroid hormones, the thyroid gland also secretes **calcitonin**, a peptide hormone that plays a role in maintaining proper levels of calcium ( $\text{Ca}^{2+}$ ) in the blood. When the blood  $\text{Ca}^{2+}$  concentration rises too high, calcitonin stimulates the uptake of calcium into bones, thus lowering its

**Figure 46.12 Thyroxine triggers metamorphosis in amphibians.** In tadpoles at the premetamorphic stage, the hypothalamus stimulates the adenohypophysis to secrete TSH (thyroid-stimulating hormone). TSH then stimulates the thyroid gland to secrete thyroxine. Thyroxine binds to its receptor and initiates the changes in gene expression necessary for metamorphosis. As metamorphosis proceeds, thyroxine reaches its maximal level, after which the forelimbs begin to form and the tail is reabsorbed.

level in the blood. Although calcitonin may be important in the physiology of some vertebrates, it appears less important in the day-to-day regulation of  $\text{Ca}^{2+}$  levels in adult humans. It may, however, play an important role in bone remodeling in rapidly growing children.

### Parathyroid hormone (PTH)

The parathyroid glands are four small glands attached to the thyroid. Because of their size, researchers ignored them until well into the 20th century. The first suggestion that these organs have an endocrine function came from experiments on dogs: If their parathyroid glands were removed, the  $\text{Ca}^{2+}$  concentration in the dogs' blood plummeted to less than half the normal value. The  $\text{Ca}^{2+}$  concentration returned to normal when an extract of parathyroid gland was administered. However, if too much of the extract was administered, the dogs'  $\text{Ca}^{2+}$  levels rose far above normal as the calcium phosphate crystals in their bones were dissolved. It was clear that the parathyroid glands produce a hormone that stimulates the release of calcium from bone.

The hormone produced by the parathyroid glands is a peptide called **parathyroid hormone (PTH)**. PTH is synthesized and released in response to falling levels of  $\text{Ca}^{2+}$  in the blood. This decline cannot be allowed to continue uncorrected because a significant fall in the blood  $\text{Ca}^{2+}$  level can cause severe muscle spasms. A normal blood  $\text{Ca}^{2+}$  level is important for the functioning of muscles, including the heart, and for proper functioning of the nervous and endocrine systems.

PTH stimulates the osteoclasts (bone cells) in bone to dissolve the calcium phosphate crystals of the bone matrix and release  $\text{Ca}^{2+}$  into the blood (figure 46.13). PTH also stimulates the kidneys to reabsorb  $\text{Ca}^{2+}$  from the urine and leads to the activation of vitamin D, needed for the absorption of calcium from food in the intestine.

### Vitamin D

Vitamin D is produced in the skin from a cholesterol derivative in response to ultraviolet light. It is called an essential vitamin because in temperate regions of the world a dietary source is needed to supplement the amount produced by the skin. (In the tropics, people generally receive enough exposure to sunlight to produce adequate vitamin D.) Diffusing into the blood from the skin, vitamin D is actually an inactive form of a hormone. In order to become activated, the molecule must gain two hydroxyl groups ( $-\text{OH}$ ); one of these is added by an enzyme in the liver, the other by an enzyme in the kidneys.

The enzyme needed for this final step is stimulated by PTH, thereby producing the active form of vitamin D known as 1,25-dihydroxyvitamin D. This hormone stimulates the intestinal absorption of  $\text{Ca}^{2+}$  and thereby helps raise blood  $\text{Ca}^{2+}$  levels so that bone can become properly mineralized. A diet deficient in vitamin D thus leads to poor bone formation, a condition called rickets.

To ensure adequate amounts of this essential hormone, vitamin D is now added to commercially produced milk in the United States and some other countries. This is certainly a preferable alternative to the prior method of vitamin D administration, the dreaded dose of cod liver oil.

**Figure 46.13 Regulation of blood  $\text{Ca}^{2+}$  levels by parathyroid hormone (PTH).** When blood  $\text{Ca}^{2+}$  levels are low, PTH is released by the parathyroid glands. PTH directly stimulates the dissolution of bone and the reabsorption of  $\text{Ca}^{2+}$  by the kidneys. PTH indirectly promotes the intestinal absorption of  $\text{Ca}^{2+}$  by stimulating the production of the active form of vitamin D.

## The adrenal gland releases both catecholamine and steroid hormones

The **adrenal glands** are located just above each kidney (figure 46.14). Each gland is composed of an inner portion, the *adrenal medulla*, and an outer layer, the *adrenal cortex*.

### The adrenal medulla

The adrenal medulla receives neural input from axons of the sympathetic division of the autonomic nervous system, and it secretes the catecholamines epinephrine and norepinephrine in response to stimulation by these axons. The actions of these hormones trigger “alarm” responses similar to those elicited by the sympathetic division, helping to prepare the body for extreme efforts. Among the effects of these hormones are an increased heart rate, increased blood pressure, dilation of the bronchioles, elevation in blood glucose, reduced blood flow to the skin and digestive organs, and

**Figure 46.14 The adrenal glands.** The adrenal medulla produces the catecholamines epinephrine and norepinephrine, which initiate a response to acute stress. The adrenal cortex produces steroid hormones, including the glucocorticoid cortisol. In response to stress, cortisol secretion increases glucose production and stimulates the immune response.

increased blood flow to the heart and muscles. The actions of epinephrine, released as a hormone, supplement those of neurotransmitters released by the sympathetic nervous system.

### The adrenal cortex

The hormones from the adrenal cortex are all steroids and are referred to collectively as *corticosteroids*. *Cortisol* (also called hydrocortisone) and related steroids secreted by the adrenal cortex act on various cells in the body to maintain glucose homeostasis. In mammals, these hormones are referred to as glucocorticoids, and their secretion is primarily regulated by ACTH from the anterior pituitary.

The glucocorticoids stimulate the breakdown of muscle protein into amino acids, which are carried by the blood to the liver. They also stimulate the liver to produce the enzymes needed for gluconeogenesis, which can convert amino acids

into glucose. Glucose synthesis from protein is particularly important during very long periods of fasting or exercise, when blood glucose levels might otherwise become dangerously low.

Whereas glucocorticoids are important in the daily regulation of glucose and protein, they, like the adrenal medulla hormones, are also secreted in large amounts in response to stress. It has been suggested that during stress they activate the production of glucose at the expense of protein and fat synthesis.

In addition to regulating glucose metabolism, the glucocorticoids modulate some aspects of the immune response. The physiological significance of this action is still unclear, and it may be apparent only when glucocorticoids are maintained at elevated levels for long periods of time (such as long-term stress). Glucocorticoids are used to suppress the immune system in persons with immune disorders (such as rheumatoid arthritis) and to prevent the immune system from rejecting organ and tissue transplants. Derivatives of cortisol, such as prednisone, have widespread medical use as anti-inflammatory agents.

*Aldosterone*, the other major corticosteroid, is classified as a mineralocorticoid because it helps regulate mineral balance. The secretion of aldosterone from the adrenal cortex is activated by angiotensin II, a product of the renin-angiotensin system described in chapter 51, as well as high blood  $K^+$ . Angiotensin II activates aldosterone secretion when blood pressure falls.

A primary action of aldosterone is to stimulate the kidneys to reabsorb  $Na^+$  from the urine. (Blood levels of  $Na^+$  decrease if  $Na^+$  is not reabsorbed from the urine.) Sodium is the major extracellular solute; it is needed for the maintenance of normal blood volume and pressure, as well as for the generation of action potentials in neurons and muscles. Without aldosterone, the kidneys would lose excessive amounts of blood  $Na^+$  in the urine.

Aldosterone-stimulated reabsorption of  $Na^+$  also results in kidney excretion of  $K^+$  in the urine. Aldosterone thus prevents  $K^+$  from accumulating in the blood, which would lead to malfunctions in electrical signaling in nerves and muscles. Because of these essential functions performed by aldosterone, removal of the adrenal glands, or diseases that prevent aldosterone secretion, are invariably fatal without hormone therapy.

## Pancreatic hormones are primary regulators of carbohydrate metabolism

The pancreas is located adjacent to the stomach and is connected to the duodenum of the small intestine by the pancreatic duct. It secretes bicarbonate ions and a variety of digestive enzymes into the small intestine through this duct (see chapter 48), and for a long time the pancreas was thought to be solely an exocrine gland.

### Insulin

In 1869, however, a German medical student named Paul Langerhans described some unusual clusters of cells scattered throughout the pancreas; these clusters came to be called *islets of Langerhans*. They are now more commonly called pancreatic islets. Laboratory workers later observed that the surgical removal of the pancreas caused glucose to appear in the urine, the hallmark of the disease diabetes mellitus. This led to the discovery that the pancreas, specifically the islets of Langerhans, produced a hormone that prevents this disease.

That hormone is **insulin**, secreted by the beta ( $\beta$ ) cells of the islets. Insulin was not isolated until 1922 when Banting and Best succeeded where many others had not. On January 11, 1922, they injected an extract purified from beef pancreas into a 13-year-old diabetic boy, whose weight had fallen to 65 pounds and who was not expected to survive. With that single injection, the glucose level in the boy's blood fell 25%. A more potent extract soon brought the level down to near normal. The doctors had achieved the first instance of successful insulin therapy.

### Glucagon

The islets of Langerhans produce another hormone; the alpha ( $\alpha$ ) cells of the islets secrete **glucagon**, which acts antagonistically to insulin (figure 46.15). When a person eats carbohydrates, the blood glucose concentration rises. Blood glucose directly activates the secretion of insulin by the  $\beta$  cells and inhibits the secretion of glucagon by the  $\alpha$  cells. Insulin promotes the cellular uptake of glucose into the liver, muscle, and fat cells. It also activates the storage of glucose as glycogen in liver and muscle or as fat in fat cells. Between meals, when the concentration of blood glucose falls, insulin secretion decreases, and glucagon secretion increases. Glucagon promotes the hydrolysis of stored glycogen in the liver and fat in

**Figure 46.15** The antagonistic actions of insulin and glucagon on blood glucose. Insulin stimulates the cellular uptake of blood glucose into skeletal muscles, adipose cells, and the liver after a meal. Glucagon stimulates the hydrolysis of liver glycogen between meals, so that the liver can secrete glucose into the blood. These antagonistic effects help to maintain homeostasis of the blood glucose concentration.

adipose tissue. As a result, glucose and fatty acids are released into the blood and can be taken up by cells and used for energy.

### Treatment of diabetes

Although many hormones favor the movement of glucose into cells, insulin is the only hormone that promotes movement of glucose from blood into cells. For this reason, disruptions in insulin signaling can have serious consequences. People with *type I*, or insulin-dependent, diabetes mellitus, lack the insulin-secreting  $\beta$  cells and consequently produce no insulin. Treatment for these patients consists of insulin injections. (Because insulin is a peptide hormone, it would be digested if taken orally and must instead be injected subcutaneously.)

In the past, only insulin extracted from the pancreas of pigs or cattle was available, but today people with insulin-dependent diabetes can inject themselves with human insulin produced by genetically engineered bacteria. Active research on the possibility of transplanting islets of Langerhans holds much promise of a lasting treatment for these patients.

Most diabetic patients, however, have *type II*, or noninsulin-dependent, diabetes mellitus. They generally have normal or even above-normal levels of insulin in their blood, but their cells have a reduced sensitivity to insulin. These people may not require insulin injections and can often control their diabetes through diet and exercise. It is estimated that over 90% of the cases of diabetes in North America are type II. Worldwide at least 171 million suffer from diabetes, and it is expected that this number will grow. Type II diabetes is especially common in developed countries, and it has been suggested that there is a linkage between type II diabetes and obesity.

### Learning Outcomes Review 46.4

The major peripheral endocrine glands are the thyroid and parathyroid glands, the adrenal glands, and the pancreas. Calcium homeostasis results from the action of calcitonin, parathyroid hormone, and vitamin D. The adrenal glands produce stress hormones. Insulin and glucagon, antagonists from the pancreas, help maintain blood glucose at a normal level.

- Why does your body need two hormones to maintain blood sugar at a constant level?

## 46.5 Other Hormones and Their Effects

### Learning Outcomes

1. Characterize the role of sex steroids in development.
2. List nonendocrine sources of hormones.
3. Identify the insect hormones involved in molting and metamorphosis.

A variety of vertebrate and invertebrate processes are regulated by hormones and other chemical messengers, and in this section we review the most important ones.

## Sex steroids regulate reproductive development

The ovaries and testes in vertebrates are important endocrine glands, producing the sex steroid hormones, including estrogens, progesterone, and testosterone (to be described in detail in chapter 53). Estrogen and progesterone are the primary “female” sex steroids, and testosterone and its immediate derivatives are the primary “male” sex steroids, or androgens. Both types of hormone can be found in both sexes, however.

During embryonic development, testosterone production in the male embryo is critical for the development of male sex organs. In mammals, sex steroids are responsible for the development of secondary sexual characteristics at puberty. These characteristics include breasts in females, body hair, and increased muscle mass in males. Because of this latter effect, some athletes have misused androgens to increase muscle mass. Use of steroids for this purpose has been condemned by virtually all major sports organizations, and it can cause liver disorders as well as a number of other serious side effects.

In females, sex steroids are especially important in maintaining the sexual cycle. Estrogen and progesterone produced in the ovaries are critical regulators of the menstrual and ovarian cycles. During pregnancy, estrogen production in the placenta maintains the uterine lining, which protects and nourishes the developing embryo.

## Melatonin is crucial to circadian cycles

Another major endocrine gland is the pineal gland, located in the roof of the third ventricle of the brain in most vertebrates (see figure 44.22). It is about the size of a pea and is shaped like a pinecone, which gives it its name.

The pineal gland evolved from a medial light-sensitive eye (sometimes called a “third eye,” although it could not form images) at the top of the skull in primitive vertebrates. This pineal eye is still present in primitive fish (cyclostomes) and some modern reptiles. In other vertebrates, however, the

pineal gland is buried deep in the brain, and it functions as an endocrine gland by secreting the hormone melatonin.

Melatonin was named for its ability to cause blanching of the skin of lower vertebrates by reducing the dispersal of melanin granules. We now know, however, that it serves as an important timing signal delivered through the blood. Melatonin levels in the blood increase in darkness and fall during the daytime.

The secretion of melatonin is regulated by activity of the *suprachiasmatic nucleus (SCN)* of the hypothalamus. The SCN is known to function as the major biological clock in vertebrates, entraining (synchronizing) various body processes to a circadian rhythm—one that repeats every 24 hr. Through regulation by the SCN, the secretion of melatonin by the pineal gland is activated in the dark.

This daily cycling of melatonin release regulates sleep/wake and temperature cycles. Disruptions of these cycles, as occurs with jet lag or night shift work, can sometimes be minimized by melatonin administration. Melatonin also helps regulate reproductive cycles in some vertebrate species that have distinct breeding seasons.

## Some hormones are not produced by endocrine glands

A variety of hormones are secreted by organs that are not exclusively endocrine glands. The thymus is the site of T cell production in many vertebrates and T cell maturation in mammals. It also secretes a number of hormones that function in the regulation of the immune system.

The right atrium of the heart secretes *atrial natriuretic hormone*, which stimulates the kidneys to excrete salt and water in the urine. This hormone acts antagonistically to aldosterone, which promotes salt and water retention.

The kidneys secrete *erythropoietin*, a hormone that stimulates the bone marrow to produce red blood cells. Other organs, such as the liver, stomach, and small intestine, also secrete hormones, and as mentioned earlier, the skin secretes vitamin D.

**Figure 46.16** Hormonal control of metamorphosis in the silkworm moth, *Bombyx mori*. Molting hormone, ecdysone, controls when molting occurs. Brain hormone stimulates the prothoracic gland to produce ecdysone. Juvenile hormone determines the result of a particular molt. Juvenile hormone is produced by bodies near the brain called the corpora allata. High levels of juvenile hormone inhibit the formation of the pupa. Low levels of juvenile hormone are necessary for the pupal molt and metamorphosis.

## Insect hormones control molting and metamorphosis

Most invertebrate groups produce hormones as well; these control reproduction, growth, and color change. A dramatic action of hormones in insects is similar to the role of thyroid hormones in amphibian metamorphosis.

As insects grow during postembryonic development, their hardened exoskeletons do not expand. To overcome this problem, insects undergo a series of molts wherein they shed their old exoskeleton (figure 46.16) and secrete a new, larger one. In some insects, a juvenile insect, or larva, undergoes a radical transformation to the adult form during a single molt. This process is called metamorphosis.

Hormonal secretions influence both molting and metamorphosis in insects. Prior to molting, neurosecretory cells on the surface of the brain secrete a small peptide, **prothoracicotrophic hormone (PTTH)**, which in turn stimulates a gland in the thorax called the prothoracic gland to produce **molting hormone**, or **ecdysone** (see figure 46.16). High levels of ecdysone bring about the biochemical and behavioral changes that cause molting to occur.

Another pair of endocrine glands near the brain, called the *corpora allata*, produce a hormone called **juvenile hormone**. High levels of juvenile hormone prevent the transformation to the adult and result in a larval-to-larval molt. If the level of juvenile hormone is low, however, the molt will result in metamorphosis (figure 46.17).

## Cancer cells may alter hormone production or have altered hormonal responses

Hormones and paracrine secretions actively regulate growth and cell division. Normally, hormone production is kept under precise control, but malfunctions in signaling systems can sometimes occur. Unregulated hormone stimulation can then lead to serious physical consequences.

Tumors that develop in endocrine glands, such as the anterior pituitary or the thyroid, can produce excessive amounts of hormones, causing conditions such as gigantism or hyperthyroidism. Spontaneous mutations can damage receptors or intracellular signaling proteins, with the result that target cell responses are activated even in the absence of hormone stimulation. Mutations in growth factor receptors, for example, can activate excessive cell division, resulting in tumor formation. Some tumors that develop in steroid-responsive tissues, such as the breast and prostate, remain sensitive to hormone stimulation. Blocking steroid hormone production can therefore diminish tumor growth.

The important effects of hormones on development and differentiation are illustrated by the case of diethylstilbestrol (DES). DES is a synthetic estrogen that was given to pregnant women from 1940 to 1970 to prevent miscarriage. It was subsequently discovered that daughters who had been exposed to DES as fetuses had an elevated probability of developing a rare form of cervical cancer later in life. Developmental alterations elicited by hormone treatment may thus take many years to become apparent.

## SCIENTIFIC THINKING

**Hypothesis:** Juvenile hormone blocks or inhibits the stimulation of gene expression by ecdysone.

**Prediction:** Treatment of isolated imaginal discs with ecdysone plus increasing amounts of JH should show a decrease in ecdysone stimulated transcription.

**Test:** Discs dissected from late third instar *Drosophila* larvae are incubated in the presence of ecdysone, with and without JH. Incorporation of  $^3\text{H}$ -UTP into RNA was used as a measure of gene expression.

**Result:** The graph shows a relatively high incorporation of  $^3\text{H}$ -UTP in the presence of ecdysone alone. The addition of JH causes dose-dependent reduction of RNA synthesis.

**Conclusion:** JH inhibits the ecdysone-stimulated synthesis of RNA in imaginal discs.

**Further Experiments:** How else can this system with isolated imaginal discs be used to analyze metamorphosis?

**Figure 46.17** Effect of ecdysone and juvenile hormone on RNA synthesis in isolated *Drosophila* imaginal discs.

## Learning Outcomes Review 46.5

Testosterone causes an embryo to develop as a male; testosterone and estrogen produced at puberty are responsible for secondary sex characteristics. The female menstrual cycle is regulated by sex hormone balance. The thymus, the right atrium of the heart, and the kidneys secrete hormones although it is not their main function. In insects, molting hormone elicits molting, and low levels of juvenile hormone cause metamorphosis.

- **Atrial natriuretic hormone reduces blood volume; would this affect blood pressure?**

### 46.1 Regulation of Body Processes by Chemical Messengers

Hormones are signaling molecules carried by the blood and may have distant targets. Paracrine regulators act locally, and pheromones released into the environment communicate between individuals of the same species.

**Some molecules act as both circulating hormones and neurotransmitters.**

Norepinephrine is a neurotransmitter in the sympathetic nervous system and also is a hormone that is released into the blood by the adrenal glands.

**Endocrine glands produce three chemical classes of hormones.**

The three classes of endocrine hormones are peptides and proteins, such as TSH; amino acid derivatives, such as thyroxine; and steroids, such as estrogen and testosterone (see table 46.1).

**Hormones can be categorized as lipophilic or hydrophilic.**

Lipophilic hormones are fat-soluble and can cross the cell membrane; hydrophilic hormones are water-soluble and cannot cross membranes.

**Paracrine regulators exert powerful effects within tissues.**

Paracrine regulation occurs in most organs and among immune-system cells. Prostaglandins are involved in inflammation, and they are the target of NSAIDs.

### 46.2 Actions of Lipophilic Versus Hydrophilic Hormones

**Lipophilic hormones activate intracellular receptors.**

Circulating lipophilic hormones are carried in the blood bound to transport proteins (see figure 46.3). They pass through the plasma membrane and activate intracellular receptors. The hormone-receptor complex can bind to specific gene promoter regions termed hormone response elements to activate transcription.

**Hydrophilic hormones activate receptors on target cell membranes.**

Hydrophilic hormones bind to a membrane receptor to initiate a signal transduction pathway (see figure 46.6). Many receptors are kinases that phosphorylate proteins directly. Others are G protein-coupled receptors that activate a second-messenger system. Hydrophilic hormones tend to be short-lived, but lipophilic hormones tend to have effects of longer duration.

### 46.3 The Pituitary and Hypothalamus: The Body's Control Centers

**The pituitary is a compound endocrine gland.**

The anterior pituitary (adenohypophysis) is composed of glandular tissue derived from epithelial tissue; the posterior pituitary (neurohypophysis) is fibrous and is derived from neural tissue.

**The posterior pituitary stores and releases two neurohormones.**

The posterior pituitary contains axons from the hypothalamus that release neurohormones. One of these is ADH, involved in water reabsorption; the other is oxytocin.

**The anterior pituitary produces seven hormones.**

The hormones produced by the anterior pituitary include peptide, protein and glycoprotein hormones. These hormones tend to stimulate growth, and many are tropic hormones that stimulate other endocrine glands (see table 46.1).

**Hypothalamic neurohormones regulate the anterior pituitary.**

Releasing and inhibiting hormones produced in the hypothalamus pass to the anterior pituitary through a portal system and regulate the anterior pituitary's hormone production (see figure 46.8).

**Feedback from peripheral endocrine glands regulates anterior-pituitary hormones.**

The activity of the anterior pituitary is also regulated by negative feedback; for example, thyroxine, produced by the thyroid in response to TSH, inhibits further secretion of TSH (see figure 46.9).

**Hormones of the anterior pituitary work directly and indirectly.**

Three of the seven hormones, GH, prolactin, and MSH, work directly on nonendocrine tissues; the other four, ACTH, TSH, LH, and FSH, are tropic hormones that have endocrine glands as their targets. Defects in GH production can lead to either pituitary dwarfism (low), or gigantism (high).

### 46.4 The Major Peripheral Endocrine Glands

Some endocrine glands are controlled by tropic hormones of the pituitary, others are independent of pituitary control.

**The thyroid gland regulates basal metabolism and development.**

The thyroid hormones thyroxine and triiodothyronine regulate basal metabolism in vertebrates and trigger metamorphosis in amphibians (see figure 46.12).

**Calcium homeostasis is regulated by several hormones.**

Blood calcium is regulated by calcitonin, which lowers blood calcium levels, and parathyroid hormone, which raises blood calcium levels (see figure 46.13).

**The adrenal gland releases both catecholamine and steroid hormones.**

Catecholamines, epinephrine and norepinephrine, trigger “alarm” responses (see figure 46.14). Corticosteroids maintain glucose homeostasis and modulate some aspects of the immune response.

**Pancreatic hormones are primary regulators of carbohydrate metabolism.**

Blood glucose is controlled by antagonistic hormones. The pancreas secretes insulin, which reduces blood glucose, and glucagon, which raises blood glucose (see figure 46.15). Type I diabetes arises from loss of insulin-producing cells, and type II is a result of insulin insensitivity.

### 46.5 Other Hormones and Their Effects

**Sex steroids regulate reproductive development.**

Sex steroids regulate sexual development and reproduction. The ovaries primarily produce estrogen and progesterone, which are responsible for the menstrual cycle. The testes produce testosterone.

**Melatonin is crucial to circadian cycles.**

The pineal gland produces melatonin, which can control the dispersion of pigment granules and the daily wake-sleep cycles.

**Some hormones are not produced by endocrine glands.**

The thymus secretes hormones that regulate the immune system. The right atrium of the heart secretes atrial natriuretic hormone, which acts antagonistically to aldosterone. The skin manufactures and secretes vitamin D.

### ***Insect hormones control molting and metamorphosis.***

In insects the hormone ecdysone stimulates molting, and juvenile hormone levels control the nature of the molt. Metamorphosis requires high ecdysone and low juvenile hormone.

### ***Cancer cells may alter hormone production or have altered hormonal responses.***

Cancer developing from cells targeted by hormones, such as in the breast and prostate, may still be stimulated by those hormones.

## Review Questions

### UNDERSTAND

- Which of the following best describes hormones?
  - Hormones are relatively unstable and work only in the area adjacent to the gland that produced them.
  - Hormones are long-lasting chemicals released from glands.
  - All hormones are lipid-soluble.
  - Hormones are chemical messengers that are released into the environment.
- Steroid hormones
  - can diffuse through the membrane without a carrier.
  - have a direct effect on gene expression.
  - bind to membrane receptors.
  - both a and b
- Second messengers are activated in response to
  - steroid hormones.
  - thyroxine.
  - hydrophilic hormones.
  - all of these.
- Which of the following is true about lipophilic hormones?
  - They are freely soluble in the blood.
  - They require a transport protein in the bloodstream.
  - They cannot enter their target cells.
  - They are rapidly deactivated after binding to their receptors.
- An organ is classified as part of the endocrine system if it
  - produces cholesterol.
  - is capable of converting amino acids into hormones.
  - has intracellular receptors for hormones.
  - secretes hormones into the circulatory system.
- Hormones released from the pituitary gland have two different sources. Those that are produced by the neurons of the hypothalamus are released through the \_\_\_\_\_, and those produced within the pituitary are released through the \_\_\_\_\_.
  - thalamus; hippocampus
  - neurohypophysis; adenohypophysis
  - right pituitary; left pituitary
  - cortex; medulla
- Which of the following conditions is unrelated to the production of growth hormone?
  - Control of blood calcium
  - Pituitary dwarfism
  - Increased milk production in cows
  - Acromegaly

### APPLY

- You think one of your teammates is using anabolic steroids to build muscle. You know that continued use of steroids can cause profound changes in cell function. This is due in part to the fact that these hormones act
  - to regulate gene expression.
  - by activating second messengers.
  - as protein kinases.
  - via G protein-coupled receptors.
- Your Uncle Sal likes to party. When he goes out drinking, he complains that he needs to urinate more often. You explain to him that this is because alcohol suppresses the release of the hormone
  - thyroxine, which increases water reabsorption from the kidney.
  - thyroxine, which decreases water reabsorption from the kidney.
  - ADH, which decreases water reabsorption from the kidney.
  - ADH, which increases water reabsorption from the kidney.
- Your new research project is to design a pesticide that will disrupt the endocrine systems of arthropods without harming humans and other mammals. Which of the following substances should be the target of your investigations?
  - Insulin
  - ADH
  - Juvenile hormone
  - Cortisol
- Coat color in mammals is controlled by a hormone receptor called the melanocortin receptor. When this receptor is bound by the hormone MSH, pigment cells produce dark eumelanin. When the receptor is bound by an MSH antagonist that prevents MSH binding, pigment cells make yellow/red pheomelanin. In the Irish Setter, the overall red coat color could be due to a mutation in the
  - receptor that prevents the antagonist from binding.
  - receptor that prevents MSH from binding.
  - MSH protein such that it binds the receptor more efficiently.
  - antagonist such that it no longer binds to the receptor.
- Tumors that affect the pituitary can lead to decreases in some, but not all, hormones released by the pituitary. A patient with such a tumor exhibits fatigue, weight loss, and low blood sugar. This is probably due to lack of production of
  - GH, which leads to loss of muscle mass.
  - ACTH, which leads to loss of production of glucocorticoids.

- c. TSH, which leads to loss of production of thyroxin.
  - d. ADH, which leads to excess urine production.
6. You experience a longer period than normal between meals. Your body's response to this will be to produce
- a. insulin to raise your blood sugar.
  - b. glucagon to raise your blood sugar.
  - c. insulin to lower your blood sugar.
  - d. glucagon to lower your blood sugar.
7. Mild vitamin D deficiency can lead to osteoporosis, or reduced bone mineral density. This is thought to be due to an association with increased levels of
- a. calcitonin, which leads to an increase in serum  $\text{Ca}^{2+}$  and bone loss.
  - b. PTH, which leads to an increase in serum  $\text{Ca}^{2+}$  and bone loss.
  - c. ADH, which reduces blood pressure and leads to bone loss.
  - d. insulin, which leads to a decrease in blood glucose and bone loss.

### SYNTHESIZE

1. How can blocking hormone production decrease cancerous tumor growth?

2. Suppose that two different organs, such as the liver and heart, are sensitive to a particular hormone (such as epinephrine). The cells in both organs have identical receptors for the hormone, and hormone-receptor binding produces the same intracellular second messenger in both organs. However, the hormone produces different effects in the two organs. Explain how this can happen.
3. Many physiological parameters, such as blood  $\text{Ca}^{2+}$  concentration and blood glucose levels, are controlled by two hormones that have opposite effects. What is the advantage of achieving regulation in this manner instead of by using a single hormone that changes the parameters in one direction only?

Chapter **47**

# The Musculoskeletal System

## Chapter Outline

---

- 47.1** Types of Skeletal Systems
- 47.2** A Closer Look at Bone
- 47.3** Joints and Skeletal Movement
- 47.4** Muscle Contraction
- 47.5** Modes of Animal Locomotion

## Introduction

---

*The ability to move is so much a part of our daily lives that we tend to take it for granted. It is made possible by the combination of a semirigid skeletal system, joints that act as hinges, and a muscular system that can pull on this skeleton. Animal locomotion can be thought of as muscular action that produces a change in body shape, which places a force on the outside environment. When a race horse runs down the track, its legs move forward and backward. As its feet contact the ground, the force they exert move its body forward at a considerable speed. In a similar way, when a bird takes off into flight, its wings exert force on the air; a swimming fish's movements push against the water. In this chapter, we will examine the nature of the muscular and skeletal systems that allow animal movement.*

## 47.1 Types of Skeletal Systems

### Learning Outcomes

1. Compare hydrostatic skeletons, exoskeletons, and endoskeletons.
2. Explain how animals with hydrostatic skeletons move.

Muscles have to pull against something to produce the changes that cause movement. This necessary form of supporting structure is called a skeletal system. Zoologists commonly recognize three types of skeletal systems in animals: **hydrostatic skeletons**, **exoskeletons**, and **endoskeletons**.

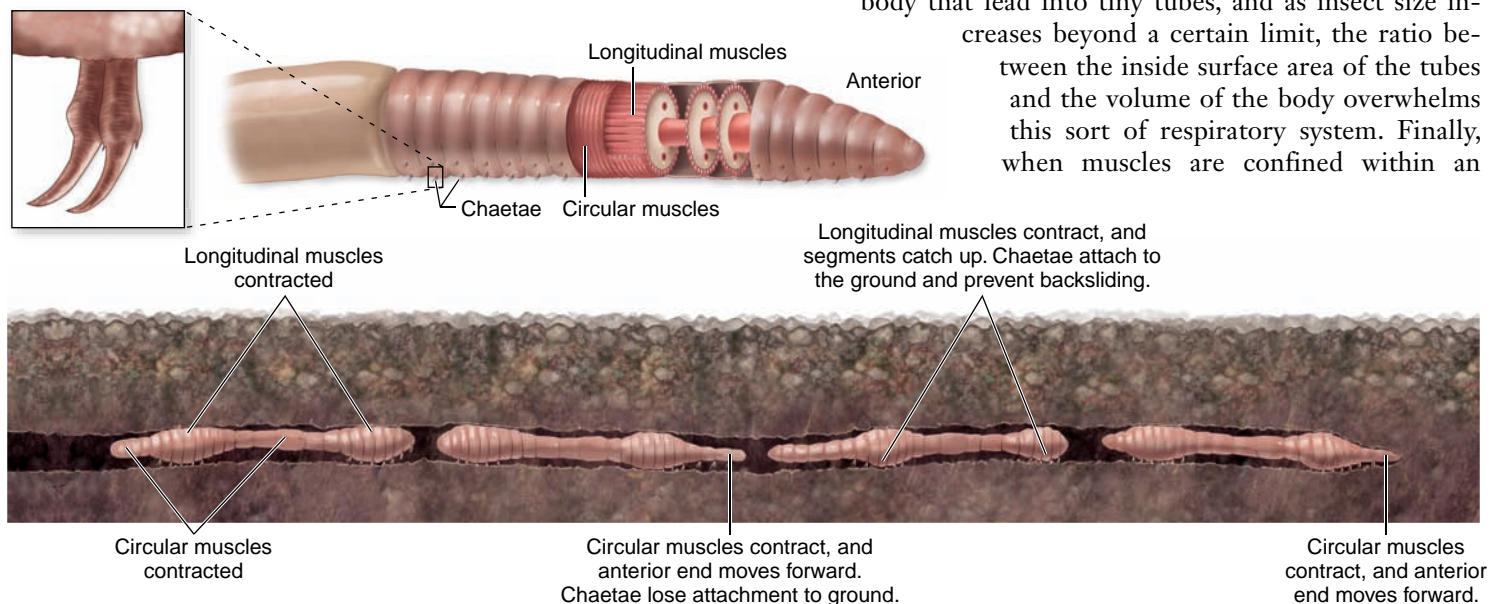

### Hydrostatic skeletons use water pressure inside a body wall

**Hydrostatic skeletons** are found primarily in soft-bodied terrestrial invertebrates, such as earthworms and slugs, and soft-bodied aquatic invertebrates, such as jellyfish, and squids.

### Musculoskeletal action in earthworms

In these animals a fluid-filled central cavity is encompassed by two sets of muscles in the body wall: circular muscles that are repeated in segments and run the length of the body, and longitudinal muscles that oppose the action of the circular muscles.

Muscles act on the fluid in the body's central space, which represents the hydrostatic skeleton. As locomotion begins (figure 47.1) the anterior circular muscles contract, pressing on

**Figure 47.1 Locomotion in earthworms.** The hydrostatic skeleton of the earthworm uses muscles to move fluid within the segmented body cavity, changing the shape of the animal. When circular muscles contract the pressure in the fluid rises. At the same time the longitudinal muscles relax, and the body becomes longer and thinner. When the longitudinal muscles contract and the circular muscles relax, the chaetae of the worm's lower surface extend to prevent backsliding. A wave of circular followed by longitudinal muscle contractions down the body produces forward movement.

the inner fluid, and forcing the front of the body to become thin as the body wall in this region extends forward.

On the underside of a worm's body are short, bristle-like structures called chaetae. When circular muscles act, the chaetae of that region are pulled up close to the body and lose contact with the ground. Circular-muscle activity is passed backward, segment by segment, to create a backward wave of contraction.

As this wave continues, the anterior circular muscles now relax, and the longitudinal muscles take over, thickening the front end of the worm and allowing the chaetae to protrude and regain contact with the ground. The chaetae now prevent that body section from slipping backward. This locomotion process proceeds as waves of circular muscle contraction are followed by waves of longitudinal muscle effects.

### Exoskeletons consist of a rigid outer covering

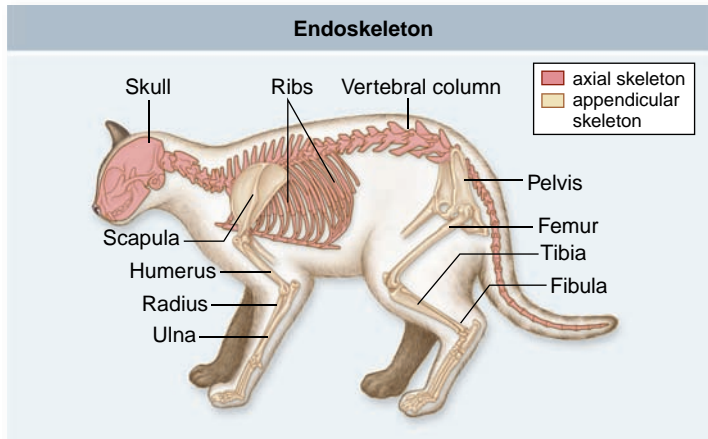

Exoskeletons are a rigid, hard case that surrounds the body. Arthropods, such as crustaceans and insects, have exoskeletons made of the polysaccharide *chitin* (figure 47.2a). As you learned in earlier chapters, chitin is found in the cell walls of fungi and some protists as well as in the exoskeletons of arthropods.

A chitinous exoskeleton resists bending and thus acts as the skeletal framework of the body; it also protects the internal organs and provides attachment sites for the muscles, which lie inside the exoskeletal casing. But in order to grow, the animal must periodically molt, shedding the exoskeleton (see chapter 34). The animal is vulnerable to predation until the new (slightly larger) exoskeleton forms. Molting crabs and lobsters often hide until the process is completed.

Exoskeletons have other limitations. The chitinous framework is not as strong as a bony, internal one. This fact by itself would set a limit for insect size, but there is a more important factor: Insects breathe through openings in their body that lead into tiny tubes, and as insect size increases beyond a certain limit, the ratio between the inside surface area of the tubes and the volume of the body overwhelms this sort of respiratory system. Finally, when muscles are confined within an

a.

b.

**Figure 47.2 Exoskeleton and endoskeleton.**

a. The hard, tough outer covering of an arthropod, such as this grasshopper, is its exoskeleton and is composed of chitin.

b. Vertebrates, such as this cat, have endoskeletons formed of bone and cartilage. Some of the major bony features are labeled.

exoskeleton, they cannot enlarge in size and power with increased use, as they can in animals with endoskeletons.

## Endoskeletons are composed of hard, internal structures

**Endoskeletons**, found in vertebrates and echinoderms, are rigid internal skeletons that form the body's framework and offer surfaces for muscle attachment. Echinoderms, such as sea urchins and sand dollars, have skeletons made of calcite, a crystalline form of calcium carbonate. This calcium compound is different from that in bone, which is based on calcium phosphate.

### Vertebrate skeletal tissues

The vertebrate endoskeleton (figure 47.2b) includes fibrous dense connective tissue along with the more rigid special connective tissues, cartilage or bone (see chapter 43). Cartilage is strong and slightly flexible, a characteristic important in such functions as padding the ends of bones where they come together in a joint. Although some large, active animals such as sharks have totally cartilaginous skeletons, bone is the main component in vertebrate skeletons. Bone is much stronger than cartilage and much less flexible.

Unlike chitin, both cartilage and bone are living tissues. Bone, particularly, can have high metabolic activity,

especially if bone cells are present throughout the matrix, a common condition. Bone, and to some extent cartilage, can change and remodel itself in response to injury or to physical stresses.

### Learning Outcomes Review 47.1

With a hydrostatic skeleton, muscle contraction puts pressure on the fluid inside the body, forcing the body to extend. Opposing muscles then shorten the body to draw the animal forward. Invertebrate exoskeletons consist of hard chitin; they must be shed and renewed (molting) for the animal to grow. Endoskeletons are composed of fibrous dense connective tissue along with cartilage or mineralized bone.

- **What limitations does an exoskeleton impose on terrestrial invertebrates?**

## 47.2 A Closer Look at Bone

### Learning Outcomes

1. Compare intramembranous and endochondral development.
2. Describe how growth occurs in epiphyses.
3. Explain how bone remodeling occurs.

Bone is a hard but resilient tissue that is unique to vertebrate animals. This connective tissue first appeared over 520 MYA and is now found in all vertebrates except cartilaginous fishes (see chapter 35).

## Bones can be classified by two modes of development

Bone tissue itself can be of several types classified in a few different ways. The most common system is based on the way in which bone develops.

### Intramembranous development

In intramembranous development, bones form within a layer of connective tissue. Many of the flat bones that make up the exterior of the skull and jaw are intramembranous.

Typically, the site of the intramembranous bone-to-be begins in a designated region in the dermis of the skin. During embryonic development, the dermis is formed largely of **mesenchyme**—a loose tissue consisting of undifferentiated mesenchyme cells and other cells that have arisen from them—along with collagen fibers. Some of the undifferentiated mesenchyme cells differentiate to become specialized cells called **osteoblasts** (figure 47.3). These osteoblasts arrange themselves along the collagenous fibers and begin to secrete the enzyme alkaline phosphatase, which causes calcium phosphate salts to form in a crystalline configuration called *hydroxyapatite*. The crystals merge along the fibers to encase them.

**Figure 47.3 Cells involved in bone development.** The lineage of cell types involved in bone formation is depicted beginning with undifferentiated mesenchyme cells, which give rise to a variety of cell types with distinct functions. Fibroblasts produce collagen, chondroblasts form cartilage and become chondrocytes (the cartilage cells), and osteoblasts are bone-forming cells. When an osteoblast becomes trapped in the bone matrix it is constructing, it becomes an osteocyte, or bone cell. The osteocyte is shown with a section of bone with Haversian systems and osteocytes between their lamellae. Osteocytes reside in spaces called lacunae. Small canals (canaliculi) radiate out from the central lacunar space, which contains the arms of the osteocyte. Osteoclasts, bone-removing cells, are not derived from mesenchyme cells but are formed by fusion of monocytes, a type of white blood cell.

The crystals give the bone its hardness, but without the resilience afforded by collagen's stretching ability, bone would be rigid but dangerously brittle. Typical bones have roughly equal volumes of collagen and hydroxyapatite, but hydroxyapatite contributes about 65% to the bone's weight.

As the osteoblasts continue to make bone crystals, some become trapped in the bone matrix and undergo dramatic changes in shape and function, now becoming cells called osteocytes (see figure 47.3). They lie in tight spaces within the bone matrix called lacunae. Little canals extending from the lacunae, called **canaliculi**, permit contact of the starburst-like extensions of each osteocyte with those of its neighbors (see figure 47.3). In this way, many cells within bones can participate in intercellular communication.

As an intramembranous bone grows, it requires alterations of shape. Imagine that you were modeling with clay, and you wanted to take a tiny clay bowl and make it larger. Simply putting more clay on the outside would not work; you would need to remove clay from the inside to increase the bowl's capacity as well. As bone grows, it must also undergo a remodeling process, with matrix being added in some regions and removed in others. This is where osteoclasts come in. These unusual cells are formed from the fusion of monocytes, a type of white blood cell, to form large multinucleate cells. Their function is to break down the bone matrix.

### Endochondral development

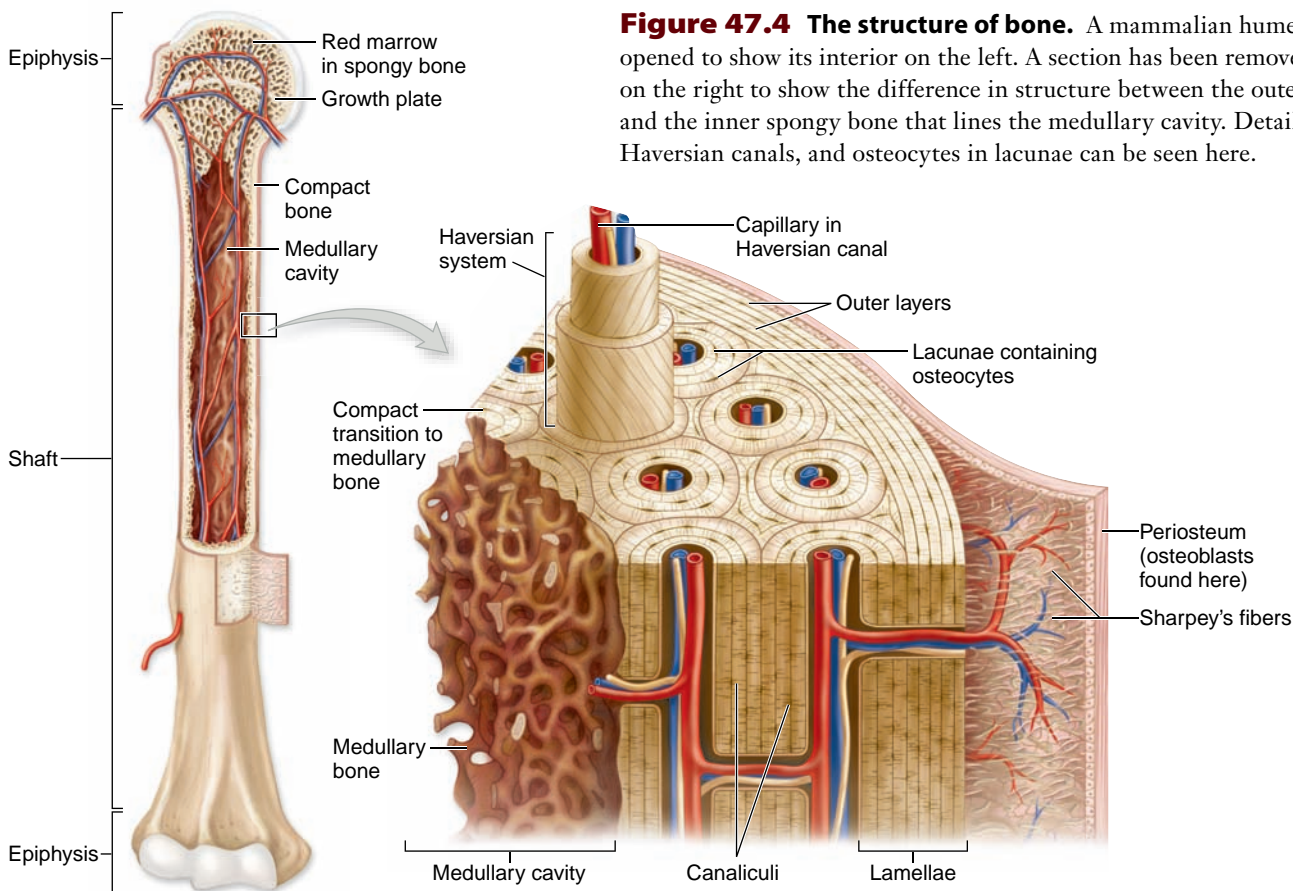

Bones that form through endochondral development are typically those that are deeper in the body and form its architectural framework. Examples include vertebrae, ribs, bones of the shoulder and pelvis, long bones of the limbs, and the most

internal of the skull bones. Endochondral bones begin as tiny, cartilaginous models that have the rough shape of the bones that eventually will be formed. Bone development of this kind consists of adding bone to the outside of the cartilaginous model, while replacing the interior cartilage with bone.

Bone added to the outside of the model is produced in the fibrous sheath that envelops the cartilage. This sheath is tough and made of collagen fibers, but it also contains undifferentiated mesenchyme cells. Osteoblasts arise and sort themselves out along the fibers in the deepest part of the sheath. Bone is then formed between the sheath and the cartilaginous matrix. This process is somewhat similar to what occurs in the dermis in the production of intramembranous bone.

As the outer bone is formed, the interior cartilage begins to calcify. The calcium source for this process seems to be the cartilage cells themselves. As calcification continues, the inner cartilaginous tissue breaks down into pieces of debris. Blood vessels from the sheath, now called the periosteum, force their way through the outer bony jacket, thus entering the interior of the cartilaginous model, and cart off the debris. Again, trapped osteoblasts transform into osteocytes, and osteoclasts for bone remodeling arise from cell fusions in the same manner as occurs in intramembranous bone. Growth in bone thickness occurs by adding additional bone layers just beneath the periosteum.

Endochondral bones increase in length in a different way, unlike growth in intramembranous development. As an example, consider a long bone such as a mammalian humerus (in humans, the upper arm bone). Like many limb bones, it is formed of a slender shaft with widened ends, called **epiphyses** (figure 47.4).

**Figure 47.4 The structure of bone.** A mammalian humerus is partly opened to show its interior on the left. A section has been removed and magnified on the right to show the difference in structure between the outer compact bone and the inner spongy bone that lines the medullary cavity. Details of basic layers, Haversian canals, and osteocytes in lacunae can be seen here.

Within the epiphyses are the *epiphyseal growth plates* that separate the epiphyses from the shaft itself. As long as the bone is growing in length, these growth plates are composed of cartilage (see figure 47.4). The actual events taking place in the plates are not simple, but they can be simply summarized.

1. During growth of a long bone, the cartilage of the growth plates is actively growing in the lengthwise direction to thicken the plate.
2. This growth pushes the epiphysis farther away from the slender shaft portion, which effectively increases the length of the bone.
3. At the same time, from the shaft's side, a process of cartilage calcification encroaches on the cartilaginous growth plate, so that the bony portion of the shaft elongates.

As long as the rate of new cartilage thickening stays ahead of the creeping calcification, the bone continues to grow in length. Eventually the cartilaginous expansion slows and is overtaken by the calcification, which obliterates this region of growth.

Growth in length usually ceases in humans by late adolescence. Although growth of the bone length is curtailed at this time, growth in width is not. The diameter of the shaft can be enhanced by bone addition just beneath the periosteum throughout an individual's life.

### Bone structure may include blood vessels and nerves

Developing bone often has an internal blood supply, which is especially evident in endochondral bones. The internal blood routes, however, do not necessarily remain after the bones have completed development. In most mammals the endochondral bones retain internal blood vessels and are called **vascular bones**. Vascular bone is also found in many reptiles and a few amphibians. *Cellular bones* contain osteocytes, and many such bones are also vascular. This bone remains metabolically active (see figure 47.4).

In fishes and birds, bones are **avascular**. Typically avascular bone does not contain osteocytes and is termed *acellular bone*. This type of bone is fairly inert except for its surface, where the periosteum with its mesenchyme cells is capable of repairing the bone.

Many bones, particularly the endochondral long bones, contain a central cavity termed the *medullary cavity*. In many vertebrates, the medullary cavity houses the bone marrow, important in the manufacture of red and white blood cells. In such cases this cavity is termed the **marrow cavity**. Not all medullary cavities contain marrow, however. Light-boned birds, for example, have huge interior cavities, but they are empty of marrow. Birds depend on stem cells in other body locations to produce red blood cells.

Bone lining the medullary cavities differs from the smooth, dense bone found closer to the outer surface. Based on density and texture, bone falls into three categories: the outer dense **compact bone**, the **medullary bone** that lines the internal cavity, and **spongy bone** that has a honeycomb structure and typically forms the epiphyses inside a thick shell of compact bone. Both compact and spongy bone contribute to a bone's strength. Medullary cavities are lined with thin tissues called the **endosteum**, which contains no

collagenous fibers but does possess other constituents including mesenchyme cells.

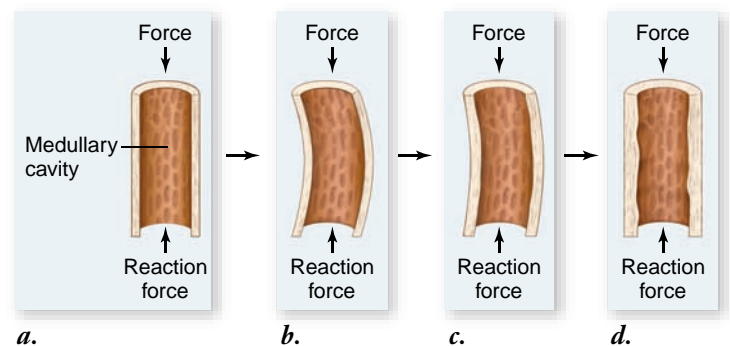

Vascular bone usually has a special internal organization called the **Haversian system**. Beneath the outer basic layers, endochondral bone is constructed of concentric layers called *Haversian lamellae*. These concentric tubes are laid down around narrow channels called *Haversian canals* that run parallel to the length of the bone. Haversian canals may contain nerve fibers but always contain blood vessels that keep the osteocytes alive even though they are entombed in the bony matrix.

The small vessels within the canals include both arterioles and venules or capillaries, and they connect to larger vessels that extend internally from both the periosteum and endosteum and that run in canals perpendicular to the Haversian canals.

### Bone remodeling allows bone to respond to use or disuse

It is easy to think of bones as being inert, especially since we rarely encounter them except as the skeletons of dead animals. But just as muscles, skin, and other body tissues may change depending on the stresses of the environment, bone also is a dynamic tissue that can change with demands made on it.

Mechanical stresses such as compression at joints, the forces of muscles on certain portions and features of a bone, and similar effects may all be remodeling factors that not only shape the bone during its embryonic development, but after birth as well. Depending on the directions and magnitudes of forces impinging on a bone, it may thicken; the size and shape of surface features to which muscles, tendons, or ligaments attach may change in size and shape; even the direction of the tiny bony struts that make up spongy bone may be altered.

**Figure 47.5 Model of stress and remodeling in a long bone.** This figure shows a diagrammatic section of a long bone, such as a leg bone. The section is placed under a load or force, which causes a reaction force from the ground the leg is standing upon. *a.* Under a mild compressive load the bone does not bend. *b.* If the load is large enough, and the bone is not sufficiently thick, the bone will bend (the bending shown is exaggerated for clarity). *c.* Osteoblasts are signaled by the stresses in the bending section to produce additional bone. As the bone becomes thicker, the degree of bending is reduced. *d.* When sufficient bone is added to prevent significant bending, the production of new osteoblasts stops and no more bone is added.

Exercise and frequent use of muscles for a particular task change more than just the muscles; blood vessels and fibrous connective tissue increase, and the skeletal frame becomes more robust through bone thickening and enhancement.

The phenomenon of remodeling is known for all bones, but it is easiest to demonstrate in a long bone. Small forces may not have much of an effect on the bone, but larger ones—if frequent enough—can initiate remodeling (figure 47.5). In the example shown, larger compressive forces may tend to bend a bone, even if the bend is imperceptible to the eye. This bending stress promotes bone formation that thickens the bone. As the bone becomes thicker the amount of bending is reduced (figure 47.5c). Further bone addition produces sufficient bone thickness to entirely prevent significant bending (figure 47.5d). Once this point has been attained, the bone addition stops. This is another example of a negative-feedback system.

The effect of remodeling can be seen by examining bone thickness in rodents forced to exercise. The continual stresses placed on the limb bones cause additional bone to be deposited, leading to thicker and stronger bone (figure 47.6).

This phenomenon also has important medical implications. Osteoporosis, which is characterized by a loss of bone mineral density, is a debilitating and potentially life-threatening ailment that afflicts more than 25 million people in the United States, affecting primarily postmenopausal women, but also those suffering from malnutrition and a number of diseases. One treatment is a regimen of weight-lifting to stimulate bone deposition and thus counter the effects of osteoporosis.

### SCIENTIFIC THINKING

**Hypothesis:** Bone remodeling strengthens bones in response to external pressures.

**Prediction:** Bones that are used in more strenuous activities will deposit more bone and become stronger.

**Test:** Provide laboratory mice with an exercise wheel and make sure they run for several hours a day; keep a control group without a wheel.

Mouse with exercise wheel

Mouse without exercise wheel

**Result:** After 10 weeks, the running mice developed thicker limb bones.

**Further Experiments:** Modern microelectronics allow the development of stress sensors small enough to implant on the limb bone of a mouse. With such sensors, experiments can quantify how much stress different activities place on a bone and can more accurately investigate the relationship between the direction and magnitude of forces placed on a bone and the extent to which the bone remodels.

**Figure 47.6** The effect of exercise on bone remodeling.

### Learning Outcomes Review 47.2

Intramembranous bone forms within a layer of connective tissue; endochondral bone originates with a cartilaginous model that is then replaced with bone tissue. Epiphyses are cartilaginous growth plates of endochondral bones. As the epiphyseal cartilage becomes calcified, bone growth ceases. Bone remodeling occurs in response to repeated stresses on bones from weight or muscle use, allowing bones to adapt.

- Why is vitamin D especially important for children and the elderly?

## 47.3 Joints and Skeletal Movement

### Learning Outcomes

1. Define the different types of joints.
2. Explain how muscles produce movement at joints.
3. Describe how antagonistic muscles work at a joint.

Movements of the endoskeleton are powered by the skeletal musculature. The skeletal movements that respond to muscle action occur at **joints**, or articulations, where one bone meets another.

### Moveable joints have different ranges of motion, depending on type

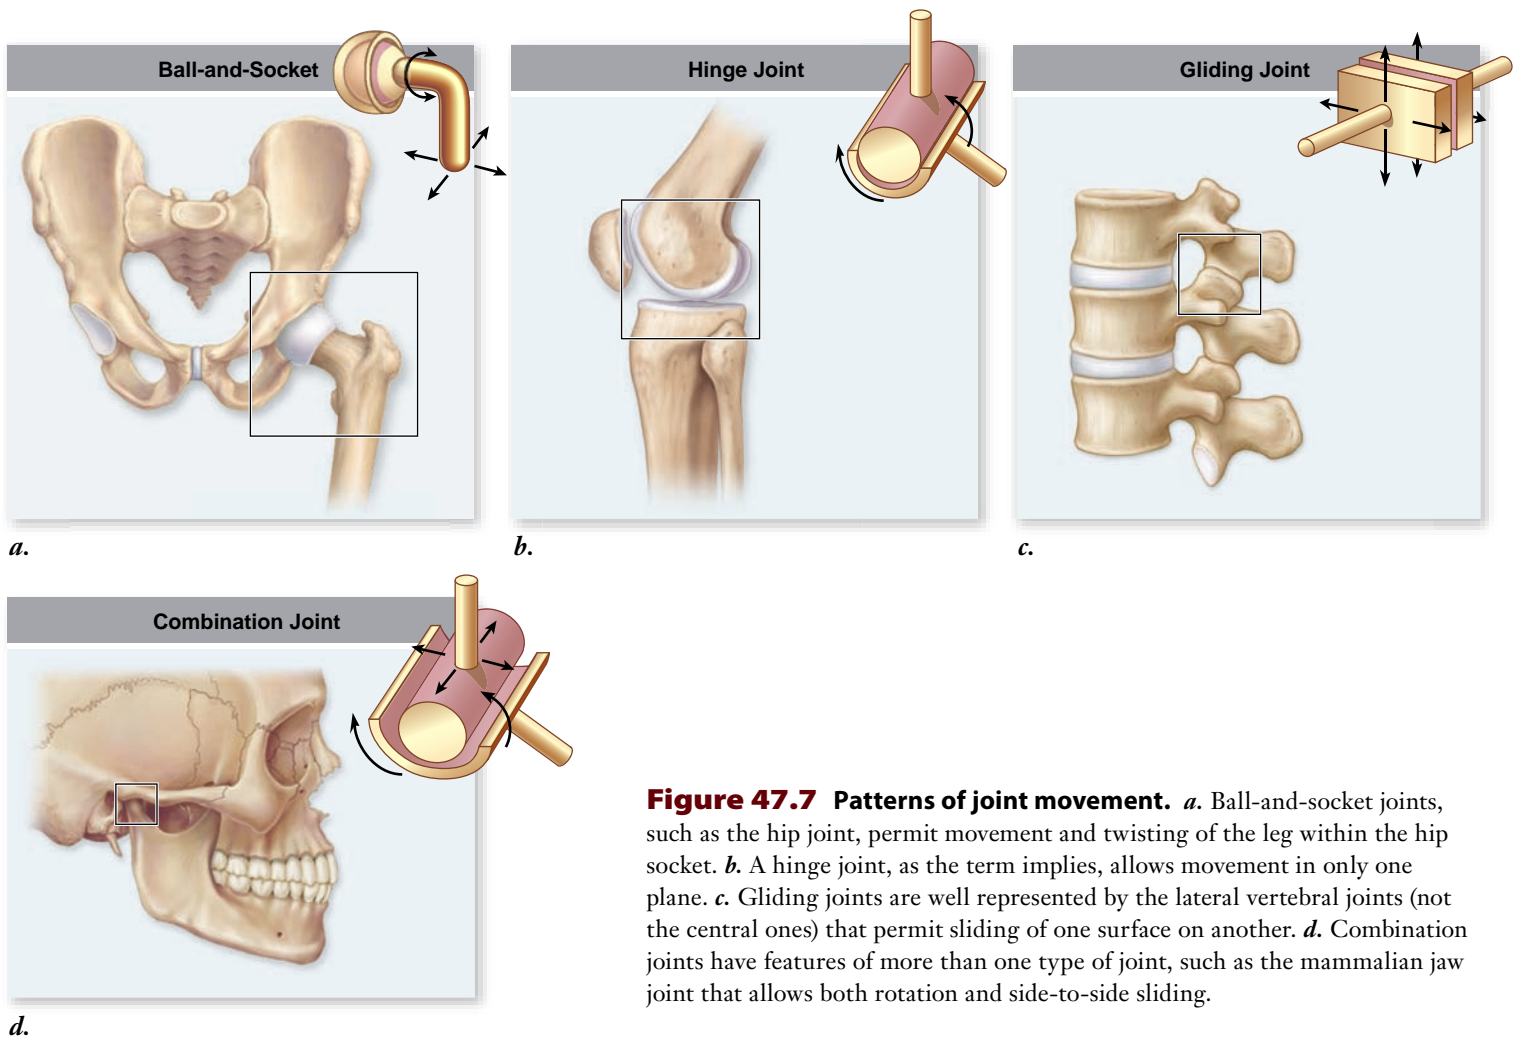

Each movable joint within the skeleton has a characteristic range of motion. Four basic joint movement patterns can be distinguished: *ball-and-socket*, *hinge*, *gliding*, and *combination*.

**Ball-and-socket joints** are like those of the hip, where the upper leg bone forms a ball fitting into a socket in the pelvis. This type of joint can perform universal movement in all directions, plus twisting of the ball (figure 47.7a).

The simplest type of joint is the **hinge joint**, such as the knee, where movement of the lower leg is restricted to rotate forward or backward, but not side to side (figure 47.7b).

**Gliding joints** can be found in the skulls of a number of nonmammalian vertebrates, but are also present between the lateral vertebral projections in many of them and in mammals as well (figure 47.7c). The vertebral projections are paired and extend from the front and back of each vertebra. The projections in front are a little lower, and each can slip along the undersurface of the posterior projection from the vertebra just ahead of it. This sliding joint gives stability to the vertebral column while allowing some flexibility of movement between vertebrae.

**Combination joints** are, as you might suppose, those that have movement characteristics of two or more joint types. The typical mammalian jaw joint is a good example.

**Figure 47.7** Patterns of joint movement. *a.* Ball-and-socket joints, such as the hip joint, permit movement and twisting of the leg within the hip socket. *b.* A hinge joint, as the term implies, allows movement in only one plane. *c.* Gliding joints are well represented by the lateral vertebral joints (not the central ones) that permit sliding of one surface on another. *d.* Combination joints have features of more than one type of joint, such as the mammalian jaw joint that allows both rotation and side-to-side sliding.

Most mammals chew food into small pieces. To chew food well, the lower jaw needs to move from side to side to get the best contact between upper and lower teeth. The lower jaw can also slip forward and backward to some extent. At the same time, the jaw joint must be shaped to allow the hinge-like opening and closing of the mouth. The mammalian joint conformation thus combines features from hinge and gliding joints (figure 47.7*d*).

### Skeletal muscles pull on bones to produce movement at joints

Skeletal muscles produce movement of the skeleton when they contract. Usually, the two ends of a skeletal muscle are attached to different bones, although some may be attached to other structures, such as skin. There are two means of bone attachment: Muscle fibers may connect directly to the periosteum, the bone's fibrous covering, or sheets of muscle may be connected to bone by a dense connective tissue strap or cord, called a *tendon* that attaches to the periosteum (figure 47.8).

One attachment of the muscle, the origin, remains relatively stationary during a contraction. The other end, the insertion, is attached to a bone that moves when the muscle

contracts. For example, contraction of the quadriceps muscles of the leg causes the lower leg to rotate forward relative to the upper leg section.

Typically, muscles are arranged so that any movement produced by one muscle can be reversed by another. The leg flexor muscles, called hamstrings (see figure 47.8), draw the lower leg back and upward, bending the knee. Its movement is countered by the quadriceps muscles. The important concept is that two muscles or muscle groups can be mutually antagonistic, with the action of one countered by the action of the other.

#### Learning Outcomes Review 47.3

Types of joints include ball-and-socket, hinge, gliding, and combination joints. Muscles, positioned across joints, cause movement of bones relative to each other by contracting and exerting pulling force. Antagonistic muscles oppose each other, a key feature since muscles can only contract and cannot push.

- *In what ways does a bony endoskeleton overcome the limitations of an exoskeleton for terrestrial life forms?*

**Figure 47.8 Flexor and extensor muscles of the leg.** Antagonistic muscles act in opposite ways. In humans, the hamstrings, a group of three muscles, cause the lower leg to move backward relative to the upper leg, whereas the quadriceps, a group of four muscles, pull the lower leg forward.

### Inquiry question

- ? Would the antagonistic muscles work in the same way in the legs of an animal with an exoskeleton, such as the grasshopper in figure 47.2?

## 47.4 Muscle Contraction

### Learning Outcomes

1. Explain the sliding filament mechanism of muscle contraction.
2. Describe the role of calcium in muscle contraction.
3. Differentiate between slow-twitch and fast-twitch muscle fibers.

This section concentrates on the skeletal muscle of vertebrates. Vertebrate muscle has enjoyed the most attention and is thus the best understood of animal muscular func-

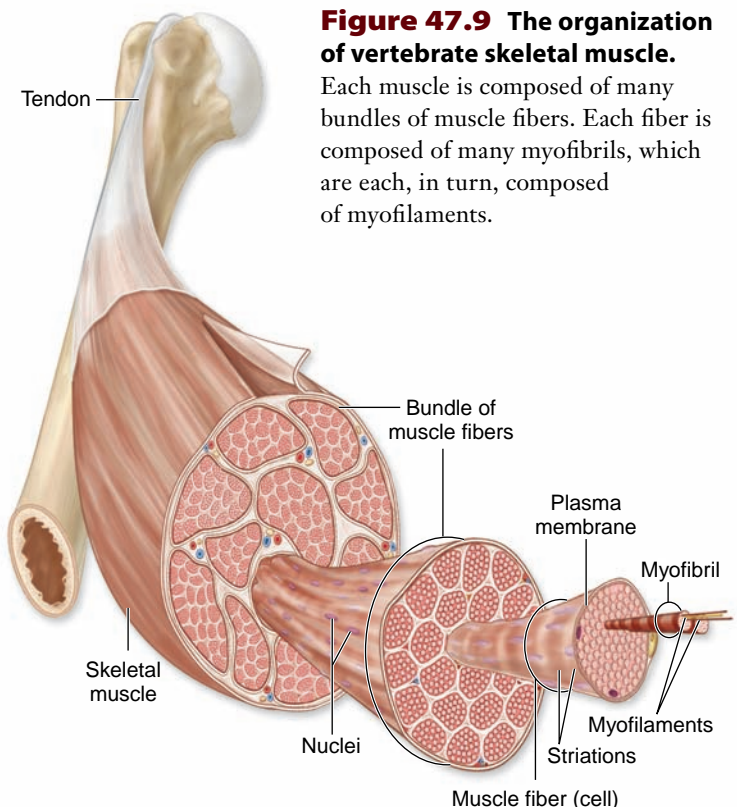

tion. Each skeletal muscle contains numerous muscle fibers, as described in chapter 43. Each muscle fiber encloses a bundle of 4 to 20 elongated structures called **myofibrils**. Each myofibril, in turn, is composed of thick and thin **myofilaments** (figure 47.9).

Under a microscope, the myofibrils have alternating dark and light bands, which give skeletal muscle fiber its striped appearance. The thick myofilaments are stacked together to produce the dark bands, called *A bands*; the thin filaments alone are found in the light bands, or *I bands*.

Each I band in a myofibril is divided in half by a disk of protein called a *Z line* because of its appearance in electron micrographs. The thin filaments are anchored to these disks. In an electron micrograph of a myofibril (figure 47.10), the structure of the myofibril can be seen to repeat from Z line to Z line. This repeating structure, called a **sarcomere**, is the smallest subunit of muscle contraction.

### Muscle fibers contract as overlapping filaments slide together

The thin filaments overlap with thick filaments on each side of an A band, but in a resting muscle, they do not project all the way to the center of the A band. As a result, the center of an A band (called an *H band*) is lighter than the areas on each side, which have interdigitating thick and thin filaments. This appearance of the sarcomeres changes when the muscle contracts.

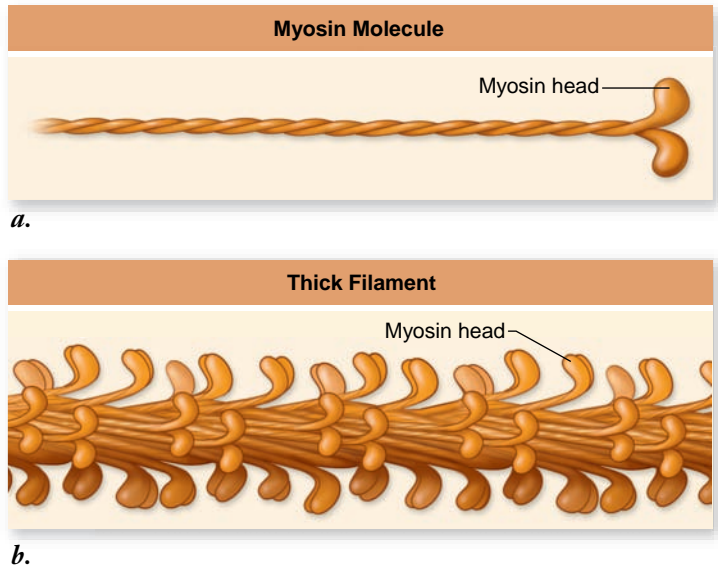

**Figure 47.9 The organization of vertebrate skeletal muscle.**

Each muscle is composed of many bundles of muscle fibers. Each fiber is composed of many myofibrils, which are each, in turn, composed of myofilaments.

**Figure 47.10 The structure of sarcomeres in relaxed and contracted muscles.** Two sarcomeres are shown in micrographs and as drawings of thick and thin filaments. The Z lines form the borders of each sarcomere and the A bands represent thick filaments. The thin filaments are within the I bands and extend into the A bands interdigitated with thick filaments. The H band is the lighter-appearing central region of the A band containing only thick filaments. The muscle on the top is shown relaxed. In the contracted muscle in the bottom, the Z lines have moved closer together, with the I bands and H bands becoming shorter. The A band does not change in size as it contains the thick filaments, which do not change in length.

A muscle contracts and shortens because its myofibrils contract and shorten. When this occurs, the myofilaments do *not* shorten; instead, the thick and thin myofilaments slide relative to each other (see figure 47.10). The thin filaments slide deeper into the A bands, making the H bands narrower until, at maximal shortening, they disappear entirely. This also makes

**Figure 47.11 Thick filaments are composed of myosin.** *a.* Each myosin molecule consists of two polypeptide chains shaped like golf clubs and wrapped around each other; at the end of each chain is a globular region referred to as the “head.” *b.* Thick filaments consist of myosin molecules combined into bundles from which the heads protrude at regular intervals.

the I bands narrower, as the Z lines are brought closer together. This is the sliding filament mechanism of contraction.

### The sliding filament mechanism

Electron micrographs reveal cross-bridges that extend from the thick to the thin filaments, suggesting a mechanism that might cause the filaments to slide. To understand how this is accomplished requires examining the thick and thin filaments at a molecular level. Biochemical studies show that each thick filament is composed of many subunits of the protein myosin packed together. The myosin protein consists of two subunits, each shaped like a golf club with a head region that protrudes from a long filament, with the filaments twisted together. Thick filaments are composed of many copies of myosin arranged with heads protruding from along the length of the fiber (figure 47.11). The myosin heads form the cross-bridges seen in electron micrographs.

Each thin filament consists primarily of many globular actin proteins arranged into two fibers twisted into a double helix (figure 47.12). If we were able to see a sarcomere at the molecular level, it would have the structure depicted in figure 47.13.

**Figure 47.12 Thin filaments are composed of globular actin proteins.** Two rows of actin proteins are twisted together in a helix to produce the thin filaments. Other proteins, tropomyosin and troponin, associate with the strands of actin and are involved in muscle contraction. These other proteins are discussed later in the chapter.

a.

b.

**Figure 47.13** The interaction of thick and thin filaments in striated muscle sarcomeres. *a.* The heads on the two ends of the thick filaments are oriented in opposite directions so that the cross-bridges pull the thin filaments and the Z lines on each side of the sarcomere toward the center. *b.* This sliding of the filaments produces muscle contraction.

Myosin is a member of the class of protein called *motor proteins* that are able to convert the chemical energy in ATP into mechanical energy (see chapter 4). This occurs by a series of events called the cross-bridge cycle (figure 47.14). When the myosin heads hydrolyze ATP into ADP and  $P_i$ , the conformation of myosin is changed, activating it for the later power stroke. The ADP and  $P_i$  both remain attached to the myosin head, keeping it in this activated conformation. The analogy to a mousetrap, set and ready to spring, is often made to describe this action. In this set position, the myosin head can bind to actin, forming cross-bridges. When a myosin head binds to actin, it releases the  $P_i$  and undergoes another conformational change, pulling the thin filament toward the center of the sarcomere in the *power stroke*, at which point it loses the ADP (see figures 47.13*b*, 47.14). At the end of the power stroke, the myosin head binds to a new molecule of ATP, which displaces it from actin. This cross-bridge cycle repeats as long as the muscle is stimulated to contract. This sequence of events can be thought of like pulling a rope hand-over-hand. The myosin heads are the hands and the actin fibers the rope.

In death, the cell can no longer produce ATP, and therefore the cross-bridges cannot be broken—causing the muscle stiffness of death called *rigor mortis*. A living cell, however, always has enough ATP to allow the myosin heads to detach from actin. How, then, is the cross-bridge cycle arrested so that the muscle can relax? We discuss the regulation of contraction and relaxation next.

**Figure 47.14** The cross-bridge cycle in muscle contraction.

*a.* Hydrolysis of ATP by myosin causes a conformational change that moves the head into an energized state. The ADP and  $P_i$  remain bound to the myosin head, which can bind to actin. *b.* Myosin binds to actin forming a cross-bridge. *c.* During the power stroke, myosin returns to its original conformation, releasing ADP and  $P_i$ . *d.* ATP binds to the myosin head breaking the cross-bridge. ATP hydrolysis returns the myosin head to its energized conformation, allowing the cycle to begin again.

**Figure 47.15** How calcium controls striated muscle contraction. *a.* When the muscle is at rest, a long filament of the protein tropomyosin blocks the myosin-binding sites on the actin molecule. Because myosin is unable to form cross-bridges with actin at these sites, muscle contraction cannot occur. *b.* When  $\text{Ca}^{2+}$  binds to another protein, troponin, the  $\text{Ca}^{2+}$ -troponin complex displaces tropomyosin and exposes the myosin-binding sites on actin, permitting cross-bridges to form and contraction to occur.

## Contraction depends on calcium ion release following a nerve impulse

When a muscle is relaxed, its myosin heads are in the activated conformation bound to ADP and  $\text{P}_i$ , but they are unable to bind to actin. In the relaxed state, the attachment sites for the myosin heads on the actin are physically blocked by another protein, known as **tropomyosin**, in the thin filaments. Cross-bridges therefore cannot form and the filaments cannot slide.

For contraction to occur, the tropomyosin must be moved out of the way so that the myosin heads can bind to the uncovered actin-binding sites. This requires the action of **troponin**, a regulatory protein complex that holds tropomyosin and actin together. The regulatory interactions between troponin and tropomyosin are controlled by the calcium ion ( $\text{Ca}^{2+}$ ) concentration of the muscle fiber cytoplasm.

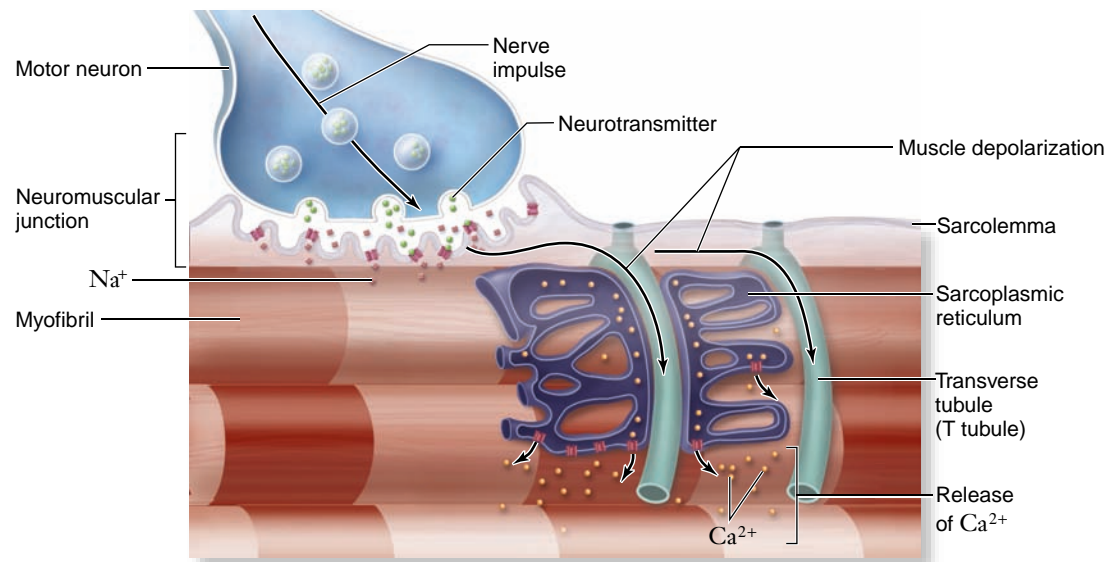

When the  $\text{Ca}^{2+}$  concentration of the cytoplasm is low, tropomyosin inhibits cross-bridge formation (figure 47.15*a*). When the  $\text{Ca}^{2+}$  concentration is raised,  $\text{Ca}^{2+}$  binds to tro-

ponin, altering its conformation and shifting the troponin-tropomyosin complex. This shift in conformation exposes the myosin-binding sites on the actin. Cross-bridges can thus form, undergo power strokes, and produce muscle contraction (figure 47.15*b*).

Muscles need a reliable supply of  $\text{Ca}^{2+}$ . Muscle fibers store  $\text{Ca}^{2+}$  in a modified endoplasmic reticulum called a **sarcoplasmic reticulum (SR)** (figure 47.16). When a muscle fiber is stimulated to contract, the membrane of the muscle fiber becomes depolarized. This is transmitted deep into the muscle fiber by invaginations of the cell membrane called the **transverse tubules (T tubules)**. Depolarization of the T tubules causes  $\text{Ca}^{2+}$  channels in the SR to open, releasing  $\text{Ca}^{2+}$  into the cytosol.  $\text{Ca}^{2+}$  then diffuses into the myofibrils, where it binds to troponin, altering its conformation and allowing contraction. The involvement of  $\text{Ca}^{2+}$  in muscle contraction is called **excitation-contraction coupling** because it is the release of  $\text{Ca}^{2+}$  that links the excitation of the muscle fiber by the motor neuron to the contraction of the muscle.

## Figure 47.16 Relationship between the myofibrils, transverse tubules, and sarcoplasmic reticulum.

Neurotransmitter released at a neuromuscular junction binds chemically gated  $\text{Na}^+$  channels, causing the muscle cell membrane to depolarize. This depolarization is conducted along the muscle cell membrane and down the transverse tubules to stimulate the release of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum.  $\text{Ca}^{2+}$  diffuses through the cytoplasm to myofibrils, causing contraction.

## Nerve impulses from motor neurons

Muscles are stimulated to contract by motor neurons. The motor neurons that stimulate skeletal muscles are called *somatic motor neurons*. The axon of a somatic motor neuron extends from the neuron cell body and branches to make synapses with a number of muscle fibers. These synapses between neurons and muscle cells are called *neuromuscular junctions* (see figure 47.16). One axon can stimulate many muscle fibers, and in some animals, a muscle fiber may be innervated by more than one motor neuron. However, in humans, each muscle fiber has only a single synapse with a branch of one axon.

When a somatic motor neuron delivers electrochemical impulses, it stimulates contraction of the muscle fibers it innervates (makes synapses with) through the following events:

1. The motor neuron, at the neuromuscular junction, releases the neurotransmitter acetylcholine (ACh). ACh binds to receptors in the muscle cell membrane to open  $\text{Na}^+$  channels. The influx of  $\text{Na}^+$  ions depolarizes the muscle cell membrane.
2. The impulses spread along the membrane of the muscle fiber and are carried into the muscle fibers through the T tubules.
3. The T tubules conduct the impulses toward the sarcoplasmic reticulum, opening  $\text{Ca}^{2+}$  channels and releasing  $\text{Ca}^{2+}$ . The  $\text{Ca}^{2+}$  binds to troponin, exposing the myosin-binding sites on the actin myofilaments and stimulating muscle contraction.

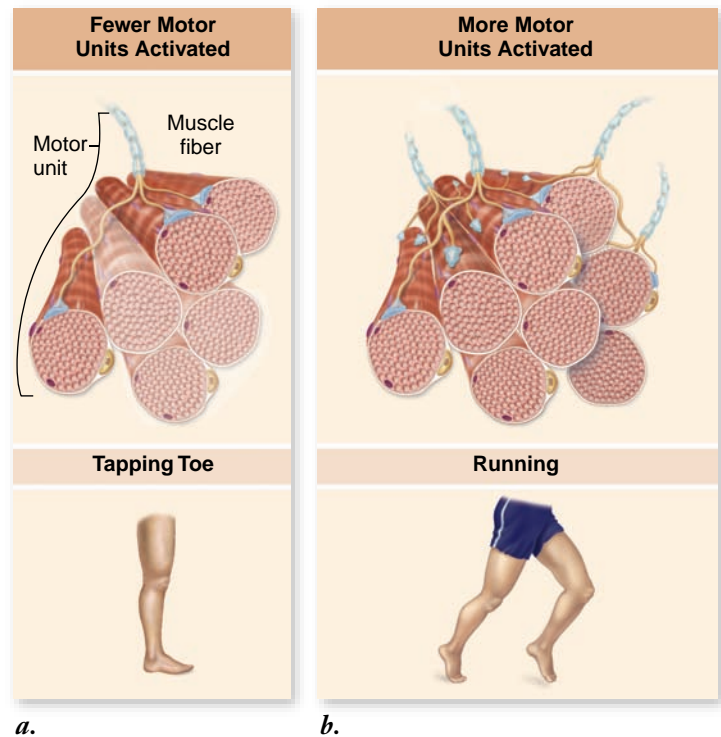

When impulses from the motor neuron cease, it stops releasing ACh, in turn stopping the production of impulses in the muscle fiber. Another membrane protein in the SR then uses energy from ATP hydrolysis to pump  $\text{Ca}^{2+}$  back into the SR by active transport. Troponin is no longer bound to  $\text{Ca}^{2+}$ , so tropomyosin returns to its inhibitory position, allowing the muscle to relax.

## Motor units and recruitment

A single muscle fiber can produce variable tension depending on the frequency of stimulation. The response of an entire muscle depends on the number of individual fibers involved and their degree of tension. The set of muscle fibers innervated by all the axonal branches of a motor neuron, plus the motor neuron itself, is defined as a **motor unit** (figure 47.17).

Every time the motor neuron produces impulses, all muscle fibers in that motor unit contract together. The division of the muscle into motor units allows the muscle's strength of contraction to be finely graded, a requirement for coordinated movements. Muscles that require a finer degree of control, such as those that move the eyes, have smaller motor units (fewer muscle fibers per neuron). Muscles that require less precise control but must exert more force, such as the large muscles of the legs, have more fibers per motor neuron.

Most muscles contain motor units in a variety of sizes, and these can be selectively activated by the nervous system. The weakest contractions of a muscle involve activation of a few small motor units. If a slightly stronger contraction is necessary, additional small motor units are also activated. The initial increments of increased force are therefore relatively small. As ever greater forces are required, more units and larger units are brought into action, and the force increments become larger.

a.

b.

### Figure 47.17 The number and size of motor units.

A motor unit consists of a motor neuron and all of the muscle fibers it innervates. *a.* Precise muscle contractions require smaller motor units. *b.* Large muscle movements require larger motor units. The more motor units activated, the stronger the contraction.

This cumulative increase of numbers and sizes of motor units to produce a stronger contraction is termed **recruitment**.

## The two main types of muscle fibers are slow-twitch and fast-twitch

An isolated skeletal muscle can be studied by stimulating it artificially with electric shocks. A muscle stimulated with a single electric shock quickly contracts and relaxes in a response called a twitch. Increasing the stimulus voltage increases the strength of the twitch up to a maximum. If a second electric shock is delivered immediately after the first, it produces a second twitch that may partially “ride piggyback” on the first. This cumulative response is called summation (figure 47.18).

An increasing frequency of electric shocks shortens the relaxation time between successive twitches as the strength of contraction increases. Finally, at a particular frequency of stimulation, no visible relaxation occurs between successive twitches. Contraction is smooth and sustained, as it is during normal muscle contraction in the body. This sustained contraction is called **tetanus**. (The disease known as tetanus gets its name because the muscles of its victims go into an agonizing state of contraction.)

Skeletal muscle fibers can be divided on the basis of their contraction speed into *slow-twitch*, or *type I, fibers* and *fast-twitch*, or *type II, fibers*. The muscles that move the eyes, for example, have a high proportion of fast-twitch fibers and reach maximum tension in about 7.3 milliseconds (msec); the soleus muscle in the leg, by contrast, has a high proportion

**Figure 47.18 Summation.** Muscle twitches summate to produce a sustained, tetanic contraction. This pattern is produced when the muscle is stimulated electrically or naturally by neurons. Tetanus, a smooth, sustained contraction, is the normal type of muscle contraction in the body.

### Inquiry question

? What determines the maximum amplitude of a summated muscle contraction?

of slow-twitch fibers and requires about 100 msec to reach maximum tension (figure 47.19).

### Slow-twitch fibers

**Slow-twitch fibers** have a rich capillary supply, numerous mitochondria and aerobic respiratory enzymes, and a high concentration of **myoglobin** pigment. Myoglobin is a red pigment similar to the hemoglobin in red blood cells, but its higher affinity for oxygen improves the delivery of oxygen to the slow-

**Figure 47.19 Skeletal muscles have different proportions of fast-twitch and slow-twitch fibers.**

The muscles that move the eye contain mostly fast-twitch fibers, whereas the deep muscle of the leg (the soleus) contains mostly slow-twitch fibers. The calf muscle (gastrocnemius) is intermediate in its composition.

### Inquiry question

? How would you determine if the calf muscle contains a mix of fast-twitch and slow-twitch fibers, or instead is composed of an intermediate form of fiber?

twitch fibers. Because of their high myoglobin content, slow-twitch fibers are also called *red fibers*. These fibers can sustain action for a long period of time without fatigue.

### Fast-twitch fibers

The thicker **fast-twitch fibers** have fewer capillaries and mitochondria than slow-twitch fibers and not as much myoglobin; hence, these fibers are also called *white fibers*. Fast-twitch fibers can respire anaerobically by using a large store of glycogen and high concentrations of glycolytic enzymes. The “dark meat” and “white meat” found in chicken and turkey consists of muscles with primarily red and white fibers, respectively. Fast-twitch fibers are adapted for the rapid generation of power and can grow thicker and stronger in response to weight training; however, they lack the endurance characteristics of slow-twitch fibers.

In addition to the type I and type II fibers, human muscles have an intermediate form of fibers that are fast-twitch, but they also have a high oxidative capacity and so are more resistant to fatigue. Endurance training increases the proportion of these fibers in muscles.

In general, human sprinters tend to have more fast-twitch fibers, whereas long-distance runners have more slow-twitch fibers. These differences are paralleled in the animal world. Comparisons of closely related species that differ in their lifestyles show that species that rely on short, high-speed movements to capture prey or evade predators tend to have more fast-twitch fibers, whereas closely related species that move more slowly, but for longer periods of time, have more slow-twitch fibers.

### Muscle metabolism changes with the demands made on it

Skeletal muscles at rest obtain most of their energy from the aerobic respiration of fatty acids (see chapter 7). During use of the muscle, such as during exercise, muscle stores of glycogen and glucose delivered by the blood are also used as energy sources. The energy obtained by cellular respiration is used to make ATP, which is needed for the movement of the cross-bridges during muscle contraction and the pumping of  $\text{Ca}^{2+}$  back into the sarcoplasmic reticulum during muscle relaxation.

Skeletal muscles respire anaerobically for the first 45 to 90 sec of moderate-to-heavy exercise because the cardiopulmonary system requires this amount of time to increase the oxygen supply to the muscles. If exercise is not overly strenuous, aerobic respiration then contributes the major portion of the skeletal muscle energy requirements following the first 2 min of exercise. However, more vigorous exercise may require more ATP than can be provided by aerobic respiration, in which case anaerobic respiration continues to provide ATP as well.

Whether exercise is light, moderate, or intense for a particular individual depends on that person’s maximal capacity for aerobic exercise. The maximum rate of oxygen consumption in the body is called the *aerobic capacity*. In general, individuals in better condition have greater aerobic capacity and thus can sustain higher levels of aerobic exercise for longer periods without having to also use anaerobic respiration.

## Physical training increases aerobic capacity and muscle strength

**Muscle fatigue** refers to the use-dependent decrease in the ability of a muscle to generate force. Fatigue is highly variable and can arise from a number of causes. The intensity of contraction as well as duration of contraction are involved. In addition, fatigue is affected by cellular metabolism: aerobic or anaerobic. In the case of short-duration maximal exertion, fatigue was long thought to be caused by a buildup of lactic acid (from anaerobic metabolism). More recent data also implicate a buildup in inorganic phosphate ( $P_i$ ) from the breakdown of creatine phosphate, which also occurs during anaerobic metabolism. In longer term, lower intensity exertion, fatigue appears to result from depletion of glycogen.

Because the depletion of muscle glycogen places a limit on exercise, any adaptation that spares muscle glycogen will improve physical endurance. Trained athletes have an increased proportion of energy derived from the aerobic respiration of fatty acids, resulting in a slower depletion of their muscle glycogen reserve. Athletes also have greater muscle vascularization, which facilitates both oxygen delivery and lactic acid removal. Because the aerobic capacity of endurance-trained athletes is higher than that of untrained people, athletes can perform for longer and put forth more effort before muscle fatigue occurs.

Endurance training does not increase muscle size. Muscle enlargement is produced only by frequent periods of high-intensity exercise in which muscles work against high resistance, as in weight lifting. Resistance training increases the thickness of type II (fast-twitch) muscle fibers, causing skeletal muscles to grow by hypertrophy (increased cell size) rather than by cell division and an increased number of cells.

### Learning Outcomes Review 47.4

Sliding of myofilaments within muscle myofibrils is responsible for contraction; it involves the motor protein myosin, which forms cross-bridges on actin fibers. The process of shortening is controlled by  $Ca^{2+}$  ions released from the sarcoplasmic reticulum. The  $Ca^{2+}$  binds to troponin, making myosin-binding sites in actin available. Slow-twitch fibers can sustain activity for a longer period of time; fast-twitch fibers use glycogen for rapid generation of power.

- What advantages do increased myoglobin and mitochondria confer on slow-twitch fibers?

## 47.5 Modes of Animal Locomotion

### Learning Outcomes

1. Describe how friction and gravity affect locomotion.
2. Discuss how lift is created by wings.
3. Explain how evolution has shaped structures used for locomotion.

Animals are unique among multicellular organisms in their ability to move actively from one place to another. Locomotion requires both a propulsive mechanism and a control mechanism. There are a wide variety of propulsive mechanisms, most involving contracting muscles to generate the necessary force. Ultimately, it is the nervous system that activates and coordinates the muscles used in locomotion. In large animals, active locomotion is almost always produced by appendages that oscillate—*appendicular locomotion*—or by bodies that undulate, pulse, or undergo peristaltic waves—*axial locomotion*.

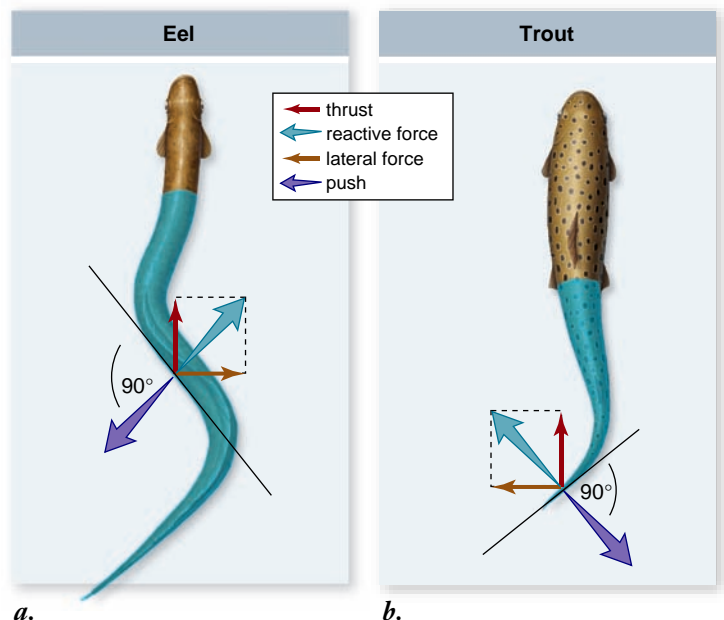

Although animal locomotion occurs in many different forms, the general principles remain much the same in all groups. The physical constraints to movement—gravity and friction—are the same in every environment, differing only in degree.

### Swimmers must contend with friction when moving through water

For swimming animals, the buoyancy of water reduces the effect of gravity. As a result, the primary force retarding forward movement is frictional drag, so body shape is important in reducing the force needed to push through the water.

Some marine invertebrates move about using hydraulic propulsion. For example, scallops clap the two sides of their shells together forcefully, and squids and octopuses squirt water like a marine jet, as described in chapter 34.

In contrast, many invertebrates and all aquatic vertebrates swim. Swimming involves pushing against the water with some part of the body. At one extreme, eels and sea snakes swim by sinuous undulations of the entire body (figure 47.20*a*). The undulating body waves of eel-like swimming are created by waves of muscle contraction alternating between the left and right axial musculature. As each body segment in turn pushes against the water, the moving wave forces the eel forward.

**Figure 47.20** Movements of swimming fishes. *a*. An eel pushes against the water with its whole body, whereas (*b*) a trout pushes only with its posterior half.

Other types of fish use similar mechanics as the eel but generate most of their propulsion from the posterior part of the body using the caudal (rear) fin (figure 47.20*b*). This also allows considerable specialization in the front end of the body without sacrificing propulsive force. Reptiles, such as alligators, swim in the same manner using undulations of the tail.

Whales and other marine mammals such as sea lions have evolutionarily returned to an aquatic lifestyle (see figure 21.12) and have convergently evolved a similar form of locomotion. Like fish, marine mammals also swim using undulating body waves. However, unlike any of the fishes, the waves pass from top to bottom and not from side to side. This difference illustrates how past evolutionary history can shape subsequent evolutionary change. The mammalian vertebral column is structured differently from that of fish in a way that stiffens the spine and allows little side-to-side flexibility. For this reason, when the ancestor of whales reentered aquatic habitats, they evolved adaptations for swimming that used dorsoventral (top-to-bottom) flexing.

Many terrestrial tetrapod vertebrates are able to swim, usually through movement of their limbs. Most birds that swim, such as ducks and geese, propel themselves through the water by pushing against it with their hind legs, which typically have webbed feet. Frogs and most aquatic mammals also swim with their hind legs and have webbed feet. Tetrapod vertebrates that swim with their forelegs usually have these limbs modified as flippers and “fly” through the water using motions very similar to those used by aerial fliers; examples include sea turtles, penguins, and fur seals.

## Terrestrial locomotion must deal primarily with gravity

Air is a much less dense medium than water, and thus the frictional forces countering movement on land are much less than those in water. Instead, countering the force of gravity is the biggest challenge for nonaquatic organisms, which either must move on land or fly through the air.

The three great groups of terrestrial animals—mollusks, arthropods, and vertebrates—each move over land in different ways.

Mollusk locomotion is much slower than that of the other groups. Snails, slugs, and other terrestrial mollusks secrete a path of mucus that they glide along, pushing with a muscular foot.

Only vertebrates and arthropods (insects, spiders, and crustaceans) have developed a means of rapid surface locomotion. In both groups, the body is raised above the ground and moved forward by pushing against the ground with a series of jointed appendages, the legs.

Although animals may walk on only two legs or more than 100, the

same general principles guide terrestrial locomotion. Because legs must provide support as well as propulsion, it is important that the sequence of their movements not shove the body’s center of gravity outside the legs’ zone of support, unless the duration of such imbalance is short. Otherwise, the animal will fall. The need to maintain stability determines the sequence of leg movements, which are similar in vertebrates and arthropods.

The apparent differences in the walking gaits of these two groups reflect the differences in leg number. Vertebrates walk on two or four legs; all arthropods have six or more limbs. Although the many legs of arthropods increase stability during locomotion, they also appear to reduce the maximum speed that can be attained.

The basic walking pattern of quadrupeds, from salamanders to most mammals, is left hind leg, right foreleg, right hind leg, left foreleg. The highest running speeds of quadruped mammals, such as the gallop of a horse, may involve the animal being supported by only one leg, or even none at all. This is because mammals have evolved changes in the structure of both their axial and appendicular skeleton that permit running by a series of leaps.

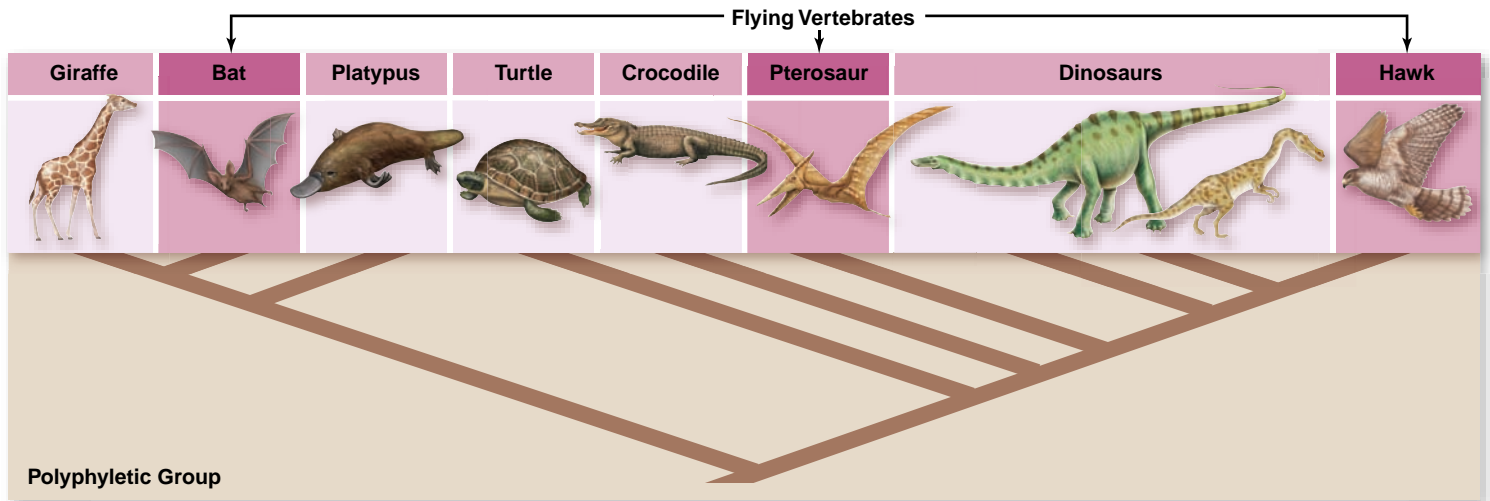

Vertebrates such as kangaroos, rabbits, and frogs are effective leapers (figure 47.21). However, insects are the true Olympians of the leaping world. Many insects, such as grasshoppers, have enormous leg muscles, and some small insects can jump to heights more than 100 times the length of their body!

## Flying uses air for support

The evolution of flight is a classic example of convergent evolution, having occurred independently four times, once in insects and three times among vertebrates (figure 47.22*a*). All three vertebrate fliers modified the forelimb into a wing structure, but they did so in different ways, illustrating how natural selection can sometimes build similar structures through different evolutionary pathways (figure 47.22*b*). In both birds and pterosaurs (an extinct group of reptiles that flourished alongside

**Figure 47.21** Animals that hop or leap use their rear legs to propel themselves through the air. The powerful leg muscles of this frog allow it to explode from a crouched position to a takeoff in about 100 msec.

**b.**

**Figure 47.22 Convergent evolution of wings in vertebrates.** Wings evolved independently in birds, bats and pterosaurs, in each case by elongation of different elements of the forelimb.

the dinosaurs), the wing is built on a single support, but in birds it is elongation of the radius, ulna, and wrist bones, whereas in pterosaurs it is an elongation of the fourth finger bone. By contrast, in bats the wing is supported by multiple bones, each of which is an elongated finger bone. A second difference is that the wings of pterosaurs and bats are composed of a membrane formed from skin, whereas birds use feathers, which are modified from reptile scales.

In all groups, active flying takes place in much the same way. Propulsion is achieved by pushing down against the air with wings. This alone provides enough lift to keep insects in the air. Vertebrates, being larger, need greater lift, obtaining it with wings whose upper surface is more convex (in cross section) than the lower. Because air travels farther over the top surface, it moves faster. A fluid, like air, decreases its internal pressure the faster it moves. Thus, there is a lower pressure on top of the wing and higher pressure on the bottom of the wing. This is the same principle used by airplane wings.

In birds and most insects, the raising and lowering of the wings is achieved by the alternate contraction of extensor muscles (elevators) and flexor muscles (depressors). Four insect orders (including those containing flies, mosquitoes, wasps, bees, and beetles) beat their wings at frequencies ranging from 100 to more than 1000 times per second, faster than nerves can carry successive impulses!

In these insects, the flight muscles are not attached to the wings at all, but rather to the stiff wall of the thorax, which

is distorted in and out by their contraction. The reason these muscles can contract so fast is that the contraction of one muscle set stretches the other set, triggering its contraction in turn without waiting for the arrival of a nerve impulse.

In addition to active flight, many species have evolved adaptations—primarily flaps of skin that increase surface area and thus slow down the rate of descent—to enhance their ability to glide long distances. Gliders have done this in many ways, including flaps of skin along the body in flying squirrels, snakes, and lizards; webbing between the toes in frogs; and the evolution in some lizards of ribs that extend beyond the body wall and that are connected by skin that can be spread out to form a large gliding surface.

### Learning Outcomes Review 47.5

Locomotion involves friction and pressure created by body parts, often appendages, against water, air, or ground. Walking, running, and flying require supporting the body against gravity's pull. Flight is achieved when a pressure difference between air flowing over the top and bottom of a wing creates lift. Solutions to locomotion have evolved convergently many times, in both homologous and nonhomologous structures.

- In what ways would locomotion by a series of leaps be more advantageous than by alternation of legs?

### 47.1 Types of Skeletal Systems

#### **Hydrostatic skeletons use water pressure inside a body wall.**

By muscular contractions, earthworms press fluid into different parts of the body, causing them to move (see figure 47.1).

#### **Exoskeletons consist of a rigid outer covering.**

The exoskeleton, composed of hard chitin, must be shed for the organism to grow (see figure 47.2a).

#### **Endoskeletons are composed of hard, internal structures.**

Endoskeletons of vertebrates are living connective tissues that may be mineralized with calcium phosphate (see figure 47.2b).

### 47.2 A Closer Look at Bone

#### **Bones can be classified by two modes of development.**

In intramembranous development, bone forms within a layer of connective tissue (see figure 47.3). In endochondral development, bone fills in a cartilaginous model.

Osteoblasts initiate bone development; osteocytes form from osteoblasts; and osteoclasts break down and resorb bone.

Bones grow by lengthening and widening. Cartilage remaining after development of the epiphyses serves as a pad between bone surfaces (see figure 47.4).

#### **Bone structure may include blood vessels and nerves.**

In birds and fishes, bone is avascular and basically acellular. In other vertebrates, bone contains bone cells, blood capillaries, and nerves collected in Haversian systems.

#### **Bone remodeling allows bone to respond to use or disuse.**

Bone structure may thicken or thin depending on use and on forces impinging on the bone (see figure 47.5).

### 47.3 Joints and Skeletal Movement

#### **Moveable joints have different ranges of motion, depending on type.**

Ball-and-socket joints can perform movement in all directions; hinge joints have restricted movement; gliding joints slide, providing stability and flexibility; and combination joints allow rotation and sliding (see figure 47.7).

#### **Skeletal muscles pull on bones to produce movement at joints.**

Muscles attach to the periosteum directly or through a tendon. Skeletal muscles occur in antagonistic pairs that oppose each other's movement (see figure 47.8).

### 47.4 Muscle Contraction

#### **Muscle fibers contract as overlapping filaments slide together.**

The different myofibril bands seen microscopically result from the degree of overlap of actin and myosin filaments (see figure 47.10). Muscle

contraction occurs when actin and myosin filaments form cross-bridges and slide relative to each other.

The globular head of myosin forms a cross-bridge with actin when ATP is hydrolyzed to ADP and  $P_i$ . Upon bridging, it pulls the thin filament toward the center of the sarcomere. The head then binds to a new ATP, releasing from actin (see figure 47.14).

#### **Contraction depends on calcium ion release following a nerve impulse.**

Tropomyosin, attached to actin by troponin, blocks formation of a cross-bridge. Nerve stimulation releases calcium from the sarcoplasmic reticulum into the cytosol, and formation of a troponin–calcium complex displaces tropomyosin, allowing cross-bridges to form (see figures 47.15, 47.16).

Motor units are composed of a single motor neuron and all the muscle fibers innervated by its branches (see figure 47.17).

#### **The two main types of muscle fibers are slow-twitch and fast-twitch.**

A twitch is the interval between contraction and relaxation of a single muscle stimulation. Summation occurs when a second twitch “piggybacks” on the first twitch. Tetanus is the state when no relaxation occurs between twitches (see figure 47.18).

The two major types of skeletal muscle fibers are slow-twitch fibers (endurance), and fast-twitch fibers (power bursts).

#### **Muscle metabolism changes with the demands made on it.**

At rest skeletal muscles obtain energy by metabolism of fatty acids. When active, energy comes from glucose and glycogen.

Muscle fatigue is a use-dependent decrease in the ability of the muscle to generate force.

Endurance training does not increase muscle size; high-intensity exercise with resistance increases the size of the muscle (hypertrophy).

### 47.5 Modes of Animal Locomotion

#### **Swimmers must contend with friction when moving through water.**

Among vertebrates, aquatic locomotion occurs by pushing some or all of the body against the water. Many vertebrates undulate the body or tail for propulsion, but others use their limbs (see figure 47.20).

#### **Terrestrial locomotion must deal primarily with gravity.**

Most terrestrial animals move by lifting their bodies off the ground and pushing against the ground with appendages. Terrestrial animals that walk or run use fundamentally the same mechanisms during locomotion.

#### **Flying uses air for support.**

Propulsion is accomplished as wings push down against the air. Lift in larger organisms is created by a pressure difference as air flows above and below a convex wing.

In both flying and gliding, convergent evolution has produced the same outcome through different evolutionary pathways.

## Review Questions

### UNDERSTAND

- Exoskeletons and endoskeletons differ in that
  - an exoskeleton is rigid, and an endoskeleton is flexible.
  - endoskeletons are found only in vertebrates.
  - exoskeletons are composed of calcium, and endoskeletons are built from chitin.
  - exoskeletons are external to the soft tissues, and endoskeletons are internal.
- Worms use a hydrostatic skeleton to generate movement. How do they do this?
  - Their bones are filled with water, which provides the weight of the skeleton.
  - The change in body structure is caused by contraction of muscles compressing the watery body fluid.
  - The muscles contain water vacuoles, which, when filled, provide a rigid internal structure.
  - The term *hydrostatic* simply refers to moist environment. They generate movement just as arthropods do.
- You take X-rays of two individuals. Ray has been a weight lifter and body builder for 30 years; Ben has led a mostly sedentary life. What differences would you expect in their X-rays?
  - No difference, they would both have thicker bones than a younger person due to natural thickening with age.
  - No difference, lifestyle does not affect bone density.
  - Ray would have thicker bones due to reshaping as a result of physical stress.
  - Ben would have thicker bones because bone accumulates like fat tissue from a sedentary lifestyle.
- Which of the following statements best describes the sliding filament mechanism of muscle contraction?
  - Actin and myosin filaments do not shorten, but rather, slide past each other.
  - Actin and myosin filaments shorten and slide past each other.
  - As they slide past each other, actin filaments shorten, but myosin filaments do not shorten.
  - As they slide past each other, myosin filaments shorten, but actin filaments do not shorten.
- Motor neurons stimulate muscle contraction via the release of
  - $\text{Ca}^{2+}$ .
  - ATP.
  - acetylcholine.
  - hormones.
- Which of the following statements about muscle metabolism is false?
  - Skeletal muscles at rest obtain most of their energy from muscle glycogen and blood glucose.
  - ATP can be quickly obtained by combining ADP with phosphate derived from creatine phosphate.
  - Exercise intensity is related to the maximum rate of oxygen consumption.
  - ATP is required for the pumping of the  $\text{Ca}^{2+}$  back into the sarcoplasmic reticulum.
- If you wanted to study the use of ATP during a single contraction cycle within a muscle cell, which of the following processes would you use?
  - Summation
  - Twitch
  - Treppe
  - Tetanus
- Place the following events in the correct order.
  - Sarcoplasmic reticulum releases  $\text{Ca}^{2+}$ .
  - Myosin binds to actin.
  - Action potential arrives from neuron.
  - $\text{Ca}^{2+}$  binds to troponin.
  - 1, 2, 3, 4
  - 3, 1, 2, 4
  - 2, 4, 3, 1
  - 3, 1, 4, 2

### APPLY

- Bone develops by one of two mechanisms depending on the underlying scaffold. Which pairing correctly describes these mechanisms?
  - Intramembranous and extramembranous
  - Endochondral and exochondral
  - Extramembranous and exochondral
  - Endochondral and intramembranous
- You have identified a calcium storage disease in rats. How would this inability to store  $\text{Ca}^{2+}$  affect muscle contraction?
  - $\text{Ca}^{2+}$  would be unable to bind to tropomyosin, which enables troponin to move and reveal binding sites for cross-bridges.
  - $\text{Ca}^{2+}$  would be unable to bind to troponin, which enables tropomyosin to move and reveal binding sites for cross-bridges.
  - $\text{Ca}^{2+}$  would be unable to bind to tropomyosin, which enables troponin to release ATP.
  - $\text{Ca}^{2+}$  would be unable to bind to troponin, which enables tropomyosin to release ATP.
- How do the muscles move your hand through space?
  - By contraction
  - By attaching to two bones across a joint
  - By lengthening
  - Both a and b are correct
- How can osteocytes remain alive within bone?
  - Bones are composed of only dead or dormant cells.
  - Haversian canals are bone structures that contain blood vessels that provide materials for the osteocytes.
  - Osteocytes have membrane extensions that protrude from bone and allow them to exchange materials with the surrounding fluids.
  - Bones are hollow in the middle and the low pressure there draws fluid from the blood that nourishes the osteocytes.

5. Swimming underwater using forelimbs for propulsion is similar to flying through the air because
  - a. birds are the only class of vertebrates that have species that do both.
  - b. both involve coordinating movements of the forelimbs and hindlimbs.
  - c. both must counter strong forces caused by friction.
  - d. both involve generating lift by pushing down on the air or water to counter gravity.
6. If a drug inhibits the release of ACh, what will happen?
  - a. Somatic motor neurons will fail to activate.
  - b. Somatic motor neuron impulses will not lead to muscle fiber contraction.
  - c. Myosin molecules will fail to release ADP.
  - d. An influx of sodium ions will lead to muscle cell membrane depolarization.

### SYNTHESIZE

1. You are designing a space-exploration vehicle to use on a planet with a gravity greater than Earth. Given a choice between a hydrostatic or an exoskeleton, which would you choose? Why?

2. You start running as fast as you can. Then, you settle into a jog that you can easily maintain. How do energy sources utilized by your skeletal muscles change during the switch? Why?
3. The nerve gas methylphosphonofluoridic acid (sarin) inhibits the enzyme acetylcholinesterase, required to break down acetylcholine. Based on this information, what are the likely effects of this nerve gas on muscle function?
4. If natural selection favors the evolution of wings in different types of vertebrates, why didn't it produce structures that were built in the same way?

### ONLINE RESOURCE

[www.ravenbiology.com](http://www.ravenbiology.com)

Understand, Apply, and Synthesize—enhance your study with animations that bring concepts to life and practice tests to assess your understanding. Your instructor may also recommend the interactive eBook, individualized learning tools, and more.

# Chapter 48
