Few people move beyond Stage 4. In fact, postconventional morality is so rare that no clear evidence exists that Kohlberg's Stage 6 actually follows Stage 5. This poses a key challenge to Kohlberg's theory: If people must reach Stages 5 and 6 to be considered truly morally mature, few individuals anywhere would measure up! According to one reexamination of Kohlberg's stages, moral maturity can be found in a revised understanding of Stages 3 and 4 (Gibbs, 1991, 2010b). These stages are not "conventional"—based on social conformity—as Kohlberg assumed. Rather, they require profound moral constructions—an understanding of ideal reciprocity as the basis for relationships (Stage 3) and for widely accepted moral standards, set forth in rules and laws (Stage 4). In this view, "postconventional" morality is a highly reflective endeavor limited to a handful of people who have attained advanced education, usually in philosophy.

TAKE A MOMENT... Think of an actual moral dilemma you faced recently. How did you solve it? Did your reasoning fall at the same stage as your thinking about Heinz? Real-life conflicts often elicit moral reasoning below a person's actual capacity because they involve practical considerations and mix cognition with intense emotion (Carpendale, 2000). Although adolescents and adults mention reasoning as their most frequent strategy for resolving these dilemmas, they also refer to other strategies—talking through issues with others, relying on intuition, and calling on religious and spiritual ideas. And they report feeling drained, confused, and torn by temptation—an emotional side of moral judgment not tapped by hypothetical situations, which evoke the upper limits of moral thought because they allow reflection without the interference of personal risk (Walker, 2004).

The influence of situational factors on moral judgments indicates that like Piaget's cognitive stages, Kohlberg's moral stages are loosely organized and overlapping. Rather than developing in a neat, stepwise fashion, people draw on a range of moral responses that vary with context. With age, this range shifts upward as less mature moral reasoning is gradually replaced by more advanced moral thought.

Are There Sex Differences in Moral Reasoning?

As we have seen, real-life moral dilemmas often highlight the role of emotion in moral judgment. In the discussion at the beginning of this section, notice how Sabrina's moral argument focuses on caring and commitment to others. Carol Gilligan (1982) is the best-known of those who have argued that

Kohlberg's theory does not adequately represent the morality of girls and women. Gilligan believes that feminine morality emphasizes an "ethic of care" that Kohlberg's system devalues. Sabrina's reasoning falls at Stage 3 because it is based on mutual trust and affection, whereas Louis's is at Stage 4 because he emphasizes following the law. According to Gilligan, a concern for others is a *different* but no less valid basis for moral judgment than a focus on impersonal rights.

Many studies have tested Gilligan's claim that Kohlberg's approach underestimates the moral maturity of females, and most do not support it (Turiel, 2006; Walker, 2006). On hypothetical dilemmas as well as everyday moral problems, adolescent and adult females display reasoning at the same stage as their male age mates and often at a higher stage. And themes of justice and caring appear in the responses of both sexes (Jadack et al., 1995; Walker, 1995). These findings suggest that although Kohlberg emphasized justice rather than caring as the highest moral ideal, his theory taps both sets of values.

Nevertheless, some evidence indicates that although the morality of males and females taps both orientations, females tend to emphasize care, whereas males either stress justice or focus equally on justice and care (Jaffee & Hyde, 2000; Wark & Krebs, 1996; Weisz & Black, 2002). This difference in emphasis, which appears more often in real-life dilemmas than in hypothetical ones, may reflect women's greater involvement in daily activities involving care and concern for others.

Indeed, cultural context profoundly affects use of a care orientation. In one study, U.S. and Canadian 17- to 26-year-old females exceeded their male counterparts in complex reasoning about care issues. But Norwegian males were just as advanced as Norwegian females in care-based understanding (Skoe, 1998). Perhaps Norwegian culture, which explicitly endorses gender equality, induces boys and men to think deeply about interpersonal obligations.

Coordinating Moral, Social-Conventional, and Personal Concerns

Adolescents' moral advances are also evident in their reasoning about situations that raise competing moral, social-conventional, and personal issues. In diverse Western and non-Western cultures, concern with matters of personal choice strengthens during the teenage years—a reflection of adolescents' quest for identity and increasing independence (Neff & Helwig, 2002; Nucci, 2002). As young people firmly insist that parents not encroach on the personal arena (dress, hairstyle, diary records, friendships), disputes over these issues increase. Teenagers whose parents frequently intrude into their personal affairs report greater psychological stress (Hasebe, Nucci, & Nucci, 2004). In contrast, adolescents typically say that parents have a right to tell them what to do in moral and social-conventional situations. And when these issues spark disagreements, teenagers seldom challenge parental authority (Smetana & Daddis, 2002).

As they enlarge the range of issues they regard as personal, adolescents think more intently about conflicts between personal choice and community obligations—for example, whether,

These teenagers participate in a demonstration in favor of gun control. Adolescent moral development involves thinking intently about conflicts between personal choice and community obligation—for example, whether, and under what conditions, individuals' right to bear arms should be restricted.

and under what conditions, it is permissible to restrict speech, religion, marriage, childbearing, group membership, and other individual rights (Wainryb, 1997). When asked if it is OK to exclude a child from a peer group on the basis of race or gender, fourth graders usually say exclusion is always unfair. But by tenth grade, young people, though increasingly mindful of fairness, indicate that under certain conditions—in intimate relationships (friendship) and private contexts (at home or in a small club), and on the basis of gender more often than race—exclusion is OK (Killen et al., 2002, 2007; Rutland, Killen, & Abrams, 2010). In explaining, they mention the right to personal choice as well as concerns about effective group functioning. Justifying her opinion that members of an all-boys music club need not let a girl in, one tenth grader commented, “[The girl and the boys] probably wouldn’t relate on very many things” (Killen et al., 2002, p. 62; 2007).

As adolescents integrate personal rights with ideal reciprocity, they demand that the protections they want for themselves extend to others. For example, with age, they are more likely to defend the government’s right to limit the individual freedom to engage in risky health behaviors such as smoking and drinking, in the interest of the larger public good (Flanagan, Stout, & Gallay, 2008). Similarly, they eventually realize that violating strongly held conventions in favor of asserting personal choices—showing up at a wedding in a T-shirt, talking out of turn at a student council meeting—can harm others, either by inducing distress or by undermining fair treatment (Nucci, 2001). As their grasp of fairness deepens, young people realize that many social conventions have moral implications: They are vital for maintaining a just and peaceful society. Notice how this understanding is central to Kohlberg’s Stage 4, which is typically attained as adolescence draws to a close.

Influences on Moral Reasoning

Many factors influence moral understanding, including child-rearing practices, schooling, peer interaction, and culture. Growing evidence suggests that, as Kohlberg believed, these experiences work by presenting young people with cognitive challenges, which stimulate them to think about moral problems in more complex ways.

Child-Rearing Practices. As in childhood, parenting practices associated with moral maturity in adolescence combine warmth, exchange of ideas, and appropriate demands for maturity. Adolescents who gain most in moral understanding have parents who engage in moral discussions, encourage prosocial behavior, and create a supportive atmosphere by listening sensitively, asking clarifying questions, and presenting higher-level reasoning (Carlo et al., 2011; Pratt, Skoe, & Arnold, 2004; Wyatt & Carlo, 2002). In one study, 11-year-olds were asked what they thought an adult would say to justify a moral rule, such as not lying, stealing, or breaking a promise. Those with warm, demanding, communicative parents were far more likely than their agemates to point to the importance of ideal reciprocity: “You wouldn’t like it if I did it to you” (Leman, 2005). In contrast, when parents lecture, use threats, or make sarcastic remarks, adolescents show little or no change in moral reasoning over time (Walker & Taylor, 1991a).

Schooling. Years of schooling is a powerful predictor of movement to Kohlberg’s Stage 4 or higher (Dawson et al., 2003; Gibbs et al., 2007). Higher education introduces young people to social issues that extend beyond personal relationships to entire political or cultural groups. Consistent with this idea, college students who report more perspective-taking opportunities (for example, classes that emphasize open discussion of opinions, friendships with others of different cultural backgrounds) and who indicate that they have become more aware of social diversity tend to be advanced in moral reasoning (Comunian & Gielen, 2006; Mason & Gibbs, 1993a, 1993b).

Peer Interaction. Interaction among peers who present differing viewpoints promotes moral understanding. When young people negotiate and compromise, they realize that social life can be based on cooperation between equals rather than authority relations (Killen & Nucci, 1995). Adolescents who report more close friendships and who more often participate in conversations with their friends are advanced in moral reasoning (Schonert-Reichl, 1999). The mutuality and intimacy of friendship, which foster decisions based on consensual agreement, may be particularly important for moral development. Furthermore, recall from Chapter 10 that intergroup contact—cross-race friendships and interactions in schools and communities—reduces racial and ethnic prejudice. It also affects young people morally, strengthening their conviction that race-based and other forms of peer exclusion are wrong (Crystal, Killen, & Ruck, 2008).

Peer discussions and role playing of moral problems have provided the basis for interventions aimed at improving high school and college students' moral understanding. For these discussions to be effective, young people must be highly engaged—confronting, critiquing, and attempting to clarify one another's viewpoints, as Sabrina and Louis did when they argued over Mrs. Perry's plight (Berkowitz & Gibbs, 1983; Comunian & Gielen, 2006). And because moral development occurs gradually, many peer interaction sessions over weeks or months typically are needed to produce moral change.

Culture. Individuals in industrialized nations move through Kohlberg's stages more quickly and advance to a higher level than individuals in village societies, who rarely move beyond Stage 3. One explanation of these cultural differences is that in village societies, moral cooperation is based on direct relations between people and does not allow for the development of advanced moral understanding (Stages 4 to 6), which depends on appreciating the role of larger social structures, such as laws and government institutions (Gibbs et al., 2007).

A second possible reason for cultural variation is that responses to moral dilemmas in collectivist cultures (including village societies) are often more other-directed than in Western Europe and North America (Miller, 2006). In both village and industrialized cultures that highly value interdependency, statements portraying the individual as vitally connected to the social group are common. In one study, Japanese adolescents, who almost always integrated care- and justice-based reasoning, placed greater weight on care, which they regarded as a communal responsibility (Shimizu, 2001). Similarly, in research conducted in India, even highly educated people

(expected to have attained Kohlberg's Stages 4 and 5) viewed solutions to moral dilemmas as the responsibility of the entire society, not of a single person (Miller & Bersoff, 1995).

These findings raise the question of whether Kohlberg's highest level represents a culturally specific way of thinking—one limited to Western societies that emphasize individualism and an appeal to an inner, private conscience. At the same time, a review of over 100 studies confirmed an age-related trend consistent with Kohlberg's Stages 1 to 4 across diverse societies (Gibbs et al., 2007). A common justice morality is clearly evident in the dilemma responses of people from vastly different cultures.

Moral Reasoning and Behavior

A central assumption of the cognitive-developmental perspective is that moral understanding should affect moral action. According to Kohlberg, mature moral thinkers realize that behaving in line with their beliefs is vital for creating and maintaining a just social world (Gibbs, 2010b). Consistent with this idea, higher-stage adolescents more often act prosocially by helping, sharing, and defending victims of injustice and by volunteering in their communities (Carlo et al., 1996, 2011; Comunian & Gielen, 2000, 2006). Also, they less often engage in cheating, aggression, and other antisocial behaviors (Gregg, Gibbs, & Fuller, 1994; Raaijmakers, Engels, & van Hoof, 2005; Stams et al., 2006).

Yet the connection between mature moral reasoning and action is only modest. As we have seen, moral behavior is influenced by many factors besides cognition, including the emotions of empathy, sympathy, and guilt; individual differences in temperament; and a long history of cultural experiences and intuitive beliefs that affect moral decision making (Haidt & Kesebir, 2010). **Moral identity**—the degree to which morality is central to self-concept—also affects moral behavior (Hardy & Carlo, 2011). In a study of low-SES African-American and Hispanic teenagers, those who emphasized moral traits and goals in their self-descriptions displayed exceptional levels of community service (Hart & Fegley, 1995). But they did not differ from their agemates in moral reasoning.

Researchers have begun to identify factors that strengthen moral identity in hopes of capitalizing on them to promote moral commitment. Certain parenting practices—inductive discipline (see page 264 in Chapter 8) and clearly conveyed moral expectations—augment adolescents' moral identity (Patrick & Gibbs, 2011). And *just educational environments*—in which teachers guide students in democratic decision making and rule setting, resolving disputes civilly, and taking responsibility for others' welfare—are influential (Atkins, Hart, & Donnelly, 2004). In one study, tenth graders who reported fair teacher treatment were more likely than those who had experienced unjust treatment (an unfair detention or a lower grade than they deserved) to regard excluding a peer on the basis of race as a moral transgression (Crystal, Killen, & Ruck, 2010).

Members of this small village community in Mozambique experience moral cooperation as based on direct relations between people. Consequently, their moral reasoning is unlikely to advance beyond Kohlberg's Stage 3.

Schools can also foster students' opportunities to experience and explore moral emotions, thoughts, and actions through civic engagement. As the Social Issues: Education box on the following page reveals, civic engagement can help young people see the connection between their personal interests and the public interest—an insight that may foster all aspects of morality.

Religious Involvement and Moral Development

Recall that in resolving real-life moral dilemmas, many people voice notions of religion and spirituality. Religion is especially important in U.S. family life. In recent national polls, nearly two-thirds of Americans reported actively practicing religion, compared with one-half of those in Canada, one-third of those in Great Britain and Italy, and even fewer elsewhere in Europe (CIA, 2012; Gallup News Service, 2006; Jones, 2003). People who regularly attend religious services include many parents with children. But as adolescents search for a personally meaningful identity, formal religious involvement declines—for U.S. youths, from 55 percent at ages 13 to 15 to 40 percent at ages 17 to 18 (Kerestes & Youniss, 2003; Pew Research Center, 2010b).

Nevertheless, teenagers who remain part of a religious community are advantaged in moral values and behavior. Compared with nonaffiliated youths, they are more involved in community service activities aimed at helping the less fortunate (Kerestes, Youniss, & Metz, 2004). And religious involvement promotes responsible academic and social behavior and discourages

Playing in a brass quartet at church gives these adolescents a sense of connection to their faith. Religious involvement promotes teenagers' moral development, encouraging responsible academic work and community service.

misconduct (Dowling et al., 2004). It is associated with lower levels of drug and alcohol use, early sexual activity, and delinquency (Regnerus, Smith, & Fritsch, 2003).

A variety of factors probably contribute to these favorable outcomes. In a study of inner-city high school students, religiously involved young people were more likely to report trusting relationships with parents, adults, and friends who hold similar worldviews. The more activities they shared with this network, the higher they scored in empathy and prosocial behavior (King & Furrow, 2004). Furthermore, religious education and youth activities directly teach concern for others and provide opportunities for moral discussions and civic engagement. And adolescents who feel connected to a higher being may develop certain inner strengths, including prosocial values and a strong moral identity, that help them translate their thinking into action (Hardy & Carlo, 2005; Sherrod & Spiewak, 2008).

Because most teenagers, regardless of formal affiliation, identify with a religious denomination and say they believe in a higher being, religious institutions may be uniquely suited to foster moral and prosocial commitments. For youths in inner-city neighborhoods with few alternative sources of social support, outreach by religious institutions can lead to life-altering involvement (Jang & Johnson, 2001). An exception is seen in religious cults, where rigid indoctrination into the group's beliefs, suppression of individuality, and estrangement from society all work against moral maturity (Scarlett & Warren, 2010).

Further Challenges to Kohlberg's Theory

Although much evidence is consistent with the cognitive-developmental approach to morality, Kohlberg's theory has faced major challenges. The most radical opposition comes from researchers who—referring to wide variability in moral reasoning across situations—claim that Kohlberg's stage sequence inadequately accounts for morality in everyday life (Krebs and Denton, 2005). These investigators favor abandoning Kohlberg's stages for a *pragmatic approach to morality*. They assert that each person makes moral judgments at varying levels of maturity, depending on the individual's current context and motivations: Conflict over a business deal is likely to evoke Stage 2 (instrumental purpose) reasoning, a friendship or romantic dispute Stage 3 (ideal reciprocity) reasoning, and a breach of contract Stage 4 (social-order-maintaining) reasoning (Krebs et al., 1991).

According to the pragmatic view, everyday moral judgments—rather than being efforts to arrive at just solutions—are practical tools that people use to achieve their goals. To benefit personally, they often must advocate cooperation with others. But people often act first and then invoke moral judgments to rationalize their actions, regardless of whether their behavior is self-centered or prosocial (Haidt, 2001; Haidt & Kesebir, 2010). And sometimes people use moral judgments for immoral purposes—for example, to excuse their transgressions.

Is the pragmatic approach correct that people strive to resolve moral conflicts fairly only when they themselves have nothing to lose? Supporters of the cognitive-developmental

Social Issues: Education

Development of Civic Engagement

On Thanksgiving Day, Jules, Martin, Louis, and Sabrina joined their parents to serve a holiday dinner to poverty-stricken people. Throughout the year, Sabrina volunteered on Saturday mornings at a nursing home. During a congressional election campaign, all four adolescents raised questions about issues at special youth meetings with candidates. At school, Louis and his girlfriend, Cassie, formed an organization devoted to promoting ethnic and racial tolerance.

These young people show a strong sense of *civic engagement*—a complex combination of cognition, emotion, and behavior. Civic engagement involves knowledge of political issues, commitment to making a difference in the community, and skills for achieving civic goals, such as how to resolve differing views fairly (Zaff et al., 2010).

When young people engage in community service that exposes them to people in need or to public issues, they are especially likely to express a commitment to future service. And youth volunteers—who tend to be advanced in moral reasoning—gain further in moral maturity as a result of participating (Gibbs et al., 2007; Hart, Atkins, & Donnelly, 2006). Family, school, and community experiences contribute to adolescents' civic engagement.

Family Influences

Teenagers whose parents encourage their children to form opinions about controversial issues are more knowledgeable about civic issues and better able to see them from more than one perspective (Santoloupo & Pratt, 1994). Also, adolescents whose parents engage in community service and stress compassion for the less fortunate tend to hold socially responsible values. When asked what causes unemployment or poverty, they more often mention situational and societal factors (lack of education, government policies, or the state of the economy) than individual factors (low intelligence or personal problems). Youths who endorse situational and societal causes, in turn, have more altruistic life goals (Flanagan & Tucker, 1999). And

they engage in more civic activities into early adulthood (Zaff, Malanchuk, & Eccles, 2008).

School and Community Influences

A democratic climate at school, in which teachers promote respectful discussion of controversial issues, fosters knowledge and critical analysis of political issues and commitment to social causes (Torney-Purta, Barber, & Wilkenfeld, 2007). Furthermore, high school students who view their community as one in which adults care about youths and work to make the community better report higher levels of civic participation (Kahne & Sporte, 2008). Participation in extracurricular activities at school whose primary objectives are to induce social change outside the organization itself is also associated with civic commitment that persists into adulthood (Obradović & Masten, 2007; Zaff et al., 2003).

Two aspects of these involvements seem to account for their lasting impact. First, they introduce adolescents to the vision and skills required for mature civic engagement. Within student government, political and vocational clubs, music and drama groups, and student newspaper and yearbook staffs, young people see how their actions affect the wider school and community. They realize that collectively they can achieve results greater than any one person can achieve alone. And they learn to work together, balancing strong convictions with compromise (Atkins, Hart, & Donnelly, 2004; Kirshner, 2009). Second, while producing a weekly newspaper, participating in a school play, or implementing a service project, young people explore political and moral ideals. Often they redefine their identities to include a responsibility to combat others' misfortunes (Wheeler, 2002).

The power of family, school, and community to promote civic engagement may lie in discussions, educational practices, and activities that jointly foster moral thought,

For this young teenager, planting a tree during an Earth Day celebration in Los Angeles promotes a sense of civic engagement—an effect that may persist into adulthood.

emotion, and behavior. In a comparison of nationally representative samples of 14-year-olds in 28 nations, U.S. young people excelled at community service, with 50 percent reporting membership in organizations devoted to volunteering (Torney-Purta, 2002).

Currently, two-thirds of U.S. public schools provide students with community service opportunities. Nearly half of these have *service-learning programs*, which integrate service activities into the academic curriculum, and about one-third of students enroll. High school students who are required to serve their communities express as strong a desire to remain engaged as do students who volunteer. And when they reach early adulthood, they are equally likely to vote and participate in community organizations (Hart et al., 2007; Metz & Youniss, 2005).

Still, most U.S. schools offering service learning do not have policies encouraging or mandating such programs. Furthermore, low-SES, inner-city youths—although they express high interest in contributing to society—attend schools and live in neighborhoods with fewer civic-training opportunities. As a result, they score substantially lower than higher-SES youths in civic knowledge and participation (Balsano, 2005; Zaff et al., 2010). A broad societal commitment to fostering civic character must pay special attention to supportive experiences for these young people, so their eagerness to make a difference can be realized.

perspective point out that people frequently rise above self-interest to defend others' rights. For example, moral leaders in business—rather than resorting to Stage 2 reasoning—endorse trust, integrity, good faith, and just laws and codes of conduct (Damon, 2004; Gibbs, 2006). Also, adolescents and adults are well aware of the greater adequacy of higher-stage moral reasoning, which some people act on despite highly corrupt environments. And individuals who engage in sudden altruistic action may have previously considered relevant moral issues so thoroughly that their moral judgment activates automatically, triggering an immediate response (Gibbs et al., 2009a; Pizarro & Bloom, 2003). In these instances, people who appear to be engaging in after-the-fact moral justification are actually behaving with great forethought.

In sum, the cognitive-developmental approach to morality has done much to clarify our profound moral potential. And despite opposition, Kohlberg's central assumption—that with age, humans everywhere construct a deeper understanding of fairness and justice that guides moral action—remains powerfully influential.

Gender Typing

As Sabrina entered adolescence, she began to worry about walking, talking, eating, dressing, laughing, and competing in ways consistent with a feminine gender role. According to one hypothesis, the arrival of adolescence is typically accompanied by **gender intensification**—increased gender stereotyping of attitudes and behavior, and movement toward a more traditional gender identity. Research on gender intensification, however, is mixed, with some studies finding evidence for it and others reporting few instances (Basow & Rubin, 1999; Galambos, Almeida, & Petersen, 1990; Huston & Alvarez, 1990; Priess, Lindberg, & Hyde, 2009). When gender intensification is evident, it seems to be stronger for adolescent girls. Although girls continue to be less gender-typed than boys, some may feel less free to experiment with “other-gender” activities and behaviors than they did in middle childhood.

In young people who do exhibit gender intensification, biological, social, and cognitive factors likely are involved. As puberty magnifies sex differences in appearance, teenagers may spend more time thinking about themselves in gender-linked ways. Pubertal changes might also prompt gender-typed pressures from others. Parents with traditional gender-role beliefs may encourage “gender-appropriate” activities and behavior more than they did earlier (Crouter et al., 2007; Shanahan et al., 2007). And when adolescents start to date, they may become more gender-typed as a way of increasing their attractiveness (Maccoby, 1998). Finally, cognitive changes—in particular, greater concern with what others think—might make young teenagers more responsive to gender-role expectations.

Gender intensification declines by late adolescence, but not all affected young people move beyond it to the same degree. Teenagers who are encouraged to explore non-gender-typed options and to question the value of gender stereotypes for

For some young people, early adolescence is a time of gender intensification. Pubertal changes in appearance, traditional gender-role expectations of parents, and increased concern with what others think can prompt a move toward a more traditional gender identity.

themselves and society are more likely to build an androgynous gender identity (see Chapter 8, page 276). Overall, androgynous adolescents, especially girls, tend to be psychologically healthier—more self-confident, more willing to speak their own mind, better-liked by peers, and identity-achieved (Bronstein, 2006; Dusek, 1987; Harter, 2006).

The Family

Franca and Antonio remember their son Louis's freshman year of high school as a difficult time. Because of a demanding project at work, Franca was away from home many evenings and weekends. In her absence, Antonio took over, but when business declined and he had to cut costs at his hardware store, he, too, had less time for the family. That year, Louis and two friends

used their computer know-how to gain entry to their classmates' systems to pirate video game software. Louis's grades fell, and he often left the house without saying where he was going. Franca and Antonio began to feel uncomfortable about the long hours Louis spent at his computer and their lack of contact with him. One day, when Franca and Antonio noticed the video-game icons covering Louis's computer desktop, they knew they had cause for concern.

During adolescence, striving for **autonomy**—a sense of oneself as a separate, self-governing individual—becomes a salient task. Autonomy has two vital aspects: (1) an *emotional component*—relying more on oneself and less on parents for support and guidance, and (2) a *behavioral component*—making decisions independently by carefully weighing one's own judgment and the suggestions of others to arrive at a well-reasoned course of action (Collins & Laursen, 2004; Steinberg & Silk, 2002). As we will see, parent-child relationships remain vital for helping adolescents become autonomous, responsible individuals.

Parent-Child Relationships

A variety of changes within the adolescent support autonomy. In Chapter 11, we saw that puberty triggers psychological distancing from parents. In addition, as young people look more mature, parents give them more freedom to think and decide for themselves, more opportunities to regulate their own activities, and more responsibility (McElhaney et al., 2009). Cognitive development also paves the way toward autonomy: Gradually, adolescents solve problems and make decisions more effectively. And an improved ability to reason about social relationships leads teenagers to *deidealize* their parents, viewing them as “just people.” Consequently, they no longer bend as easily to parental authority as they did when younger.

Yet as Franca and Antonio's episode with Louis reveals, teenagers still need guidance and protection from dangerous situations. (Recall from Chapter 11 our discussion of adolescent brain development, in which changes in the emotional/social network outpace gains in the cognitive-control network.) Warm, supportive parenting that grants young people freedom to explore while making appropriate demands for maturity fosters autonomy—in diverse ethnic and SES groups, nations, and family structures (including single-parent, two-parent, and stepparent). Autonomy, in turn, predicts high self-reliance, effortful control, academic achievement, positive work orientation, favorable self-esteem, and ease of separation in the transition to college (Bean, Barber, & Crane, 2007; Eisenberg et al., 2005b; Supple et al., 2009; Vazsonyi, Hibbert, & Snider, 2003; Wang, Pomerantz, & Chen, 2007).

Conversely, parents who are coercive or psychologically controlling interfere with the development of autonomy. These tactics are linked to low self-esteem, depression, drug and alcohol use, and antisocial behavior—outcomes that often persist into early adulthood (Barber, Stolz, & Olsen, 2005; Bronte-Tinkew, Moore, & Carrano, 2006; Wissink, Deković, & Meijer, 2006).

In Chapter 2, we described the family as a *system* that must adapt to changes in its members. The rapid physical and

Parent-child relationships are vital for helping adolescents attain autonomy. Though teenagers benefit from freedom to explore ideas and make their own decisions, they need guidance and protection from dangerous situations.

psychological changes of adolescence trigger conflicting expectations in parent-child relationships. Earlier we noted that interest in making choices about personal matters strengthens in adolescence. Yet parents and teenagers—especially young teenagers—differ sharply on the appropriate age for granting certain privileges, such as control over clothing, school courses, going out with friends, and dating (Smetana, 2002). Consistent parental monitoring of the young person's daily activities, through a cooperative relationship in which the adolescent willingly discloses information, is linked to a variety of positive outcomes—prevention of delinquency, reduction in sexual activity, improved school performance, and positive psychological well-being (Crouter & Head, 2002; Jacobson & Crockett, 2000).

LOOK AND LISTEN

Ask an early adolescent and his or her parent for their views on when the young person is mature enough to begin dating, own a cell phone, create a Facebook page, and be given other privileges. Do adolescent and parent perspectives differ? ●

Parents' own development can also lead to friction with teenagers. While their children face a boundless future and a wide array of choices, middle-aged parents must accept the fact that their own possibilities are narrowing (Holmbeck, 1996). Often parents can't understand why the adolescent wants to skip family activities to be with peers. And teenagers fail to appreciate that parents want the family to spend as much time together as possible because an important period in their adult life—child rearing—will soon end.

Immigrant parents from cultures that place a high value on family closeness and obedience to authority have greater difficulty adapting to their teenagers' push for autonomy, often reacting more strongly to adolescent disagreement. And as adolescents acquire the host culture's language and are increasingly

exposed to its individualistic values, immigrant parents may become even more critical, causing teenagers to rely less on the family network for social support, disclosing less about peer relationships, potentially risky activities, and personal feelings (Yau, Tasopoulos-Chan, & Smetana, 2009). The resulting *acculturative stress* is associated with a decline in self-esteem and a rise in anxiety, depressive symptoms, and deviant behavior, including alcohol use and delinquency (Park, 2009; Suarez-Morales & Lopez, 2009; Warner et al., 2006).

Throughout adolescence, the quality of the parent–child relationship is the single most consistent predictor of mental health. In well-functioning families, teenagers remain attached to parents and seek their advice, but they do so in a context of greater freedom (Collins & Steinberg, 2006). The mild conflict that typically arises facilitates adolescent identity and autonomy by helping family members express and tolerate disagreement. Conflicts also inform parents of teenagers’ changing needs and expectations, signaling a need for adjustments in the parent–child relationship.

By middle to late adolescence, most parents and children achieve this mature, mutual relationship, and harmonious interaction is on the rise. The reduced time that Western teenagers spend with parents—for U.S. youths, a drop from 33 percent of waking hours in fifth grade to 14 percent in twelfth grade—has little to do with conflict (Larson et al., 1996). Rather, it results from the large amount of unstructured time available to teenagers in North America and Western Europe—on average, nearly half their waking hours (Larson, 2001). Young people tend to fill these hours with activities that take them away from home—part-time jobs, leisure and volunteer pursuits, and time with friends.

But this drop in family time is not universal. In one study, urban low- and middle-SES African-American youths showed no decline in hours spent with family—a pattern typical in cultures with collectivist values (Larson et al., 2001). Furthermore, teenagers living in risky neighborhoods tend to have more trusting relationships with parents and adjust more favorably when parents maintain tighter control and pressure them not to engage in worrisome behaviors (McElhaney & Allen, 2001). In harsh surroundings, young people seem to interpret more measured granting of autonomy as a sign of parental caring.

Family Circumstances

As Franca and Antonio’s experience with Louis reminds us, adult life stress can interfere with warm, involved parenting and, in turn, with children’s adjustment at any period of development. But parents who are financially secure, not overloaded with job pressures, and content with their marriages usually find it easier to grant teenagers appropriate autonomy and experience less conflict with them (Cowan & Cowan, 2002; Crouter & Bumpus, 2001). When Franca and Antonio’s work stress eased and they recognized Louis’s need for more involvement and guidance, his problems subsided.

Among the minority of families with seriously troubled parent–adolescent relationships, most difficulties began in childhood (Collins & Laursen, 2004). Table 12.2 summarizes family

TABLE 12.2 Family Circumstances with Implications for Adolescent Adjustment

FAMILY CIRCUMSTANCE	TO REVIEW, TURN TO . . .
TYPE OF FAMILY

Economic hardship	Chapter 2, pages 61–62
Child maltreatment	Chapter 8, pages 281–283 Chapter 10, pages 352–354
Adolescent parenthood	Chapter 11, pages 378–380

conditions considered in earlier chapters that pose challenges for adolescents. Teenagers who develop well despite family stress continue to benefit from factors that fostered resilience in earlier years: an appealing, easy-going disposition; a parent who combines warmth with high expectations; and (especially if parental supports are lacking) bonds with prosocial adults outside the family who care deeply about the adolescent’s well-being (Masten, 2001; Masten & Shaffer, 2006).

Siblings

Like parent–child relationships, sibling interactions adapt to development at adolescence. As younger siblings become more self-sufficient, they accept less direction from their older brothers and sisters, and sibling influence declines. Also, as teenagers become more involved in friendships and romantic relationships, they invest less time and energy in siblings, who are part of the family from which they are trying to establish autonomy. As a result, sibling relationships often become less intense, in both positive and negative feelings (Hetherington, Henderson, & Reiss, 1999; Kim et al., 2006).

Nevertheless, attachment between siblings remains strong for most young people. Overall, siblings who established a positive bond in early childhood continue to display greater affection and caring, which contribute to more favorable adolescent adjustment (Kim et al., 2007; Samek & Rueter, 2011). Culture also influences quality of sibling relationships. In one study, Mexican-American adolescents who expressed a strong Mexican cultural orientation resolved sibling conflicts more cooperatively than did those more oriented toward U.S. individualistic values (Killoren, Thayer, & Updegraff, 2008).

Finally, mild sibling differences in perceived parental affection no longer trigger jealousy but, instead, predict greater sibling warmth (Feinberg et al., 2003). Perhaps adolescents interpret a unique relationship with parents, as long as it is generally accepting, as a gratifying sign of their own individuality.

Peer Relations

As adolescents spend less time with family members, peers become increasingly important. In industrialized nations, young people spend most of each weekday with agetates in school. Teenagers also spend much out-of-class time together, more in some cultures than others. For example, U.S. young people have about 50 hours of free time per week, Europeans about 45 hours, and East Asians about 33 hours (Larson, 2001). A shorter school year and less demanding academic standards, which lead American youths to devote much less time to school-work, account for this difference.

In the following sections, we will see that adolescent peer relations can be both positive and negative. At their best, peers serve as critical bridges between the family and adult social roles.

Friendships

Number of best friends declines from about four to six in early adolescence to one or two in adulthood (Hartup & Stevens, 1999). At the same time, the nature of the relationship changes.

Characteristics of Adolescent Friendships. When asked about the meaning of friendship, teenagers stress three characteristics. The most important is *intimacy*, or psychological closeness, which is supported by *mutual understanding* of each other's values, beliefs, and feelings. In addition, more than younger children, teenagers want their friends to be *loyal*—to stick up for them and not leave them for somebody else (Collins & Madsen, 2006).

As frankness and faithfulness increase, *self-disclosure* (sharing of private thoughts and feelings) between friends rises over the adolescent years (see Figure 12.1). As a result, teenage friends get to know each other better as personalities. In addition to the

many characteristics that school-age friends share (see page 340 in Chapter 10), adolescent friends tend to be alike in identity status, educational aspirations, political beliefs, and willingness to try drugs and engage in lawbreaking acts. Over time, they become increasingly similar in these ways (Berndt & Murphy, 2002; Selfhout, Branje, & Meeus, 2008). Occasionally, however, teenagers choose friends with differing attitudes and values, which permits them to explore new perspectives within the security of a compatible relationship.

During adolescence, cooperation and mutual affirmation between friends increase—changes that reflect greater skill at preserving the relationship and sensitivity to a friend's needs and desires (De Goede, Branje, & Meeus, 2009). Adolescents also are less possessive of their friends than they were in childhood (Parker et al., 2005). Desiring a certain degree of autonomy for themselves, they recognize that friends need this, too.

Sex Differences in Friendships. TAKE A MOMENT...

Ask several adolescent girls and boys to describe their close friendships. You are likely to find a consistent sex difference: Emotional closeness is more common between girls than between boys (Markovits, Benenson, & Dolensky, 2001). Girls frequently get together to “just talk,” and their interactions contain more self-disclosure and supportive statements. In contrast, boys more often gather for an activity—usually sports and competitive games. Boys' discussions usually focus on achievements in sports and school and involve more competition and conflict (Brendgen et al., 2001; Rubin, Bukowski, & Parker, 2006).

Because of gender-role expectations, girls' friendships typically focus on communal concerns, boys' on achievement and status. Boys do form close friendship ties, but the quality of their friendships is more variable. Gender identity plays a role: Androgynous boys are just as likely as girls to form intimate same-sex ties, whereas highly “masculine” boys are less likely to do so (Jones & Dembo, 1989).

FIGURE 12.1 Age changes in reported self-disclosure to parents and peers, based on findings of several studies. Self-disclosure to friends increases steadily during adolescence, reflecting intimacy as a major basis of friendship. Self-disclosure to romantic partners also rises, but it does not surpass intimacy with friends until the college years. Self-disclosure to parents declines in early adolescence, a time of mild parent-child conflict. As family relationships readjust to the young person's increasing autonomy, self-disclosure to parents rises. (From D. Buhrmester, 1996, “Need Fulfillment, Interpersonal Competence, and the Developmental Contexts of Early Adolescent Friendship,” in W. M. Bukowski, A. F. Newcomb, & W. W. Hartup [Eds.], *The Company They Keep: Friendship in Childhood and Adolescence*, New York: Cambridge University Press, p. 168. Reprinted with permission of Cambridge University Press.)

JENNA CITRUS/FLICKR/GETTY IMAGES

Compared to boys, adolescent girls place a higher value on emotional closeness, engaging in more self-disclosure and supportive statements with friends.

Friendship closeness has costs as well as benefits. When friends focus on deeper thoughts and feelings, they tend to *coruminate*, or repeatedly mull over problems and negative emotions. Corumination, while contributing to high friendship quality, also triggers anxiety and depression—symptoms more common among girls than among boys (Hankin, Stone, & Wright, 2010; Rose, Carlson, & Waller, 2007). And when conflict arises between intimate friends, more potential exists for one party to harm the other through relational aggression—for example, by divulging sensitive personal information to outsiders. Partly for this reason, girls' closest same-sex friendships tend to be of shorter duration than boys' (Benenson & Christakos, 2003).

Friendships on the Internet. Teenagers frequently use cell phones and the Internet to communicate with friends. About 75 percent of U.S. 12- to 17-year-olds own a cell phone, a rate that has nearly doubled during the past decade. Cell-phone texting has become the preferred means of electronic interaction between teenage friends, with cell calling second, followed by social networking sites and instant messaging (see Figure 12.2). Girls use cell phones to text and call their friends considerably more often than boys (Lenhart et al., 2010). These forms of online interaction seem to support friendship closeness. In several studies, as amount of online messaging between preexisting friends increased, so did young people's perceptions of intimacy in the relationship and feelings of well-being (Reich, Subrahmanyam, & Espinoza, 2012; Valkenburg & Peter, 2007a, 2007b, 2009). The effect is largely due to friends' online disclosure of personal information, such as worries, secrets, and romantic feelings.

Although mostly communicating with friends they know, teenagers are also drawn to meeting new people over the Internet. Social networking sites such as Facebook and MySpace (used by nearly three-fourths of U.S. teenagers) along with blogs, message boards, and chat rooms open up vast alternatives

beyond their families, schools, and communities (Lenhart et al., 2010). Through these online ties, young people explore central adolescent issues—sexuality, challenges in parent and peer relationships, and identity issues, including attitudes and values—in contexts that grant anonymity and, therefore, may feel less threatening than similar everyday conversations (Subrahmanyam, Smahel, & Greenfield, 2006; Valkenburg & Peter, 2011). Online interactions with strangers also offer some teenagers vital social support. Young people suffering from depression, eating disorders, and other problems can access message boards where participants provide mutual assistance, including a sense of group belonging and acceptance (Whitlock, Powers, & Eckenrode, 2006).

But online communication also poses dangers. In unmonitored chat rooms, teenagers are likely to encounter degrading racial and ethnic slurs and sexually obscene and harassing remarks (Subrahmanyam & Greenfield, 2008). Furthermore, in a survey of a nationally representative sample of U.S. 10- to 17-year-olds, 14 percent reported having formed online close friendships or romances. Although some of these youths were well-adjusted, many reported high levels of conflict with parents, peer victimization, depression, and delinquency (Wolak, Mitchell, & Finkelhor, 2003). They also more often had been asked by online friends for face-to-face meetings and had attended those meetings—without telling their parents.

Finally, time devoted to social media is rising among older children and adolescents. For example, nearly 45 percent send more than 50 texts per day, and more than 70 percent use social networking sites for an average of 37 minutes per day. Some evidence suggests that very high social media use is linked to unsatisfying face-to-face social experiences, boredom, unhappiness, and Internet addiction (obsessive Internet use) (Pea et al., 2012; Rideout, Foehr, & Roberts, 2010; Smahel, Brown, & Blinka, 2012). Furthermore, high Internet consumers often engage in “face-to-face multitasking,” such as texting at the dinner table or web surfing while chatting with friends (Abelson,

FIGURE 12.2 Percentage of U.S. 12- to 17-year-olds who use various communication channels daily to contact friends. A nationally representative sample of 800 U.S. 12- to 17-year-olds responded to a survey about their communication strategies with friends. Cell-phone texting emerged as the preferred channel, with over half of teenagers reporting that they used it daily. (Adapted from Lenhart et al., 2010.)

Ledeen, & Lewis, 2008). These behaviors detract from high-quality face-to-face communication.

In sum, the Internet's value for enabling convenient and satisfying interaction among teenage friends must be weighed against its potential for facilitating harmful social consequences. Parents are wise to point out the risks of Internet communication, including excessive use, harassment, and exploitation, and to insist that teenagers follow Internet safety rules (see www.safeteens.com).

Friendship and Adjustment. As long as adolescent friendships are high in trust, intimate sharing, and support and not characterized by relational aggression or attraction to anti-social behavior, they contribute to many aspects of psychological health and competence into early adulthood (Bukowski, 2001; Waldrip, 2008), for several reasons:

- *Close friendships provide opportunities to explore the self and develop a deep understanding of another.* Through open, honest communication, friends become sensitive to each other's strengths and weaknesses, needs and desires—a process that supports the development of self-concept, perspective taking, and identity.
- *Close friendships provide a foundation for future intimate relationships.* Recall from Figure 12.1 that self-disclosure to friends precedes disclosure to romantic partners. Conversations with teenage friends about sexuality and romance, along with the intimacy of friendship itself, may help adolescents establish and work out problems in romantic partnerships (Connolly & Goldberg, 1999).
- *Close friendships help young people deal with the stresses of adolescence.* By enhancing sensitivity to and concern for another, supportive friendships promote empathy, sympathy, and prosocial behavior. As a result, friendships contribute to involvement in constructive youth activities, avoidance of antisocial acts, and psychological well-being (Lansford et al., 2003; Wentzel, Barry, & Caldwell, 2004).
- *Close friendships can improve attitudes toward and involvement in school.* Close friendships promote good school adjustment, academically and socially (Wentzel, Barry, & Caldwell, 2004). When teenagers enjoy interacting with friends at school, they may begin to view all aspects of school life more positively.

LOOK AND LISTEN

Interview several adolescents about qualities they value most in their best friends. Ask how friendships have helped them cope with stress and resulted in other personal benefits. ●

Cliques and Crowds

In early adolescence, *peer groups* (see Chapter 10) become increasingly common and tightly knit. They are organized into **cliques**, groups of about five to seven members who are friends and, therefore, usually resemble one another in family background, attitudes, and values (Brown & Dietz, 2009). At first,

© THE STAR-LEDGER/BILL PERLMAN/THE IMAGE WORKS

These high school drama club members form a crowd, establishing relationships on the basis of shared abilities and interests. Crowd membership grants them an identity within the larger social structure of the school.

cliques are limited to same-sex members. Among girls but not boys, being in a clique predicts academic and social competence. Clique membership is more important to girls, who use it as a context for expressing emotional closeness (Henrich et al., 2000). By midadolescence, mixed-sex cliques are common.

Among Western adolescents attending high schools with complex social structures, often several cliques with similar values form a larger, more loosely organized group called a **crowd**. Unlike the more intimate clique, membership in a crowd is based on reputation and stereotype, granting the adolescent an identity within the larger social structure of the school. Prominent crowds in a typical high school might include “brains” (nonathletes who enjoy academics), “jocks” (who are very involved in sports), “populars” (class leaders who are highly social and involved in activities), “partyers” (who value socializing but care little about schoolwork), “nonconformists” (who like unconventional clothing and music), “druggies” (who frequently use substances, engage in sexual risk-taking, and otherwise get into trouble), and “normals” (average to good students who get along with most other peers) (Kinney, 1999; Stone & Brown, 1999).

What influences the sorting of teenagers into cliques and crowds? Crowd affiliations are linked to strengths in adolescents' self-concepts, which reflect their abilities and interests (Prinstein & La Greca, 2002). Ethnicity also plays a role. Minority teenagers who associate with an ethnically defined crowd, as opposed to a crowd reflecting their abilities and interests, may be motivated by discrimination in their school or neighborhood. Alternatively, they may be expressing a strong ethnic identity (Brown et al., 2008). Family factors are important, too. In a study of 8,000 ninth to twelfth graders, adolescents who described their parents as authoritative were members of “brain,” “jock,” and “popular” groups that accepted both adult and peer reward systems. In contrast, boys with permissive parents aligned themselves with the “partyers” and “druggies,” suggesting lack of identification with adult reward systems (Durbin et al., 1993).

These findings indicate that many peer-group values are extensions of ones acquired at home. Once adolescents join a clique or crowd, it can modify their beliefs and behavior. But the positive impact of having academically and socially skilled peers is greatest for teenagers whose own parents are authoritative. And the negative impact of having antisocial, drug-using friends is strongest for teenagers whose parents use less effective child-rearing styles (Mounts & Steinberg, 1995). In sum, family experiences affect the extent to which adolescents become like their peers over time.

As interest in dating increases, boys' and girls' cliques come together. Mixed-sex cliques provide boys and girls with models of how to interact and a chance to do so without having to be intimate (Connolly et al., 2004). By late adolescence, when boys and girls feel comfortable enough about approaching each other directly, the mixed-sex clique disappears (Connolly & Goldberg, 1999).

Crowds also decline in importance. As adolescents settle on personal values and goals, they no longer feel a need to broadcast, through dress, language, and activities, who they are. From tenth to twelfth grade, about half of young people switch crowds, mostly in favorable directions (Strouse, 1999). "Brains" and "normal" crowds grow and deviant crowds lose members as teenagers focus more on their future.

Dating

The hormonal changes of puberty increase sexual interest, but cultural expectations determine when and how dating begins. Asian youths start dating later and have fewer dating partners than young people in Western societies, which tolerate and even encourage romantic involvements from middle school on (see Figure 12.3). At age 12 to 14, these relationships are usually

FIGURE 12.3 Increase in romantic relationships in adolescence. More than 16,000 U.S. youths responded to an interview in which they indicated whether they had been involved in a romantic relationship during the past 18 months. At age 12, about one-fourth of young people reported them, a figure that rose to about three-fourths at age 18. (Adapted from Carver, Joyner, & Udry, 2003.)

For this young couple out shopping together, dating extends the benefits of adolescent friendships, promoting sensitivity, empathy, self-esteem, and identity development.

casual, lasting only five months on average. By age 16, they have become steady relationships, continuing, on average, for nearly two years (Carver, Joyner, & Udry, 2003). Early adolescents tend to mention recreation and achieving peer status as reasons for dating. By late adolescence, as young people are ready for greater psychological intimacy, they seek dating partners who offer personal compatibility, companionship, affection, and social support (Collins & van Dulmen, 2006b; Meier & Allen, 2009).

The achievement of intimacy between dating partners typically lags behind that between friends. And positive relationships with parents and friends contribute to the development of warm romantic ties, whereas conflict-ridden parent-adolescent and peer relationships forecast hostile dating interactions (Connolly, Furman, & Konarski, 2000; Furman & Collins, 2009). Recall from Chapter 6 that according to ethological theory, early attachment bonds lead to an *internal working model*, or set of expectations about attachment figures, that guides later close relationships. Consistent with this idea, secure attachment to parents in infancy and childhood—together with recollections of that security in adolescence—predicts quality of teenagers' friendship and romantic ties (Collins & van Dulmen, 2006a; Collins, Welsh, & Furman, 2009). And in a study of high school seniors, secure models of parental attachment and supportive interactions with parents predicted secure models of friendship, which, in turn, were related to the security of romantic relationships (Furman et al., 2002).

Perhaps because early adolescent dating relationships are shallow and stereotyped, early dating is related to drug use, delinquency, and poor academic achievement (Eaton et al., 2007; Miller et al., 2009). These factors, along with a history of uninvolved parenting and aggression in family and peer relationships, increase the likelihood of dating violence. About 10 to 20 percent of adolescents are physically or sexually abused

by dating partners, with boys and girls equally likely to report being victims, and violence by one partner often returned by the other (Cyr, McDuff, & Wright, 2006; Williams et al., 2008). Mental health consequences are severe, including increased anxiety, depression, suicide attempts, and risky sexual behavior (Wekerle & Avgoustis, 2003). Young teenagers are better off sticking with group activities, such as parties and dances, before becoming involved with a steady boyfriend or girlfriend.

Gay and lesbian youths face special challenges in initiating and maintaining visible romances. Their first dating relationships seem to be short-lived and to involve little emotional commitment, but for reasons different from those of heterosexuals: They fear peer harassment and rejection (Diamond & Lucas, 2004). Recall from Chapter 11 that because of intense prejudice, homosexual adolescents often retreat into heterosexual dating. In addition, many have difficulty finding a same-sex partner because their gay and lesbian peers have not yet come out. Often their first contacts with other sexual-minority youths occur in support groups, where they are free to date publicly and can discuss concerns about coming out (Diamond, 2003).

As long as it does not begin too soon, dating provides lessons in cooperation, etiquette, and dealing with people in a wide range of situations. Among older teenagers, close romantic ties promote sensitivity, empathy, self-esteem, social support, and identity development. In addition, teenagers' increasing capacity for interdependence and compromise within dating enhances the quality of other peer relationships (Collins, Welsh, & Furman, 2009).

Still, about half of first romances do not survive high school graduation, and those that do usually become less satisfying (Shaver, Furman, & Buhrmester, 1985). Because young people are still forming their identities, high school couples often find that they have little in common after graduation. Nevertheless, warm, caring romantic ties in adolescence can have long-term implications. They are positively related to gratifying, committed relationships in early adulthood (Meier & Allen, 2009).

ASK YOURSELF

REVIEW Describe the distinct positive functions of friendships, cliques, and crowds in adolescence. What factors lead some friendships and peer-group ties to be harmful?

CONNECT How might gender intensification contribute to the shallow quality of early adolescent dating relationships?

APPLY Thirteen-year-old Mattie's parents are warm, firm in their expectations, and consistent in monitoring her activities. At school, Mattie met some girls who want her to tell her parents she's going to a friend's house and then, instead, join them at the beach for a party. Is Mattie likely to comply? Explain.

REFLECT How did family experiences influence your crowd membership in high school? How did your crowd membership influence your behavior?

Problems of Development

Most young people move through adolescence with little disturbance. But as we have seen, some encounter major disruptions in development, such as early parenthood, substance abuse, and school failure. In each instance, biological and psychological changes, families, schools, peers, communities, and culture combine to yield particular outcomes. Serious difficulties rarely occur in isolation but are usually interrelated—as is apparent in three additional problems of the teenage years: depression, suicide, and delinquency.

Depression

Depression—feeling sad, frustrated, and hopeless about life, accompanied by loss of pleasure in most activities and disturbances in sleep, appetite, concentration, and energy—is the most common psychological problem of adolescence. Among U.S. teenagers, 20 to 50 percent experience mild to moderate feelings of depression, bouncing back after a short time. More worrisome are the 15 to 20 percent who have had one or more major depressive episodes, a rate comparable to that of adults. From 2 to 8 percent are chronically depressed—gloomy and self-critical for many months and sometimes years (Graber & Sontag, 2009; Rushton, Forcier, & Schectman, 2002).

Serious depression affects only 1 to 2 percent of children, many of whom (especially girls) remain depressed in adolescence. In addition, depression increases sharply from ages 12 to 16 in industrialized nations, with many more girls than boys displaying adolescent onset. Teenage girls are twice as likely as boys to report persistent depressed mood—a difference sustained throughout the lifespan (Dekker et al., 2007; Hankin & Abela, 2005; Nolen-Hoeksema, 2006). If allowed to continue, depression seriously impairs social, academic, and vocational functioning. Unfortunately, the stereotypical view of adolescence as a period of storm and stress leads many adults to minimize the seriousness of adolescent depression, misinterpreting it as just a passing phase.

Factors Related to Depression. The precise combination of biological and environmental factors leading to depression varies from one individual to the next. Kinship studies reveal that heredity plays an important role (Glowinski et al., 2003). Genes can induce depression by affecting the balance of neurotransmitters in the brain, the development of brain regions involved in inhibiting negative emotion, or the body's hormonal response to stress.

But experience can also activate depression, promoting any of these biological changes. Parents of depressed children and adolescents display a high incidence of depression and other psychological disorders. Although a genetic risk may be passed from parent to child, in earlier chapters we saw that depressed or otherwise stressed parents often engage in maladaptive parenting. As a result, their child's emotional self-regulation,

In industrialized nations, stressful life events and gender-typed coping styles—passivity, dependency, and rumination—make adolescent girls more prone to depression than boys.

attachment, and self-esteem may be impaired, with serious consequences for many cognitive and social skills (Abela et al., 2005; Yap, Allen, & Ladouceur, 2008). Depressed youths usually display a learned-helpless attributional style (see Chapter 10) (Graber, 2004). In a vulnerable young person, numerous events can spark depression—for example, failing at something important, parental divorce, or the end of a close friendship or romantic partnership.

Sex Differences. Why are girls more prone to depression than boys? Biological changes associated with puberty cannot be responsible because the gender difference is limited to industrialized nations. In developing countries, rates of depression are similar for males and females and occasionally higher in males (Culbertson, 1997). Even in nations where females exceed males in depression, the size of the difference varies.

Instead, stressful life events and gender-typed coping styles seem to be responsible. Early-maturing girls are especially prone to depression (see Chapter 11). Adolescent gender intensification may strengthen girls' passivity, dependency, and tendency to ruminate on their anxieties and problems—maladaptive approaches to tasks expected of teenagers in complex cultures. Consistent with this explanation, adolescents who identify strongly with “feminine” traits ruminate more and are more depressed, regardless of their sex (Lopez, Driscoll, & Kistner, 2009; Papadakis et al., 2006). And having friends with depressive symptoms is linked to a rise in teenagers' own depressive symptoms, perhaps because corumination is high in such relationships (Conway et al., 2011).

Girls who repeatedly feel troubled and insecure develop an overly reactive physiological stress response and cope more poorly with future challenges (Hyde, Mezulis, & Abramson, 2008; Nolen-Hoeksema, 2006). In this way, stressful experiences

and stress reactivity feed on one another, sustaining depression. Profound depression can lead to suicidal thoughts, which all too often are translated into action.

Suicide

The suicide rate increases from childhood to old age, but it jumps sharply at adolescence. Currently, suicide is the third-leading cause of death among American youths, after motor vehicle collisions and homicides. Perhaps because U.S. teenagers experience more stress and fewer supports than in the past, the adolescent suicide rate tripled between the mid-1960s and mid-1990s, followed by a slight decline (Spirito & Esposito-Smythers, 2006; U.S. Census Bureau, 2012b). At the same time, rates of adolescent suicide vary widely among industrialized nations—low in Greece, Italy, the Netherlands, and Spain; intermediate in Australia, Canada, Japan, and the United States; and high in Finland, New Zealand, and Singapore (Bridge, Goldstein, & Brent, 2006). These international differences remain unexplained.

Factors Related to Adolescent Suicide. Despite girls' higher rates of depression, the number of boys who kill themselves exceeds the number of girls by a ratio of 3 or 4 to 1. Girls make more unsuccessful suicide attempts and use methods from which they are more likely to be revived, such as a sleeping pill overdose. In contrast, boys tend to choose techniques that lead to instant death, such as firearms or hanging (Langhinrichsen-Rohling, Friend, & Powell, 2009). Gender-role expectations may contribute; less tolerance exists for feelings of helplessness and failed efforts in males than in females.

Possibly due to higher levels of support from extended families, African Americans and Hispanics have lower suicide rates than Caucasian Americans. Recently, however, suicide has risen among African-American adolescent males; the current rate approaches that of Caucasian-American males. And Native-American youths commit suicide at rates two to six times national averages (Balis & Postolache, 2008; U.S. Census Bureau, 2012b). High rates of profound family poverty, school failure, alcohol and drug use, and depression probably underlie these trends.

Gay, lesbian, and bisexual youths are also at high risk, attempting suicide three times as often as other adolescents. Those who have tried to kill themselves report more family conflict over their gender-atypical behavior, inner turmoil about their sexuality, and peer victimization due to their sexual orientation (D'Augelli et al., 2005).

Suicide tends to occur in two types of young people. The first group includes adolescents who are highly intelligent but solitary, withdrawn, and unable to meet their own standards or those of important people in their lives. Members of the second, larger group show antisocial tendencies and express their unhappiness through bullying, fighting, stealing, increased risk taking, and drug abuse (Evans, Hawton, & Rodham, 2004). Besides being hostile and destructive, they turn their anger and disappointment inward.

Suicidal adolescents often have a family history of emotional and antisocial disorders. In addition, they are likely to have experienced multiple stressful life events, including economic disadvantage, parental divorce, frequent parent–child conflict, and abuse and neglect. Stressors typically increase during the period preceding a suicide attempt or completion (Beautrais, 2003; Kaminski et al., 2010). Triggering events include parental blaming of the teenager for family problems, the breakup of an important peer relationship, or the humiliation of having been caught engaging in antisocial acts.

Public policies resulting in cultural disintegration have amplified suicide rates among Native-American youths. From the late 1800s to the 1970s, Native-American families were forced to enroll their children in government-run residential boarding schools designed to erase tribal affiliations. In these repressive institutions, children were not allowed to “be Indian” in any way—culturally, linguistically, artistically, or spiritually (Goldston et al., 2008). The experience left many young people academically unprepared and emotionally scarred, contributing to family and community disorganization in current and succeeding generations (Barnes, Josefowitz, & Cole, 2006; Howell & Yuille, 2004). Consequently, alcohol abuse, youth crime, and suicide rates escalated.

Why does suicide increase in adolescence? One factor seems to be teenagers’ improved ability to plan ahead. Although some act impulsively, many young people take purposeful steps toward killing themselves. Other cognitive changes also contribute. Belief in the personal fable (see Chapter 11) leads many depressed young people to conclude that no one could possibly understand their intense pain. As a result, despair, hopelessness, and isolation deepen.

Prevention and Treatment. To prevent suicides, parents and teachers must be trained to pick up on the signals that a troubled teenager sends (see Table 12.3). Schools and community settings, such as recreational and religious organizations, can help by strengthening adolescents’ connection with their cultural heritage and providing counseling and support (Goldston et al., 2008; Miller, 2011). Once a teenager takes steps toward suicide, staying with the young person, listening, and expressing compassion and concern until professional help can be obtained are essential.

Treatments for depressed and suicidal adolescents range from antidepressant medication to individual, family, and group therapy. Until the adolescent improves, removing weapons, knives, razors, scissors, and drugs from the home is vital. On a broader scale, gun-control legislation that limits adolescents’ access to the most frequent and deadly suicide method in the United States would greatly reduce both the number of suicides and the high teenage homicide rate (Commission on Adolescent Suicide Prevention, 2005).

After a suicide, family and peer survivors need support to help them cope with grief, anger, and guilt over not having been able to help the victim. Teenage suicides often occur in clusters, with one death increasing the likelihood of others among depressed peers who knew the young person or heard about the

TABLE 12.3 Warning Signs of Suicide

Efforts to put personal affairs in order—smoothing over troubled relationships, giving away treasured possessions
Verbal cues—saying goodbye to family members and friends, making direct or indirect references to suicide (“I won’t have to worry about these problems much longer”; “I wish I were dead”)
Feelings of sadness, despondency, “not caring” anymore
Extreme fatigue, lack of energy, boredom
No desire to socialize; withdrawal from friends
Easily frustrated
Emotional outbursts—spells of crying or laughing, bursts of energy
Inability to concentrate, distractible
Decline in grades, absence from school, discipline problems
Neglect of personal appearance
Sleep change—loss of sleep or excessive sleepiness
Appetite change—eating more or less than usual
Physical complaints—stomachaches, backaches, headaches

suicide through the media (Bearman & Moody, 2004; Feigelman & Gorman, 2008). In view of this trend, an especially watchful eye must be kept on vulnerable adolescents after a suicide happens. Restraint by journalists in publicizing teenage suicides also aids prevention.

Delinquency

Juvenile delinquents are children or adolescents who engage in illegal acts. Although youth crime has declined in the United States since the mid-1990s, 12- to 17-year-olds account for about 14 percent of police arrests, although they constitute only 8 percent of the population (U.S. Department of Justice, 2010). When asked directly and confidentially about lawbreaking, almost all teenagers admit to having committed some sort of offense—usually a minor crime, such as petty stealing or disorderly conduct (Flannery et al., 2003).

Both police arrests and self-reports show that delinquency rises over early and middle adolescence and then declines (Farrington, 2009; U.S. Department of Justice, 2010). Recall that antisocial behavior increases among teenagers as a result of heightened reward seeking and desire for peer approval. Over time, peers become less influential; decision making, emotional self-regulation, and moral reasoning improve; and young people enter social contexts (such as higher education, work, marriage, and career) that are less conducive to lawbreaking.

For most adolescents, a brush with the law does not forecast long-term antisocial behavior. But repeated arrests are cause for concern. Teenagers are responsible for 15 percent of violent offenses in the United States (U.S. Department of Justice, 2010).

Biology and Environment

Two Routes to Adolescent Delinquency

Persistent adolescent delinquency follows two paths of development, one involving a small number of youths with an onset of conduct problems in childhood, the second a larger number with an onset in adolescence. The early-onset type is far more likely to lead to a life-course pattern of aggression and criminality (Moffitt, 2007). The late-onset type usually does not persist beyond the transition to early adulthood.

Both childhood-onset and adolescent-onset youths engage in serious offenses; associate with deviant peers; participate in substance abuse, unsafe sex, and dangerous driving; and spend time in correctional facilities. Why does antisocial activity more often continue and escalate into violence in the first group? Longitudinal studies yield similar answers to this question. Most research has focused on boys, but several investigations report that girls who were physically aggressive in childhood are also at risk for later problems—occasionally violent delinquency but more often other norm-violating behaviors and psychological disorders

(Broidy et al., 2003; Chamberlain, 2003). Early relational aggression is linked to adolescent conduct problems as well.

Early-Onset Type

Early-onset youngsters seem to inherit traits that predispose them to aggressiveness (Pettit, 2004). For example, violence-prone boys are emotionally negative, restless, willful, and physically aggressive as early as age 2. They also show subtle deficits in cognitive functioning that seem to contribute to disruptions in the development of language, memory, and cognitive and emotional self-regulation (Moffitt, 2007; Shaw et al., 2003). Some have attention-deficit hyperactivity disorder (ADHD), which compounds their learning and self-control problems (see Chapter 9, pages 304–305).

Yet these biological risks are not sufficient to sustain antisocial behavior: Most early-onset boys decline in aggression over time. Among those who follow the life-course path, inept parenting transforms their undercontrolled style into defiance and persistent

aggression (Brame, Nagin, & Tremblay, 2001; Broidy et al., 2003). As they fail academically and are rejected by peers, they befriend other deviant youths, who facilitate one another's violent behavior while relieving loneliness (see Figure 12.4) (Hughes, 2010; Lacourse et al., 2003). Limited cognitive and social skills result in high rates of school dropout and unemployment, contributing further to anti-social involvements. Often these boys experience their first arrest before age 14—a good indicator that they will be chronic offenders by age 18 (Patterson & Yoerger, 2002).

Preschoolers high in relational aggression also tend to be hyperactive and frequently in conflict with peers and adults (Willoughby, Kupersmidt, & Bryant, 2001). As these behaviors trigger peer rejection, relationally aggressive girls befriend other girls high in relational hostility, and their relational aggression rises (Werner & Crick, 2004). Adolescents high in relational aggression are often angry, vengeful, and defiant of adult rules. Among teenagers who combine physical and relational hostility, these oppositional reactions intensify, increasing the likelihood of serious antisocial activity (Harachi et al., 2006; Prinstein, Boergers, & Vernberg, 2001).

A small percentage become recurrent offenders, who commit most of these crimes, and some enter a life of crime. As the Biology and Environment box above reveals, childhood-onset conduct problems are far more likely to persist than conduct problems that first appear in adolescence.

Factors Related to Delinquency. In adolescence, the gender gap in physical aggression widens. Although girls account for about one in five adolescent arrests for violence, their offenses are largely limited to simple assault (such as pushing and spitting). Serious violent crime is mostly the domain of boys (Dahlberg & Simon, 2006). SES and ethnicity are strong predictors of arrests but only mildly related to teenagers' self-reports of antisocial acts. The difference is due to the tendency to arrest, charge, and punish low-SES ethnic minority youths more often than their higher-SES white and Asian counterparts (Farrington, 2009; U.S. Department of Justice, 2010).

Difficult temperament, low intelligence, poor school performance, peer rejection in childhood, and association with antisocial peers are linked to chronic delinquency (Laird et al.,

Delinquency—usually petty stealing and disorderly conduct—rises over early and middle adolescence and then declines. But a small percentage of young people engage in repeated, serious offenses and are at risk for a life of crime.

Late-Onset Type

Other youths first display antisocial behavior around the time of puberty, gradually increasing their involvement. Their conduct problems arise from the peer context of early adolescence, not from biological deficits and a history of unfavorable development. For some, quality of parenting may decline for a time, perhaps due to family stresses or the challenges of disciplining an unruly teenager (Moffitt, 2007). When age brings gratifying

adult privileges, these youths draw on prosocial skills mastered before adolescence and abandon their antisocial ways.

A few late-onset youths do continue to engage in antisocial acts. The seriousness of their adolescent offenses seems to trap them in situations that close off opportunities for responsible behavior. Being employed or in school and forming positive, close relationships predict an end to criminal offending by age 20 to 25 (Clingempeel &

Henggeler, 2003; Stouthamer-Loeber et al., 2004). In contrast, the longer antisocial young people spend in prison, the more likely they are to sustain a life of crime.

These findings suggest a need for a fresh look at policies aimed at stopping youth crime. Keeping youth offenders locked up for many years disrupts their vocational lives and access to social support during a crucial period of development, condemning them to a bleak future.

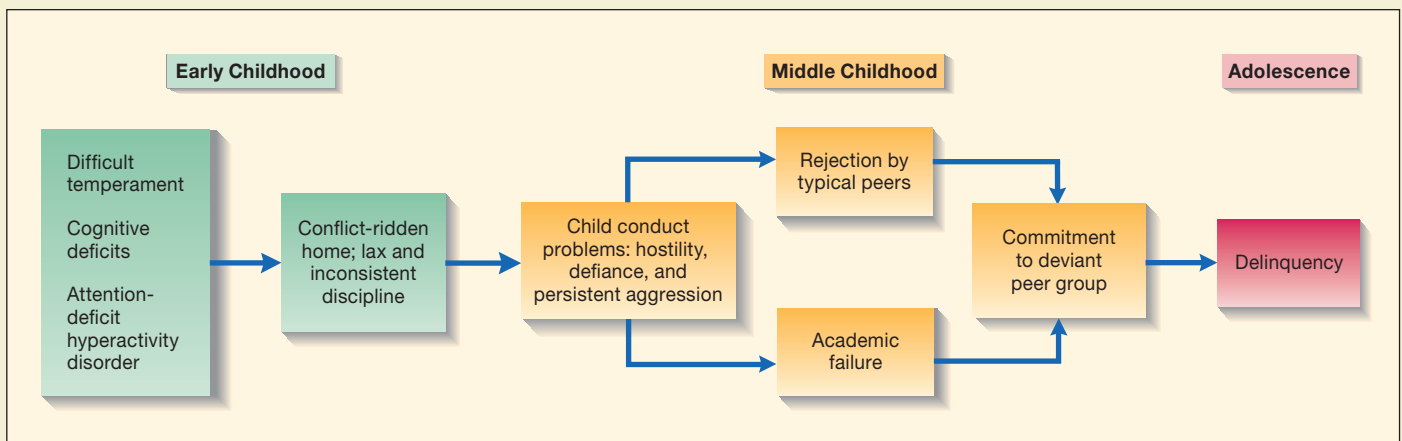

FIGURE 12.4 Path to chronic delinquency for adolescents with childhood-onset antisocial behavior. Difficult temperament and cognitive deficits characterize many of these youths in early childhood; some have attention-deficit hyperactivity disorder. Inept parenting transforms biologically based self-control difficulties into hostility and defiance.

2005). How do these factors fit together? One of the most consistent findings about delinquent youths is that their families are low in warmth, high in conflict, and characterized by harsh, inconsistent discipline and low monitoring (Barnes et al., 2006; Capaldi et al., 2002a). Because marital transitions often contribute to family discord and disrupted parenting, boys who experience parental separation and divorce are especially prone to delinquency (Farrington, 2004). And youth crime peaks on weekdays between 2:00 and 8:00 P.M., when many teenagers are unsupervised (U.S. Department of Justice, 2010).

Our discussion on page 259 in Chapter 8 explained how ineffective parenting can promote and sustain children's aggression, with boys—who are more active and impulsive—more often targets of parental anger, physical punishment, and inconsistency. When these child temperamental traits combine with emotionally negative, inept parenting, aggression rises sharply during childhood, leads to violent offenses in adolescence, and persists into adulthood (again, see the Biology and Environment box).

Teenagers commit more crimes in poverty-stricken neighborhoods with limited recreational and employment opportuni-

ties and high adult criminality (Leventhal, Duprere, & Brooks-Gunn, 2009). In such neighborhoods, adolescents have easy access to deviant peers, drugs, and firearms and are likely to be recruited into antisocial gangs, whose members commit the vast majority of violent delinquent acts. Furthermore, schools in these locales typically fail to meet students' developmental needs (Chung, Mulvey, & Steinberg, 2011; Flannery et al., 2003). Large classes, weak instruction, rigid rules, and reduced academic expectations and opportunities are associated with higher rates of lawbreaking, even after other influences are controlled.

Prevention and Treatment. Because delinquency has roots in childhood and results from events in several contexts, prevention must start early and take place at multiple levels (Frey et al., 2009). Positive family relationships, authoritative parenting, high-quality teaching in schools, and communities with healthy economic and social conditions go a long way toward reducing adolescent antisocial acts.

Lacking resources for effective prevention, many U.S. schools have implemented *zero tolerance policies*, which severely

punish all disruptive and threatening behavior, major and minor, usually with suspension or expulsion. Yet often these policies are implemented inconsistently: Low-SES minority students are two to three times as likely to be punished, especially for minor misbehaviors (Goode & Goode, 2007; Reppucci, Meyer, & Kostelnik, 2011). No evidence exists that zero tolerance achieves its objective of reducing youth aggression and other forms of misconduct (Stinchcomb, Bazemore, & Riestenberg, 2006). To the contrary, some studies find that by excluding students from school, zero tolerance heightens high school dropout and antisocial behavior.

Treating serious offenders requires an intensive, often lengthy approach, also directed at the multiple determinants of delinquency. The most effective methods include training parents in communication, monitoring, and discipline strategies and providing youths with experiences that improve cognitive and social skills, moral reasoning, anger management, and other aspects of emotional self-regulation (DiBiase et al., 2011; Heilbrun, Lee, & Cottle, 2005).

Yet even these multidimensional treatments can fall short if young people remain embedded in hostile home lives, anti-social peer groups, and fragmented neighborhoods. In a program called *multisystemic therapy*, counselors combined family intervention with integrating violent youths into positive school, work, and leisure activities and disengaging them from deviant peers. Compared with conventional services or indi-

vidual therapy, the intervention led to greater improvement in parent–adolescent relationships and school performance, a dramatic drop in number of arrests, and—when participants did commit crimes—a reduction in their severity. Multisystemic therapy also helped limit family instability once youth offenders reached adulthood, as measured by involvement in civil suits over divorce, paternity, or child support (Borduin, 2007; Henggeler et al., 2009; Sawyer & Borduin, 2011). Efforts to create nonaggressive environments—at the family, community, and cultural levels—are needed to help delinquent youths and to foster healthy development of all young people.

ASK YOURSELF

REVIEW Why are adolescent girls at greater risk for depression and adolescent boys at greater risk for suicide?

CONNECT Reread the sections on adolescent pregnancy and substance abuse in Chapter 11. What factors do these problems have in common with suicide and delinquency?

APPLY Zeke had been well-behaved in elementary school, but at age 13 he started spending time with the “wrong crowd.” At 16, he was arrested for property damage. Is Zeke likely to become a long-term offender? Why or why not?

SUMMARY

Erikson’s Theory: Identity versus Role Confusion (p. 402)

According to Erikson, what is the major personality achievement of adolescence?

- Erikson viewed **identity** as the major personality achievement of adolescence. Young people who successfully resolve the psychological conflict of **identity versus role confusion** construct a unified self-definition based on self-chosen values and goals.

Self-Understanding (p. 402)

Describe changes in self-concept and self-esteem during adolescence.

- Cognitive changes enable adolescents to develop more organized, consistent self-descriptions, with social, personal, and moral values as key themes.
- Self-esteem further differentiates and, for most adolescents, rises. Authoritative parenting and encouragement from teachers support positive self-esteem.

Describe the four identity statuses, along with factors that promote identity development.

- Researchers evaluate progress in identity development on two key criteria: exploration and commitment. **Identity achievement** (exploration followed by commitment to values, beliefs, and goals) and **identity moratorium** (exploration without having reached commitment) are psychologically healthy identity statuses. Long-term **identity foreclosure** (commitment without exploration) and **identity diffusion** (lack of both exploration and commitment) are related to adjustment difficulties.

- An information-gathering cognitive style, healthy parental attachment, interaction with diverse peers, close friendships, and schools and communities offering rich and varied opportunities promote healthy identity development. Supportive parents, peers, and schools can foster a strong, secure **ethnic identity** among minority adolescents, who often must overcome **acculturative stress**. A **bicultural identity** offers additional emotional and social benefits.

Moral Development (p. 405)

Describe Kohlberg’s theory of moral development, and evaluate its accuracy.

- Kohlberg organized moral development into three levels, each with two stages. At the **preconventional level**, morality is externally controlled and actions are judged by their consequences; at the **conventional level**, conformity to laws and rules is regarded as necessary for positive human relationships and societal order; and at the **postconventional level**, morality is defined by abstract, universal principles.

© KATHY MCLAUGHLIN/THE IMAGE WORKS

- A reexamination of Kohlberg's stages suggests that moral maturity can be found at Stages 3 and 4; few people attain the post-conventional level. Because situational factors influence moral judgments, Kohlberg's stages are best viewed as loosely organized and overlapping.
- Contrary to Gilligan's claim, Kohlberg's theory does not underestimate the moral maturity of females but instead taps both justice and caring orientations.
- Compared with children, teenagers display more subtle reasoning about conflicts between personal choice and community obligation and are increasingly aware of the moral implications of following social conventions.

Describe influences on moral reasoning and its relationship to moral behavior.

- Factors contributing to moral maturity include warm, rational child-rearing practices, education level, and peer discussions of moral issues. In village societies, where moral cooperation is based on direct relations between people, moral reasoning rarely moves beyond Kohlberg's Stage 3. In collectivist cultures, moral dilemma responses are more other-directed than in Western societies.
- The connection between mature moral reasoning and action is only modest. Moral behavior is also influenced by empathy and guilt, temperament, history of morally relevant experiences, and **moral identity**. Although formal religious involvement declines in adolescence, most religiously affiliated teenagers are advantaged in moral values and behavior.
- Researchers favoring a pragmatic approach to morality assert that moral maturity varies depending on context and motivations.

Gender Typing (p. 414)

How does gender typing change in adolescence?

- Some research suggests that adolescence is a time of **gender intensification**, in which gender stereotyping of attitudes and behavior increases, though evidence is mixed.

The Family (p. 414)

Discuss changes in parent–child and sibling relationships during adolescence.

- In their quest for **autonomy**, adolescents rely more on themselves and less on parents for decision making. Teenagers deidealize their parents, often questioning parental authority. Warm, supportive parenting, appropriate demands for maturity, and consistent monitoring predict favorable outcomes.
- Sibling influence declines as adolescents separate from the family and turn toward peers. Still, attachment to siblings remains strong for most young people.

Peer Relations (p. 417)

Describe adolescent friendships, peer groups, and dating relationships and their consequences for development.

- Adolescent friendships are based on intimacy, mutual understanding, and loyalty and contain more self-disclosure. Girls place greater emphasis on emotional closeness, boys on shared activities and accomplishments.
- Online communication supports closeness with existing friends. Though online communication with strangers provides some teenagers with vital social support, it also poses risks. High social media use is linked to unsatisfying face-to-face social experiences.
- Adolescent friendships—when not characterized by relational aggression or attraction to antisocial behavior—promote self-concept, perspective taking, identity, and the capacity for intimate relationships. They also help young people deal with stress and can foster improved attitudes toward and involvement in school.
- Adolescent peer groups are organized into **cliques**, particularly important to girls, and **crowds**, which grant teenagers an identity within the larger social structure of the school. With interest in dating, mixed-sex cliques increase in importance. Both cliques and crowds diminish as teenagers settle on personal values and goals.

- Intimacy in dating relationships lags behind that between friends. Positive relationships with parents and friends contribute to secure romantic ties.

© SCOTT HORTOP/LAMY

Problems of Development

(p. 421)

Describe factors related to adolescent depression and suicide.

- Depression is the most common psychological problem of adolescence, with girls at greater risk in industrialized nations. Combinations of biological and environmental factors are implicated, including heredity, maladaptive parenting, a learned-helpless attributional style, and negative life events.
- The suicide rate increases sharply at adolescence. Although teenage girls make more unsuccessful suicide attempts, boys account for more deaths. Teenagers at risk for suicide may be withdrawn but more often are anti-social. Family turmoil is common in the backgrounds of suicidal adolescents.

Discuss factors related to delinquency.

- Delinquency rises over early and middle adolescence and then declines. But only a few teenagers are serious repeat offenders—usually boys with a childhood history of conduct problems.
- A family environment low in warmth, high in conflict, and characterized by inconsistent discipline and low monitoring is consistently related to delinquency, as are poverty-stricken neighborhoods with high crime rates and ineffective schools.

Important Terms and Concepts

acculturative stress (p. 406)
 autonomy (p. 415)
 bicultural identity (p. 406)
 clique (p. 419)
 conventional level (p. 408)
 crowd (p. 419)

ethnic identity (p. 406)
 gender intensification (p. 414)
 identity (p. 402)
 identity achievement (p. 403)
 identity diffusion (p. 403)
 identity foreclosure (p. 403)

identity moratorium (p. 403)
 identity versus role confusion (p. 402)
 moral identity (p. 411)
 postconventional level (p. 408)
 preconventional level (p. 407)

milestones

Development in Adolescence

© BOB DAEMIRICH/PHOTODEBIT

Early Adolescence: 11–14

PHYSICAL

- If a girl, reaches peak of growth spurt. (363)
- If a girl, adds more body fat than muscle. (363–364)
- If a girl, starts to menstruate. (366)
- If a boy, begins growth spurt. (363)
- If a boy, starts to ejaculate seminal fluid. (366)
- Is likely to be aware of sexual orientation. (376)
- If a girl, motor performance increases gradually, leveling off by age 14. (364)
- Reacts more strongly to stressful events; shows heightened sensation-seeking and risk-taking behavior. (367–368)

COGNITIVE

- Gains in hypothetico-deductive reasoning and propositional thought. (383–384)
- Gains in scientific reasoning—coordinating theory with evidence—on complex, multivariable tasks. (385)

- Becomes more self-conscious and self-focused. (386–387)
- Becomes more idealistic and critical. (387)
- Metacognition and self-regulation continue to improve. (367–368, 385)

EMOTIONAL/SOCIAL

- Self-concept includes abstract descriptors unifying separate personality traits, but these are not interconnected and often contradictory. (402)
- In striving for autonomy, spends less time with parents and siblings, more time with peers. (416–417)
- Friendships decline in number and are based on intimacy, mutual understanding, and loyalty. (417)
- Peer groups become organized around same-sex cliques. (419)
- In high schools with complex social structures, cliques with similar values form crowds. (419)

© CINDY CHARLES/PHOTODEBIT

© RUDY VON BRIEL/PHOTODEBIT

Middle Adolescence: 14–16

PHYSICAL

- If a girl, completes growth spurt. (363)
- If a boy, reaches peak of growth spurt. (363)
- If a boy, voice deepens. (366)
- If a boy, adds muscle while body fat declines. (363)
- If a boy, motor performance improves dramatically. (364)
- May have had sexual intercourse. (375)

COGNITIVE

- Continues to improve in hypothetico-deductive reasoning and propositional thought. (383–384)
- Continues to improve in scientific reasoning, following a similar sequential order on different types of tasks. (385–386)

© BOB DAEMIRICH/PHOTODEBIT

- Becomes less self-conscious and self-focused. (386–387)
- Improves in decision making. (387–388)

EMOTIONAL/SOCIAL

- Combines features of the self into an organized self-concept. (402)
- Self-esteem differentiates further and tends to rise. (402–403)
- In most cases, begins to move from “lower” to “higher” identity statuses. (404)
- Increasingly emphasizes ideal reciprocity and societal laws as the basis for resolving moral dilemmas. (408–409)
- Engages in more subtle reasoning about conflicts between moral, social-conventional, and personal-choice issues. (409–410)

© JIM WEST/ALAMY

- Mixed-sex cliques become common. (420)
- Has probably started dating. (420)

Late Adolescence: 16–18

PHYSICAL

- If a boy, completes growth spurt. (363)
- If a boy, gains in motor performance continue. (364)

© ZUMA PRESS, INC./ALAMY

COGNITIVE

- Continues to improve in metacognition, scientific reasoning, and decision making. (385–386, 387–388)

© SPENCER GRANT/PHOTODISC

EMOTIONAL/SOCIAL

- Self-concept emphasizes personal and moral values. (402)
- Continues to construct an identity, typically moving to higher identity statuses. (404–405)
- Continues to advance in maturity of moral reasoning. (408–409)
- Cliques and crowds decline in importance. (420)
- Seeks psychological intimacy in romantic ties, which last longer. (420–421)

© CEZARO DE LUCA/EPA/CORBIS

Early adulthood brings momentous changes—among them, choosing a vocation, starting full-time work, and attaining economic independence. This Argentinean forensic anthropologist, who recently completed her higher education, has joined a team identifying people who went missing several decades ago, during a dark period of her country's history.

Physical and Cognitive Development in Early Adulthood

The back seat and trunk piled high with belongings, 23-year-old Sharese hugged her mother and brother goodbye, jumped in the car, and headed toward the interstate with a sense of newfound freedom mixed with apprehension. Three months earlier, the family had watched proudly as Sharese received her bachelor's degree in chemistry from a small university 40 miles from her home. Her college years had been a time of gradual release from economic and psychological dependency on her family. She returned home periodically on weekends and lived there during the summer months. Her mother supplemented Sharese's loans with a monthly allowance. But this day marked a turning point. She was moving to her own apartment in a city 800 miles away, with plans to work on a master's degree. With a teaching assistantship and a student loan, Sharese felt more "on her own" than at any previous time in her life.

During her college years, Sharese made lifestyle changes and settled on a vocational direction. Overweight throughout high school, she lost 20 pounds in her sophomore year, revised her diet, and began an exercise regimen by joining the university's Ultimate Frisbee team, eventually becoming its captain. A summer spent as a counselor at a camp for chronically ill children helped convince Sharese to apply her background in science to a career in public health.

Still, two weeks before she was to leave, Sharese confided in her mother that she had doubts about her decision. "Sharese," her mother advised, "we never know if our life choices are going to suit us just right, and most times they aren't perfect. It's what we make of them—how we view and mold them—that turns them into successes." So Sharese embarked on her journey and found herself face-to-face with a multitude of exciting challenges and opportunities.

In this chapter, we take up the physical and cognitive sides of early adulthood, which extends from about age 18 to 40. As noted in Chapter 1, the adult years are difficult to divide into discrete periods because the timing of important milestones varies greatly among individuals—much more so than in childhood and adolescence. But for most people, early adulthood involves a common set of tasks: leaving home, completing education, beginning full-time work, attaining economic independence, establishing a long-term sexually and emotionally intimate relationship, and starting a family. These are energetic decades filled with momentous decisions that, more than any other time of life, offer the potential for living to the fullest. ●

PHYSICAL DEVELOPMENT

We have seen that throughout childhood and adolescence, the body grows larger and stronger, coordination improves, and sensory systems gather information more effectively. Once body structures reach maximum capacity and efficiency, **biological aging**, or **senescence**, begins—genetically influenced declines in the functioning of organs and systems that are universal in all members of our species. Like physical growth, however, biological aging varies widely across parts of the body, and individual differences are great—variation that the *lifespan perspective* helps us understand. A host of contextual factors—including each person’s genetic makeup, lifestyle, living environment, and historical period—influence biological aging, each of which can accelerate or slow age-related declines (Arking, 2006). As a result, the physical changes of the adult years are, indeed, *multidimensional* and *multidirectional* (see page 9 in Chapter 1).

In the following sections, we examine the process of biological aging. Then we turn to physical and motor changes already under way in early adulthood. As you will see, biological aging can be modified substantially through behavioral and environmental interventions. During the twentieth century, improved nutrition, medical treatment, sanitation, and safety added 25 to 30 years to *average life expectancy* in industrialized nations, a trend that is continuing (see Chapter 1, page 8). We will take up life expectancy in greater depth in Chapter 17.

Biological Aging Is Under Way in Early Adulthood

At an intercollegiate tournament, Sharese dashed across the playing field for hours, leaping high to catch Frisbees sailing her way. In her early twenties, she is at her peak in strength, endurance, sensory acuteness, and immune system responsiveness. Yet over the next two decades, she will age and, as she moves into middle and late adulthood, will show more noticeable declines.

Biological aging is the combined result of many causes, some operating at the level of DNA, others at the level of cells, and still others at the level of tissues, organs, and the whole organism. Hundreds of theories exist, indicating that our understanding is incomplete (Arking, 2006). For example, one popular idea—the “wear-and-tear” theory—is that the body wears out from use. But no relationship exists between physical activity and early death. To the contrary, regular, moderate-to-vigorous exercise predicts healthier, longer life for people differing widely in SES and ethnicity (Ruiz et al., 2011; Stessman et al., 2005). We now know that this “wear-and-tear” theory is an oversimplification.

This whitewater kayaker, in his early twenties, is at his peak in strength, endurance, and sensory acuteness.

Aging at the Level of DNA and Body Cells

Current explanations of biological aging at the level of DNA and body cells are of two types: (1) those that emphasize the *programmed effects of specific genes* and (2) those that emphasize the *cumulative effects of random events* that damage genetic and cellular material. Support for both views exists, and a combination may eventually prove to be correct.

Genetically programmed aging receives some support from kinship studies indicating that longevity is a family trait. People whose parents had long lives tend to live longer themselves. And greater similarity exists in the lifespans of identical than fraternal twins. But the heritability of longevity is modest, ranging from .15 to .35 for age at death and from .27 to .57 for various measures of current biological age, such as strength of hand grip, respiratory capacity, blood pressure, and bone density (Cevenini et al., 2008; Dutta et al., 2011; Gögele et al., 2011). Rather than inheriting longevity directly, people probably inherit risk and protective factors, which influence their chances of dying earlier or later.

One “genetic programming” theory proposes the existence of “aging genes” that control certain biological changes, such as menopause, gray hair, and deterioration of body cells. The strongest evidence for this view comes from research showing that human cells allowed to divide in the laboratory have a lifespan of 50 divisions, plus or minus 10 (Hayflick, 1998). With each duplication, a special type of DNA called **telomeres**—located at the ends of chromosomes, serving as a “cap” to protect the ends from destruction—shortens. Eventually, so little remains that the cells no longer duplicate at all. Telomere shortening acts as a brake against somatic mutations (such as those involved in cancer), which become more likely as cells duplicate (Shay & Wright, 2011). But an increase in the number of senescent cells (ones with short telomeres) also contributes to age-related disease, loss of function, and earlier mortality (Epel et al., 2009; Shin et al., 2006). As the Biology and Environment box on the following page reveals, researchers have begun to

Biology and Environment

Telomere Length: A Marker of the Impact of Life Circumstances on Biological Aging

In the not-too-distant future, your annual physical exam may include an assessment of the length of your *telomeres*—DNA at the ends of chromosomes, which safeguard the stability of your cells. Telomeres shorten with each cell duplication; when they drop below a critical length, the cell can no longer divide and becomes senescent (see Figure 13.1). Although telomeres shorten with age, the rate at which they do so varies greatly. An enzyme called *telomerase* prevents shortening and can even reverse the trend, causing telomeres to lengthen and, thus, protecting the aging cell.

Over the past decade, research examining the influence of life circumstances on telomere length has exploded. A well-established finding is that chronic illnesses, such as cardiovascular disease and cancer, hasten telomere shortening in white blood cells, which play a vital role in the immune response (see page 437). Telomere shortening, in turn, predicts more rapid disease progression and earlier death (Fuster & Andres, 2006).

Accelerated telomere shortening has been linked to a variety of unhealthy behaviors, including cigarette smoking and the physical inactivity and overeating that lead to obesity and to insulin resistance, which often precedes type 2 diabetes (Epel et al., 2006; Gardner et al., 2005). Unfavorable health conditions may alter telomere length as early as the prenatal period, with possible long-term negative consequences for biological aging. In research on rats, poor maternal nutrition during pregnancy resulted in low birth weight and development of shorter telomeres in kidney and heart tissue

(Jennings et al., 1999; Tarry-Adkins et al., 2008). In a related human investigation, preschoolers who had been low-birth-weight as infants had shorter telomeres in their white blood cells than did their normal-birth-weight agemates (Raqib et al., 2007).

Persistent psychological stress—in childhood, abuse or bullying; in adulthood, parenting a child with a chronic illness or caring for an elder with dementia—is linked to reduced telomerase activity and telomere shortness in white blood cells (Damjanovic et al., 2007; McEwen, 2007; Shalev, 2012; Simon et al., 2006). Can stress actually modify telomeres?

In a laboratory experiment, researchers exposed human white blood cells to the stress hormone cortisol. The cells responded by decreasing production of telomerase (Choi, Fauce, & Effros, 2008).

Fortunately, when adults make positive lifestyle changes, telomeres seem to respond accordingly. In a study of obese women, those who responded to a lifestyle intervention with reduced psychological stress and healthier eating behaviors also displayed gains in telomerase activity (Daubenmier et al., 2012). In another investigation of men varying widely in age, greater maximum vital capacity of the lungs (a measure of physical

fitness) was associated with reduced age-related accumulation of senescent white blood cells (Spielmann et al., 2011).

Currently, researchers are working on identifying sensitive periods of telomere change—times when telomeres are most susceptible to modification. Early intervention—for example, enhanced prenatal care and interventions to reduce obesity in childhood—may be particularly powerful. But telomeres are changeable well into late adulthood (Epel et al., 2009). As our understanding of predictors and consequences of telomere length expands, it may become an important index of health and aging throughout life.

FIGURE 13.1 Telomeres at the ends of chromosomes. (a) Telomeres in a newly created cell. (b) With each cell duplication, telomeres shorten; when too short, they expose DNA to damage, and the cell dies.

identify health behaviors and psychological states that accelerate telomere shortening—powerful biological evidence that certain life circumstances compromise longevity.

According to an alternative, “random events” theory, DNA in body cells is gradually damaged through spontaneous or externally caused mutations. As these accumulate, cell repair and replacement become less efficient, and abnormal cancerous

cells are often produced. Animal studies confirm an increase in DNA breaks and deletions and damage to other cellular material with age. Similar evidence is accruing for humans (Freitas & Magalhães, 2011).

One hypothesized cause of age-related DNA and cellular abnormalities is the release of **free radicals**—naturally occurring, highly reactive chemicals that form in the presence of oxygen.

Kinship studies indicate that longevity is a family trait. In addition to favorable heredity, these grandsons will likely benefit from the model of a fit, active grandfather who buffers stress by enjoying life.

(Radiation and certain pollutants and drugs can trigger similar effects.) When oxygen molecules break down within the cell, the reaction strips away an electron, creating a free radical. As it seeks a replacement from its surroundings, it destroys nearby cellular material, including DNA, proteins, and fats essential for cell functioning. Free radicals are thought to be involved in more than 60 disorders of aging, including cardiovascular disease, neurological disorders, cancer, cataracts, and arthritis (Cutler & Mattson, 2006; Stohs, 2011). Although our bodies produce substances that neutralize free radicals, some harm occurs, and it accumulates over time.

Some researchers believe that genes for longevity work by defending against free radicals. In support of this view, animal species with longer life expectancies tend to display slower rates of free-radical damage to DNA (Sanz, Pamplona, & Barja, 2006). But contrary evidence also exists. Experimental manipulation of the mouse genome, by either augmenting or deleting antioxidant genes, has no impact on longevity. And scientists have identified a cave-dwelling salamander with exceptional longevity—on average, 68 years, making it the longest-living amphibian—with no unusual genetic defenses against free-radical damage (Speakman & Selman, 2011).

Research suggests that foods low in saturated fat and rich in vitamins can forestall free-radical damage (Bullo, Lamuela-Raventos, & Salas-Salvado, 2011). Nevertheless, the role of free radicals in aging is controversial.

Aging at the Level of Tissues and Organs

What consequences might age-related DNA and cellular deterioration have for the overall structure and functioning of organs and tissues? There are many possibilities. Among those with clear support is the **cross-linkage theory of aging**. Over time, protein fibers that make up the body's connective tissue

form bonds, or links, with one another. When these normally separate fibers cross-link, tissue becomes less elastic, leading to many negative outcomes, including loss of flexibility in the skin and other organs, clouding of the lens of the eye, clogging of arteries, and damage to the kidneys. Like other aspects of aging, cross-linking can be reduced by external factors, including regular exercise and a healthy diet (Kragstrup, Kjaer, & Mackey, 2011; Wickens, 2001).

Gradual failure of the endocrine system, which produces and regulates hormones, is yet another route to aging. An obvious example is decreased estrogen production in women, which culminates in menopause. Because hormones affect many body functions, disruptions in the endocrine system can have widespread effects on health and survival. For example, a gradual drop in growth hormone (GH) is associated with loss of muscle and bone mass, addition of body fat, thinning of the skin, and decline in cardiovascular functioning. In adults with abnormally low levels of GH, hormone therapy can slow these symptoms, but it has serious side effects, including increased risk of fluid retention in tissues, muscle pain, and cancer (Harman & Blackman, 2004; Ceda et al., 2010). So far, diet and physical activity are safer ways to limit these aspects of biological aging.

Finally, declines in immune system functioning contribute to many conditions of aging, including increased susceptibility to infectious disease and cancer and changes in blood vessel walls associated with cardiovascular disease. Decreased vigor of the immune response seems to be genetically programmed, but other aging processes we have considered (such as weakening of the endocrine system) can intensify it (Alonso-Fernández & De la Fuente, 2011; Hawkey & Cacioppo, 2004). Indeed, combinations of theories—the ones just reviewed as well as others—are needed to explain the complexities of biological aging. With this in mind, let's turn to physical signs and other characteristics of aging.

Physical Changes

During the twenties and thirties, changes in physical appearance and declines in body functioning are so gradual that most are hardly noticeable. Later, they will accelerate. The physical changes of aging are summarized in Table 13.1. We will examine several in detail here and take up others in later chapters. Before we begin, let's note that these trends are derived largely from cross-sectional studies. Because younger cohorts have experienced better health care and nutrition, cross-sectional evidence can exaggerate impairments associated with aging. Fortunately, longitudinal evidence is expanding, helping to correct this picture.

Cardiovascular and Respiratory Systems

During her first month in graduate school, Sharese pored over research articles on cardiovascular functioning. In her African-American extended family, her father, an uncle, and three aunts had died of heart attacks in their forties and fifties. These tragedies prompted Sharese to enter the field of public health in hopes

TABLE 13.1 Physical Changes of Aging

ORGAN OR SYSTEM	TIMING OF CHANGE	DESCRIPTION
Sensory		
Vision	From age 30	As the lens stiffens and thickens, ability to focus on close objects declines. Yellowing of the lens, weakening of muscles controlling the pupil, and clouding of the vitreous (gelatin-like substance that fills the eye) reduce light reaching the retina, impairing color discrimination and night vision. Visual acuity, or fineness of discrimination, decreases, with a sharp drop between ages 70 and 80.
Hearing	From age 30	Sensitivity to sound declines, especially at high frequencies but gradually extending to all frequencies. Change is more than twice as rapid for men as for women.
Taste	From age 60	Sensitivity to the four basic tastes—sweet, salty, sour, and bitter—is reduced. This may be due to factors other than aging, since number and distribution of taste buds do not change.
Smell	From age 60	Loss of smell receptors reduces ability to detect and identify odors.
Touch	Gradual	Loss of touch receptors reduces sensitivity on the hands, particularly the fingertips.
Cardiovascular	Gradual	As the heart muscle becomes more rigid, maximum heart rate decreases, reducing the heart's ability to meet the body's oxygen requirements when stressed by exercise. As artery walls stiffen and accumulate plaque, blood flow to body cells is reduced.
Respiratory	Gradual	Under physical exertion, respiratory capacity decreases and breathing rate increases. Stiffening of connective tissue in the lungs and chest muscles makes it more difficult for the lungs to expand to full volume.
Immune	Gradual	Shrinking of the thymus limits maturation of T cells and disease-fighting capacity of B cells, impairing the immune response.
Muscular	Gradual	As nerves stimulating them die, fast-twitch muscle fibers (responsible for speed and explosive strength) decline in number and size to a greater extent than slow-twitch fibers (which support endurance). Tendons and ligaments (which transmit muscle action) stiffen, reducing speed and flexibility of movement.
Skeletal	Begins in the late thirties, accelerates in the fifties, slows in the seventies	Cartilage in the joints thins and cracks, leading bone ends beneath it to erode. New cells continue to be deposited on the outer layer of the bones, and mineral content of bone declines. The resulting broader but more porous bones weaken the skeleton and make it more vulnerable to fracture. Change is more rapid in women than in men.
Reproductive	In women, accelerates after age 35; in men, begins after age 40	Fertility problems (including difficulty conceiving and carrying a pregnancy to term) and risk of having a baby with a chromosomal disorder increase.
Nervous	From age 50	Brain weight declines as neurons lose water content and die, mostly in the cerebral cortex, and as ventricles (spaces) within the brain enlarge. Development of new synapses and limited generation of new neurons can, in part, compensate for these declines.
Skin	Gradual	Epidermis (outer layer) is held less tightly to the dermis (middle layer); fibers in the dermis and hypodermis (inner layer) thin; fat cells in the hypodermis decline. As a result, the skin becomes looser, less elastic, and wrinkled. Change is more rapid in women than in men.
Hair	From age 35	Grays and thins.
Height	From age 50	Loss of bone strength leads to collapse of disks in the spinal column, leading to a height loss of as much as 2 inches by the seventies and eighties.
Weight	Increases to age 50; declines from age 60	Weight change reflects a rise in fat and a decline in muscle and bone mineral. Since muscle and bone are heavier than fat, the resulting pattern is weight gain followed by loss. Body fat accumulates on the torso and decreases on the extremities.

Sources: Arking, 2006; Lemaitre et al., 2012; Whitbourne, 1996.

of finding ways to relieve health problems among black Americans. *Hypertension*, or high blood pressure, occurs 12 percent more often in the U.S. black than in the U.S. white population; the rate of death from heart disease among African Americans is 30 percent higher (American Heart Association, 2012).

Sharese was surprised to learn that fewer age-related changes occur in the heart than we might expect, given that heart disease is a leading cause of death throughout adulthood, responsible for as many as 10 percent of U.S. male and 5 percent of U.S. female deaths between ages 20 and 34—figures that more than double

in the following decade and, thereafter, continue to rise steadily with age (American Heart Association, 2012). In healthy individuals, the heart's ability to meet the body's oxygen requirements under typical conditions (as measured by heart rate in relation to volume of blood pumped) does not change during adulthood. Only during stressful exercise does heart performance decline with age—a change due to a decrease in maximum heart rate and greater rigidity of the heart muscle (Arking, 2006). Consequently, the heart has difficulty delivering enough oxygen to the body during high activity and bouncing back from strain.

One of the most serious diseases of the cardiovascular system is *atherosclerosis*, in which heavy deposits of plaque containing cholesterol and fats collect on the walls of the main arteries. If present, it usually begins early in life, progresses during middle adulthood, and culminates in serious illness. Atherosclerosis is multiply determined, making it hard to separate the contributions of biological aging from individual genetic and environmental influences. The complexity of causes is illustrated by research indicating that before puberty, a high-fat diet produces only fatty streaks on the artery walls (Oliveira, Patin, & Escrivao, 2010). In sexually mature adults, however, it leads to serious plaque deposits, suggesting that sex hormones may heighten the insults of a high-fat diet.

Heart disease has decreased considerably since the mid-twentieth century, with a larger drop in the last 25 years due to a decline in cigarette smoking, to improved diet and exercise among at-risk individuals, and to better medical detection and treatment of high blood pressure and cholesterol (American Heart Association, 2012). And as a longitudinal follow-up of an ethnically diverse sample of U.S. black and white 18- to 30-year-olds revealed, those at low risk—defined by not smoking, normal body weight, healthy diet, and regular physical activity—were far less likely to be diagnosed with symptoms of heart disease over the succeeding two decades (Liu et al., 2012). Later, when we consider health and fitness, we will see why heart attacks were so common in Sharese's family—and why they occur at especially high rates in the African-American population.

Like the heart, the lungs show few age-related changes in functioning at rest, but during physical exertion, respiratory volume decreases and breathing rate increases with age. Maximum vital capacity (amount of air that can be forced in and out of the lungs) declines by 10 percent per decade after age 25 (Mahanran et al., 1999; Wilkie et al., 2012). Connective tissue in the lungs, chest muscles, and ribs stiffens with age, making it more difficult for the lungs to expand to full volume (Smith & Cotter, 2008). Fortunately, under normal conditions, we use less than half our vital capacity. Nevertheless, aging of the lungs contributes to older adults' difficulty in meeting the body's oxygen needs while exercising.

Motor Performance

Declines in heart and lung functioning under conditions of exertion, combined with gradual muscle loss, lead to changes in motor performance. In most people, the impact of biological

aging on motor skills is difficult to separate from decreases in motivation and practice. Therefore, researchers study competitive athletes, who try to attain their very best performance in real life (Tanaka & Seals, 2003). As long as athletes continue intensive training, their attainments at each age approach the limits of what is biologically possible.

Many athletic skills peak between ages 20 and 35, then gradually decline. In several investigations, the mean ages for best performance of Olympic and professional athletes in a variety of sports were charted over time. Absolute performance in most events improved over the past century. Athletes continually set new world records, suggesting improved training methods. But ages of best performance remained relatively constant. Athletic tasks that require speed of limb movement, explosive strength, and gross-motor coordination—sprinting, jumping, and tennis—typically peak in the early twenties. Those that depend on endurance, arm-hand steadiness, and aiming—long-distance running, baseball, and golf—usually peak in the late twenties and early thirties (Bradbury, 2009; Schulz & Curnow, 1988). Because these skills require either stamina or precise motor control, they take longer to perfect.

Research on outstanding athletes tells us that the upper biological limit of motor capacity is reached in the first part of early adulthood. How quickly do athletic skills weaken in later years? Longitudinal research on master runners reveals that as long as practice continues, speed drops only slightly from the mid-thirties into the sixties, when performance falls off at an accelerating pace (see Figure 13.2) (Tanaka & Seals, 2003; Trappe, 2007). In the case of long-distance swimming—a non-weight-bearing exercise with a low incidence of injury—the decline in speed is even more gradual: The accelerating performance drop-off is delayed until the seventies (Tanaka & Seals, 1997).

AP IMAGES/ALAN DIAZ

In her early thirties, professional tennis champion Serena Williams recently became the oldest player to be ranked World No. 1 in the history of the Women's Tennis Association. Sustained training leads to adaptations in body structures that minimize motor decline into the sixties.

FIGURE 13.2 Ten-kilometer running times with advancing age, based on longitudinal performances of hundreds of master athletes. Runners maintain their speed into the mid-thirties, followed by modest increases in running times into the sixties, with a progressively steeper increase thereafter. (From H. Tanaka & D. R. Seals, 2003, “Dynamic Exercise Performance in Masters Athletes: Insight into the Effects of Primary Human Aging on Physiological Functional Capacity,” *Journal of Applied Physiology*, 5, p. 2153. © The American Physiological Society (APS). All rights reserved. Adapted with permission.)

Indeed, sustained training leads to adaptations in body structures that minimize motor declines. For example, vital capacity is one-third greater in both younger and older people who participate actively in sports than in healthy inactive age-mates (Pimentel et al., 2003; Zaccagni, Onisto, & Gualdi-Russo, 2009). Training also slows muscle loss, increases speed and force of muscle contraction, and leads fast-twitch muscle fibers to be converted into slow-twitch fibers, which support excellent long-distance running performance and other endurance skills (Faulkner et al., 2007). In a study of hundreds of thousands of amateur marathon competitors, 25 percent of the 65- to 69-year-old runners were faster than 50 percent of the 20- to 54-year-old runners (Leyk et al., 2010). Yet many of the older runners had begun systematic marathon training only in the past five years.

In sum, although athletic skills are at their best in early adulthood, biological aging accounts for only a small part of age-related declines until advanced old age. Lower levels of performance by healthy people into their sixties and seventies largely reflect reduced capacities resulting from adaptation to a less physically demanding lifestyle.

Immune System

The immune response is the combined work of specialized cells that neutralize or destroy antigens (foreign substances) in the body. Two types of white blood cells play vital roles. *T cells*, which originate in the bone marrow and mature in the thymus (a small gland located in the upper part of the chest), attack antigens directly. *B cells*, manufactured in the bone marrow, secrete antibodies into the bloodstream that multiply, capture antigens, and permit the blood system to destroy them. Because

receptors on their surfaces recognize only a single antigen, T and B cells come in great variety. They join with additional cells to produce immunity.

The capacity of the immune system to offer protection against disease increases through adolescence and declines after age 20. The trend is partly due to changes in the thymus, which is largest during the teenage years, then shrinks until it is barely detectable by age 50. As a result, production of thymic hormones is reduced, and the thymus is less able to promote full maturity and differentiation of T cells (Fülöp et al., 2011). Because B cells release far more antibodies when T cells are present, the immune response is compromised further.

Withering of the thymus is not the only reason that the body gradually becomes less effective in warding off illness. The immune system interacts with the nervous and endocrine systems. For example, psychological stress can weaken the immune response. During final exams, for example, Sharese was less resistant to colds. And in the month after her father died, she had great difficulty recovering from the flu. Conflict-ridden relationships, caring for an ill aging parent, sleep deprivation, and chronic depression can also reduce immunity (Fagundes et al., 2011; Robles & Carroll, 2011). And physical stress—from pollution, allergens, poor nutrition, and rundown housing—undermines immune functioning throughout adulthood (Friedman & Lawrence, 2002). When physical and psychological stressors combine, the risk of illness is magnified.

The link between stress and illness makes sense when we consider that stress hormones mobilize the body for action, whereas the immune response is fostered by reduced activity. But this also means that increased difficulty coping with physical and psychological stress can contribute to age-related declines in immune system functioning.

Reproductive Capacity

Sharese was born when her mother was in her early twenties. At the same age a generation later, Sharese was still single and entering graduate school. Many people believe that pregnancy during the twenties is ideal, not only because of lower risk of miscarriage and chromosomal disorders (see Chapter 2) but also because younger parents have more energy to keep up with active children. Nevertheless, as Figure 13.3 on page 438 reveals, first births to women in their thirties have increased greatly over the past three decades. Many people are delaying childbearing until their education is complete, their careers are well-established, and they know they can support a child.

Nevertheless, reproductive capacity does decline with age. Between ages 15 and 29, 11 percent of U.S. married childless women report fertility problems, a figure that rises to 14 percent among 30- to 34-year-olds and to over 40 percent among 35- to 44-year-olds, when the success of reproductive technologies drops sharply (see page 54 in Chapter 2) (U.S. Department of Health and Human Services, 2012b). Because the uterus shows no consistent changes from the late thirties through the forties, the decline in female fertility is largely due to reduced number and quality of ova. In many mammals, including humans, a

FIGURE 13.3 First births to American women of different ages in 1970 and 2010. The birthrate decreased during this period for women 20 to 24 years of age, whereas it increased for women 25 years of age and older. For women in their thirties, the birthrate increased six-fold, and for those in their early forties, it doubled. Similar trends have occurred in other industrialized nations. (From U.S. Census Bureau, 2012b.)

certain level of reserve ova in the ovaries is necessary for conception (Balasch, 2010; Djahanbakhch, Ezzati, & Zosmer, 2007). Some women have normal menstrual cycles but do not conceive because their reserve of ova is too low.

In males, semen volume, sperm motility, and percentage of normal sperm decrease gradually after age 35, contributing to reduced fertility rates in older men (Lambert, Masson, & Fisch, 2006). Although there is no best time in adulthood to begin parenthood, individuals who postpone childbearing until their late thirties or their forties risk having fewer children than they desired or none at all.

ASK YOURSELF

REVIEW How does research on life conditions that accelerate telomere shortening illustrate the concept of epigenesis, discussed in Chapter 2 (see pages 73–75)?

CONNECT How do heredity and environment jointly contribute to age-related changes in cardiovascular, respiratory, and immune system functioning?

APPLY Penny is a long-distance runner for her college track team. What factors will affect Penny's running performance 30 years from now?

REFLECT Before reading this chapter, had you thought of early adulthood as a period of aging? Why is it important for young adults to be aware of influences on biological aging?

Health and Fitness

Figure 13.4 displays leading causes of death in early adulthood in the United States. Death rates for all causes exceed those of other industrialized nations (OECD, 2012b). The difference is likely due to a combination of factors, including higher rates of poverty and extreme obesity, more lenient gun-control policies, and historical lack of universal health insurance in the United States. In later chapters, we will see that homicide rates decline with age, while disease and physical disability rates rise. Biological aging clearly contributes to this trend. But, as we have noted, wide individual and group differences in physical changes are linked to environmental risks and health-related behaviors.

SES variations in health over the lifespan reflect these influences. With the transition from childhood to adulthood, health inequalities associated with SES increase; income, education, and occupational status show strong, continuous relationships with almost every disease and health indicator (Braveman et al., 2010; Smith & Infurna, 2011). Furthermore, SES largely accounts for the sizable health advantage of white over ethnic minority adults in the United States (Phuong, Frank, & Finch, 2012). Consequently, improving socioeconomic conditions is essential for closing ethnic gaps in health.

Health-related circumstances and habits—stressful life events, crowding, pollution, diet, exercise, overweight and obesity, substance abuse, jobs with numerous health risks, availability of supportive social relationships, and (in the United States) access to affordable health care—underlie SES health disparities (Ertel, Glymour, & Berkman, 2009; Smith & Infurna, 2011). Furthermore, poor health in childhood, which is linked to low SES, affects health in adulthood. The overall influence of

FIGURE 13.4 Leading causes of death between 25 and 44 years of age in the United States. Nearly half of unintentional injuries are motor vehicle accidents. As later chapters will reveal, unintentional injuries remain a leading cause of death at older ages, rising sharply in late adulthood. Rates of cancer and cardiovascular disease rise steadily during middle and late adulthood. (Adapted from U.S. Department of Health and Human Services, 2011b.)

SES variations in health in the United States—larger than in other industrialized nations—are in part due to lack of access to affordable health care. This Los Angeles free clinic helps address the problem by offering preventive services, including eye exams, to over 1,200 patients per day.

childhood factors lessens if SES improves. But in most instances, child and adult SES remain fairly consistent, exerting a cumulative impact that amplifies SES differences in health with age (Herd, Robert, & House, 2011).

Why are SES variations in health and mortality larger in the United States than in other industrialized nations? Besides lack of universal health insurance, low-income and poverty-stricken U.S. families are financially less well-off than families classified in these ways in other countries (Wilkinson & Pickett, 2006). In addition, SES groups are more likely to be segregated by neighborhood in the United States, resulting in greater inequalities in environmental factors that affect health, such as housing, pollution, education, and community services.

These findings reveal, once again, that the living conditions that nations and communities provide combine with those that people create for themselves to affect physical aging. Because the incidence of health problems is much lower during the twenties and thirties than later on, early adulthood is an excellent time to prevent later problems. In the following sections, we take up a variety of major health concerns—nutrition, exercise, substance abuse, sexuality, and psychological stress.

Nutrition

Bombarded with advertising claims and an extraordinary variety of food choices, adults find it increasingly difficult to make wise dietary decisions. An abundance of food, combined with a heavily scheduled life, means that most Americans eat because

they feel like it or because it is time to do so rather than to maintain the body's functions (Donatelle, 2012). As a result, many eat the wrong types and amounts of food. Overweight and obesity and a high-fat diet are widespread nutritional problems with long-term consequences for adult health.

Overweight and Obesity. In Chapter 9, we noted that obesity (a greater than 20 percent increase over average body weight, based on age, sex, and physical build) has increased dramatically in many Western nations, and it is on the rise in the developing world as well. Among adults, a body mass index (BMI) of 25 to 29 constitutes overweight, a BMI of 30 or greater (amounting to 30 or more excess pounds) constitutes obesity. Today, 36 percent of U.S. adults are obese. The rate rises to 38 percent among Hispanics, 39 percent among Native Americans, and 50 percent among African Americans (Flegal et al., 2012). The overall prevalence of obesity is similar among men and women.

Overweight—a less extreme but nevertheless unhealthy condition—affects an additional 33 percent of Americans. Combine the rates of overweight and obesity and the total, 69 percent, makes Americans the heaviest people in the world. **TAKE A MOMENT...** Notice in these figures that the U.S. obesity rate now exceeds its rate of overweight, a blatant indicator of the growing severity of the problem.

Recall from Chapter 9 that overweight children are very likely to become overweight adults. But a substantial number of people show large weight gains in adulthood, most often between ages 25 and 40. And young adults who were already overweight or obese typically get heavier, leading obesity rates to rise steadily between ages 20 and 65 (Flegel et al., 2012).

Causes and Consequences. As noted in Chapter 9, heredity makes some people more vulnerable to obesity than others. But environmental pressures underlie the rising rates of obesity in industrialized nations: With the decline in need for physical labor in the home and workplace, our lives have become more sedentary. Meanwhile, the average number of calories and amount of sugar and fat consumed by Americans rose over most of the twentieth and early twenty-first century, with a sharp increase after 1970 (see the Social Issues: Health box on pages 440–441).

Adding some weight between ages 25 and 50 is a normal part of aging because **basal metabolic rate (BMR)**, the amount of energy the body uses at complete rest, gradually declines as the number of active muscle cells (which create the greatest energy demand) drops off. But excess weight is strongly associated with serious health problems (see page 291 in Chapter 9)—including type 2 diabetes, heart disease, and many forms of cancer—and with early death.

Furthermore, overweight adults suffer enormous social discrimination. Compared with their normal-weight agemates, they are less likely to find mates, be rented apartments, receive financial aid for college, or be offered jobs. And they report frequent mistreatment by family members, peers, co-workers, and health professionals (Ickes, 2011; Puhl, Heuer, & Brownell,

Social Issues: Health

The Obesity Epidemic: How Americans Became the Heaviest People in the World

In the late 1980s, obesity in the United States started to soar. As the maps in Figure 13.5 show, it quickly engulfed the nation and has continued to expand. The epidemic also spread to other Western nations and, more recently, to developing countries. For example, as noted in Chapter 9, obesity was rare in China 30 years ago, but today it affects 7 percent of Chinese children and adolescents and 11 percent of adults; an additional 15 percent of the Chinese population is overweight (Xi et al., 2012). Yet China is a low-prevalence country! Worldwide, overweight afflicts more than 1.4 billion adults, 500 million of whom are obese. American Samoa leads the globe in overweight and obesity, with a staggering 94 percent of people affected (World Health Organization, 2013a). Among industrialized nations, no country matches the United States in prevalence of this life-threatening condition.

A Changing Food Environment and Lifestyle

Several societal factors have encouraged widespread rapid weight gain:

- *Availability of cheap commercial fat and sugar.* The 1970s saw two massive changes in the U.S. food economy: (1) the discovery

and mass production of high-fructose corn syrup, a sweetener six times as sweet as ordinary sugar and therefore far less expensive; and (2) the importing from Malaysia of large quantities of palm oil, which is lower in cost than other vegetable oils and also tastier because of its high saturated fat content. Use of corn syrup and palm oil in soft drinks and calorie-dense convenience foods lowered production costs for these items, launching a new era of “cheap, abundant, and tasty calories” (Crisler, 2003).

- *Portion supersizing.* Fast-food chains discovered a successful strategy for attracting customers: increasing portion sizes substantially and prices just a little for foods that had become inexpensive to produce. Customers thronged to buy “value meals,” jumbo burgers and burritos, and 20-ounce Cokes (Crisler, 2003). Research reveals that when presented with larger portions, individuals 2 years and older increase their intake, on average, by 25 to 30 percent (Fisher, Rolls, & Birch, 2003; Steenhuis & Vermeer, 2009).
- *Increasingly busy lives.* Between the 1970s and 1990s, women entered the labor force in record numbers, and the average

amount of time Americans worked increased dramatically. Today, 86 percent of employed U.S. men and 66 percent of employed women work over 40 hours per week—substantially more than in most other countries (Schor, 2002; United Nations, 2012). As time for meal preparation shrank, eating out increased (Midlin, Jenkins, & Law, 2009). In addition, Americans became frequent snackers, tempted by a growing assortment of high-calorie snack foods on supermarket shelves. And the number of calories Americans consumed away from home doubled, with dietary fat increasing from 19 to 38 percent (Nielsen & Popkin, 2003).

- *Declining rates of physical activity.* During the 1980s, physical activity, which had risen since the 1960s, started to fall as Americans spent more time in sedentary transportation and jobs—driving to and from work and sitting throughout the work day, often behind a computer. At home, a rise in TV viewing to an average of more than four hours per day has been linked to weight gain in adults and children alike (Foster, Gore, & West, 2006).

Combating the Obesity Epidemic

Obesity is responsible for \$150 billion in health expenditures and an estimated

2010). Since the mid-1990s, discrimination experienced by overweight Americans has increased, with serious physical and mental health consequences. Weight stigma triggers anxiety, depression, and low self-esteem, which increase the chances that unhealthy eating behaviors will persist and even worsen (Puhl & Heuer, 2010). The widespread but incorrect belief, perpetuated by the media, that obesity is a personal choice promotes negative stereotyping of obese persons.

Treatment. Because obesity climbs in early and middle adulthood, treatment for adults should begin as soon as possible—preferably in the early twenties. Even moderate weight loss reduces health problems substantially (Poobalan et al., 2010). But successful intervention is difficult. Most individuals who start a weight-loss program return to their original

weight, and often to a higher weight, within two years (Vogels, Diepvens, & Westerterp-Plantenga, 2005). The high rate of failure is partly due to limited evidence on just how obesity disrupts the complex neural, hormonal, and metabolic factors that maintain a normal body-weight set point. Until more information is available, researchers are examining the features of treatments and participants associated with greater success. The following elements promote lasting behavior change:

- *A lifestyle change to a nutritious diet lower in calories, sugar, and fat, plus regular exercise.* To lose weight, Sharese sharply reduced calories, sugar, and fat in her diet and exercised regularly. The precise balance of dietary protein, carbohydrates, and fats that best helps adults lose weight is a matter of heated debate. Although scores of diet books offer different recommendations, no clear-cut evidence exists for

300,000 premature deaths per year in the United States alone (Finkelstein et al., 2009; Flegal et al., 2007). Because multiple social and economic influences have altered the environment to promote this epidemic, broad societal efforts are needed to combat it. Effective policies include

- Government funding to support massive public education efforts about healthy eating and physical activity
- A high priority placed on building parks and recreation centers and replacing unhealthy fast-food outlets with access to healthy, affordable foods in low-income neighborhoods, where overweight and obesity are highest
- Laws that mandate prominent posting of the calorie, sugar, and fat content of foods sold in restaurants, movie theaters, and convenience stores
- Incentives to schools and workplaces for promoting healthy eating and daily exercise and for offering weight-management programs
- Increased obesity-related medical coverage in government-sponsored health insurance programs for low-income families

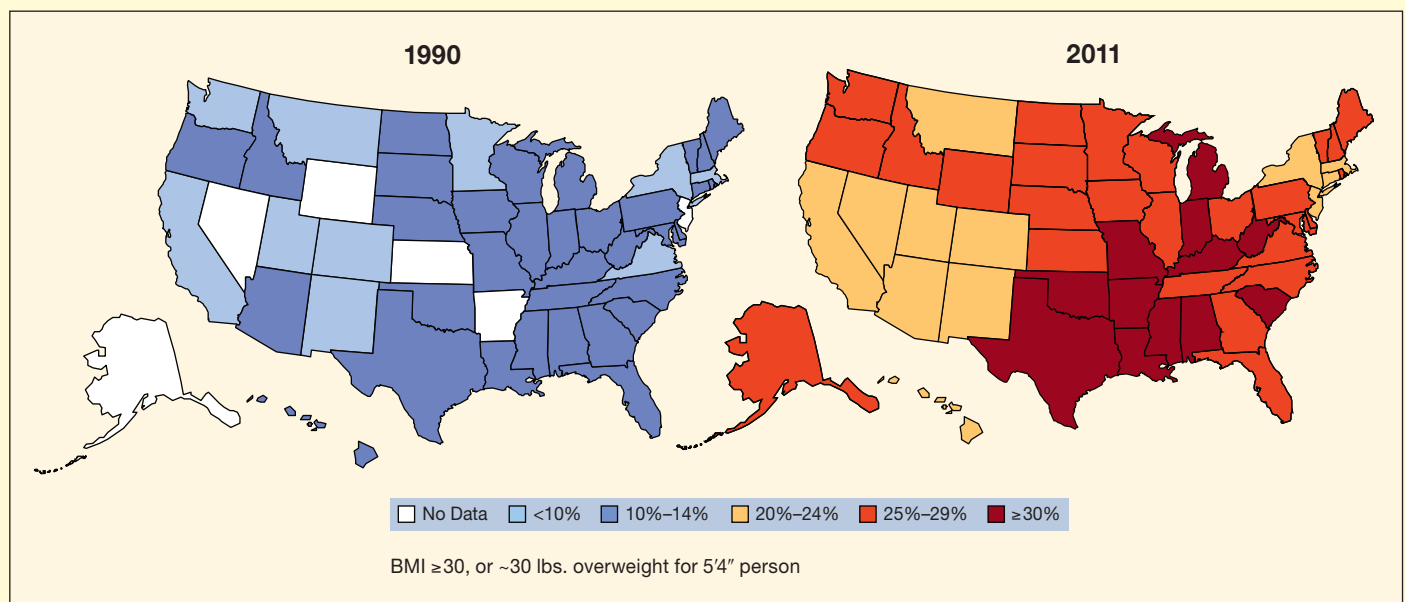

FIGURE 13.5 Obesity trends among U.S. adults, 1990 and 2011. The maps show that obesity has increased sharply. In 2011, twelve states (Alabama, Arkansas, Indiana, Kentucky, Louisiana, Michigan, Mississippi, Missouri, Oklahoma, South Carolina, Texas, and West Virginia) had rates equal to or greater than 30 percent. (From Centers for Disease Control and Prevention, 2012a.)

the long-term superiority of one approach over others (Tsai & Wadden, 2005).

Research does confirm that a permanent lifestyle alteration that restricts calorie intake and fat (to no more than 20 to 30 percent of calories) and that increases physical activity is essential for reducing the impact of a genetic tendency toward overweight. But most people mistakenly believe that only temporary lifestyle changes are needed (MacLean et al., 2011).

- *Training participants to keep an accurate record of food intake and body weight.* About 30 to 35 percent of obese people sincerely believe they eat less than they do. And although they have continued to gain weight, American adults generally report weight losses—suggesting that they are in denial about the seriousness of their weight condition

(Wetmore & Mokdad, 2012). Furthermore, from 25 to 45 percent report problems with binge eating—a behavior associated with weight-loss failure (Blaine & Rodman, 2007). As Sharese recognized how often she ate when not actually hungry and regularly recorded her weight, she was better able to limit food intake.

- *Social support.* Group or individual counseling and encouragement from friends and relatives help sustain weight-loss efforts by fostering self-esteem and self-efficacy (Poobalan et al., 2010). Once Sharese decided to act, with the support of her family and a weight-loss counselor, she felt better about herself even before the first pounds were shed.
- *Teaching problem-solving skills.* Most overweight adults do not realize that because their body has adapted to overweight, difficult periods requiring high self-control and

A permanent lifestyle change that includes an increase in physical activity is essential for treating obesity.

patience are inevitable in successful weight loss (MacLean et al., 2011). Acquiring cognitive and behavioral strategies for coping with tempting situations and periods of slowed progress is associated with long-term change (Cooper & Fairburn, 2002). Weight-loss maintainers are more likely than individuals who relapse to be conscious of their behavior, to use social support, and to confront problems directly.

- *Extended intervention.* Longer treatments (from 25 to 40 weeks) that include the components listed here grant people time to develop new habits.

Although many Americans on weight-reduction diets are overweight, about one-third of dieters are within normal range (Mokdad et al., 2001). Recall from Chapter 11 that the high value placed on thinness creates unrealistic expectations about desirable body weight and contributes to anorexia and bulimia, dangerous eating disorders that remain common in early adulthood (see pages 372–373). Throughout adulthood, both underweight and obesity are associated with increased mortality (Ringbäck, Eliasson, & Rosén, 2008). A sensible body weight—neither too low nor too high—predicts physical and psychological health and longer life.

Dietary Fat. During college, Sharese altered the diet of her childhood and adolescent years, sharply limiting red meat, eggs, butter, and fried foods. U.S. national dietary recommendations include reducing fat to 30 percent of total caloric intake, with no more than 7 percent made up of saturated fat, which generally comes from meat and dairy products and is solid at room temperature (U.S. Department of Agriculture, 2011a). Many researchers believe that dietary fat plays a role in the age-related

rise in breast cancer and (when it includes large amounts of red meat) is linked to colon cancer (Ferguson, 2010; Turner, 2011). But the main reasons for limiting dietary fat are the strong connection of total fat with obesity and of saturated fat with cardiovascular disease (Hooper et al., 2012). Nevertheless, despite a slight drop in fat consumption, most American adults eat too much.

Moderate fat consumption is essential for normal body functioning. But when we consume too much fat, especially saturated fat, some is converted to cholesterol, which accumulates as plaque on the arterial walls in atherosclerosis. Earlier in this chapter, we noted that atherosclerosis is determined by multiple biological and environmental factors. But excess fat consumption (along with other societal conditions) is an important contributor to the high rate of heart disease in the U.S. black population. As Figure 13.6 shows, when researchers compared Africans in West Africa, the Caribbean, and the United States (the historic path of the slave trade), dietary fat increased, and so did high blood pressure and heart disease (Luke et al., 2001).

The best rule of thumb is to eat less fat of all kinds, replacing saturated fat with unsaturated fat (which is derived from vegetables or fish and is liquid at room temperature) and with complex carbohydrates (whole grains, fruits, and vegetables), which are beneficial to cardiovascular health and protective against colon cancer (Kaczmarczyk, Miller, & Freund, 2012). Furthermore, regular exercise can reduce the harmful influence of saturated fat because it creates chemical byproducts that help eliminate cholesterol from the body.

FIGURE 13.6 Dietary fat and prevalence of high blood pressure among Africans in West Africa, the Caribbean, and the United States. The three regions represent the historic path of the slave trade and, therefore, have genetically similar populations. As dietary fat increases, high blood pressure and heart disease rise. Both are particularly high among African Americans. (Adapted from Luke et al., 2001.)

Exercise

Three times a week, over the noon hour, Sharese delighted in running, making her way to a wooded trail that cut through a picturesque area of the city. Regular exercise kept her fit and slim, and she noticed that she caught fewer respiratory illnesses than in previous years, when she had been sedentary and overweight. As Sharese explained to a friend, “Exercise gives me a positive outlook and calms me down. Afterward, I feel a burst of energy that gets me through the day.”

Although most Americans are aware of the health benefits of exercise, only 47 percent engage in the nationally recommended 150 minutes per week of at least moderately intense leisure-time physical activity. And just 24 percent engage in the recommended two sessions per week of resistance exercises, which place a moderately stressful load on each of the major muscle groups. Over half of Americans are inactive, with no regular brief sessions of even light activity (U.S. Department of Health and Human Services, 2011c). More women than men are inactive. And inactivity is greater among low-SES adults, who live in less safe neighborhoods, have more health problems, experience less social support for exercising regularly, and feel less personal control over their health.

LOOK AND LISTEN

Contact your local parks and recreation department to find out what community supports and services exist to increase adult physical activity. Are any special efforts made to reach low-SES adults? ●

Besides reducing body fat and building muscle, exercise fosters resistance to disease. Frequent bouts of moderate-intensity exercise enhance the immune response, lowering the risk of colds or flu and promoting faster recovery from these illnesses (Donatelle, 2012). Furthermore, animal and human evidence indicates that physical activity is linked to reduced incidence of several types of cancer, with the strongest findings for breast and colon cancer (Anzuini, Battistella, & Izzotti, 2011). Physically active people are also less likely to develop diabetes and cardiovascular disease (Bassuk & Manson, 2005). If they do, these illnesses typically occur later and are less severe than among their inactive agemates.

How does exercise help prevent these serious illnesses? First, it reduces the incidence of obesity—a risk factor for heart disease, diabetes, and cancer. In addition, people who exercise probably adopt other healthful behaviors, thereby lowering the risk of diseases associated with high-fat diets, alcohol consumption, and smoking. In animal studies, exercise directly inhibits growth of cancerous tumors—beyond the impact of diet, body fat, and the immune response (de Lima et al., 2008). Exercise also promotes cardiovascular functioning by strengthening the heart muscle, decreasing blood pressure, and producing a form of “good cholesterol” (high-density lipoproteins, or HDLs) that helps remove “bad cholesterol” (low-density lipoproteins, or LDLs) from the artery walls (Donatelle, 2012).

LORI ADAMSKI PEEK/STONE/GETTY IMAGES

Regular exercise of at least moderate intensity predicts a healthier, longer life. Participants in this kickboxing class reap both physical and mental health benefits.

Yet another way that exercise guards against illness is through its mental health benefits. Physical activity reduces anxiety and depression and improves mood, alertness, and energy. Furthermore, EEG and fMRI evidence indicates that exercise enhances neural activity in the cerebral cortex, and it improves overall cognitive functioning (Carek, Laibstain, & Carek, 2011; Etnier & Labban, 2012; Hillman, Erickson, & Kramer, 2008). The impact of exercise on a “positive outlook,” as Sharese expressed it, is most obvious just after a workout and can last for several hours (Acevedo, 2012). The stress-reducing properties of exercise undoubtedly strengthen immunity to disease. And as physical activity enhances cognitive functioning and psychological well-being, it promotes on-the-job productivity, self-esteem, ability to cope with stress, and life satisfaction.

When we consider the evidence as a whole, it is not surprising that physical activity is associated with substantially lower death rates from all causes. The contribution of exercise to longevity cannot be accounted for by preexisting illness in inactive people. In a Danish longitudinal study of a nationally representative sample of 7,000 healthy 20- to 79-year-olds followed over several decades, mortality was lower among those who increased their leisure-time physical activity from low to either moderate or high than among those who remained consistently inactive (Schnohr, Scharling, & Jensen, 2003).

How much exercise is recommended for a healthier, happier, and longer life? Moderately intense physical activity—for example, 30 minutes of brisk walking—on most days leads to health benefits for previously inactive people. Adults who exercise at greater intensity—enough to build up a sweat—derive even greater protection (American College of Sports Medicine, 2011). Regular, vigorous exercisers show large reductions in risk of cardiovascular disease, diabetes, colon cancer, and obesity.

Substance Abuse

Alcohol and drug use peaks among U.S. 19- to 25-year-olds and then declines steadily with age. Eager to try a wide range of experiences before settling down to the responsibilities of adulthood, young people of this age are more likely than younger or older individuals to smoke cigarettes, chew tobacco, use marijuana, and take stimulants to enhance cognitive or physical performance (U.S. Department of Health and Human Services, 2011e). Binge drinking, driving under the influence, and experimentation with prescription drugs (such as OxyContin, a highly addictive painkiller) and “party drugs” (such as LSD and MDMA, or Ecstasy) also increase, at times with tragic consequences. Risks include brain damage, lasting impairments in mental functioning, and unintentional injury and death (Montoya et al., 2002; National Institute on Drug Abuse, 2012).

Furthermore, when alcohol and drug taking become chronic, they intensify the psychological problems that underlie addiction. As many as 12 percent of 19- to 25-year-old men and 6 percent of women are substance abusers (U.S. Department of Health and Human Services, 2011e). Return to Chapter 11, pages 380–381, to review factors that lead to alcohol and drug abuse in adolescence. The same personal and situational conditions are predictive in the adult years. Cigarette smoking and alcohol consumption are the most commonly abused substances.

Cigarette Smoking. Dissemination of information on the harmful effects of cigarette smoking has helped reduce its prevalence among U.S. adults from 40 percent in 1965 to 19 percent in 2010 (Centers for Disease Control and Prevention, 2012e). Still, smoking has declined very slowly, and most of the drop is among college graduates, with very little change for those who did not finish high school. Furthermore, although more men than women smoke, the gender gap is much smaller today than in the past, reflecting a sharp increase in smoking among young women who did not finish high school. Smoking among college students has also risen—for students of both sexes and of diverse ethnicities. More than 90 percent of men and 85 percent of women who smoke started before age 21 (U.S. Department of Health and Human Services, 2011e). And the earlier people start smoking, the greater their daily cigarette consumption and likelihood of continuing, an important reason that preventive efforts with adolescents and young adults are vital.

The ingredients of cigarette smoke—nicotine, tar, carbon monoxide, and other chemicals—leave their damaging mark throughout the body. As smokers inhale, oxygen delivery to tissues is reduced, and heart rate and blood pressure rise. Over time, exposure to toxins and insufficient oxygen result in damage to the retina of the eye; constriction of blood vessels leading to painful vascular disease; skin abnormalities, including premature aging, poor wound healing, and hair loss; decline in bone mass; decrease in reserve ova, uterine abnormalities, and earlier menopause in women; and reduced sperm count and higher rate of sexual impotence in men (Dechanet et al., 2011; Freiman et al., 2004; Thornton et al., 2005). Other deadly outcomes include increased risk of heart attack, stroke, acute leu-

kemia, melanoma, and cancer of the mouth, throat, larynx, esophagus, lungs, stomach, pancreas, kidneys, and bladder.

Cigarette smoking is the single most important preventable cause of death in industrialized nations. One out of every three young people who become regular smokers will die from a smoking-related disease, and the vast majority will suffer from at least one serious illness (Adhikari et al., 2009). The chances of premature death rise with the number of cigarettes consumed. At the same time, the benefits of quitting include return of most disease risks to nonsmoker levels within one to ten years. In a study of 1.2 million British women, those who had been regular smokers but stopped before they reached age 45 avoided 90 percent of the elevated risk of premature death from cigarettes (Pirie et al., 2012). And those who quit before age 35 avoided 97 percent of the added risk.

Nearly 70 percent of U.S. smokers say they want to quit completely, but less than half who saw their doctors in the past year received advice to do so (Centers for Disease Control and Prevention, 2012e). Although millions have stopped without help, those who use cessation aids (for example, nicotine gum, nasal spray, or patches, designed to reduce dependency gradually) or enter treatment programs often fail: As many as 90 percent start smoking again within six months (Aveyard & Raw, 2012). Unfortunately, too few treatments last long enough, effectively combine counseling with medications that reduce nicotine withdrawal symptoms, and teach skills for avoiding relapse.

Alcohol. National surveys reveal that about 10 percent of men and 3 percent of women in the United States are heavy drinkers (U.S. Department of Health and Human Services, 2011e). About one-third of them are *alcoholics*—people who cannot limit their alcohol use. In men, alcoholism usually begins in the teens and early twenties and worsens over the following decade. In women, its onset is typically later, in the twenties and thirties, and its course is more variable. Many alcoholics are also addicted to other substances, including nicotine and illegal mood-altering drugs.

Twin and adoption studies support a genetic contribution to alcoholism. Genes moderating alcohol metabolism and those influencing impulsivity and sensation seeking (temperamental traits linked to alcohol addiction) are involved (Buscemi & Turchi, 2011). But whether a person comes to deal with life's problems through drinking is greatly affected by environment: Half of alcoholics have no family history of problem drinking. Alcoholism crosses SES and ethnic lines but is higher in some groups than others (Schuckit, 2009). In cultures where alcohol is a traditional part of religious or ceremonial activities, people are less likely to abuse it. Where access to alcohol is carefully controlled and viewed as a sign of adulthood, dependency is more likely—factors that may, in part, explain why college students drink more heavily than young people not enrolled in college (Slutske et al., 2004). Poverty, hopelessness, and a history of physical or sexual abuse in childhood are among factors that sharply increase the risk of excessive drinking (Donatelle, 2012; Lown et al., 2011; U.S. Department of Health and Human Services, 2011e).

PHOTO RESEARCHERS/GETTY IMAGES

In cultures where alcohol is a traditional part of religious or ceremonial activities, people are less likely to abuse it. For Jewish families, holiday celebrations, such as this Passover Seder, include blessing and drinking wine.

Alcohol acts as a depressant, impairing the brain's ability to control thought and action. In a heavy drinker, it relieves anxiety at first but then induces it as the effects wear off, so the alcoholic drinks again. Chronic alcohol use does widespread physical damage. Its best-known complication is liver disease, but it is also linked to cardiovascular disease, inflammation of the pancreas, irritation of the intestinal tract, bone marrow problems, disorders of the blood and joints, and some forms of cancer. Over time, alcohol causes brain damage, leading to confusion, apathy, inability to learn, and impaired memory (O'Connor, 2012). The costs to society are enormous. About 30 percent of fatal motor vehicle crashes in the United States involve drivers who have been drinking (U.S. Department of Transportation, 2012). Nearly half of convicted felons are alcoholics, and about half of police activities in large cities involve alcohol-related offenses (McKim & Hancock, 2013). Alcohol frequently plays a part in sexual coercion, including date rape, and in domestic violence.

The most successful treatments combine personal and family counseling, group support, and aversion therapy (use of medication that produces a physically unpleasant reaction to alcohol, such as nausea and vomiting). Alcoholics Anonymous, a community support approach, helps many people exert greater control over their lives through the encouragement of others with similar problems. Nevertheless, breaking an addiction that has dominated a person's life is difficult; about 50 percent of alcoholics relapse within a few months (Kirshenbaum, Olsen, & Bickel, 2009).

Sexuality

At the end of high school, about 65 percent of U.S. young people have had sexual intercourse; by age 25, nearly all have done so, and the gender and SES differences that were apparent in adolescence (see page 374 in Chapter 11) have diminished (U.S. Department of Health and Human Services, 2012d). Compared

with earlier generations, contemporary adults display a wider range of sexual choices and lifestyles, including cohabitation, marriage, extramarital experiences, and orientation toward a heterosexual or homosexual partner. In this chapter, we explore the attitudes, behaviors, and health concerns that arise as sexual activity becomes a regular event in young people's lives. In Chapter 14, we focus on the emotional side of close relationships.

Heterosexual Attitudes and Behavior. One Friday evening, Sharese accompanied her roommate Heather to a young singles bar, where two young men soon joined them. Faithful to her boyfriend, Ernie, whom she had met in college and who worked in another city, Sharese remained aloof for the next hour. In contrast, Heather was talkative and gave one of the men, Rich, her phone number. The next weekend, Heather went out with Rich. On the second date, they had intercourse, but the romance lasted only a few weeks. Aware of Heather's more adventurous sex life, Sharese wondered whether her own was normal. Only after several months of dating exclusively had she and Ernie slept together.

Since the 1950s, public display of sexuality in movies, newspapers, magazines, and books has steadily increased, fostering the impression that Americans are more sexually active than ever before. What are contemporary adults' sexual attitudes and behaviors really like? Answers were difficult to find until the National Health and Social Life Survey, the first in-depth study of U.S. adults' sex lives based on a nationally representative sample, was carried out in the early 1990s. Nearly four out of five randomly chosen 18- to 59-year-olds agreed to participate—3,400 in all. Findings were remarkably similar to those of surveys conducted at about the same time in France, Great Britain, and Finland, and to a more recent U.S. survey (Langer, 2004; Laumann et al., 1994; Michael et al., 1994).

Recall from Chapter 11 that the sex lives of most teenagers do not dovetail with exciting media images. The same is true of adults in Western nations. Although their sexual practices are diverse, they are far less sexually active than we have come to believe. Monogamous, emotionally committed couples like Sharese and Ernie are more typical (and more satisfied) than couples like Heather and Rich.

Sexual partners, whether dating, cohabiting, or married, tend to be similar in age (within five years), education, ethnicity, and (to a lesser extent) religion. In addition, people who establish lasting relationships often meet in conventional ways—through friends or family members, or at school or social events where people similar to themselves congregate. The powerful influence of social networks on sexual choice is adaptive. Sustaining an intimate relationship is easier when adults share interests and values and people they know approve of the match.

Over the past decade, the Internet has become an increasingly popular way to initiate relationships: More than one-third of single adults go to dating websites or other online venues in search of romantic partners. In a survey of a nationally representative sample of 4,000 Americans, most of whom were married or in a romantic relationship, 22 percent said they had met on the Internet, making it the second most common way

© MAMADUKE ST. JOHN/ALAMY

The Internet is an increasingly popular way to initiate romantic relationships. Here, young people attend a “speed dating” event, organized online, where they have brief conversations with potential partners.

to meet a partner, just behind meeting through friends (Finkel et al., 2012). In fact, knowing someone who has successfully engaged in Internet dating strongly predicts single adults’ willingness to look for a partner on dating websites (Sautter, Tippett, & Morgan, 2010; Sprecher, 2011). As reports of dating success spread through social networks, use of Internet dating services is likely to increase further.

Nevertheless, the services of online dating sites sometimes undermine, rather than enhance, the chances of forming a successful romantic relationship. Relying on Internet dating profiles and computer-mediated communication omits aspects of direct social interaction that are vital for assessing one’s compatibility with a potential partner. Especially when computer-mediated communication persists for a long time (six weeks or more), people form idealized impressions that often lead to disappointment at face-to-face meetings (Finkel et al., 2012; Ramirez & Zhang, 2007). Furthermore, having a large pool of potential partners from which to choose can promote a persistent “shopping mentality,” which reduces online daters’ willingness to make a commitment (Heino, Ellison, & Gibbs, 2010). Finally, the techniques that matching sites claim to use to pair partners—sophisticated analyses of information daters provide—have not demonstrated any greater success than conventional off-line means of introducing people.

Consistent with popular belief, Americans today have more sexual partners over their lifetimes than they did a generation ago. For example, one-third of adults over age 50 have had five or more partners, whereas half of 30- to 50-year-olds have accumulated that many in much less time. And although women are more opposed to casual sex than men, after excluding a small number of men (less than 3 percent) with a great many sexual partners, contemporary men and women differ little in average number of lifetime sexual partners (Langer,

2004). Why is this so? From an evolutionary perspective, contemporary effective contraception has permitted sexual activity with little risk of pregnancy, enabling women to have as many partners as men without risking the welfare of their offspring.

But when adults of any age are asked how many partners they have had in the past year, the usual reply (for about 70 percent) is one. What explains the trend toward more relationships in the context of sexual commitment? In the past, dating several partners was followed by marriage. Today, dating more often gives way to cohabitation, which leads either to marriage or to breakup. In addition, people are marrying later, and the divorce rate remains high. Together, these factors create more opportunities for new partners. Still, survey evidence indicates that most U.S. 18- to 29-year-olds want to settle down eventually with a mutually exclusive lifetime sexual partner (Arnett, 2012). In line with this goal, most people spend the majority of their lives with one partner.

How often do Americans have sex? Not nearly as frequently as the media would suggest. One-third of 18- to 59-year-olds have intercourse as often as twice a week, another third have it a few times a month, and the remaining third have it a few times a year or not at all. Three factors affect frequency of sexual activity: age, whether people are cohabiting or married, and how long the couple has been together. Single people have more partners, but this does not translate into more sex! Sexual activity increases through the twenties and (for men) the thirties as people either cohabit or marry. Then it declines, even though hormone levels have not changed much (Herbenick et al., 2010; Langer, 2004). The demands of daily life—working, commuting, taking care of home and children—are probably responsible. Despite the common assumption that sexual practices vary greatly across social groups, the patterns just described are unaffected by education, SES, or ethnicity.

Most adults say they are happy with their sex lives. For those in committed relationships, more than 80 percent report feeling “extremely physically and emotionally satisfied,” a figure that rises to 88 percent for married couples. In contrast, as number of sex partners increases, satisfaction declines sharply. These findings challenge two stereotypes—that marriage is sexually dull and that people who engage in casual dating have the “hottest” sex (Paik, 2010). In actuality, individuals prone to unsatisfying relationships are more likely to prefer “hookups” or “friends with benefits.”

A minority of U.S. adults—women more often than men—report persistent sexual problems. For women, the two most frequent difficulties are lack of interest in sex (39 percent) and inability to achieve orgasm (20 percent) (Shifren et al., 2008). Most often mentioned by men are climaxing too early (29 percent) and anxiety about performance (16 percent). Sexual difficulties are linked to low SES and psychological stress and are more common among people who are not married, have had more than five partners, and have experienced sexual abuse during childhood or (for women) sexual coercion in adulthood (Laumann, Paik, & Rosen, 1999). As these findings suggest, a history of unfavorable relationships and sexual experiences increases the risk of sexual dysfunction.

But overall, a completely untroubled physical experience is not essential for sexual happiness. Surveys of adults repeatedly show that satisfying sex involves more than technique; it is attained in the context of love, affection, and fidelity (Bancroft, 2002; Santtila et al., 2008). In sum, happiness with partnered sex is linked to an emotionally fulfilling relationship, good mental health, and overall contentment with life.

Homosexual Attitudes and Behavior. The majority of Americans support civil liberties and equal employment opportunities for gay men, lesbians, and bisexuals. And attitudes toward sex and romantic relationships between adults of the same sex have gradually become more accepting: Nearly half of U.S. adults say same-sex sexual relations are “not wrong at all” or only “sometimes wrong” and support same-sex marriage, and three-fourths favor same-sex civil unions (Pew Research Center, 2013; Smith, 2011b).

Homosexuals’ political activism and greater openness about their sexual orientation have contributed to gains in acceptance. Exposure and interpersonal contact reduce negative attitudes. But perhaps because they are especially concerned with gender-role conformity, heterosexual men judge homosexuals (and especially gay men) more harshly than do heterosexual women (Herek, 2009). Also, the United States lags behind Western Europe in positive attitudes. Nations with greatest acceptance tend to have a greater proportion of highly educated, economically well-off citizens who are low in religiosity (Smith, 2011a).

An estimated 3.5 percent of U.S. men and women—more than 8 million adults—identify as lesbian, gay, or bisexual, with women substantially more likely than men to report a bisexual orientation. Estimates from national surveys conducted in Australia, Canada, and Western Europe tend to be lower, at 1.5 to 2 percent (Gates, 2011). But many people who are gay, lesbian, or bisexual do not report themselves as such in survey research. This unwillingness to answer questions, engendered by a climate of persecution, has limited researchers’ access to

information about the sex lives of gay men and lesbians. The little evidence available indicates that homosexual sex follows many of the same rules as heterosexual sex: People tend to seek out partners similar in education and background to themselves; partners in committed relationships have sex more often and are more satisfied; and the overall frequency of sex is modest (Laumann et al., 1994; Michael et al., 1994).

Homosexuals tend to live in or near large cities, where many others share their sexual orientation, or in college towns, where attitudes are more accepting. Living in small communities where prejudice is intense and no social network exists through which to find compatible homosexual partners is isolating, lonely, and predictive of mental health problems (Meyer, 2003).

People who identify themselves as gay or lesbian also tend to be well-educated (Mercer et al., 2007). In the National Health and Social Life Survey, twice as many college-educated as high-school-educated men and eight times as many college-educated as high-school-educated women reported a same-sex orientation. Although the reasons for these findings are not clear, they probably reflect greater social and sexual liberalism among the more highly educated and therefore greater willingness to disclose homosexuality.

Sexually Transmitted Diseases. In the United States, one in every four individuals is likely to contract a sexually transmitted disease (STD) at some point in life (U.S. Department of Health and Human Services, 2011b). Although the incidence is highest in adolescence, STDs continue to be prevalent in early adulthood. During the teens and twenties, people accumulate most of their sexual partners, and they often do not take appropriate precautions to prevent the spread of STDs (see page 377 in Chapter 11). The overall rate of STDs is higher among women than men because it is at least twice as easy for a man to infect a woman with any STD, including AIDS, than for a woman to infect a man.

Although AIDS, the most deadly STD, remains concentrated among gay men and intravenous drug abusers, many homosexuals have responded to its spread by changing their sexual practices—limiting number of sexual partners, choosing partners more carefully, and using latex condoms consistently and correctly. Heterosexuals at high risk due to a history of many partners have done the same. Still, the annual number of U.S. new HIV infections—about 48,000—has remained stable since the late 1990s, and AIDS remains the sixth-leading cause of death among U.S. young adults (refer to Figure 13.4 on page 438). The incidence of HIV-positive adults is higher in the United States than in any other industrialized nation (OECD, 2012b). The disease is spreading most rapidly through men having sex with men and through heterosexual contact in poverty-stricken minority groups, among whom high rates of intravenous drug abuse coexist with poor health, inadequate education, high life stress, and hopelessness (Centers for Disease Control and Prevention, 2012c). People overwhelmed by these problems are least likely to take preventive measures.

Yet AIDS can be contained and reduced—through sex education extending from childhood into adulthood and through

Gay and lesbian romantic partners, like heterosexual partners, tend to be similar in education and background. With greater openness and political activism, attitudes toward same-sex relationships have become more accepting.

access to health services, condoms, and clean needles and syringes for high-risk individuals. In view of the rise in AIDS among women, who currently account for one-fourth of cases in North America and Western Europe and more than half in developing countries, a special need exists for female-controlled preventive measures. Drug-based vaginal gels that kill or inactivate the virus have shown promising results and are undergoing further testing.

Sexual Coercion. After a long day of classes, Sharese flipped on the TV and caught a talk show on sex without consent. Karen, a 25-year-old woman, described her husband Mike pushing, slapping, verbally insulting, and forcing her to have sex. “It was a control thing,” Karen explained tearfully. “He complained that I wouldn’t always do what he wanted. I was confused and blamed myself. I didn’t leave because I was sure he’d come after me and get more violent.”

One day, as Karen was speaking long distance to her mother on the phone, Mike grabbed the receiver and shouted, “She’s not the woman I married! I’ll kill her if she doesn’t shape up!” Alarmed, Karen’s parents arrived by plane the next day to rescue her and helped her start divorce proceedings and get treatment.

An estimated 18 percent of U.S. women, sometime in their lives, have endured *rape*, legally defined as intercourse by force, by threat of harm, or when the victim is incapable of giving consent (because of mental illness, mental retardation, or alcohol consumption). About 45 percent of women have experienced other forms of sexual aggression. The majority of victims (eight out of ten) are under age 30 (Black et al., 2011; Schewe, 2007). Women are vulnerable to partners, acquaintances, and strangers, but in most instances their abusers are men they know well. Sexual coercion crosses SES and ethnic lines; people of all walks of life are offenders and victims.

© HARISH TYAGI/EPA/CORBIS

In 2012, in New Delhi, India, the brutal gang rape of a 23-year-old student, who died a month later from her injuries, prompted candlelight vigils and other protests throughout the country. Participants demanded increased government and police action to prevent sexual violence against women.

Personal characteristics of the man with whom a woman is involved are far better predictors of her chances of becoming a victim than her own characteristics. Men who engage in sexual assault tend to be manipulative of others, lack empathy and remorse, pursue casual sexual relationships rather than emotional intimacy, approve of violence against women, and accept rape myths (such as “Women really want to be raped”). Perpetrators also tend to interpret women’s social behaviors inaccurately, viewing friendliness as seductiveness, assertiveness as hostility, and resistance as desire (Abbey & Jacques-Tiura, 2011; Abbey & McAuslan, 2004). Furthermore, sexual abuse in childhood, promiscuity in adolescence, and alcohol abuse in adulthood are associated with sexual coercion. Approximately half of all sexual assaults take place while people are intoxicated (Black et al., 2011).

LOOK AND LISTEN

Obtain from your campus student services or police department the number of sexual assaults reported by students during the most recent year. What percentage involved alcohol? What prevention and intervention services does your college offer? ●

Cultural forces also contribute. When men are taught from an early age to be dominant, competitive, and aggressive and women to be submissive and cooperative, the themes of rape are reinforced. Societal acceptance of violence also sets the stage for rape, which typically occurs in relationships in which other forms of aggression are commonplace. Exposure to sexually aggressive pornography and other media images, which portray women desiring and enjoying the assault, also promote sexual coercion by dulling sensitivity to its harmful consequences.

About 7 percent of men have been victims of coercive sexual behavior. Although rape victims report mostly male perpetrators, women are largely responsible for other forms of sexual coercion against men (Black et al., 2011). Victimized men often say that women who committed these acts used threats of physical force or actual force, encouraged them to get drunk, or threatened to end the relationship unless they complied (Anderson & Savage, 2005). Unfortunately, authorities rarely recognize female-initiated forced sex as illegal, and few men report these crimes.

Consequences. Women’s and men’s psychological reactions to rape resemble those of survivors of extreme trauma. Immediate responses—shock, confusion, withdrawal, and psychological numbing—eventually give way to chronic fatigue, tension, disturbed sleep, depression, substance abuse, social anxiety, and suicidal thoughts (Black et al., 2011; Schewe, 2007). Victims of ongoing sexual coercion may fall into a pattern of extreme passivity and fear of taking any action.

One-third to one-half of female rape victims are physically injured. From 4 to 30 percent contract sexually transmitted diseases, and pregnancy results in about 5 percent of cases. Furthermore, victims of rape (and other sexual crimes) report more symptoms of illness across almost all body systems. And they are more likely to engage in negative health behaviors, including smoking and alcohol use (McFarlane et al., 2005; Schewe, 2007).

Applying What We Know

Preventing Sexual Coercion

Suggestion	Description
Reduce gender stereotyping and gender inequalities.	The roots of men's sexual coercion of women lie in the historically subordinate status of women. Unequal educational and employment opportunities keep women economically dependent on men and therefore poorly equipped to avoid partner violence. At the same time, increased public awareness that women sometimes commit sexually aggressive acts is needed.
Mandate treatment for men and women who physically or sexually assault their partners.	Ingredients of effective intervention include combating rape myths and inducing personal responsibility for violent behavior; teaching social awareness, social skills, and anger management; and developing a support system to prevent future attacks.
Expand interventions for children and adolescents who have witnessed violence between their parents.	Although most child witnesses to parental violence do not become involved in abusive relationships as adults, they are at increased risk.
Teach both men and women to take precautions that lower the risk of sexual assault.	Risk of sexual assault can be reduced by communicating sexual limits clearly to a date; developing supportive ties to neighbors; increasing the safety of the immediate environment (for example, installing deadbolt locks, checking the back seat of the car before entering); avoiding deserted areas; not walking alone after dark; and leaving parties where alcohol use is high.
Broaden definitions of rape to be gender-neutral.	In some U.S. states, where the definition of rape is limited to vaginal or anal penetration, a woman legally cannot rape a man. A broader definition is needed to encompass women as both victims and perpetrators of sexual aggression.

Sources: Anderson & Savage, 2005; Schewe, 2007.

Prevention and Treatment. Many female rape victims are less fortunate than Karen because anxiety about provoking another attack keeps them from confiding even in trusted family members and friends. A variety of community services, including safe houses, crisis hotlines, support groups, and legal assistance, exist to help women take refuge from abusive partners, but most are underfunded and cannot reach out to everyone in need. Practically no services are available for victimized men, who are often too embarrassed to come forward.

The trauma induced by rape is severe enough that therapy is important—both individual treatment to reduce anxiety and depression and group sessions where contact with other survivors helps counter isolation and self-blame (Street, Bell, & Ready, 2011). Other critical features that foster recovery include

- *Routine screening for victimization* during health-care visits to ensure referral to community services and protection from future harm
- *Validation of the experience*, by acknowledging that many others have been physically and sexually assaulted by intimate partners; that such assaults lead to a wide range of persisting symptoms, are illegal and inappropriate, and should not be tolerated; and that the trauma can be overcome
- *Safety planning*, even when the abuser is no longer present, to prevent recontact and reassault. This includes information about how to obtain police protection, legal intervention, a safe shelter, and other aid should a rape survivor be at risk again.

Finally, many steps can be taken at the level of the individual, the community, and society to prevent sexual coercion. Some are listed in Applying What We Know above.

Psychological Stress

A final health concern, threaded throughout previous sections, has such a broad impact that it merits a comment of its own. Psychological stress, measured in terms of adverse social conditions, traumatic experiences, negative life events, or daily hassles, is related to a wide variety of unfavorable health outcomes—both unhealthy behaviors and clear physical consequences. And recall from earlier chapters that intense, persistent stress, from the prenatal period on, disrupts the brain's inherent ability to manage stress, with long-term consequences. For individuals with childhood histories of stress, continuing stressful experiences combine with an impaired capacity to cope with stress, heightening the risk of adult health impairments.

As SES decreases, exposure to diverse stressors rises—an association that likely plays an important role in the strong connection between low SES and poor health (see pages 438–439) (Chandola & Marmot, 2011). Chronic stress is linked to overweight and obesity, diabetes, hypertension, and atherosclerosis. And in susceptible individuals, acute stress can trigger cardiac events, including heart-beat rhythm abnormalities and heart attacks (Bekkouche et al., 2011; Brooks, McCabe, & Schneiderman, 2011). These relationships contribute to the high incidence of heart disease in low-income groups, especially African Americans. Compared with higher-SES individuals,

low-SES adults show a stronger cardiovascular response to stress, perhaps because they more often perceive stressors as unsolvable (Almeida et al., 2005; Carroll et al., 2007). Earlier we mentioned that stress interferes with immune system functioning, a link that may underlie its relationship to several forms of cancer. And by reducing digestive activity as blood flows to the brain, heart, and extremities, stress can cause gastrointestinal difficulties, including constipation, diarrhea, colitis, and ulcers (Donatelle, 2012).

The many challenging tasks of early adulthood make it a particularly stressful time of life. Young adults more often report depressive feelings than middle-aged people, many of whom have attained vocational success and financial security and are enjoying more free time as parenting responsibilities decline (Nolen-Hoeksema & Aldao, 2011). Also, as we will see in Chapters 15 and 16, middle-aged and older adults are better than young adults at coping with stress (Blanchard-Fields, Mienaltowski, & Baldi, 2007). Because of their longer life experience and greater sense of personal control over their lives, they are more likely to engage in problem-centered coping when stressful conditions can be changed and emotion-centered coping when nothing can be done.

In previous chapters, we repeatedly noted the stress-buffering effect of social support, which continues throughout life. Helping stressed young adults establish and maintain satisfying, caring social ties is as important a health intervention as any we have mentioned.

COGNITIVE DEVELOPMENT

The cognitive changes of early adulthood are supported by further development of the cerebral cortex, especially the prefrontal cortex and its connections with other brain regions. Pruning of synapses along with growth and myelination of stimulated neural fibers continue, though at a slower pace than

in adolescence (Nelson, Thomas, & De Haan, 2006; Zelazo & Lee, 2010). These changes result in continued fine-tuning of the *prefrontal cognitive-control network* (see page 367 in Chapter 11). Consequently, planning, reasoning, and decision making improve, supported by major life events of this period—including attaining higher education, establishing a career, and grappling with the demands of marriage and child rearing. Furthermore, fMRI evidence reveals that as young adults become increasingly proficient in a chosen field of endeavor, regions of the cerebral cortex specialized for those activities undergo further *experience-dependent brain growth* (see page 128 in Chapter 4). Besides more efficient functioning, structural changes occur as greater knowledge and refinement of skills result in more cortical tissue devoted to the task and, at times, reorganization of brain areas governing the activity (Hill & Schneider, 2006; Lenroot & Giedd, 2006).

How does cognition change in early adulthood? Lifespan theorists have examined this question from three familiar vantage points. First, they have proposed transformations in the structure of thought—new, qualitatively distinct ways of thinking that extend the cognitive-developmental changes of adolescence. Second, adulthood is a time of acquiring advanced knowledge in a particular area, an accomplishment that has important implications for information processing and creativity. Finally, researchers have been interested in the extent to which the diverse mental abilities assessed by intelligence tests remain stable or change during the adult years—a topic addressed in Chapter 15.

Changes in the Structure of Thought

Sharese described her first year in graduate school as a “cognitive turning point.” As part of her internship in a public health clinic, she observed firsthand the many factors that affect human health-related behaviors. For a time, the realization that everyday dilemmas did not have clear-cut solutions made her intensely uncomfortable. “Working in this messy reality is so different from the problem solving I did in my undergraduate classes,” she told her mother over the phone one day.

Piaget (1967) recognized that important advances in thinking follow the attainment of formal operations. He observed that adolescents prefer an idealistic, internally consistent perspective on the world to one that is vague, contradictory, and adapted to particular circumstances (see Chapter 11, pages 367–368). Sharese’s reflections fit the observations of researchers who have studied **postformal thought**—cognitive development beyond Piaget’s formal operational stage. To clarify how thinking is restructured in adulthood, let’s look at some influential theories, along with supportive research. Together, they show how personal effort and social experiences combine to spark increasingly rational, flexible, and practical ways of thinking that accept uncertainties and vary across situations.

Perry's Theory: Epistemic Cognition

The work of William Perry (1981, 1970/1998) provided the starting point for an expanding research literature on the development of *epistemic cognition*. *Epistemic* means “of or about knowledge,” and **epistemic cognition** refers to our reflections on how we arrived at facts, beliefs, and ideas. When mature, rational thinkers reach conclusions that differ from those of others, they consider the justifiability of their conclusions. When they cannot justify their approach, they revise it, seeking a more balanced, adequate route to acquiring knowledge.

Development of Epistemic Cognition. Perry wondered why young adults respond in dramatically different ways to the diversity of ideas they encounter in college. To find out, he interviewed Harvard University undergraduates at the end of each of their four years, asking “what stood out” during the previous year. Responses indicated that students’ reflections on knowing changed as they experienced the complexities of university life and moved closer to adult roles—findings confirmed in many subsequent studies (King & Kitchener, 1994, 2002; Magolda, Abes, & Torres, 2009; Moore, 2002).

Younger students regarded knowledge as made up of separate units (beliefs and propositions), whose truth could be determined by comparing them to objective standards—standards that exist apart from the thinking person and his or her situation. As a result, they engaged in **dualistic thinking**, dividing information, values, and authority into right and wrong, good and bad, we and they. As one college freshman put it, “When I went to my first lecture, what the man said was just like God’s word. I believe everything he said because he is a professor . . . and this is a respected position” (Perry, 1981, p. 81). And when asked, “If two people disagree on the interpretation of a poem, how would you decide which one is right?” a sophomore replied, “You’d have to ask the poet. It’s his poem” (Clinchy, 2002, p. 67). Dualistic thinkers, who believe knowledge is certain and teachers have that knowledge, approach learning by accepting what they are given.

Older students, in contrast, had moved toward **relativistic thinking**, viewing all knowledge as embedded in a framework of thought. Aware of a diversity of opinions on many topics, they gave up the possibility of absolute truth in favor of multiple truths, each relative to its context. As a result, their thinking became more flexible and tolerant. As one college senior put it, “Just seeing how [famous philosophers] fell short of an all-encompassing answer, [you realize] that ideas are really individualized. And you begin to have respect for how great their thought could be, without its being absolute” (Perry, 1970/1998, p. 90). Relativistic thinking leads to the realization that one’s own beliefs are often subjective, since several frameworks may satisfy the criterion of internal logical consistency (Moore, 2002; Sinnott, 2003). And from constructing, interpreting, and evaluating evidence from diverse frames of reference, relativistic thinkers become acutely aware that each person, in arriving at a position, creates her own “truth.”

Eventually, the most mature individuals progress to **commitment within relativistic thinking**. Instead of choosing between opposing views, they try to formulate a more personally satisfying perspective that synthesizes contradictions. When considering which of two theories studied in a college course is better, or which of several movies most deserves an Oscar, the individual moves beyond the stance that everything is a matter of opinion and generates rational criteria against which options can be evaluated (Moshman, 2003, 2005). At the same time, mature thinkers willingly revise their internal belief system when presented with relevant evidence.

By the end of the college years, some students reach this extension of relativism. Adults who attain it generally display a more sophisticated approach to learning, in which they actively seek differing perspectives to deepen their knowledge and understanding and to clarify the basis for their own perspective. **TAKE A MOMENT...** Notice how commitment within relativistic thinking involves the information-gathering cognitive style (see page 404 in Chapter 12) and pursuit of personally meaningful beliefs, values, and goals essential to healthy identity development. Mature epistemic cognition also contributes greatly to effective decision making and problem solving.

Importance of Peer Interaction and Reflection.

Advances in epistemic cognition depend on further gains in metacognition, which are likely to occur in situations that challenge young peoples’ perspectives and induce them to consider the rationality of their thought processes (Magolda, Abes, & Torres, 2009). In a study of the college learning experiences of seniors scoring low and high in epistemic cognition, high-scoring students frequently reported activities that encouraged them to struggle with realistic but ambiguous problems in a supportive environment, in which faculty were committed to helping them understand how knowledge is constructed and why it must be subject to revision. For example, an engineering

© JAN SHAW/ALAMY

When college students challenge one another’s reasoning while tackling realistic, ambiguous problems, they are likely to gain in epistemic cognition.

major, describing an airplane-design project that required advanced epistemic cognition, noted his discovery that “you can design 30 different airplanes and each one’s going to have its benefits and there’s going to be problems with each one” (Marra & Palmer, 2004, p. 116). Low-scoring students rarely mentioned such experiences.

In tackling challenging, ill-structured problems, interaction among individuals who are roughly equal in knowledge and authority is beneficial because it prevents acceptance of another’s reasoning simply because of greater power or expertise. When college students were asked to devise the most effective solution to a difficult logical problem, only 3 out of 32 students (9 percent) in a “work alone” condition succeeded. But in an “interactive” condition, 15 out of 20 small groups (75 percent) arrived at the correct solution following extensive discussion (Moshman & Geil, 1998). Whereas few students working alone reflected on their solution strategies, most groups engaged in a process of “collective rationality” in which members challenged one another to justify their reasoning and collaborated in working out the most defensible strategy.

Of course, reflection on one’s own thinking can also occur individually. But peer interaction fosters the necessary type of individual reflection: arguing with oneself over competing ideas and strategies and coordinating opposing perspectives into a new, more effective structure. **TAKE A MOMENT...** Return to page 320 in Chapter 9 to review how peer collaboration fosters cognitive development in childhood. It remains a highly effective basis for education in early adulthood.

LOOK AND LISTEN

Describe learning experiences in one of your college courses that advanced your epistemic cognition. How did your thinking change? ●

Perry’s theory and the research it stimulated are based on samples of highly educated young adults. These investigators acknowledge that progress in epistemic cognition is probably limited to people confronting the multiplicity of viewpoints typically encountered during a college education and that the most advanced attainment—commitment within relativism—often requires advanced graduate study (Greene, Torney-Purta, & Azevedo, 2010; King & Kitchener, 2002). But the underlying theme—thought less constrained by the need to find one answer to a question and more responsive to its context—is also evident in another theory of adult cognition.

Labouvie-Vief’s Theory: Pragmatic Thought and Cognitive-Affective Complexity

Gisella Labouvie-Vief’s (1980, 1985) portrait of adult cognition echoes features of Perry’s theory. Adolescents, she points out, operate within a world of possibility. Adulthood involves movement from hypothetical to **pragmatic thought**, a structural advance in which logic becomes a tool for solving real-world problems.

According to Labouvie-Vief, the need to specialize motivates this change. As adults select one path out of many alternatives, they become more aware of the constraints of everyday life. And in the course of balancing various roles, they accept contradictions as part of existence and develop ways of thinking that thrive on imperfection and compromise. Sharesé’s friend Christy, a married graduate student and parent of her first child at age 26, illustrates:

I’ve always been a feminist, and I wanted to remain true to my beliefs in family and career. But this is Gary’s first year of teaching high school, and he’s saddled with four preparations and coaching the school’s basketball team. At least for now, I’ve had to settle for “give-and-take feminism”—going to school part-time and shouldering most of the child-care responsibilities while he gets used to his new job. Otherwise, we’d never make it financially.

Labouvie-Vief (2003, 2006) also points out that young adults’ enhanced reflective capacities alter the dynamics of their emotional lives: They become more adept at integrating cognition with emotion and, in doing so, again make sense of discrepancies. Examining the self-descriptions of 10- to 80-year-olds diverse in SES, Labouvie-Vief found that from adolescence through middle adulthood, people gained in **cognitive-affective complexity**—awareness of conflicting positive and negative feelings and coordination of them into a complex, organized structure that recognizes the uniqueness of individual experiences (see Figure 13.7) (Labouvie-Vief, 2008; Labouvie-Vief et al., 1995, 2007). For example, one 34-year-old combined roles, traits, and diverse emotions into this coherent self-description: “With the recent birth of our first child, I find myself more fulfilled than ever, yet struggling in some ways. My elation is

FIGURE 13.7 Changes in cognitive-affective complexity from adolescence to late adulthood. Performance, based on responses of several hundred 10- to 80-year-olds’ descriptions of their roles, traits, and emotions, increased steadily from adolescence through early adulthood, peaked in middle age, and fell off in late adulthood when (as we will see in later chapters) basic information-processing skills decline. (From G. Labouvie-Vief, 2003, “Dynamic Integration: Affect, Cognition, and the Self in Adulthood,” *Current Directions in Psychological Science*, 12, p. 203, copyright © 2003, Sage Publications. Reprinted by permission of SAGE Publications.)

tempered by my gnawing concern over meeting all my responsibilities in a satisfying way while remaining an individualized person with needs and desires.”

Cognitive-affective complexity promotes greater awareness of one’s own and others’ perspectives and motivations. As Labouvie-Vief (2003) notes, it is a vital aspect of adult *emotional intelligence* (see page 313 in Chapter 9) and is valuable in solving many pragmatic problems. Individuals high in cognitive-affective complexity view events and people in a tolerant, open-minded fashion. And because cognitive-affective complexity involves accepting and making sense of both positive and negative feelings, it helps people regulate intense emotion and, therefore, think rationally about real-world dilemmas, even those that are laden with negative information (Labouvie-Vief, Grünh, & Studer, 2010).

Awareness of multiple truths, integration of logic with reality, and cognitive-affective complexity sum up qualitative transformations in thinking under way in early adulthood (Sinnott, 1998, 2003, 2008). As we will see next, adults’ increasingly specialized and context-bound thought, although it closes off certain options, opens new doors to higher levels of competence.

Expertise and Creativity

In Chapter 9, we noted that children’s expanding knowledge improves their ability to remember new information related to what they already know. For young adults, **expertise**—acquisition of extensive knowledge in a field or endeavor—is supported by the specialization that begins with selecting a college major or an occupation, since it takes many years to master any complex domain. Once attained, expertise has a profound impact on information processing.

Compared with novices, experts remember and reason more quickly and effectively. The expert knows more domain-specific concepts and represents them in richer ways—at a deeper and more abstract level and as having more features that can be linked to other concepts. As a result, unlike novices, whose understanding is superficial, experts approach problems with underlying principles in mind. For example, a highly trained physicist notices when several problems deal with conservation of energy and can therefore be solved similarly. In contrast, a beginning physics student focuses only on surface features—whether the problem contains a disk, a pulley, or a coiled spring (Chi, 2006; Chi, Glaser, & Farr, 1988). Experts can use what they know to arrive at many solutions automatically—through quick and easy remembering. And when a problem is challenging, they tend to plan ahead, systematically analyzing and categorizing elements and selecting the best from many possibilities, while the novice proceeds more by trial and error.

Expertise is necessary for creativity as well as problem solving (Weissberg, 2006). The creative products of adulthood differ from those of childhood in that they are not just original but also directed at a social or aesthetic need. Mature creativity requires a unique cognitive capacity—the ability to formulate new, culturally meaningful problems and to ask significant

A sculptor works on a statue to honor those who died in the Asian tsunami of 2004. The creative products of adulthood often are not just original but also directed at a social or aesthetic need.

questions that have not been posed before. According to Patricia Arlin (1989), movement from *problem solving* to *problem finding* is a core feature of postformal thought evident in highly accomplished artists and scientists.

Case studies support the 10-year rule in development of master-level creativity—a decade between initial exposure to a field and sufficient expertise to produce a creative work (Simonton, 2000; Winner, 2003). Furthermore, a century of research reveals that creative productivity typically rises in early adulthood, peaks in the late thirties or early forties, and gradually declines, though creative individuals near the end of their careers are usually more productive than those just starting their careers (see Figure 13.8) (Simonton, 2012). But

FIGURE 13.8 Changes in creative productivity during adulthood. Productivity typically rises over early adulthood and then declines, though creative older adults continue to produce more than adults just starting their careers. (Adapted from Simonton, 2012.)

exceptions exist. Those who get an early start in creativity tend to peak and drop off sooner, whereas “late bloomers” reach their full stride at older ages. This suggests that creativity is more a function of “career age” than of chronological age.

The course of creativity also varies across disciplines and individuals (Simonton, 2006, 2012). For example, poets, visual artists, and musicians typically show an early rise in creativity, perhaps because they do not need extensive formal education before they begin to produce. Academic scholars and scientists, who must earn higher academic degrees and spend years doing research to make worthwhile contributions, tend to display their achievements later and over a longer time. And whereas some creators are highly productive, others make only a single lifetime contribution.

Though creativity is rooted in expertise, not all experts are creative. Creativity also requires other qualities. A vital ingredient is an innovative thinking style. In one study, college students who preferred to think intuitively (rely on “first impression”) were told to solve a real-world problem using rational approach (be as “analytical” as possible) (Dane et al., 2011). Compared to controls who used their natural style, students required to use a style that differed sharply from their typical approach—who thought “outside the box”—generated many more creative ideas. Creative individuals are also tolerant of ambiguity, open to new experiences, persistent and driven to succeed, and willing to try again after failure (Lubart, 2003; Zhang & Sternberg, 2011). Finally, creativity demands time and energy. For women especially, it may be postponed or disrupted by child rearing, divorce, or an unsupportive partner (Vaillant & Vaillant, 1990).

In sum, creativity is multiply determined. When personal and situational factors jointly promote it, creativity can continue for many decades, well into old age.

ASK YOURSELF

REVIEW How does expertise affect information processing? Why is expertise necessary for, but not the same as, creativity?

CONNECT Our discussion in Chapter 9 noted that emotional intelligence is associated with life satisfaction and success in the workplace. How might cognitive-affective complexity contribute to these outcomes?

APPLY For her human development course, Marcia wrote a paper discussing the differing implications of Piaget’s and Vygotsky’s theories for education. Next, she reasoned that combining the two perspectives is more effective than relying on either position by itself. Explain how Marcia’s reasoning illustrates advanced epistemic cognition.

REFLECT Describe a classroom experience or assignment in one of your college courses that promoted relativistic thinking.

The College Experience

Looking back at the trajectory of their lives, many people view the college years as formative—more influential than any other period of adulthood. This is not surprising. College serves as a “developmental testing ground,” a time for devoting full attention to exploring alternative values, roles, and behaviors. To facilitate this exploration, college exposes students to a form of “culture shock”—encounters with new ideas and beliefs, new freedoms and opportunities, and new academic and social demands. More than 70 percent of U.S. high school graduates enroll in an institution of higher education (U.S. Department of Education, 2012b). Besides offering a route to a high-status career and its personal and monetary rewards, colleges and universities have a transforming impact on young people.

Psychological Impact of Attending College

Thousands of studies reveal broad psychological changes from the freshman to the senior year of college (Montgomery & Côté, 2003; Pascarella & Terenzini, 1991, 2005). As research inspired by Perry’s theory indicates, students become better at reasoning about problems that have no clear solution, identifying the strengths and weaknesses of opposing sides of complex issues, and reflecting on the quality of their thinking. Their attitudes and values also broaden. They show increased interest in literature, the performing arts, and philosophical and historical issues and greater tolerance for racial and ethnic diversity. Also, as noted in Chapter 12, college leaves its mark on moral reasoning by fostering concern with individual rights and human welfare, sometimes expressed in political activism. Finally, exposure to multiple worldviews encourages young people to look more closely at themselves. During the college years, students develop greater self-understanding, enhanced self-esteem, and a firmer sense of identity.

How do these interrelated changes come about? The type of four-year institution attended—public versus private, highly selective versus relatively open in enrollment—makes little difference in psychological outcomes or even in ultimate career success and earnings (Montgomery & Côté, 2003). And cognitive growth seems to be similar at two-year community colleges and at four-year institutions (Pascarella, 2001).

Rather, the impact of college is jointly influenced by the person’s involvement in academic and nonacademic activities and the richness of the campus environment. The more students interact with diverse peers in academic and extracurricular settings, the more they benefit cognitively—in grasping the complex causes of events, thinking critically, and generating effective problem solutions (Bowman, 2011a). Also, interacting with racially and ethnically mixed peers—both in courses exploring diversity issues and in out-of-class settings—predicts gains in civic engagement. And students who connect their community

© ST. PETERSBURG TIMES/BRENDAN FITZGERALD/GETTY IMAGES

Community college students join in a Peace Week activity, keeping pace with the beat of a drum circle. The more students interact with diverse peers in academic and extracurricular settings, the more they benefit cognitively from attending college.

service experiences with their classroom learning show large cognitive gains (Bowman, 2011b). These findings underscore the importance of programs that integrate commuting students into out-of-class campus life.

Dropping Out

Completing a college education has enduring effects on people's cognitive development, worldview, and postcollege opportunities. In the 1970s, the United States ranked first in the world in percentage of young adults with college degrees; today it is sixteenth, with just 41 percent of 25- to 34-year-olds having graduated. It lags far behind such countries as Canada, Japan, and South Korea, the global leader—where the rate is 63 percent (OECD, 2012a). Major contributing factors are the high U.S. child poverty rate; poor-quality elementary and secondary schools in low-income neighborhoods; and the high rate of high school dropout among teenagers. College leaving is also influential: 44 percent of U.S. students at two-year institutions and 32 percent of students at four-year institutions drop out, most within the first year and many within the first six weeks (ACT, 2010). Dropout rates are higher in colleges with less selective admission requirements; in some, first-year dropout approaches 50 percent. And ethnic minority students from low-SES families are, once again, at increased risk of dropping out (Feldman, 2005).

Both personal and institutional factors contribute to college leaving. Most entering freshmen have high hopes for college life but find the transition difficult. Those who have trouble adapting—because of lack of motivation, poor study skills, financial pressures, or emotional dependence on parents—quickly develop negative attitudes toward the college environment.

Often these exit-prone students do not meet with their advisers or professors. At the same time, colleges that do little to help high-risk students, through developmental courses and other support services, have a higher percentage of dropouts (Moxley, Najor-Durack, & Dumbrigue, 2001).

Beginning to prepare young people in early adolescence with the necessary visions and skills can do much to improve college success. In a study that followed up nearly 700 young people from sixth grade until two years after high school graduation, a set of factors—grade point average, academic self-concept, persistence in the face of challenge, parental SES and valuing of a college education, and the individual's plans to attend college—predicted college enrollment at age 20 (Eccles, Vida, & Barber, 2004). Although parental SES is difficult to modify, improving parents' attitudes and behaviors and students' academic motivation and educational aspirations is within reach, through a wide array of strategies considered in Chapters 11 and 12.

Once young people enroll in college, reaching out to them, especially during the early weeks and throughout the first year, is crucial. Programs that forge bonds between teachers and students and that generously fund student services—providing academic support, counseling to address academic and personal challenges, part-time work opportunities, and meaningful extracurricular roles—increase retention. Membership in campus-based social and religious organizations is especially helpful in strengthening minority students' sense of belonging (Chen, 2012; Fashola & Slavin, 1998). Young people who feel that their college community is concerned about them as individuals are far more likely to graduate.

Vocational Choice

Young adults, college-bound or not, face a major life decision: the choice of a suitable work role. Being a productive worker calls for many of the same qualities as being an active citizen and a nurturant family member—good judgment, responsibility, dedication, and cooperation. What influences young people's decisions about careers? What is the transition from school to work like, and what factors make it easy or difficult?

Selecting a Vocation

In societies with an abundance of career possibilities, occupational choice is a gradual process that begins long before adolescence. Major theorists view the young person as moving through several periods of vocational development (Gottfredson, 2005; Super, 1990, 1994):

1. **The fantasy period:** In early and middle childhood, children gain insight into career options by fantasizing about them (Howard & Walsh, 2010). Their preferences, guided largely by familiarity, glamour, and excitement, bear little relation to the decisions they will eventually make.

2. The **tentative period**: Between ages 11 and 16, adolescents think about careers in more complex ways, at first in terms of their *interests*, and soon—as they become more aware of personal and educational requirements for different vocations—in terms of their *abilities* and *values*. “I like science and the process of discovery,” Sharese thought as she neared high school graduation. “But I’m also good with people, and I’d like to do something to help others. So maybe teaching or medicine would suit my needs.”
3. The **realistic period**: By the late teens and early twenties, with the economic and practical realities of adulthood just around the corner, young people start to narrow their options. A first step is often further *exploration*—gathering more information about possibilities that blend with their personal characteristics. In the final phase, *crystallization*, they focus on a general vocational category and experiment for a time before settling on a single occupation (Stringer, Kerpelman, & Skorikov, 2011). As a college sophomore, Sharese pursued her interest in science, but she had not yet selected a major. Once she decided on chemistry, she considered whether to pursue teaching, medicine, or public health.

Factors Influencing Vocational Choice

Most, but not all, young people follow this pattern of vocational development. A few know from an early age just what they want to be and follow a direct path to a career goal. Some decide and later change their minds, and still others remain undecided for an extended period. College students are granted added time to explore various options. In contrast, the life conditions of many low-SES youths restrict their range of choices.

Making an occupational choice is not simply a rational process in which young people weigh abilities, interests, and values against career options. Like other developmental milestones, it is the result of a dynamic interaction between person and environment (Gottfredson & Duffy, 2008). A great many influences feed into the decision, including personality, family, teachers, and gender stereotypes, among others.

Personality. People are attracted to occupations that complement their personalities. John Holland (1985, 1997) identified six personality types that affect vocational choice:

- The *investigative person*, who enjoys working with ideas, is likely to select a scientific occupation (for example, anthropologist, physicist, or engineer).
- The *social person*, who likes interacting with people, gravitates toward human services (counseling, social work, or teaching).
- The *realistic person*, who prefers real-world problems and working with objects, tends to choose a mechanical occupation (construction, plumbing, or surveying).
- The *artistic person*, who is emotional and high in need for individual expression, looks toward an artistic field (writing, music, or the visual arts).
- The *conventional person*, who likes well-structured tasks and values material possessions and social status, has traits well-suited to certain business fields (accounting, banking, or quality control).
- The *enterprising person*, who is adventurous, persuasive, and a strong leader, is drawn to sales and supervisory positions or to politics.

TAKE A MOMENT... Does one of these personality types describe you? Or do you have aspects of more than one type? Research confirms a relationship between personality and vocational choice in diverse cultures, but it is only moderate. Many people are blends of several personality types and can do well at more than one kind of occupation (Holland, 1997; Spokane & Cruza-Guet, 2005).

Furthermore, career decisions are made in the context of family influences, financial resources, educational and job opportunities, and current life circumstances. For example, Sharese’s friend Christy scored high on Holland’s investigative dimension. But after she married, had her first child, and faced increasing financial pressures, she postponed her dream of becoming a college professor and chose a human services career that required fewer years of education and offered reasonable likelihood of employment after graduation. During the late-2000s recession, which substantially increased unemployment among new college graduates, increasing numbers of U.S. college students chose to major in business, physical or biological sciences, health professions, or computer science, where the chances of securing a job—particularly a better-paying one—were greatest (U.S. Department of Education, 2012b). Thus, personality takes us only partway in understanding vocational choice.

KEITH BROFSKY/UPPERCUT IMAGES/GETTY IMAGES

These young technicians in a genetics lab, who entered the workforce during the late-2000s recession, prepare DNA samples for analysis. They chose a career in the biological sciences, where employment opportunities were greater than in many other fields.

Family Influences. Young people's vocational aspirations correlate strongly with their parents' jobs. Individuals who grew up in higher-SES homes are more likely to select high-status, white-collar occupations, such as doctor, lawyer, scientist, or engineer. In contrast, those with lower-SES backgrounds tend to choose less prestigious, blue-collar careers—for example, plumber, construction worker, food service employee, or office worker. Parent-child vocational similarity is partly a function of similarity in personality, intellectual abilities, and—especially—educational attainment (Ellis & Bonin, 2003; Schoon & Parsons, 2002). Number of years of schooling completed powerfully predicts occupational status.

Other factors also promote family resemblance in occupational choice. Higher-SES parents are more likely to give their children important information about the worlds of education and work and to have connections with people who can help the young person obtain a high-status position (Kalil, Levine, & Ziol-Guest, 2005). In a study of African-American mothers' influence on their daughters' academic and career goals, college-educated mothers engaged in a wider range of strategies to promote their daughters' progress, including gathering information on colleges and areas of study and identifying knowledgeable professionals who could help (Kerpelman, Shoffner, & Ross-Griffin, 2002).

Parenting practices also shape work-related preferences. Recall from Chapter 2 that higher-SES parents tend to promote curiosity and self-direction, which are required in many high-status careers. Still, all parents can foster higher aspirations. Parental guidance, pressure to do well in school, and encouragement toward high-status occupations predict confidence in career choice and career attainment beyond SES (Bryant, Zvonkovic, & Reynolds, 2006; Stringer & Kerpelman, 2010).

Teachers. Young adults preparing for or engaged in careers requiring extensive education often report that teachers influenced their choice (Bright et al., 2005; Reddin, 1997). High school students who say that most of their teachers are caring and accessible, interested in their future, and expect them to work hard feel more confident about choosing a personally suitable career and succeeding at it (Metheny, McWhirter, & O'Neil, 2008). College-bound high school students tend to have closer relationships with teachers than do other students—relationships that are especially likely to foster high career aspirations in young women (Wigfield et al., 2002).

These findings provide yet another reason to promote positive teacher-student relations, especially for high school students from low-SES families. Teachers who offer encouragement and act as role models can serve as an important source of resilience for these young people.

Gender Stereotypes. Over the past four decades, young women have expressed increasing interest in occupations largely held by men (Gottfredson, 2005). Changes in gender-role attitudes, along with a dramatic rise in numbers of employed mothers who serve as career-oriented models for their daughters,

TABLE 13.2 Percentage of Women in Various Professions in the United States, 1983 and 2010

PROFESSION	1983	2010
Architect or engineer	5.8	12.9
Lawyer	15.8	31.5
Doctor	15.8	32.3
Business executive	32.4	38.2 ^a
Author, artist, entertainer	42.7	46.2
Social worker	64.3	80.8
Elementary or middle school teacher	93.5	81.8
Secondary school teacher	62.2	57.0
College or university professor	36.3	45.9
Librarian	84.4	82.8
Registered nurse	95.8	91.1
Psychologist	57.1	66.7

Source: U.S. Census Bureau, 2012.

^aThis percentage includes executives and managers at all levels. As of 2010, women made up only 4 percent of chief executive officers at Fortune 500 companies, although that figure represents more than 2½ times as many as in 2003.

ters, are common explanations for women's attraction to non-traditional careers.

But women's progress in entering and excelling at male-dominated professions has been slow. As Table 13.2 shows, although the percentage of women engineers, lawyers, doctors, and business executives has increased in the United States over the past quarter-century, it still falls far short of equal representation. Women remain concentrated in less-well-paid, traditionally feminine professions such as writing, social work, education, and nursing (U.S. Census Bureau, 2012). In virtually all fields, their achievements lag behind those of men, who write more books, make more discoveries, hold more positions of leadership, and produce more works of art.

Ability cannot account for these dramatic sex differences. Recall from Chapter 11 that girls are advantaged in reading and writing achievement, and the gender gap favoring boys in math is small and has been shrinking. Rather, gender-stereotyped messages play a key role. Although girls earn higher grades than boys, they reach secondary school less confident of their abilities, more likely to underestimate their achievement, and less likely to express interest in STEM careers (see page 389).

In college, the career aspirations of many women decline further as they question their capacity and opportunities to succeed in male-dominated fields and worry about combining a highly demanding career with family responsibilities (Chhin, Bleeker, & Jacobs, 2008; Wigfield et al., 2006). In a recent study, science professors at a broad sample of U.S. universities were

Social Issues: Education

Masculinity at Work: Men Who Choose Nontraditional Careers

Ross majored in engineering through his sophomore year of college, when he startled his family and friends by switching to nursing. “I’ve never looked back,” Ross said. “I love the work.” He noted some benefits of being a male in a female work world, including rapid advancement and the high regard of women colleagues. “But as soon as they learn what I do,” Ross remarked with disappointment, “guys on the outside question my abilities and masculinity.”

What factors influence the slowly increasing number of men who, like Ross, enter careers dominated by women? Compared to their traditional-career counterparts, these men are more liberal in their social attitudes, less gender-typed, less focused on the social status of their work, and more interested in working with people (Dodson & Borders, 2006; Jome, Surething, & Taylor, 2005). Perhaps their gender-stereotype flexibility allows them to choose occupations they find satisfying, even if those jobs are not typically regarded as appropriate for men.

In one investigation, 40 men who were primary school teachers, nurses, airline stewards, or librarians, when asked how they arrived at their choice, described diverse pathways (Simpson, 2005). Some actively sought the career, others happened on it while exploring possibilities, and still others first spent time in another occupation (usually male-dominated), found it

unsatisfying, and then settled into their current career.

The men also confirmed Ross’s observations: Because of their male minority status, co-workers often assumed they were more knowledgeable than they actually were. They also had opportunities to move quickly into supervisory positions, although many did not seek advancement (Simpson, 2004). As one teacher commented, “I just want to be a good classroom teacher. What’s wrong with that?” Furthermore, while in training and on the job, virtually all the men reported feeling socially accepted—relaxed and comfortable working with women.

But when asked to reflect on how others reacted to their choice, many men expressed anxiety about being stigmatized—by other men, not by women, whom they reported as generally accepting. To reduce these feelings, the men frequently described their job in ways that minimized its feminine image. Several librarians emphasized technical requirements by referring to their title as “information scientist” or “researcher.” The nurses sometimes distanced themselves from a feminine work identity by specializing in “adrenaline-charged” areas such as accident or emergency. Despite these tensions, as with Ross, their high level of

This nurse exemplifies the increasing number of men entering careers dominated by women. Compared with his traditional-career counterparts, he is likely to be less gender-typed and more interested in working with people.

private comfort seemed to prevail over uneasiness about the feminine public image of their work.

Still, men face certain barriers that resemble those of women preparing for nontraditional careers. For example, male students in college nursing programs often mention lack of male mentors and a “cooler” educational climate, which they attribute to implicit gender discrimination and unsupportive behaviors of women nurse educators (Bell-Scriber, 2008; Meadus & Twomey, 2011). These findings indicate that to facilitate entry into nontraditional careers, men, too, would benefit from supportive relationships with same-gender role models and an end to faculty gender-biased beliefs and behaviors.

sent an undergraduate student’s application for a lab manager position. For half, the application bore a male name; for the other half, a female name (Moss-Racusin et al., 2012). Professors of both genders viewed the female student as less competent, less deserving of mentoring, and meriting a lower salary, though her accomplishments were identical to those of the male! In line with these findings, many mathematically talented college women settle on nonscience majors. And partly because of their strong interest in working with people, women who remain in the sciences more often choose medicine or another health

profession, and less often choose engineering or a math or physical science career, than their male counterparts (Robertson et al., 2010).

These findings reveal a pressing need for programs that sensitize educators to the special problems women face in developing and maintaining high vocational aspirations and selecting nontraditional careers. Young women’s aspirations rise in response to career counseling that encourages them to set goals that match their abilities and faculty who take steps to enhance their experiences in math and science courses. Supportive rela-

tionships with women scientists and engineers add to female students' interest in and expectancies for success in STEM fields (Holdren & Lander, 2012). And such mentoring may help them see how altruistic values—which are particularly important to females—can be fulfilled within STEM occupations.

Compared to women, men have changed little in their interest in nontraditional occupations. See the Social Issues: Education box on the previous page for research on the motivations and experiences of men who do choose female-dominated careers.

Vocational Preparation of Non-College-Bound Young Adults

Sharese's younger brother Leon graduated from high school in a vocational track. Like approximately one-third of U.S. young people with a high school diploma, he had no current plans to go to college. While in school, Leon held a part-time job selling candy at the local shopping mall. He hoped to work in data processing after graduation, but six months later he was still a part-time sales clerk at the candy store. Although Leon had filled out many job applications, he got no interviews or offers.

Leon's inability to find a job other than the one he held as a student is typical for U.S. non-college-bound high school graduates. Although they are more likely to find employment than youths who drop out, they have fewer work opportunities than high school graduates of several decades ago. With rising unemployment during the late-2000s recession, these conditions worsened as entry-level positions went to the large pool of available college graduates. About 30 percent of recent U.S. high school graduates who do not continue their education are unemployed (Shierholz, Sabadish, & Wething, 2012). When they do find work, most hold low-paid, unskilled jobs. In addition, they have few alternatives for vocational counseling and job placement as they transition from school to work.

American employers regard recent high school graduates as unprepared for skilled business and industrial occupations and manual trades. And there is some truth to this impression. As noted in Chapter 11, unlike European nations, the United States has no widespread training system for non-college-bound youths. As a result, most graduate without work-related skills and experience a "floundering period" that lasts for several years.

In Germany, young people who do not go to a *Gymnasium* (college-preparatory high school) have access to one of the most successful work-study apprenticeship systems in the world for entering business and industry. About two-thirds of German youths participate. After completing full-time schooling at age 15 or 16, they spend the remaining two years of compulsory education in the *Berufsschule*, combining part-time vocational courses with an apprenticeship that is jointly planned by educators and employers. Students train in work settings for more than 350 blue- and white-collar occupations (Deissinger, 2007). Apprentices who complete the program and pass a qualifying examination are certified as skilled workers and earn union-set

wages. Businesses provide financial support because they know that the program guarantees a competent, dedicated work force (Kerckhoff, 2002). Many apprentices are hired into well-paid jobs by the firms that train them.

The success of the German system—and of similar systems in Austria, Denmark, Switzerland, and several East European countries—suggests that a national apprenticeship program would improve the transition from high school to work for U.S. young people. The many benefits of bringing together the worlds of schooling and work include helping non-college-bound young people establish productive lives right after graduation, motivating at-risk youths to stay in school, and contributing to the nation's economic growth. Nevertheless, implementing an apprenticeship system poses major challenges: overcoming the reluctance of employers to assume part of the responsibility for vocational training, ensuring cooperation between schools and businesses, and preventing low-SES youths from being concentrated in the lowest-skilled apprenticeship placements, an obstacle that Germany itself has not yet fully overcome (Lang, 2010). Currently, small-scale school-to-work projects in the United States are attempting to solve these problems and build bridges between learning and working.

Although vocational development is a lifelong process, adolescence and early adulthood are crucial periods for defining occupational goals and launching a career. Young people who are well-prepared for an economically and personally satisfying work life are much more likely to become productive citizens, devoted family members, and contented adults. The support of families, schools, businesses, communities, and society as a whole can contribute greatly to a positive outcome. In Chapter 14, we will take up the challenges of establishing a career and integrating it with other life tasks.

REVIEW What student and college-environment characteristics contribute to favorable psychological changes during the college years?

CONNECT What have you learned in previous chapters about development of gender stereotypes that helps explain women's slow progress in entering and excelling at male-dominated professions? (*Hint:* See Chapter 10, pages 343–344, and Chapter 11, page 389.)

APPLY Diane, a college freshman, knows that she wants to "work with people" but doesn't yet have a specific career in mind. Diane's father is a chemistry professor, her mother a social worker. What steps can Diane's parents take to broaden her awareness of the world of work and help her focus on an occupational goal?

REFLECT Describe personal and environmental influences on your progress in choosing a vocation.

SUMMARY

PHYSICAL DEVELOPMENT

Biological Aging Is Under Way in Early Adulthood

(p. 432)

Describe current theories of biological aging, both at the level of DNA and body cells and at the level of tissues and organs.

- Once body structures reach maximum capacity and efficiency in the teens and twenties, **biological aging**, or **senescence**, begins.

© MOODBOARD/ALAMY

- The programmed effects of specific genes may control certain age-related biological changes. For example, **telomere** shortening results in senescent cells, which contribute to disease and loss of function.
- DNA may also be damaged as random mutations accumulate, leading to less efficient cell repair and replacement and to abnormal cancerous cells. Release of highly reactive **free radicals** is a possible cause of age-related DNA and cellular damage.
- The **cross-linkage theory of aging** suggests that over time, protein fibers form links and become less elastic, producing negative changes in many organs. Declines in the endocrine and immune systems may also contribute to aging.

Physical Changes (p. 434)

Describe the physical changes of aging, paying special attention to the cardiovascular and respiratory systems, motor performance, the immune system, and reproductive capacity.

- Gradual physical changes take place in early adulthood and later accelerate. Declines in heart and lung performance are evident during exercise. Heart disease is a leading cause of death in adults, although it has decreased since the mid-twentieth century due to lifestyle changes and medical advances.

- Athletic skills requiring speed, strength, and gross-motor coordination peak in the early twenties; those requiring endurance, arm-hand steadiness, and aiming peak in the late twenties and early thirties. Less active lifestyles rather than biological aging are largely responsible for age-related declines in motor performance.
- The immune response declines after age 20 because of shrinkage of the thymus gland and increased difficulty coping with physical and psychological stress.
- Women's reproductive capacity declines with age due to reduced quality and quantity of ova. In men, semen volume and sperm quality decrease gradually after age 35.

Health and Fitness (p. 438)

Describe the impact of SES, nutrition, and exercise on health, and discuss obesity in adulthood.

- Health inequalities associated with SES increase in adulthood. Health-related circumstances and habits underlie these disparities.
- Today, Americans are the heaviest people in the world. Sedentary lifestyles and diets high in sugar and fat contribute to obesity, which is associated with serious health problems, social discrimination, and early death.
- Some weight gain in adulthood reflects a decrease in **basal metabolic rate (BMR)**, but many young adults add excess weight. Effective treatment includes a nutritious diet low in calories, sugar, and fat, plus regular exercise, recording of food intake and body weight, social support, and teaching problem-solving skills.
- Regular exercise reduces body fat, builds muscle, fosters resistance to disease, and enhances psychological well-being. Health benefits increase with greater intensity of exercise.

LORI ADAMSKI PEEKSTONE/GETTY IMAGES

What are the two most commonly abused substances, and what health risks do they pose?

- Cigarette smoking and alcohol consumption are the most commonly abused substances. Smokers, most of whom began before age 21, are at increased risk for many health problems, including decline in bone mass, heart attack, stroke, and numerous cancers.
- About one-third of heavy drinkers suffer from alcoholism, to which both heredity and environment contribute. Alcohol is implicated in liver and cardiovascular disease, certain cancers and other physical disorders, highway fatalities, crime, and sexual coercion.

Describe sexual attitudes and behavior of young adults, and discuss sexually transmitted diseases and sexual coercion.

- Most adults are less sexually active than media images suggest, but they display a wider range of sexual choices and lifestyles and have had more sexual partners than earlier generations. The Internet has become a popular way to initiate relationships.

© MAMADUKE ST. JOHN/ALAMY

- Adults in committed relationships report high satisfaction with their sex lives. Only a minority report persistent sexual problems—difficulties linked to low SES and psychological stress.
- Attitudes toward same-sex couples have become more accepting. Homosexual relationships, like heterosexual relationships, are characterized by similarity between partners in education and background, greater satisfaction in committed relationships, and modest frequency of sexual activity.
- Sexually transmitted diseases (STDs) continue to be prevalent in early adulthood; women are more vulnerable to infection than men. AIDS, the most deadly STD, is spreading most rapidly through men having sex with men and through heterosexual contact in poverty-stricken minority groups.

- Most rape victims are under age 30 and have been harmed by men they know well. Men who commit sexual assault typically support traditional gender roles, approve of violence against women, accept rape myths, and misinterpret women's social behaviors. Cultural acceptance of strong gender typing and of violence contributes to sexual coercion, which leads to psychological trauma. Female-initiated coercive sexual behavior also occurs but is less often reported and recognized by authorities.

How does psychological stress affect health?

- Chronic psychological stress induces physical responses that contribute to heart disease, several types of cancer, and gastrointestinal problems. Because the challenges of early adulthood make it a highly stressful time of life, interventions that help stressed young people form supportive social ties are especially important.

COGNITIVE DEVELOPMENT

Changes in the Structure of Thought (p. 450)

Explain how thinking changes in early adulthood.

- Development of the cerebral cortex in early adulthood results in continued fine-tuning of the prefrontal cognitive-control network, contributing to improvements in planning, reasoning, and decision making.
- Cognitive development beyond Piaget's formal operations is known as **postformal thought**. In early adulthood, personal effort and social experiences combine to spark increasingly rational, flexible, and practical ways of thinking.
- In Perry's theory of **epistemic cognition**, college students move from **dualistic thinking**, dividing information into right and wrong, to **relativistic thinking**, awareness of multiple truths. The most mature individuals progress to **commitment within relativistic thinking**, which synthesizes contradictions.

- Advances in epistemic cognition depend on gains in metacognition. Peer collaboration on challenging, ill-structured problems is especially beneficial.

© IAN SHAW/ALAMY

- In Labouvie-Vief's theory, the need to specialize motivates adults to move from hypothetical to **pragmatic thought**, which uses logic as a tool for solving real-world problems and accepts contradiction, imperfection, and compromise. Adults' enhanced reflective capacities permit gains in **cognitive-affective complexity**—coordination of positive and negative feelings into a complex, organized structure.

Expertise and Creativity

(p. 453)

What roles do expertise and creativity play in adult thought?

- Specialization in college and in an occupation leads to **expertise**, which is necessary for both problem solving and creativity. Although creativity tends to rise in early adulthood and to peak in the late thirties or early forties, its development varies across disciplines and individuals. Diverse personal and situational factors jointly promote creativity.

The College Experience

(p. 454)

Describe the impact of a college education on young people's lives, and discuss the problem of dropping out.

- College students' explorations, both academic and nonacademic, yield gains in knowledge and reasoning ability, broadening of attitudes and values, enhanced self-understanding and self-esteem, and a firmer sense of identity.

- Personal and institutional factors contribute to college dropout, which is more common in less selective colleges and among ethnic minority students from low-SES families. High-risk students benefit from interventions that show concern for them as individuals.

Vocational Choice (p. 455)

Trace the development of vocational choice, and cite factors that influence it.

- Vocational choice moves through a **fantasy period**, in which children explore career options by fantasizing about them; a **tentative period**, in which teenagers evaluate careers in terms of their interests, abilities, and values; and a **realistic period**, in which young people settle on a vocational category and then a specific occupation.
- Vocational choice is influenced by personality; parents' provision of educational opportunities, vocational information, and encouragement; and close relationships with teachers. Women's progress in male-dominated professions has been slow, and their achievements lag behind those of men in virtually all fields. Gender-stereotyped messages play a key role.

KEITH BROFSKY/UPPERCUT IMAGES/GETTY IMAGES

What problems do U.S. non-college-bound young people face in preparing for a vocation?

- Most U.S. non-college-bound high school graduates are limited to low-paid, unskilled jobs, and too many are unemployed. Work-study apprenticeships, like those widely available in European countries, would improve the transition from school to work for these young people.

THE WASHINGTON POST/GETTY IMAGES

This college student, a volunteer for a nonprofit organization called FoodCorps, helps children in economically disadvantaged communities plant a school garden, teaching them about healthy foods and how they grow. For many young people in industrialized nations, the transition to early adulthood is a time of prolonged exploration of attitudes, values, and life possibilities.

Emotional and Social Development in Early Adulthood

After completing her master's degree at age 26, Sharese returned to her hometown, where she and Ernie would soon be married.

During their year-long engagement, Sharese had vacillated about whether to follow through. At times, she looked with envy at Heather, still unattached and free to choose from an array of options before her. After graduating from college, Heather accepted a Peace Corps assignment in a remote region of Ghana, forged a romance with another Peace Corps volunteer that she ended at the conclusion of her tour of duty, and then traveled for eight months before returning to the United States to contemplate next steps.

Sharese also pondered the life circumstances of Christy and her husband, Gary—married and first-time parents by their mid-twenties. Despite his good teaching performance, Gary's relationship with the high school principal deteriorated, and he quit his job at the end of his first year. A tight job market impeded Gary's efforts to find another teaching position, and financial pressures and parenthood put Christy's education and career plans on hold. Sharese wondered whether it was really possible to combine family and career.

As her wedding approached, Sharese's ambivalence intensified, and she admitted to Ernie that she didn't feel ready to marry. Ernie's admiration for Sharese had strengthened over their courtship, and he reassured her of his love. His career as an accountant had been under way for two years, and at age 28, he looked forward to marriage and starting a family. Uncertain and conflicted, Sharese felt swept toward the altar as relatives and friends began to arrive. On the appointed day, she walked down the aisle.

In this chapter, we take up the emotional and social sides of early adulthood. Notice that Sharese, Ernie, and Heather moved toward adult roles slowly, at times vacillating along the way. Not until their mid- to late twenties did they make lasting career and romantic choices and attain full economic independence—broadly accepted markers of adulthood that young people of previous generations reached considerably earlier. Each received financial and other forms of support from parents and other family members, which enabled them to postpone taking on adult roles. We consider whether prolonged exploration of life options has become so widespread that it merits a new developmental period—*emerging adulthood*—to describe and understand it.

Career Development

Establishing a Career • Women and Ethnic Minorities • Combining Work and Family

Recall from Chapter 12 that identity development continues to be a central focus from the late teens into the mid-twenties (see page 404). As they achieve a secure identity and independence from parents, young adults seek close, affectionate ties. Yet the decade of the twenties is accompanied by a rise in feelings of personal control over events in their lives—in fact, a stronger sense of control than they will ever experience again (Grob, Krings, & Bangerter, 2001). Perhaps for this reason, like Sharese, they often fear losing their freedom. Once this struggle is resolved, early adulthood leads to new family units and parenthood, accomplished in the context of diverse lifestyles. At the same time, young adults must master the tasks of their chosen career.

Our discussion will reveal that identity, love, and work are intertwined. In negotiating these arenas, young adults do more choosing, planning, and changing course than any other age group. When their decisions are in tune with themselves and their social and cultural worlds, they acquire many new competencies, and life is full and rewarding. ●

A Gradual Transition: Emerging Adulthood

TAKE A MOMENT... Think about your own development. Do you consider yourself to have reached adulthood? When a large sample of American 18- to 25-year-olds was asked this question, the majority gave an ambiguous answer: “yes and no.” Only after reaching their late twenties and early thirties did most feel that they were truly adult—findings evident in a wide range of industrialized nations, including Argentina, Austria, the Czech Republic, Finland, Germany, Italy, Romania, Spain, and Israel (Arnett, 2001, 2003, 2007a; Buhl & Lanz, 2007; Macek, Bejček, & Vaníčková, 2007; Nelson, 2009; Sirsch et al., 2009). The life pursuits and subjective judgments of many contemporary young people indicate that the transition to adult roles has become so delayed and prolonged that it has spawned a new transitional period extending from the late teens to the mid- to late-twenties, called **emerging adulthood**.

Unprecedented Exploration

Psychologist Jeffrey Arnett is the leader of a movement that regards emerging adulthood as a distinct period of life. As Arnett explains, emerging adults have left adolescence but are still a considerable distance from taking on adult responsibilities. Their parents agree: In a survey of parents of a large sample of ethnically and religiously diverse U.S. undergraduate and graduate students, most viewed their children as not yet fully adult (Nelson et al., 2007). Furthermore, 18- to 25-year-olds who do not consider themselves adults are less adultlike in life goals and behavior—less certain about their identity and

the qualities they desire in a romantic partner and more likely to engage in risk taking, including substance use and unprotected sex (Nelson & Barry, 2005). During these years, young people who have the economic resources to do so explore alternatives in education, work, and personal values and behavior more intensely than they did as teenagers.

Not yet immersed in adult roles, many emerging adults can engage in activities of the widest possible scope. Because so little is normative, or socially expected, routes to adult responsibilities are highly diverse in timing and order across individuals (Côté, 2006). For example, more college students than in past generations pursue their education in a drawn-out, nonlinear way—changing majors as they explore career options, taking courses while working part-time, or interrupting school to work, travel, or participate in national or international service programs. About one-third of U.S. college graduates enter graduate school, taking still more years to settle into their desired career track (U.S. Department of Education, 2012b).

As a result of these experiences, young people’s interests, attitudes, and values broaden (see page 454 in Chapter 13). Exposure to multiple viewpoints also encourages young people to look more closely at themselves. Consequently, they develop a more complex self-concept that includes awareness of their own changing traits and values over time, and self-esteem rises (Labouvie-Vief, 2006; Orth, Robins, & Widaman, 2012). Together, these changes contribute to advances in identity.

Identity Development. During the college years, young people refine their approach to constructing an identity. Besides exploring in *breadth* (weighing multiple possibilities), they also explore in *depth*—evaluating existing commitments (Luyckx et al., 2006). For example, if you have not yet selected your major, you may be taking classes in a broad array of disciplines. Once you choose a major, you are likely to embark on an in-depth evaluation of your choice—reflecting on your interest, motivation, and performance and on your career prospects as you take additional classes in that field. Depending on the outcome of your evaluation, either your commitment to your major strengthens, or you return to a broad exploration of options.

In a longitudinal study extending over the first two years of college, most students cycled between making commitments and evaluating commitments in various identity domains. Fluctuations in students’ certainty about their commitments sparked movement between these two states (Luyckx, Goossens, & Soenens, 2006). **TAKE A MOMENT...** Consider your own identity progress. Does it fit this *dual-cycle model*, in which identity formation is a lengthy process of feedback loops? Notice how the model helps explain the movement between identity statuses displayed by many young people, described in Chapter 12. College students who move toward exploration in depth and certainty of commitment are higher in self-esteem, psychological well-being, and academic, emotional, and social adjustment. Those who spend much time exploring in breadth without making commitments, or who are identity diffused (engaging in no exploration), tend to be poorly adjusted—*anxious, depressed,*

and higher in alcohol and drug use, casual and unprotected sex, and other health-compromising behaviors (Kunnen et al., 2008; Schwartz et al., 2011).

Many aspects of the life course that were once socially structured—marriage, parenthood, religious beliefs, and career paths—are increasingly left to individuals to decide on their own. As a result, emerging adults are required to “individualize” their identities—a process that requires a sense of self-efficacy, purpose, determination to overcome obstacles, and responsibility for outcomes. Among young people of diverse ethnicities and SES levels, this set of qualities, termed *personal agency*, is positively related to an information-gathering cognitive style and identity exploration followed by commitment (Schwartz, Côté, & Arnett, 2005; Stringer & Kerpelman, 2010).

Religion and Worldview. Most emerging adults say that constructing a worldview, or a set of beliefs and values to live by, is essential for attaining adult status—even more important than finishing their education and settling into a career and marriage (Arnett, 2006, 2007b). During the late teens and twenties, attendance at religious services drops to its lowest level throughout the lifespan as young people continue to question the beliefs they acquired in their families (Kunnen et al., 2008; Schwartz et al., 2011). About one-fourth of U.S. 18- to 29-year-olds are unaffiliated with a particular faith—considerably more than in their parents’ generation at the same age (see Figure 14.1).

FIGURE 14.1 U.S. 18- to 29-year-olds’ religiosity across generations. The percentage of unaffiliated young people rose substantially from the 1970s to 2000s. At the same time, among those in the 2000s cohort who are religiously affiliated, about one-third say they are strong members of their faith—similar to the 1990s cohort. (Adapted from Pew Forum on Religion and Public Life, 2010.)

Yet about 50 percent of U.S. young people remain stable in their religious commitment (or lack thereof) from adolescence into emerging adulthood (Smith & Snell, 2009). And in certain ways, U.S. emerging adults are quite traditional in their religious beliefs and practices. Religion is more important in their lives than it is for young people in other developed countries. More than half of U.S. 18- to 29-year-olds say they believe in God with certainty, and more than one-third of those who are religiously affiliated say they are “strong” members of their faith—equivalent to same-age individuals who said so a decade earlier (Pew Forum on Religion and Public Life, 2010). Women are more religious than men, a difference evident in other Western nations and throughout the lifespan. Also among the more religious are immigrants and certain ethnic minorities, including African Americans and Hispanics (Barry et al., 2010). Of the small number of young people who increase in religiosity during the late teens and early twenties, many are women, African American, and Hispanic.

Whether or not they are involved in organized religion, many young people begin to construct their own individualized faith and, if attending college, discuss religious beliefs and experiences more often with friends than with parents or other adults (Montgomery-Goodnough & Gallagher, 2007; Stoppa & Lefkowitz, 2010). Often they weave together beliefs and practices from diverse sources, including Eastern and Western religious traditions, science, and popular culture, including music and other media images.

As with adolescents, U.S. emerging adults who are religious or spiritual tend to be better adjusted. They are higher in self-esteem, less likely to engage in substance use and antisocial acts, and more likely to become involved in community service (Barry & Nelson, 2008; Knox, Langelough, & Walters, 1998; White et al., 2006). But outcomes vary: Among sexual minority young people, religiosity does not protect against drug taking (Rostosky, Danner, & Riggle, 2007). A possible explanation is that their religious communities often do not support (and sometimes condemn) their sexual orientation.

Perhaps because emerging adults are so focused on exploring and “finding themselves,” a widespread view among older adults is that they forge self-centered worldviews, as the descriptor “generation me” suggests (Arnett, 2010). This issue has generated heated controversy. Analyses of large, nationally representative samples of U.S. young people, collected repeatedly over several decades, suggest that compared to past generations, the Millennial generation reports greater narcissism (egotistical self-admiration) and materialism—valuing of money and leisure and reduced empathy for the less fortunate (Gentile, Twenge, & Campbell, 2010; O’Brien, Hsing, & Konrath, 2010; Twenge, Campbell, & Freeman, 2012).

But other researchers claim that generational changes in egotism and other traits are too small to be meaningful (Trzesniewski & Donnellan, 2009, 2010). And gradual, age-related gains in self-esteem extending from adolescence through emerging adulthood and into mid-life are similar across generations, with average self-esteem of today’s young people no

higher than that of past cohorts (Orth, Robins, & Widaman, 2012; Orth, Trzesniewski, & Robins, 2010). Over these years, adults derive a greater sense of competence from making identity commitments, entering and succeeding at their careers, and becoming involved in their communities.

Additional evidence supports the view that many emerging adults are committed to improving their communities, nation, and world. In a survey of several hundred thousand first-year students enrolled in nearly 300 U.S. colleges and universities, a record number—nearly 30 percent—said that there is “a very good chance” they will participate in community service—nearly double the number two decades earlier (Pryor et al., 2009). An additional 41 percent expressed “some chance” of participating, and only 6 percent said they would not volunteer.

Among college students who expect to volunteer, the overwhelming majority actually do so within their first year (DeAngelo, Hurtado, & Pryor, 2010). And compared with their nonvolunteer counterparts, volunteers have a stronger pluralistic orientation—disposition for living in a diverse society that includes respect for others with differing beliefs and willingness to discuss and negotiate controversial issues (Pryor et al., 2009).

LOOK AND LISTEN

Ask 10 to 15 of your college classmates to answer the following question: What would you do if you had a million dollars? How often do respondents mention prosocial as opposed to self-centered acts? ●

Finally, compared to previous generations, contemporary 18- to 29-year-olds have been labeled “apathetic no shows” when it comes to voting. But in the 2012 U.S. presidential election, they made up more of the total electorate (19 percent) than did citizens over age 65 (16 percent), who traditionally have been the highest participants. In this respect, emerging adults’ civic involvement appears to have strengthened.

Cultural Change, Cultural Variation, and Emerging Adulthood

Rapid cultural change explains the recent appearance of emerging adulthood. First, entry-level positions in many fields require more education than in the past, prompting young adults to seek higher education in record numbers and thus delaying financial independence and career commitment. Second, wealthy nations with longer-lived populations have no pressing need for young people’s labor, freeing those who are financially able for rich, extended exploration.

Indeed, emerging adulthood is limited to cultures that postpone entry into adult roles until the twenties. In developing nations such as Brazil, China, India, and Mexico, only a privileged few—usually those from wealthier families who are admitted to universities—experience it, often for a shorter time than their Western counterparts (Arnett, 2011; Nelson & Chen, 2007). Furthermore, the overwhelming majority of young people in traditional non-Western countries—those who have few economic resources or who remain in the rural regions where they grew up—have no emerging adulthood. With limited education, they typically enter marriage, parenthood, and lifelong work early (UNICEF, 2010c).

In industrialized countries, many young people experience these transitional years. Typically, their families are sufficiently well-off to provide them with financial support, without which few could advance their education, explore career possibilities, or travel the country and world to—as one emerging adult put it—“experience as much as possible.” And although most emerging adults are pursuing higher education or have earned an advanced degree, some non-college-bound young people also benefit from this extended transition to adult roles (Tanner, Arnett, & Leis, 2009). But they may do so by trying out different types of work rather than college majors or travel.

Nevertheless, for the large numbers of U.S. low-SES young people who are burdened by early parenthood, do not finish high school, are otherwise academically unprepared for college, or do not have access to vocational training, emerging adulthood is limited or nonexistent (see Chapters 11 and 13). Instead of excitement and personal expansion, these individuals encounter a “floundering period” during which they alternate between unemployment and dead-end, low-paying jobs (Cohen et al., 2003; Eccles et al., 2003). When the late-2000s recession hit, work opportunities for low-SES high school graduates declined further, leaving increasing numbers in search of employment (see page 459 in Chapter 13) and without the economic resources for intensive exploration.

Because of its strong association with SES and higher education, some researchers reject the notion of emerging adulthood as a distinct period of development (see the Cultural Influences box on the following page). Others disagree, predicting that emerging adulthood will become increasingly common as *globalization*—the exchange of ideas, information, trade, and immigration among nations—accelerates. As globalization proceeds, gains in higher education and the formation of a common “global identity” among young people may lead to the spread of

Cultural Influences

Is Emerging Adulthood Really a Distinct Period of Development?

Although broad consensus exists that cultural change has prolonged the transition to adult roles for many young people, disagreement exists over whether these years of “emergence” merit the creation of a new developmental period (Hendry & Kloep, 2007, 2011). Critics of the concept of emerging adulthood offer the following arguments.

First, burgeoning higher education enrollment, delayed career entry, and later marriage and parenthood are cultural trends that began as early as the 1970s in industrialized nations, only gradually becoming more conspicuous. At no time has adulthood in complex societies been attained at a distinct moment (Côté & Bynner, 2008). Rather, young people in the past reached adult status earlier in some domains and later in others, just as they do today. They also may reverse direction—for example, move back to the parental home to get their bearings after finishing college or being laid off from a job. In accord with the lifespan perspective, development is multidimensional and multidirectional, for 18- to 29-year-olds as it is for adults of all ages. Transitions occur during all periods of adult life, with societal conditions heavily influencing their timing, length, and complexity.

Second, the term *emerging adulthood* fails to describe the experiences of the majority of the world’s youths (Galambos & Martinez, 2007). In most developing countries, young people—particularly women—are limited in education and marry and have children early. According to one estimate, over 1 billion individuals—nearly 70 percent of young people—follow this

traditional route to adulthood (World Health Organization, 2011). We have also seen that many low-SES youths in industrialized nations lack the academic preparation and financial resources to experience an emerging adulthood.

Third, research on emerging adulthood largely emphasizes its personal and societal benefits. But the extended exploration that defines this period can be risky for those who have not developed the personal agency to make good choices and acquire adult skills. These young people may remain uncommitted for too long—an outcome that impedes the focused learning required for a successful work life. A favorable emerging adulthood, then, depends on whether it is used to acquire competencies essential for contemporary living.

Finally, the financial upheaval of the late 2000s has left large numbers of bachelor’s degree holders under age 25 with restricted options. In 2011, over 9 percent were unemployed and 20 percent underemployed—in low-paid jobs not requiring a college degree and, thus, without experiences necessary for advancing their skills (Shierholz, Sabadish, & Wething, 2012). Rather than a period of unparalleled opportunities, these graduates’ delayed leap into adult roles is filled with anxiety and frustration. One young person, who might have been high in personal agency in a stable economy, remarked, “It has been tough finding a job that keeps me wanting to stick with something” (Kotkin, 2012).

Proponents of emerging adulthood as a distinct developmental period respond that, though not universal, it applies to most young people in industrialized societies and is spreading in developing nations that play

© ELLEN B. SENISI PHOTOGRAPHY

With few economic resources, this young woman in Burma already has adult responsibilities, caring for her baby while working as a food vendor. Like the majority of young people in developing countries, she has no emerging adulthood.

major roles in our global economy (Tanner & Arnett, 2011). But skeptics counter that emerging adulthood is unlikely to become a prominent period of life in developing countries with high concentrations of poverty or, in industrialized countries, among low-income youths or those not involved in higher education (Côté & Bynner, 2008; Kloep & Hendry, 2011). And for college graduates, societal conditions can readily restrict the prospects and rewards of this period.

Critics also emphasize that in developed nations, age-graded influences have declined in favor of nonnormative influences throughout contemporary adulthood (see page 12 in Chapter 1 to review) (Hendry & Kloep, 2010). In their view, rather than being unique, emerging adults are part of a general trend toward blurring of age-related expectations, yielding multiple transitions and increased diversity in development across the adult years.

emerging adulthood (Arnett, 2007a; Nelson & Chen, 2007). But, as the Cultural Influences box points out, the recession’s weak labor market has also left large numbers of college graduates with limited options. In sum, societal conditions enabling an emerging adulthood abundant in opportunity have recently contracted.

Risk and Resilience in Emerging Adulthood

In grappling with momentous choices and acquiring the skills to succeed in demanding life roles, emerging adults often encounter disappointments in love and work that require them to

Applying What We Know

Resources That Foster Resilience in Emerging Adulthood

Type of Resource	Description
Cognitive attributes	<ul style="list-style-type: none"> Effective planning and decision making Information-gathering cognitive style and mature epistemic cognition Good school performance Knowledge of vocational options and necessary skills
Emotional and social attributes	<ul style="list-style-type: none"> Positive self-esteem Good emotional self-regulation and flexible coping strategies Good conflict-resolution skills Confidence in one's ability to reach one's goals Sense of personal responsibility for outcomes Persistence and effective use of time Healthy identity development—movement toward exploration in depth and commitment certainty Strong moral character Sense of meaning and purpose in life, engendered by religion, spirituality, or other sources Desire to contribute meaningfully to one's community
Social supports	<ul style="list-style-type: none"> Positive relationships with parents, peers, teachers, and mentors Financial assistance from parents or others Sense of connection to social institutions, such as school, church, workplace, and community center

Sources: Benson et al., 2006; Eccles and Gootman, 2002.

adjust, and sometimes radically change, their life path (Arnett, 2006). Their vigorous explorations also extend earlier risks, including unprotected sexual activity, substance use, and hazardous driving behavior (see Chapter 13). And later in this chapter, we will see that feelings of loneliness are higher at this time than at any other time of life. As emerging adults move through school and employment settings, they must constantly separate from friends and forge new relationships.

Longitudinal research shows that the personal attributes and social supports listed in Applying What We Know above foster successful passage through these years, as indicated by completing a college education, forging a warm, stable intimate relationship, finding and keeping a well-paying job, and volunteering in one's community (Benson et al., 2006; Eccles & Gootman, 2002). Notice how the resources in the table overlap with ones discussed in previous chapters that promote development through *resilience*, the capacity to overcome challenge and adversity. Young people with more of these resources—and with resources in all three categories—probably make an especially smooth transition to adulthood. But many emerging adults with only a few resources also fare well.

As in childhood, certain resources strengthen others. Relationships with parents have an especially wide-ranging influence. A secure, affectionate parent-emerging adult bond that extends the balance of connection and separation established in adolescence—an empathic approach in which parents recognize

the weighty challenges the young person faces and encourage personally valued choices—predicts many aspects of adaptive functioning: favorable self-esteem, identity progress, successful transition to college life, higher academic achievement, more rewarding friendships and romantic ties, and positive psychological well-being. As one reviewer of research summed up, “What seems advantageous for emerging adults’ achievement of independence is feeling connected, secure, understood, and loved in their families, and having the willingness to call on parental resources” (Aquilino, 2006, p. 201).

In contrast, excessive parental rule-setting and regulation of the young person's daily life (including taking over when the young person encounters challenges) and psychological control (invalidating the young person's thoughts and feelings and, when dissatisfied, withdrawing love) are linked to poor adjustment, including low self-esteem, inability to make commitments in identity formation, and increased anxiety, depression, and alcohol use (Luyckz et al., 2007; Nelson et al., 2011; Patock-Peckam & Morgan-Lopez, 2009). In another form of parenting—called *helicopter parenting* in popular culture—warm, well-intentioned parents “hover” over the emerging adult out of excessive concern for his or her well-being. They might, for example, take the child to college but refuse to leave, attend classes with the child for the first week, and contact professors to discuss the child's grades. Perhaps because helicopter parenting is motivated by strong parental affection and involvement,

AP IMAGES/KEVIN RIVOLI

Although well-intentioned, these hovering “helicopter” parents make it harder for their daughter to acquire the skills she needs to manage the challenges of college life on her own.

it is not associated with the negative outcomes just noted. But it is related to reduced school engagement (going to class, completing assignments) (Padilla-Walker & Nelson, 2012). And it likely interferes with emerging adults’ ability to acquire the skills they need to act on their own.

Finally, exposure to multiple negative life events—family conflict, abusive intimate relationships, repeated romantic breakups, academic or employment difficulties, and financial strain—undermines development, even in emerging adults whose childhood and adolescence prepared them well for this transition (Masten et al., 2004). In sum, supportive family, school, and community environments are crucial, just as they were at earlier ages. The overwhelming majority of young people with access to these resources are optimistic about their future and likely to transition successfully to adult roles (Arnett, 2006). Now let’s turn to theories of psychosocial development in early adulthood.

ASK YOURSELF

REVIEW What cultural changes have led to the emergence of the period known as emerging adulthood?

CONNECT How are resources that foster resilience in emerging adulthood similar to those that promote resilience in childhood and adolescence? (See pages 10–11 in Chapter 1, page 354 in Chapter 10, and page 416 in Chapter 12.)

APPLY List supports that your college environment offers emerging adults in its health and counseling services, academic advising, residential living, and extracurricular activities. How does each help young people transition to adult roles?

REFLECT Should emerging adulthood be considered a distinct developmental period? Why or why not?

Erikson’s Theory: Intimacy versus Isolation

Erikson’s vision has influenced all contemporary theories of adult personality development. His psychological conflict of early adulthood is **intimacy versus isolation**, reflected in the young person’s thoughts and feelings about making a permanent commitment to an intimate partner.

As Sharese discovered, establishing a mutually gratifying close relationship is challenging. Most young adults are still grappling with identity issues. Yet intimacy requires that they give up some of their independent self and redefine their identity to include both partners’ values and interests. Those in their late teens and early twenties frequently say they don’t feel ready for a lasting tie (Carroll et al., 2009). During their first year of marriage, Sharese separated from Ernie twice as she tried to reconcile her desire for self-determination with her desire for intimacy. Maturity involves balancing these forces. Without intimacy, young adults face the negative outcome of Erikson’s early adulthood stage: loneliness and self-absorption. Ernie’s patience and stability helped Sharese realize that committed love requires generosity and compromise but not total surrender of the self.

Research confirms that—as Erikson emphasized—a secure identity fosters attainment of intimacy. Commitment to personally meaningful values and goals prepares young adults for interpersonal commitments, which increase as early adulthood progresses. Among large samples of college students, identity achievement was positively correlated with fidelity (loyalty in relationships) and love, for both men and women. In contrast, identity moratorium—a state of searching prior to commitment—was negatively associated with fidelity and love (Markstrom et al., 1997; Markstrom & Kalmanir, 2001). Other studies show that advanced identity development strongly predicts involvement in a deep, committed love partnership or readiness to establish such a partnership (Beyers & Seiffge-Krenke, 2010; Montgomery, 2005). Still, the coordination of identity and intimacy is more complex for women, who are more likely than men to consider the impact of their personal goals on important relationships (Archer, 2002).

In friendships and work ties, too, young people who have achieved intimacy are cooperative, tolerant, and accepting of differences in background and values. In contrast, people with a sense of isolation hesitate to form close ties because they fear loss of their own identity, tend to compete rather than cooperate, are not accepting of differences, and are easily threatened when others get too close (Marcia, 2002).

Erikson believed that successful resolution of intimacy versus isolation prepares the individual for the middle adulthood stage, which focuses on *generativity*—caring for the next generation and helping to improve society. But as noted previously, few adults follow a fixed series of tasks tied neatly to age. Some aspects of generativity—childbearing and child rearing, as well as contributions to society through work and community

service—are under way in the twenties and thirties. Still, in line with Erikson's ideas, high friendship or romantic intimacy in early adulthood does predict a stronger generative orientation (Mackinnon et al., 2011).

In sum, identity, intimacy, and generativity are concerns of early adulthood, with shifts in emphasis that differ among individuals. Recognizing that Erikson's theory provides only a broad sketch of adult personality development, other theorists have expanded his stage approach, adding detail.

Other Theories of Adult Psychosocial Development

In the 1970s, growing interest in adult development led to several widely read books on the topic. Daniel Levinson's *The Seasons of a Man's Life* (1978) and *The Seasons of a Woman's Life* (1996), and George Vaillant's *Adaptation to Life* (1977) and *Aging Well* (2002), present psychosocial theories in the tradition of Erikson.

Levinson's Seasons of Life

On the basis of in-depth biographical interviews with 35- to 45-year-old men—and, later, similar interviews with women in the same age range—Levinson (1978, 1996) depicted adult development as a sequence of qualitatively distinct eras (or “seasons”) coinciding with Erikson's stages and separated by *transitions*. The *life structure*, a key concept in Levinson's theory, is the underlying design of a person's life, consisting of relationships with significant others—individuals, groups, and institutions. Of its many components, usually only a few, relating to family, close friendships, and occupation, are central. But wide individual differences exist in the weights of central and peripheral components.

Levinson found that during the transition to early adulthood, most young people constructed a *dream*—an image of themselves in the adult world that guides their decision making. For men, the dream usually emphasized achievement in a career, whereas most career-oriented women had “split dreams” involving both marriage and career. Young adults also formed a relationship with a *mentor* who facilitated realization of their dream—often a senior colleague at work but occasionally a more experienced friend, neighbor, or relative. According to Levinson, men oriented toward high-status careers spent their twenties acquiring professional skills, values, and credentials. In contrast, for many women, career development extended into middle age.

Around age 30, a second transition occurred: Young people who had been preoccupied with career and were single usually focused on finding a life partner, while women who had emphasized marriage and family often developed more individualistic goals. For example, Christy, who had dreamed of becoming a

professor, finally earned her doctoral degree in her mid-thirties and secured a college teaching position. Married women tended to expect their spouse to recognize and accommodate their career interests and aspirations. For young people without a satisfying intimate tie or a vocational direction, this can be a time of crisis.

To create an early adulthood culminating life structure, men usually “settled down” by focusing on certain relationships and aspirations, in an effort to establish a niche in society consistent with their values, whether those be wealth, prestige, artistic or scientific achievement, or forms of family or community participation. In his late thirties, Ernie became a partner in his firm, coached his son's soccer team, and was elected treasurer of his church. He paid less attention to golf, travel, and playing the guitar than previously.

Many women, however, remained unsettled in their thirties, often because they added an occupational or relationship commitment. When her two children were born, Sharese felt torn between her research position in the state health department and her family. She took three months off after the arrival of each baby. When she returned to work, she did not pursue attractive administrative openings that required travel and time away from home. And shortly after Christy began teaching, she and Gary divorced. Becoming a single parent while starting her professional life introduced new strains. Not until middle age did many women reach career maturity and take on more authority in the community.

Vaillant's Adaptation to Life

Vaillant (1977) followed the development of nearly 250 men born in the 1920s, selected for study while they were students at a competitive liberal arts college. Participants were interviewed extensively while in college and answered lengthy questionnaires

during each succeeding decade. Then Vaillant (2002) interviewed them at ages 47, 60, and 70 about work, family, and physical and mental health.

Looking at how the men altered themselves and their social world to adapt to life, Vaillant—like Levinson—confirmed Erikson’s stages but filled gaps between them. After focusing on intimacy concerns in their twenties, the men turned to career consolidation in their thirties. During their forties, they became more generative. In their fifties and sixties, they extended that generativity; they became “keepers of meaning,” or guardians of their culture, expressing a deep need to preserve and pass on cultural traditions by teaching others what they had learned from life experience (Vaillant & Koury, 1994). Finally, in their seventies, the men became more spiritual and reflective, contemplating the meaning of life and accepting its finiteness. In a later lifelong study of a sample of well-educated women, Vaillant (2002) identified a similar series of changes.

Nevertheless, the developmental patterns Vaillant and Levinson described are based largely on interviews with people born in the first few decades of the twentieth century. As our discussion of emerging adulthood illustrates, development is far more variable today—so much so that some researchers doubt that adult psychosocial changes can be organized into distinct stages (Newton & Stewart, 2010). Rather, people may assemble the themes and dilemmas identified by these theorists into individualized arrangements, in a *dynamic system* of interacting biological, psychological, and social forces. Studies of new generations—both men and women of diverse backgrounds—are needed to shed light on the extent of commonality and variation among young people in psychosocial development.

The Social Clock

As we have seen, changes in society from one generation to the next can affect the life course. Bernice Neugarten (1968a, 1979) identified an important cultural and generational influence on adult development: the **social clock**—age-graded expectations for major life events, such as beginning a first job, getting married, birth of the first child, buying a home, and retiring. All societies have such timetables. Research of two to three decades ago revealed that conformity to or departure from the social clock can be a major source of adult personality change, affecting self-esteem, independence, responsibility, and other attributes because adults (like children and adolescents) make social comparisons, measuring their progress against that of age-mates (Helson, 1992; Vandewater & Stewart, 1997).

But as noted earlier, age-graded expectations for appropriate behavior have become increasingly flexible. Among economically better-off young people, finishing one’s education, marrying, and having children occur much later in the life-span than they did a generation or two ago. Furthermore, departures from social-clock life events have become increasingly

ISTOCK/LLCTANYA CONSTANTINE/GETTY IMAGES

Because the social clock has become increasingly flexible, this 30-year-old attorney, committed to her challenging, demanding career, may not feel pressure to conform to a strict timetable for major life events such as marriage and parenthood.

common. As we will see later, a growing number of women, mostly of lower income, are not marrying and, instead, rearing children as single mothers, turning not to a spouse but rather to their own parents and extended families for assistance (Furstenberg, 2010).

LOOK AND LISTEN

Describe your social clock, listing major life events along with the age you expect to attain each. Then ask a parent and/or grandparent to recall his or her own early adulthood social clock. Analyze generational differences. ●

These conditions can create intergenerational tensions when parents expect their young-adult children to attain adult milestones on an outdated schedule, at odds with their children’s current opportunities and desires. Young adults may also feel distressed because their own timing of major milestones is not widely shared by their contemporaries or supported by current public policies, thereby weakening the availability of both informal and formal social supports (Settersten, 2007). And while rendering greater flexibility and freedom to young people’s lives, an ill-defined social clock likely causes them to feel inadequately grounded—unsure of what others expect and of what to expect of themselves.

In sum, following a social clock of some kind seems to foster confidence and social stability because it guarantees that young people will develop skills, engage in productive work, and gain in understanding of self and others (Hendry & Kloep, 2007). In contrast, “crafting a life of one’s own,” whether self-chosen or the result of circumstances, is risky—more prone to breakdown (Settersten, 2007, p. 244). With this in mind, let’s take a closer look at how men and women traverse major tasks of young adulthood.

ASK YOURSELF

REVIEW According to Levinson, how do the life structures of men and women differ?

CONNECT Return to pages 403–404 in Chapter 12 and review the contributions of exploration and commitment to a mature identity. Using the two criteria, explain why identity achievement is positively related to attainment of intimacy (fidelity and love), whereas identity moratorium is negatively predictive.

APPLY In view of contemporary changes in the social clock, explain Sharese’s conflicted feelings about marrying Ernie.

REFLECT Describe your early adulthood dream. Then ask a friend or classmate of the other gender to describe his or her dream, and compare the two. Are they consistent with Levinson’s findings?

Close Relationships

To establish an intimate tie to another person, people must find a partner and build an emotional bond that they sustain over time. Although young adults are especially concerned with romantic love, the need for intimacy can also be satisfied through other relationships involving mutual commitment—with friends, siblings, and co-workers.

Romantic Love

At a party during her junior year of college, Sharese fell into conversation with Ernie, a senior and one of the top students in her government class. Sharese had already noticed Ernie in class, and as they talked, she discovered that he was as warm and interesting as he had seemed from a distance. Ernie found Sharese to be lively, intelligent, and attractive. By the end of the evening, the two realized that they had similar opinions on important social issues and liked the same leisure activities. They began dating steadily. Six years later, they married.

Finding a life partner is a major milestone of early adult development, with profound consequences for self-concept and psychological well-being (Meeus et al., 2007). As Sharese and Ernie’s relationship reveals, it is also a complex process that unfolds over time and is affected by a variety of events.

Selecting a Mate. Recall from Chapter 13 that intimate partners generally meet in places where they are likely to find people of their own age, level of education, ethnicity, and religion, or they connect through dating websites. People usually select partners who resemble themselves in other ways—attitudes, personality, educational plans, intelligence, physical attractiveness, and even height (Keith & Schafer, 1991; Simpson & Harris, 1994). Romantic partners sometimes have complementary

personality traits—one self-assured and dominant, the other hesitant and submissive. Because this difference permits each to sustain their preferred style of behavior, it contributes to compatibility (Sadler, Ethier, & Woody, 2011). But partners differing in other ways generally are not complementary! For example, a warm, agreeable person and an emotionally cool person usually react with discomfort to each other. Overall, little support exists for the idea that “opposites attract.” Rather, adults typically indicate that their romantic ideal is someone with a personality similar to their own (Markey & Markey, 2007). And partners who are similar in personality and other attributes tend to be more satisfied with their relationship and more likely to stay together (Blackwell & Lichter, 2004; Furnham, 2009).

Nevertheless, in choosing a long-term partner, men and women differ in the importance they place on certain characteristics. In research carried out in diverse industrialized and developing countries, women assign greater weight to intelligence, ambition, financial status, and moral character, whereas men place more emphasis on physical attractiveness and domestic skills. In addition, women prefer a same-age or slightly older partner, men a younger partner (Buunk, 2002; Cramer, Schaefer, & Reid, 2003; Stewart, Stinnett, & Rosenfeld, 2000).

According to an evolutionary perspective, because their capacity to reproduce is limited, women seek a mate with traits, such as earning power and emotional commitment, that help ensure children’s survival and well-being. In contrast, men look for a mate with traits that signal youth, health, sexual pleasure, and ability to give birth to and care for offspring. As further evidence for this difference, men often want a relationship to move quickly toward physical intimacy, whereas women typically prefer to take the time to achieve psychological intimacy first (Buss, 2012).

In an alternative, social learning view, gender roles profoundly influence criteria for mate selection. Beginning in childhood, men learn to be assertive and independent—behaviors needed for success in the work world. Women acquire nurturant behaviors, which facilitate caregiving. Then each sex learns to value traits in the other that fit with this traditional division of labor (Eagly & Wood, 2012). In support of this theory, in cultures and in younger generations experiencing greater gender equity, men and women are more alike in their mate preferences. For example, compared with men in China and Japan, American men place more emphasis on their mate’s financial prospects, less on her domestic skills. Also, when either male or female young adults are asked to imagine themselves as a future homemaker, their preferences for a good provider and an older partner strengthen (Eagly, Eastwick, & Johannesen-Schmidt, 2009).

But neither men nor women put good looks, earning power, and mate’s age relative to their own at the top of their wish list. Rather, they place a higher value on attributes that contribute to relationship satisfaction: mutual attraction, caring, dependability, emotional maturity, and a pleasing disposition (Buss et al., 2001; Toro-Morn & Sprecher, 2003). Nevertheless, men continue to emphasize physical attractiveness more than women do, and women earning capacity more than men do. Furthermore, these

gender differences—along with gender similarity in desire for a caring partner—also characterize gay men and lesbians (Impett & Peplau, 2006; Regan, Medina, & Joshi, 2001). In sum, both biological and social forces contribute to mate selection.

As the Social Issues: Health box on page 474 reveals, young people's choice of an intimate partner and the quality of their relationship also are affected by memories of their early parent-child bond. Finally, for romance to lead to a lasting partnership, it must happen at the right time. Two people may be right for each other, but if one or both do not feel ready to marry, the relationship is likely to dissolve.

The Components of Love. How do we know that we are in love? Robert Sternberg's (1988, 2000, 2006) **triangular theory of love** identifies three components—intimacy, passion, and commitment—that shift in emphasis as romantic relationships develop. *Intimacy*, the emotional component, involves warm, tender communication, expressions of concern about the other's well-being, and a desire for the partner to reciprocate. *Passion*, the desire for sexual activity and romance, is the physical- and psychological-arousal component. *Commitment* is the cognitive component, leading partners to decide that they are in love and to maintain that love.

At the beginning of a relationship, **passionate love**—intense sexual attraction—is strong. Gradually, passion declines in favor of intimacy and commitment, which form the basis for **companionate love**—warm, trusting affection and caregiving (Acker & Davis, 1992; Fehr, 1994). Each aspect of love, however, helps sustain the relationship. Early passionate love is a strong predictor of whether partners keep dating. But without the quiet intimacy, predictability, and shared attitudes and values of companionate love, most romances eventually break up (Hendrick & Hendrick, 2002).

An ongoing relationship requires effort from both partners. Research on newlyweds' feelings and behavior over the first year of marriage reveals that partners gradually felt less “in love” and less pleased with married life (Huston, McHale, & Crouter, 1986; Murray et al., 2011). A variety of factors contributed, including a sharp drop in time spent talking to each other and doing things that brought each other pleasure (for example, saying “I love you” or making the other person laugh). Joint leisure pursuits gave way to more household tasks and chores and, therefore, fewer enjoyable times together. Also, when discussing areas of conflict, partners declined in accurate reading of each other's thoughts and feelings (Kilpatrick, Bissonnette, & Rusbult, 2002). Perhaps after an increasing number of such interactions, they tried less hard to grasp the other's point of view and resorted to well-established habits, such as giving in or withdrawing.

But couples whose relationships endure generally report that they love each other more than they did earlier (Sprecher, 1999). In the transformation of romantic involvements from passionate to companionate, *commitment* may be the aspect of love that determines whether a relationship survives. Communicating that commitment in ways that strengthen *intimacy*—through warmth, attentiveness, empathy, caring, acceptance,

© ALEX FARNSWORTH/THE IMAGE WORKS

The warmth and intimacy of this couple's communication form the basis for mutual affection, caring, acceptance, and respect, which are vital for a satisfying, enduring bond.

and respect—strongly predicts relationship maintenance and satisfaction (Neff & Karney, 2008; Lavner & Bradbury, 2012). For example, Sharese's doubts about getting married subsided largely because of Ernie's expressions of commitment. In the most dramatic of these, he painted a large sign, reading “I LOVE SHARESE” and placed it in their front yard on her birthday. Sharese returned Ernie's sentiments, and the intimacy of their bond deepened.

Partners who consistently express their commitment report higher-quality and longer-lasting relationships (Fitzpatrick & Sollie, 1999; Madey & Rodgers, 2009). An important feature of their communication is constructive conflict resolution—directly expressing wishes and needs, listening patiently, asking for clarification, compromising, accepting responsibility, forgiving their partner, and avoiding the escalation of negative interaction sparked by criticism, contempt, defensiveness, and stonewalling (Johnson et al., 2005; Schneewind & Gerhard, 2002). In a longitudinal study, newlyweds' negativity during problem solving predicted marital dissatisfaction and divorce over the following decade (Sullivan et al., 2010). Those who displayed little warmth and caring often resorted to anger and contempt when dealing with problems.

These findings reveal that deficits in intimacy foreshadow poor conflict-resolution skills and eventual weakening of the marital tie. Although the capacity for constructive conflict resolution is a vital ingredient of enduring marriages, a tender, caring bond seems to energize that capacity, motivating couples to resolve conflicts in ways that preserve a gratifying sense of intimacy.

Compared with women, men are less skilled at communicating in ways that foster intimacy, offering less comfort and helpful support in their close relationships. Men also tend to be less effective at negotiating conflict, frequently avoiding discussion (Burleson & Kunkel, 2006; Wood, 2009).

Social Issues: Health

Childhood Attachment Patterns and Adult Romantic Relationships

In Bowlby's ethological theory of attachment, the early attachment bond leads to construction of an *internal working model*, or set of expectations about attachment figures, that serves as a guide for close relationships throughout life. Adults' evaluations of their early attachment experiences are related to their parenting behaviors—specifically, to the quality of attachments they build with their children (see page 201 in Chapter 6). Additional evidence indicates that recollections of childhood attachment patterns predict romantic relationships in adulthood.

In studies carried out in Australia, Israel, and the United States, researchers asked people about their early parental bonds (attachment history), their attitudes toward intimate relationships (internal working model), and their actual experiences with romantic partners. In a few studies, investigators also observed couples' behaviors. Consistent with Bowlby's theory, adults' memories and interpretations of childhood attachment patterns were good indicators of internal working models and relationship experiences. (To review patterns of attachment, see pages 197–198.)

Secure Attachment

Adults who described their attachment history as secure (warm, loving, and supportive parents) had internal working models that reflected this security. They viewed themselves as likable and easy to get to know, were comfortable with intimacy, and rarely worried about abandonment. They characterized their most important love relationship in terms of trust, happiness, and friendship (Cassidy, 2001). Their behaviors toward their partner were empathic and supportive and their conflict resolution strategies constructive. They were also at ease in turning to their partner for comfort and assistance and reported mutually initiated, enjoyable sexual activity (Collins et al., 2006; Creasey & Jarvis, 2009; Roisman et al., 2002).

Avoidant Attachment

Adults who reported an avoidant attachment history (demanding, disrespectful, and critical parents) displayed internal working models that stressed independence, mistrust of love partners, and anxiety about people

getting too close. They were convinced that others disliked them and that romantic love is hard to find and rarely lasts. Jealousy, emotional distance, lack of support in response to their partner's distress, and little enjoyment of physical contact pervaded their most important love relationship (Collins et al., 2006). Avoidant adults often deny attachment needs through excessive work and brief sexual encounters and affairs (Feeney, 1998). They endorse many unrealistic beliefs about relationships—for example, that partners cannot change, that males' and females' needs differ, and that “mind reading” is expected (Stackert & Bursik, 2003).

Resistant Attachment

Adults recalling a resistant attachment history (parents who responded unpredictably and unfairly) presented internal working models in which they sought to merge completely with another person and fall in love quickly (Cassidy, 2001). At the same time, they worried that their intense feelings would overwhelm others, who really did not love them and would not want to stay with them. Their most important love relationship was riddled with jealousy, emotional highs and lows, and desperation about whether the partner would return their affection (Feeney, 1999). Resistant adults, though offering support, do so in ways that fit poorly with their partner's needs (Collins et al., 2006). They are also quick to express fear and anger, and they disclose information about themselves at inappropriate times (Brennan & Shaver, 1995).

Are adults' descriptions of their childhood attachment experiences accurate, or are they distorted or even completely invented? In several longitudinal studies, quality of parent-child interactions, observed or assessed through family interviews 5 to 23 years earlier, were good predictors of internal working models and romantic-relationship quality in early adulthood (Donnellan, Larsen-Rife, & Conger, 2005; Ogawa et al., 1997; Roisman et al., 2001). These findings suggest that adult recollections bear some resemblance to actual parent-child experiences. However, attributes of the current partner also influence internal working models and intimate ties. When generally insecure individuals

COURTESY OF CAROL ALPER

Did the internal working model constructed by this baby, held tenderly by his father, influence the relationship he later forged with his wife? Research indicates that early attachment pattern is one of several factors associated with the quality of later intimate ties.

manage to form a secure representation of their partner, they report stronger feelings of affection and concern and reduced relationship conflict and anxiety (Sibley & Overall, 2010; Sprecher & Fehr, 2011).

In sum, negative parent-child experiences can be carried forward into adult close relationships. At the same time, internal working models are continuously “updated.” When adults with a history of unhappy love lives have a chance to form a satisfying intimate tie, they may revise their internal working model. As the new partner approaches the relationship with a secure state of mind and sensitive, supportive behavior, the insecure partner may reappraise her expectations and respond in kind (Creasey & Jarvis, 2009). This reciprocity creates a feedback loop through which a revised, more favorable internal working model, along with mutually gratifying interaction, persists over time.

Applying What We Know

Keeping Love Alive in a Romantic Partnership

Suggestion	Description
Make time for your relationship.	To foster relationship satisfaction and a sense of being “in love,” plan regular times to be together.
Tell your partner of your love.	Express affection and caring, including the powerful words “I love you,” at appropriate times. These messages increase perceptions of commitment, strengthen intimacy, and encourage your partner to respond in kind.
Be available to your partner in times of need.	Provide emotional support, giving of yourself when your partner is distressed.
Communicate constructively and positively about relationship problems.	When you or your partner is dissatisfied, suggest ways of overcoming difficulties, and ask your partner to collaborate in choosing and implementing a course of action. Avoid the four enemies of a gratifying, close relationship: criticism, contempt, defensiveness, and stonewalling.
Show an interest in important aspects of your partner’s life.	Ask about your partner’s work, friends, family, and hobbies and express appreciation for his or her special abilities and achievements. In doing so, you grant your partner a sense of being valued.
Confide in your partner.	Share innermost feelings, keeping intimacy alive.
Forgive minor offenses and try to understand major offenses.	Whenever possible, overcome feelings of anger through forgiveness. In this way, you acknowledge unjust behavior but avoid becoming preoccupied with it.

Sources: Donatelle, 2012; McCarthy & McCarthy, 2004.

Finally, for gay and lesbian couples, widespread social stigma complicates the process of forging a satisfying, committed bond. Those who worry most about being stigmatized, try to conceal their romance, or harbor negative attitudes toward their own sexual orientation report lower-quality and less enduring love relationships (Mohr & Daly, 2008; Mohr & Fassinger, 2006). Applying What We Know above lists ways to help keep the embers of love aglow in a romantic partnership.

Culture and the Experience of Love. Passion and intimacy, which form the basis for romantic love, became the dominant basis for marriage in twentieth-century Western nations as the value of individualism strengthened. From this vantage point, mature love is based on autonomy, appreciation of the partner’s unique qualities, and intense emotion (Hatfield, Rapson, & Martel, 2007). Trying to satisfy dependency needs through an intimate bond is regarded as immature.

This Western view contrasts sharply with the perspectives of Eastern cultures. In Japan, for example, lifelong dependency is accepted and viewed positively. The Japanese word *amae*, or love, means “to depend on another’s benevolence.” The traditional Chinese collectivist view defines the self through role relationships—son or daughter, brother or sister, husband or wife. Feelings of affection are distributed across a broad social network, reducing the intensity of any one relationship.

In choosing a mate, Chinese and Japanese young people are expected to consider obligations to others, especially parents. As one writer summarized, “An American asks, ‘How does my heart feel?’ A Chinese asks, ‘What will other people say?’” (Hsu, 1981, p. 50). College students of Asian heritage are less likely than those of American or European descent to endorse a view of love based solely on physical attraction and deep emotion

(Hatfield, Rapson, & Martel, 2007; Hatfield & Sprecher, 1995). Instead, compared to Westerners, they place greater weight on companionship and practical matters—similarity of background, career promise, and likelihood of being a good parent. Similarly, compared with American couples, dating couples in China report less passion but equally strong feelings of intimacy and commitment (Gao, 2001).

© ELLEN B. SENISI PHOTOGRAPHY

Although arranged marriages are still common in parts of Southeast Asia, young couples increasingly expect love to be a prerequisite for marriage, and their parents are likely to acquiesce.

Still, even in countries where arranged marriages are still fairly common (including China, India, and Japan), parents and prospective brides and grooms consult one another before moving forward (Goodwin & Pillay, 2006). If parents try to force their children into an unappealing marriage with little chance of love, sympathetic extended family members may come to children's defense. And in developing countries, women who attain higher education are more likely to insist on actively participating in an arranged marriage. They have acquired more of an autonomous identity, along with knowledge and skills from which to bargain for a greater say (Bhopal, 2011). In sum, today young people in many countries consider love to be a prerequisite for marriage, though Westerners assign greater importance to love—especially, its passionate component.

Friendships

Like romantic partners and childhood friends, adult friends are usually similar in age, sex, and SES—factors that contribute to common interests, experiences, and needs and therefore to the pleasure derived from the relationship. As in earlier years, friends in adulthood enhance self-esteem and psychological well-being through affirmation, acceptance, autonomy support (permitting disagreement and choice), and support in times of stress (Collins & Madsen, 2006; Deci et al., 2006). Friends also make life more interesting by expanding social opportunities and access to knowledge and points of view.

Trust, intimacy, and loyalty, along with shared interests and values and enjoyment of each other's company, continue to be important in adult friendships, as they were in adolescence (Blieszner & Roberto, 2012). Sharing thoughts and feelings is sometimes greater in friendship than in marriage, although commitment is less strong as friends come and go over the life course. Even so, some adult friendships continue for many years, at times throughout life. Seeing each other with frequency contributes to friendship continuity and—because female friends get together more than male friends do—to longer-lasting friendship ties among women (Sherman, de Vries, & Lansford, 2000).

But because of the dramatic rise in social media use, today's friendships are no longer as constrained by physical proximity. Nearly three-fourths of 18- to 29-year-olds who access the Internet use social networking sites; Facebook reports more than 500 million active users worldwide. Consequently, networks of “friends” have expanded. These include new types of friends—for example, people who meet through an interest-group chat room or blog and may never meet in person but who offer emotional support (Lefkowitz, Vukman, & Loken, 2012). As yet, little is known about the role of these online ties in adults' lives.

Do social networking sites lead young adults to form a large number of acquaintances at the expense of intimate friendships? Research reveals that people with 500 or more Facebook friends actually interact individually—by “liking” posts, leaving comments on walls, or engaging in Facebook chats—with far fewer. Among these large-network Facebook users, men engaged in one-on-one communication with an average of just 10 friends,

women with just 16 (Henig & Henig, 2012). Facebook led passive tracking of casual relationships to rise while core friendships remained limited.

LOOK AND LISTEN

Ask your Facebook friends to indicate the size of their Facebook network along with the number of friends they interacted with individually during the past month. Do large-network users have only a limited number of core friendships? ●

Same-Sex Friendships. Throughout life, women have more intimate same-sex friendships than men. Extending a pattern evident in childhood and adolescence, female friends often say they prefer to “just talk,” whereas male friends say they like to “do something” such as play sports (see Chapter 12, page 417). Barriers to intimacy between male friends include competitiveness, which may make men unwilling to disclose weaknesses, and concern that if they tell about themselves, their friends will not reciprocate (Reid & Fine, 1992). Because of greater intimacy and give-and-take, women generally evaluate their same-sex friendships more positively than men do. But they also have higher expectations of friends (Blieszner & Roberto, 2012). Thus, they are more disapproving if friends do not meet their expectations.

Of course, individual differences in friendship quality exist. The longer-lasting men's friendships are, the closer they become and the more they include disclosure of personal information (Sherman, de Vries, & Lansford, 2000). Furthermore, involvement in family roles affects reliance on friends. For single adults, friends are the preferred companions and confidants. The more intimate young adults' same-sex friendships are in terms of warmth, exchange of social support, and self-disclosure, the more satisfying and longer-lasting the relationship and the

ROB LANG/GETTY IMAGES

Male friends usually like to “do something” together, whereas female friends prefer to “just talk.” But the longer-lasting men's friendships are, the more intimate they become, increasingly including disclosure of personal information.

greater its contribution to psychological well-being (Sanderson, Rahm, & Beigbeder, 2005; Sherman, Lansford, & Volling, 2006). Gay and lesbian romantic relationships often develop out of close same-sex friendships, with lesbians, especially, forging compatible friendships before becoming involved romantically (Diamond, 2006).

As they develop romantic ties and marry, young adults—especially men—direct more of their disclosures toward their partners (Carbery & Buhrmester, 1998). Still, friendships continue to be vital contexts for personal sharing throughout adulthood. A best friendship can augment well-being when a marriage is not fully satisfying (but not when the marriage is low in quality) (Birditt & Antonucci, 2007). Turn back to Figure 12.1 on page 417 to view developmental trends in self-disclosure to romantic partners and friends.

Other-Sex Friendships. From the college years through career exploration and settling into work roles, other-sex friendships increase. After marriage, they decline for men but continue to rise for women, who more often form them in the workplace. Highly educated, employed women have the largest number of other-sex friends. Through these relationships, young adults often gain in companionship and self-esteem and learn about masculine and feminine styles of intimacy (Bleske & Buss, 2000). Because men confide especially easily in their female friends, such friendships offer them a unique opportunity to broaden their expressive capacity. And women sometimes say male friends offer objective points of view on problems and situations—perspectives not available from female friends (Monsour, 2002).

Many people try to keep other-sex friendships platonic to safeguard their integrity (Messman, Canary, & Hause, 2000). But sometimes the relationship changes into a romantic bond. When a solid other-sex friendship does evolve into a romance, it may be more stable and enduring than a romantic relationship formed without a foundation in friendship. And emerging adults, especially, are flexible about people they include in their friendship networks (Barry & Madsen, 2010). After a breakup, they may even keep a former romantic partner on as a friend.

Siblings as Friends. Whereas intimacy is essential to friendship, commitment—willingness to maintain a relationship and care about the other—is the defining characteristic of family ties. As young people marry and invest less time in developing a romantic partnership, siblings—especially sisters whose earlier bond was positive—become more frequent companions than in adolescence (Birditt & Antonucci, 2007). Often, friend and sibling roles merge. For example, Sharese described Heather’s practical assistance—helping with moving and running errands during an illness—in kinship terms: “She’s like a sister to me. I can always turn to her.” And adult sibling ties resemble friendships, in which the main concerns are staying in contact, offering social support, and enjoying being together.

A childhood history of intense parental favoritism and sibling rivalry can disrupt sibling bonds in adulthood (Panish

& Stricker, 2002). But when family experiences have been positive, relationships between adult siblings can be especially close and are important sources of psychological well-being (Sherman, Lansford, & Volling, 2006). A shared background promotes similarity in values and perspectives and the possibility of deep mutual understanding.

In families with five to ten siblings, common in industrialized nations in the past and still widespread in some cultures, close sibling bonds may replace friendships (Fuller-Iglesias, 2010). One 35-year-old with five siblings, who all—with their partners and children—resided in the same small city, remarked, “With a family like this, who needs friends?”

Loneliness

Young adults are at risk for **loneliness**—unhappiness resulting from a gap between the social relationships we currently have and those we desire—when they either do not have an intimate partner or lack gratifying friendships. Though both situations give rise to similar emotions, they are not interchangeable. For example, even though she had several enjoyable friendships, Heather sometimes felt lonely because she was not dating someone she cared about. And although Sharese and Ernie were happily married, they felt lonely after moving to a new town where they did not know anyone.

Loneliness peaks in the late teens and early twenties and then declines steadily into the seventies. Figure 14.2 shows this trend, based on a large Canadian sample ranging in age from 13 to 80 (Rokach, 2001). The rise in loneliness during early adulthood is understandable. As young people move through school and employment settings, they must constantly develop new relationships. Also, young adults may expect more from their intimate ties than older adults, who have learned to live with imperfections (Rokach, 2003). With age, people become better at accepting loneliness and using it for positive ends—to sharpen awareness of their personal fears and needs.

FIGURE 14.2 Changes in emotional distress due to loneliness from adolescence to late adulthood. More than 700 Canadian 13- to 80-year-olds responded to a questionnaire assessing the extent to which they experienced emotional distress due to loneliness. Loneliness rose sharply from the early teens to the late teens and early twenties and then declined. (Adapted from Rokach, 2001.)

Loneliness is intense after loss of an intimate tie: Separated, divorced, or widowed adults are lonelier than their married, cohabiting, or single counterparts. And immigrants from collectivist cultures report higher levels of loneliness than people born in the United States and Canada (DiTommaso, Brannen, & Burgess, 2005). Leaving a large, close-knit family system for an individualistic society seems to prompt intense feelings of isolation.

Personal characteristics also contribute to loneliness. Young adults who are socially anxious or who have insecure working models of attachment to parents are more often intensely lonely (Jackson et al., 2002). When extreme loneliness persists, it is associated with self-defeating attitudes and behaviors. To prevent anticipated rejection, people who are chronically lonely tend to be socially unresponsive, insensitive, and even hostile to others (Cacioppo & Patrick, 2008). These defensive responses, whether cause or consequence of loneliness, promote further isolation.

As long as loneliness is not overwhelming, it can motivate young people to reach out to others. It can also encourage them to find ways to be comfortably alone and to use this time to understand themselves better (Rokach & Neto, 2006). Healthy personality development involves striking this balance between gratifying relationships with others and contentment within ourselves.

ASK YOURSELF

REVIEW Describe gender differences in traits usually desired in a long-term partner. What findings indicate that *both* biological and social forces contribute to those differences?

CONNECT How might recollections and evaluations of childhood attachment history, discussed on page 474, affect intimate partners' readiness to develop companionate love?

APPLY After dating for two years, Mindy and Graham reported greater love and relationship satisfaction than during their first few months of dating. What features of communication probably deepened their bond, and why is it likely to endure?

REFLECT Do you have a nonromantic, close other-sex friendship? If so, how has it enhanced your emotional and social development?

The Family Life Cycle

For most young people, the life course takes shape within the **family life cycle**—a series of phases characterizing the development of most families around the world. In early adulthood, people typically live on their own, marry, and bear and rear children. In middle age, as their children leave home, their parenting responsibilities diminish. Late adulthood brings retirement, growing old, and (more often for women) death of one's spouse (McGoldrick & Shibusawa, 2012). Stress tends to be

greatest during transitions between phases, as family members redefine and reorganize their relationships.

But as our earlier discussion made clear, we must be careful not to view the family life cycle as a fixed progression. Wide variations exist in the sequence and timing of its phases—high rates of out-of-wedlock births, delayed marriage and childbearing, divorce, and remarriage, among others. And some people, voluntarily or involuntarily, do not experience all family life-cycle phases. Still, the family life-cycle model is useful. It offers an organized way of thinking about how the family system changes over time and the impact of each phase on the family unit and the individuals within it.

Leaving Home

During her first semester of college, Sharese noticed a change in how she related to her mother. She found it more enjoyable to discuss daily experiences and life goals, sought advice and listened with greater openness, and expressed affection more freely.

Departure from the parental home is a major step toward assuming adult responsibilities. The average age of leaving has risen since the 1960s; today, it resembles the departure age at the beginning of the twentieth century. But reasons for coresidence have changed: Early twentieth-century young adults resided with parents so they could contribute to the family economy. Twenty-first-century young adults living at home are typically financially dependent on their parents. This trend toward later home-leaving is evident in most industrialized nations, though substantial variation in timing exists. Because government support is available, young adults in the Scandinavian countries move out relatively early (Furstenberg, 2010). In contrast, cultural traditions in Mediterranean countries promote lengthy coresidence, extending for men into the mid-thirties.

Departures for education tend to occur at earlier ages, those for full-time work and marriage later. Because the majority of U.S. young adults enroll in higher education, many leave home around age 18. Those from divorced, single-parent homes tend to be early leavers, perhaps because of family stress (Cooney & Mortimer, 1999). Compared with the previous generation, fewer North American and Western European young people leave home to marry; more do so just to be “independent”—to express their adult status.

Slightly over half of U.S. 18- to 25-year-olds return to their parents' home for brief periods after first leaving (U.S. Census Bureau, 2012b). Usually, role transitions, such as the end of college or military service, bring young people back. But tight job markets, high housing costs, or failures in work or love can also prompt a temporary return home. Also, young people who left because of family conflict often return—largely because they were not ready for independent living.

Residential independence rises steadily with age; by the early thirties, 90 percent of U.S. young adults live on their own (U.S. Census Bureau, 2012b). Contrary to popular belief, returning home usually is not a sign of weakness (Ward & Spitze, 2007). Rather, as people encounter unexpected twists and turns

JILL FERRY PHOTOGRAPHY/GETTY IMAGES

A father helps his son, a recent college graduate, move belongings back into the parental home. Parents usually respond to their children's return with generous financial and emotional support, doing everything possible to help them move into adult roles.

on the road to independence, the parental home offers a safety net and base of operations for launching adult life.

The extent to which young people live on their own before marriage varies with SES and ethnicity. Those who are economically well-off are more likely to establish their own residence. Among African-American, Hispanic, and Native-American groups, poverty and a cultural tradition of extended-family living lead to lower rates of leaving home, even among young people in college or working (De Marco & Berzin, 2008; Fussell & Furstenberg, 2005). Unmarried Asian young adults also tend to live with their parents. But the longer Asian families have lived in the United States, where they are exposed to individualistic values, the more likely young people are to move out before marriage (Lou, Lalonde, & Giguère, 2012).

Parents of young adults living at home are usually highly committed to helping their children move into adult roles. Many provide wide-ranging assistance—not just financial support, but material resources, advice, companionship, and emotional support as well. A survey of large sample of U.S. parents diverse in SES and ethnicity and their adult children revealed that parents gave more to those with greater needs (because of problems or younger age) and to those they perceived as more successful in education and career progress. Furthermore, most parents and young-adult children judged the amount of parental support to be appropriate, though a sizable minority viewed intense support (provided several times a week) as excessive (Fingerman et al., 2009, 2012a). Nevertheless, children receiving intense support adjusted especially well, expressing firmer goals and greater life satisfaction—perhaps because the intense support matched their needs.

Still, in homes where parents and young adults live together, conflict over personal and moral values related to the young person's future tends to rise (Rodríguez & López, 2011).

But when young adults feel securely attached to parents and well-prepared for independence, departure from the home is linked to more satisfying parent-child interaction and successful transition to adult roles, even among ethnic minorities that strongly emphasize family loyalty and obligations (Smetana, Metzger, & Campione-Barr, 2004; Whiteman, McHale, & Crouter, 2010). And regardless of living arrangements, young people doing well often have close, enjoyable relationships with their parents, who offer help because they see it as key to their child's future success (Fingerman et al., 2012b).

Finally, leaving home very early can contribute to long-term disadvantage because it is associated with lack of parental financial and emotional support, job seeking rather than education, and earlier childbearing (Furstenberg, 2010). Not surprisingly, non-college-bound youths who move out in their late teens tend to have less successful educational, marriage, and work lives. U.S. poverty-stricken young people are more likely than their nonpoor counterparts to leave home by age 18 (Berzin & De Marco, 2010). But if still at home beyond that age, they are less likely to move out well into their thirties—a trend that may reflect the steep challenges they face in attaining self-sufficiency and exiting poverty.

Joining of Families in Marriage

The average age of first marriage in the United States has risen from about 20 for women and 23 for men in 1960 to 26½ for women and 29 for men today. Consequently, just 20 percent of contemporary U.S. 18- to 29-year-olds are married, compared to 60 percent a half-century ago (U.S. Census Bureau, 2012b). Postponement of marriage is even more marked in Western Europe—to the early thirties for men and the late twenties for women.

The number of first and second marriages has declined over the last few decades as more people stay single, cohabit, or do not remarry after divorce. In 1960, 85 percent of Americans had been married at least once; today, the figure is 70 percent. At present, 51 percent of U.S. adults, only a slight majority, live together as married couples (U.S. Census Bureau, 2012b). In one recent survey, 4 out of 10 American adults agreed that “marriage is becoming obsolete.” Nevertheless, marriage remains a central life goal for young people (Pew Forum on Religion and Public Life, 2010; Smith & Snell, 2009). Irrespective of SES and ethnicity, most U.S. 18- to 23-year-olds say they want to marry and have children.

Same-sex marriages are recognized nationwide in Argentina, Belgium, Brazil, Canada, Denmark, France, Iceland, the Netherlands, New Zealand, Norway, Portugal, South Africa, Spain, and Sweden. In the United States, 12 states—Connecticut, Delaware, Iowa, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New York, Rhode Island, Vermont, and Washington—as well as the District of Columbia have legalized same-sex marriage. Several other states either grant people in same-sex unions the same legal status as married couples or extend nearly all spousal rights to same-sex partnerships.

Because legalization is so recent, research on same-sex couples in the context of marriage is scant. But evidence on cohabiting same-sex couples suggests that the same factors that contribute to happiness in other-sex marriages do so in same-sex unions (Diamond, 2006).

Marriage is more than the joining of two individuals. It also requires that two systems—the spouses' families—adapt and overlap to create a new subsystem. Consequently, marriage presents complex challenges. This is especially so today because husband–wife roles are only gradually moving toward true partnership—educationally, occupationally, and in emotional connectedness. Among same-sex couples, acceptance of the relationship by parents, inclusion of the partner in family events, and living in a supportive community where they can be open about their bond benefit relationship satisfaction and durability (Diamond, 2006).

Marital Roles. Their honeymoon over, Sharese and Ernie turned to a multitude of issues they had previously decided individually or their families of origin had prescribed—from everyday matters (when and how to eat, sleep, talk, work, relax, have sex, and spend money) to family traditions and rituals (which to retain, which to work out for themselves). And as they related to their social world as a couple, they modified relationships with parents, siblings, extended family, friends, and co-workers.

Contemporary alterations in the context of marriage, including changing gender roles and living farther from family members, mean that couples must work harder than in the past to define their relationships. Although partners are usually similar in religious and ethnic background, “mixed” marriages are increasingly common today. Among new marriages in the United States, 15 percent are between partners of a different race or ethnicity, more than double the rate in 1980 (Taylor et al., 2012). Because of increased opportunities for interracial contact in colleges, workplaces, and neighborhoods and more positive attitudes toward intermarriage, highly educated young adults are more likely than their less educated counterparts to marry partners of another race or ethnicity (Qian & Lichter, 2011). Nevertheless, couples whose backgrounds differ face extra challenges in transitioning to married life.

Because many couples live together beforehand, marriage has become less of a turning point in the family life cycle. Still, defining marital roles can be difficult. Age of marriage is the most consistent predictor of marital stability. Young people who marry in their teens to mid-twenties are more likely to divorce than those who marry later (Lehrer & Chen, 2011). Most of those who marry early have not developed a secure identity or sufficient independence to form a mature marital bond. Both early marriage followed by childbirth and childbirth before marriage are more common among low-SES adults (U.S. Census Bureau, 2012b). This acceleration of family formation complicates adjustment to life as a couple.

Despite progress in the area of women's rights, **traditional marriages**, involving a clear division of roles—husband as head of household responsible for family economic well-being, wife as caregiver and homemaker—still exist in Western nations. In

© ARELSKELLEY/BLEND IMAGES/CORBIS

Arms laden with her toddler, a briefcase, and a bag of groceries, an employed mother heads home to prepare dinner. In industrialized nations, women in dual-earner marriages continue to shoulder most housework responsibilities.

recent decades, however, these marriages have changed, with many women who focused on motherhood while their children were young returning to the work force later.

In **egalitarian marriages**, partners relate as equals, sharing power and authority. Both try to balance the time and energy they devote to their occupations, their children, and their relationship. Most well-educated, career-oriented women expect this form of marriage. And college-student couples who eventually intend to marry often plan in advance how they will coordinate work and family roles, especially if the woman intends to enter a male-dominated career (Peake & Harris, 2002).

In Western nations, men in dual-earner marriages participate much more in child care than in the past. U.S. fathers in such marriages put in 85 percent as much time as mothers do (see pages 202–203 in Chapter 6). But housework—cleaning, cooking, laundry, and picking up clutter, which (unlike children) do not require immediate attention—reveals a different story. Recent surveys indicate that women in the United States and most Western European nations spend nearly twice as much time as men on housework, and women in Australia spend four times as much (Sayer, 2010). In Sweden, which places a high value on gender equality, men do more than in other nations. In contrast, men typically do little housework or child care in Japan, where corporate jobs demand long work hours and traditional marriages are common (Geist, 2010; Shwalb et al., 2004).

Women's housework hours do decline as their employment hours increase. But a close look at gender differences in most industrialized countries reveals that men fail to compensate (Cooke, 2010; Lippe, 2010). As Figure 14.3 shows for Australia, the United Kingdom, and the United States, men spend the same amount of time at housework, irrespective of their partners' employment schedules. Therefore, employed women's reduced housework hours are made possible by either purchase of time-saving services (cleaning help, prepackaged meals) or greater tolerance for unkempt homes, or both. Perhaps women continue to do the lion's share of housework because their paid

FIGURE 14.3 Women's and men's housework hours by women's employment for couples in Australia, the United Kingdom, and the United States. In each nation, as women's employment hours increase, they devote less time to housework. Men's contribution to housework is substantially less than women's. And women's level of employment has no influence on men's housework hours. (From L. P. Cooke, 2010, "The Politics of Housework," in J. Treas & S. Drobnic, [Eds.], *Dividing the Domestic: Men, Women, and Household Work in Cross-National Perspective*, p. 70. Copyright © 2010 by the Board of Trustees of the Leland Stanford Jr. University. Adapted with the permission of Stanford University Press, www.sup.org.)

work is viewed as secondary to their husband's, regardless of how much they earn (Lachance-Grzela & Boucard, 2010). In sum, true equality in marriage is still rare, and couples who strive for it usually attain a form of marriage in between traditional and egalitarian.

Marital Satisfaction. Despite its rocky beginnings, Sharese and Ernie's marriage grew to be especially happy. In contrast, Christy and Gary became increasingly discontented. What distinguishes satisfying marriages from less successful partnerships? Differences between these two couples mirror the findings of a large body of research on personal and contextual factors, summarized in Table 14.1.

Christy and Gary had children early and struggled financially. Gary's negative, critical personality led him to get along poorly with Christy's parents and to feel threatened when he and Christy disagreed. Christy tried to offer Gary encouragement and support, but her own needs for nurturance and individuality were not being met. Gary was uncomfortable with Christy's career aspirations. As she came closer to attaining them, the couple grew further apart. In contrast, Sharese and Ernie married later, after their educations were complete. They postponed having children until their careers were under way and they had built a sense of togetherness that allowed each to thrive as an individual. Patience, caring, common values and interests, humor, affection, sharing of personal experiences through conversation, cooperating in household responsibilities, and good conflict-resolution skills contributed to their compatibility.

Men tend to report feeling slightly happier with their marriages than women do (Howard, Galambos, & Krahn, 2010; Kurdek, 2005). In the past, quality of the marital relationship had a greater impact on women's psychological well-being, but today it predicts mental health similarly for both genders. Women, however, feel particularly dissatisfied with marriage when the demands of husband, children, housework, and career are overwhelming (Forry, Leslie, & Letiecq, 2007; Saginak & Saginak, 2005). Research in both Western and non-Western industrialized nations reveals that equal power in the relationship and sharing of family responsibilities usually enhance both partners' satisfaction, largely by strengthening marital harmony (Amato & Booth, 1995; Xu & Lai, 2004).

TABLE 14.1 Factors Related to Marital Satisfaction

FACTOR	HAPPY MARRIAGE	UNHAPPY MARRIAGE
Family backgrounds	Partners similar in SES, education, religion, and age	Partners very different in SES, education, religion, and age
Age at marriage	After mid-20s	Before mid-20s
Timing of first pregnancy	After first year of marriage	Before or within first year of marriage
Relationship to extended family	Warm and positive	Negative; wish to maintain distance
Marital patterns in extended family	Stable	Unstable; frequent separations and divorces
Financial and employment status	Secure	Insecure
Family responsibilities	Shared; perception of fairness	Largely the woman's responsibility; perception of unfairness
Personality characteristics and behavior	Emotionally positive; common interests; good conflict-resolution skills	Emotionally negative and impulsive; lack of common interests; poor conflict-resolution skills

Note: The more factors present, the greater the likelihood of marital happiness or unhappiness.

Social Issues: Health

Partner Abuse

Violence in families is a widespread health and human rights issue, occurring in all cultures and SES groups.

Often one form of domestic violence is linked to others. Recall the story of Karen in Chapter 13. Her husband, Mike, not only assaulted her sexually and physically but also abused her psychologically—isolating, humiliating, and demeaning her. Violent adults also break their partner's favorite possessions, punch holes in walls, or throw objects. If children are present, they may become victims.

Partner abuse in which husbands are perpetrators and wives are physically injured is most likely to be reported to authorities. But many acts of family violence are not reported. When researchers ask American couples about fights that led to acts of hostility, men and women report similar rates of assault (Dutton, 2007). Women victims are more often physically injured, but sex differences in severity of abuse are small (Dutton, 2012; Ehrensaft, Moffitt, & Caspi, 2004). Partner abuse occurs at about the same rate in same-sex relationships as in heterosexual relationships (Schwartz & Waldo, 2004).

Although self-defense is a frequently reported cause of domestic assault by women, American men and women are

equally likely to “strike first” (Currie, 1999; Dutton, 2007). “Getting my partner’s attention,” “gaining control,” and “expressing anger” are reasons that partners typically give for abusing each other.

Factors Related to Partner Abuse

In abusive relationships, dominance–submission sometimes proceeds from husband to wife, sometimes from wife to husband. In about one-third to one-half of cases, both partners are violent (Dutton, Nicholls, & Spidel, 2005). Marvin’s and Pat’s relationship helps us understand how partner abuse escalates. Shortly after their wedding, Pat began complaining about the demands of Marvin’s work and insisted that he come home early to spend time with her. When he resisted, she hurled epithets, threw objects, and slapped him. One evening, Marvin became so angry at Pat’s hostilities that he smashed a dish against the wall, threw his wedding ring at her, and left the house. The next morning, Pat apologized and promised not to attack again. But her outbursts became more frequent and desperate.

These violence–remorse cycles, in which aggression escalates, characterize many abusive relationships. Why do they occur?

Personality and developmental history, family circumstances, and cultural factors combine to make partner abuse more likely (Diamond, Fagundes, & Butterworth, 2010).

Many abusers are overly dependent on their spouses as well as jealous, possessive, and controlling. For example, the thought of Karen ever leaving induced such high anxiety in Mike that he monitored all her activities. Depression, anxiety, and low self-esteem also characterize abusers. And because they have great difficulty managing anger, trivial events—such as an unwashed shirt or a late meal—can trigger abusive episodes. When asked to explain their offenses, they attribute greater blame to their partner than to themselves (Henning, Jones, & Holdford, 2005).

A high proportion of spouse abusers grew up in homes where parents engaged in hostile interactions, used coercive discipline, and were abusive toward their children (Ehrensaft, 2009). Perhaps this explains why conduct problems in childhood and violent delinquency in adolescence also predict partner abuse (Dutton, 2007). Adults with childhood exposure to domestic violence are not doomed to repeat it. But their parents provided them with negative expectations and behaviors that they often transfer to their close relationships. Stressful life events, such as job loss or financial difficulties, increase the likelihood of partner abuse (Emery &

Of course, from time to time, individuals are bound to say or do something upsetting to their partner. When this happens, the partner’s attributions, or explanations for the behavior, make a difference. For example, a wife who interprets her husband’s critical remark about her weight as unintentional (“He just isn’t aware I’m sensitive about that”) is far more likely to express both current and long-term marital satisfaction than a wife who views such comments as malicious (“He’s trying to hurt my feelings”) (Barelds & Dijkstra, 2011; Fincham & Bradbury, 2004). In fact, partners who hold overly positive (but still realistic) biases concerning each other’s attributes are happier with their relationships (Claxton et al., 2011). As they turn to each other for feedback about themselves, these “positive illusions” enhance self-esteem and psychological well-being. And over time, positive illusions favorably influence behavior, as partners modify their actions to bring them closer to their partner’s generous perceptions. In contrast, people who feel devalued

by their partner tend to react with anxiety and insecurity—more so when they are low in self-esteem, which heightens fear of rejection. To protect themselves, they often mete out criticism and contempt in kind, setting in motion hostile, defensive exchanges that create the very rejection they fear (Murray, 2008). Alternatively, individuals may disengage emotionally, suppressing negative feelings so as not to poison the relationship (Driver et al., 2012). In the process, shared positive emotion also declines, and intimacy erodes.

At their worst, marital relationships can become contexts for intense opposition, dominance–submission, and emotional and physical violence. As the Social Issues: Health box above explains, although women are more often targets of severe partner abuse, both men and women play both roles: perpetrator and victim.

High school and college courses in family life education can promote better mate selection and teach communication

Laumann-Billings, 1998). Because of widespread poverty, African Americans and Native Americans report high rates of partner violence (Hoff, 2001). Alcohol abuse is another related factor.

At a societal level, cultural norms that endorse male dominance and female submissiveness promote partner abuse (Kaya & Cook, 2010). As Figure 14.4 shows, in countries with widespread poverty that also sanction gender inequality, partner violence against women is especially high, affecting nearly half or more of the female population.

Victims are chronically anxious and depressed and experience frequent panic attacks (Warshaw, Brashler, & Gil, 2009). Why don't they simply leave these destructive relationships? A variety of situational factors discourage them from leaving. A victimized wife may depend on her husband's earning power or fear even worse harm to herself or her children. Extreme assaults, including homicide, tend to occur after partner separation (Campbell & Glass, 2009). And victims of both sexes, but especially men, are deterred by the embarrassment of going to the police. Also, victims may falsely believe that their partner will change.

Intervention and Treatment

Community services available to battered women include crisis telephone lines that

provide anonymous counseling and social support and shelters that offer safety and treatment (see page 449). Because many women return to their abusive partners several times before making their final move, community agencies usually offer therapy to male batterers. Most rely on several months to a year of group sessions that confront rigid gender stereotyping; teach communication, problem solving, and anger control; and use social support to motivate behavior change (Whitaker, Baker, & Arias, 2007).

Although existing treatments are better than none, most are not effective at dealing with relationship difficulties or alcohol abuse. Consequently, many treated perpetrators repeat their violent behavior with the same or a new partner (Hamberger et al., 2009). At present, few interventions

acknowledge that men also are victims. Yet ignoring their needs perpetuates domestic violence. When victims do not want to separate from a violent partner, a whole-family treatment approach that focuses on changing partner interaction and reducing high life stress is crucial.

skills that contribute to gratifying romantic partnerships and marriages. And counseling aimed at helping couples listen to each other with understanding and empathy, focus on positive traits and memories, and use effective conflict-resolution strategies can cultivate the self-esteem, affection, and respect needed for the relationship to be resilient and enduring (Gottman, 2011).

Parenthood

In the past, the issue of whether to have children was, for many adults, a biological given or a compelling social expectation. Today, in Western industrialized nations, it is a matter of true individual choice. Effective birth control techniques enable adults to avoid having children in most instances. And changing cultural values allow people to remain childless with far less fear of social criticism and rejection than a generation or two ago.

FIGURE 14.4 Assaults by intimate partners against women in seven nations. In each country, samples of women were asked to indicate whether they had ever experienced partner physical abuse. The incidence, always underreported, is high in all nations. It is especially high in countries that endorse traditional gender roles and suffer from widespread poverty. (From Kaya & Cook, 2010; World Health Organization, 2000, 2005.)

In 1950, 78 percent of American married couples were parents. Today, 70 percent bear children, and they tend to be older when they have their first child. Consistent with this pattern of delayed childbearing and with the decision of most women to divide their energies between family and work, family size in industrialized nations has declined. In 1950, the average number of children per woman was 3.1. Currently, it is 2.1 in the United States, 1.9 in the United Kingdom, 1.7 in Sweden, 1.6 in Canada, 1.4 in Germany, and 1.3 in Italy and Japan (U.S. Census Bureau, 2012a, 2012b). Nevertheless, the vast majority of married people continue to embrace parenthood as one of life's most meaningful experiences. Why do they do so, and how do the challenges of child rearing affect the adult life course?

The Decision to Have Children. The choice of parenthood is affected by a complex array of factors, including financial circumstances, personal and religious values, and health

conditions. Women with traditional gender identities usually decide to have children. Whether a woman is employed has less impact on childbearing than her occupation. Women in high-status, demanding careers less often choose parenthood and, when they do, more often delay it than women with less consuming jobs. Parenthood typically reduces work hours and slows career progress among career-oriented women but has no impact on men (Abele & Spurk, 2011). Professional women seem to consider these consequences in decision making about parenthood.

When Americans are asked about their desire to have children, they mention a variety of advantages and disadvantages. Some ethnic and regional differences exist, but in all groups, the most important reasons for having children include the warm, affectionate relationship and the stimulation and fun that children provide. Also frequently mentioned are growth and learning experiences that children bring to the lives of adults, the desire to have someone carry on after one's own death, and feelings of accomplishment and creativity that come from helping children grow (Cowan & Cowan, 2000; O'Laughlin & Anderson, 2001).

Most young adults also realize that having children means years of extra burdens and responsibilities. Among disadvantages of parenthood, they cite loss of freedom most often, followed by concerns about role overload (not enough time for both family and work responsibilities) and about the financial strains of child rearing. According to a conservative estimate, today's new parents in the United States will spend about \$280,000 to rear a child from birth to age 18, and many will incur substantial additional expense for higher education and financial dependency during emerging adulthood (U.S. Department of Agriculture, 2012).

Greater freedom to choose whether and when to have children makes family planning more challenging today than in the past. With each partner expecting an equal say, childbearing often becomes a matter of delicate negotiation (Cowan & Cowan, 2000). Yet carefully weighing the pros and cons of parenthood means that many more couples are making informed and personally meaningful choices—a trend that should increase the chances that they will have children when ready and will find parenting an enriching experience.

Transition to Parenthood. The early weeks after a baby enters the family are full of profound changes: constant caregiving, added financial responsibilities, and less time for the couple's relationship. In response, gender roles of husband and wife usually become more traditional—even for couples like Sharese and Ernie who are strongly committed to gender equality (Katz-Wise, Priess, & Hyde, 2010; Lawrence et al., 2010).

First and Second Births. For most new parents, the arrival of a baby—though often associated with mild declines in relationship satisfaction and communication quality—does not cause significant marital strain. Marriages that are gratifying and supportive tend to remain so (Doss et al., 2009; Feeney et al., 2001; Miller, 2000). And the small decrease in satisfaction from

© MICHAEL NEWMAN/PHOTODEBIT

Compared to a first birth, a second birth typically requires that fathers become more actively involved in parenting, sharing in the high demands of tending to both a baby and a young child.

pregnancy to post-birth may not be unique to early parenthood (Mitnick, Heyman, & Slep, 2009). Couples who do not become parents also experience a slight decrease in relationship satisfaction across a similar time frame.

Nevertheless, troubled marriages usually become even more distressed after childbirth (Houts et al., 2008; Kluwer & Johnson, 2007). And when expectant mothers anticipate lack of partner support in parenting, their prediction generally becomes reality, yielding an especially difficult post-birth adjustment (Driver et al., 2012; McHale & Rotman, 2007).

Violated expectations about division of labor in the home powerfully affect new parents' well-being. In dual-earner marriages, the larger the difference in men's and women's caregiving responsibilities, the greater the decline in marital satisfaction after childbirth, especially for women—with negative consequences for parent–infant interaction. In contrast, sharing caregiving predicts greater parental happiness and sensitivity to the baby (McHale et al., 2004; Moller, Hwang, & Wickberg, 2008). An exception exists, however, for employed lower-SES women who endorse traditional gender roles. When their husbands take on considerable child-care responsibilities, these mothers tend to report more distress, perhaps because of disappointment at being unable to fulfill their desire to do most of the caregiving (Goldberg & Perry-Jenkins, 2003).

Postponing childbearing until the late twenties or thirties, as more couples do today, eases the transition to parenthood. Waiting permits couples to pursue occupational goals, gain life experience, and strengthen their relationship. Under these circumstances, men are more enthusiastic about becoming fathers and therefore more willing to participate. And women whose careers are well under way and whose marriages are happy are more likely to encourage their husbands to share housework and child care, which fosters fathers' involvement (Lee & Doherty, 2007; Schoppe-Sullivan et al., 2008).

A second birth typically requires that fathers take an even more active role in parenting—by caring for the firstborn while the mother is recuperating and by sharing in the high demands of tending to both a baby and a young child. Consequently, well-functioning families with a newborn second child typically pull back from the traditional division of responsibilities that occurred after the first birth. Fathers' willingness to place greater emphasis on the parenting role is strongly linked to mothers' adjustment after the arrival of a second baby (Stewart, 1990). And the support and encouragement of family, friends, and spouse are crucial for fathers' well-being.

Interventions. Couples' groups led by counselors are effective in easing the transition to parenthood (Gottman, Gottman, & Shapiro, 2010). Therapists report that many couples know little about caring for infants, perhaps because they grew up in small families where they had few sibling caregiving responsibilities. They are also unaware of the potential impact of a new baby on their relationship.

In one program, first-time expectant couples gathered once a week for six months to discuss their dreams for the family and changes in relationships sparked by the baby's arrival. Eighteen months after the program ended, participating fathers described themselves as more involved with their child than did fathers in a no-intervention condition. Perhaps because of fathers' caregiving assistance, participating mothers maintained their pre-birth satisfaction with family and work roles. Three years after the birth, the marriages of participating couples were intact and just as happy as they had been before parenthood. In contrast, 15 percent of couples receiving no intervention had divorced (Cowan & Cowan, 1997; Schulz, Cowan, & Cowan, 2006). For high-risk parents struggling with poverty or the birth of a child with disabilities, interventions must be more intensive, focusing on enhancing social support and parenting skills (Petch & Halford, 2008).

Generous, paid employment leave—widely available in industrialized nations but not in the United States—is crucial for parents of newborns (see Chapter 3, pages 104–105). But financial pressures mean that many new mothers who are eligible for unpaid work leave take far less than they are guaranteed by U.S. federal law, while new fathers take little or none. When favorable workplace policies exist and parents take advantage of them, couples are more likely to support each other and experience family life as gratifying (Feldman, Sussman, & Zigler, 2004; Han & Waldfogel, 2003). As a result, the stress caused by the birth of a baby stays at manageable levels.

Families with Young Children. A year after the birth of their first child, Sharese and Ernie received a phone call from Heather, who asked how they liked parenthood: "Is it a joy, a dilemma, a stressful experience—how would you describe it?"

Chuckling, Sharese and Ernie responded in unison, "All of the above!"

In today's complex world, men and women are less certain about how to rear children than in previous generations. Clarifying child-rearing values and implementing them in warm,

involved, and appropriately demanding ways are crucial for the welfare of the next generation and society. Yet cultures do not always place a high priority on parenting, as indicated by lack of many societal supports for children and families (see Chapter 2, pages 66–67). Furthermore, changing family forms mean that the lives of today's parents differ substantially from those of past generations.

In previous chapters, we discussed a wide variety of influences on child-rearing styles, including personal characteristics of children and parents, SES, and ethnicity. The couple's relationship is also vital. Parents who engage in effective coparenting, collaborating and showing solidarity and respect for each other in parenting roles, are more likely to gain in warm marital interaction, feel competent as parents, use effective child-rearing practices, and have children who are developing well (McHale et al., 2002a; Schoppe-Sullivan et al., 2004). When parents forge this supportive coparenting alliance within the first few months after childbirth, it is more likely to persist (Fivaz-Depeursinge & Corboz-Warnery, 1999).

For employed parents, a major struggle is finding good child care and, when their child is ill or otherwise in need of emergency care, taking time off from work or making other urgent arrangements. The younger the child, the greater parents' sense of risk and difficulty—especially low-income parents, who must work longer hours to pay bills; who often, in the United States, have no workplace benefits (health insurance or paid sick leave); who typically cannot afford the cost of child care; and who experience more immediate concerns about their children's safety (Halpern, 2005b; Nomaguchi & Brown, 2011). When competent, convenient child care is not available, the woman usually faces added pressures. She must either curtail or give up her work, with profound financial consequences in low-income families, or endure unhappy children, missed workdays, and constant searches for new arrangements.

Despite its challenges, rearing young children is a powerful source of adult development. Parents report that it expands their emotional capacities, enriches their lives, and enhances psychological well-being (Nomaguchi & Milkie, 2003; Schindler, 2010). For example, Ernie remarked that through sharing in child rearing, he felt "rounded out" as a person. Other involved parents say that parenthood helped them tune in to others' feelings and needs, required that they become more tolerant, self-confident, and responsible, and broadened their extended family, friendship, and community ties. In a survey of a large, nationally representative sample of U.S. fathers, paternal history of engagement with children predicted greater community service and assistance of extended family members in middle adulthood (Eggebeen, Dew, & Knoester, 2010).

Families with Adolescents. Adolescence brings sharp changes in parental roles. In Chapters 11 and 12, we noted that parents must establish a revised relationship with their adolescent children—blending guidance with freedom and gradually loosening control. As adolescents gain in autonomy and explore values and goals in their search for identity, parents often complain that their teenager is too focused on peers and no longer

cares about being with the family. Heightened parent–child bickering over everyday issues takes a toll, especially on mothers, who do most of the negotiating with teenagers.

Overall, children seem to navigate the challenges of adolescence more easily than parents, many of whom report a dip in marital and life satisfaction. More people seek family therapy during this period of the family life cycle than during any other (Steinberg & Silk, 2002).

Parent Education. In the past, family life changed little from one generation to the next, and adults learned what they needed to know about parenting through modeling and direct experience. Today’s world confronts adults with a host of factors that impinge on their ability to succeed as parents.

Contemporary parents eagerly seek information on child rearing. In addition to popular parenting books, magazines, and websites, new mothers access knowledge about parenting through social media, including chat rooms and blogs. They also reach out to networks of other women for knowledge and assistance. Fathers, by contrast, rarely have social networks through which they can learn about child care and child rearing. Consequently, they frequently turn to mothers to figure out how to relate to their child, especially if they have a close, confiding marriage (Lamb & Lewis, 2004; McHale, Kuersten-Hogan, & Rao, 2004). Recall from Chapter 6 that marital harmony fosters both parents’ positive engagement with babies, but it is especially important for fathers.

Parent education courses exist to help parents clarify child-rearing values, improve family communication, understand how children develop, and apply more effective parenting strategies. A variety of programs yield positive outcomes, including enhanced knowledge of effective parenting practices, improved parent–child interaction, and heightened awareness by parents of their role as educators of their children (Bert, Ferris, & Borkowski, 2008; Smith, Perou, & Lesesne, 2002). Another benefit is social support—opportunities to discuss concerns

Men are less likely than women to learn about child rearing through informal social networks. Fathers especially may benefit from parent education programs that help them clarify child-rearing values, learn about child development, and parent effectively.

The Diversity of Adult Lifestyles

The current array of adult lifestyles dates back to the 1960s, when young people began to question the conventional wisdom of previous generations and to ask, “How can I find happiness? What kinds of commitments should I make to live a full and rewarding life?” As the public became more accepting of diverse lifestyles, choices such as staying single, cohabiting, remaining childless, and divorcing seemed more available.

Today, nontraditional family options have penetrated the American mainstream. Many adults experience not just one but several. As we will see, some adults make a deliberate decision to adopt a lifestyle, whereas others drift into it. The lifestyle may be imposed by society, as is the case for cohabiting same-sex couples in the United States, who cannot marry legally in most states. Or people may choose a certain lifestyle because they feel pushed away from another, such as a marriage gone sour. In sum, the adoption of a lifestyle can be within or beyond the person’s control.

Singlehood

On finishing her education, Heather joined the Peace Corps and spent four years in Ghana. Though open to a long-term relationship, she had only fleeting romances. After she returned to the United States, she went from one temporary job to another until, at age 30, she finally found steady employment in a large international travel company as a tour director. A few years later, she

Compared with single men, single women more easily come to terms with their lifestyle, in part because of the greater social support available to women through intimate same-sex friendships.

advanced into a management position. At age 35, over lunch with Sharese, she reflected on her life: “I was open to marriage, but after I got my career going, it would have interfered. Now I’m so used to independence that I question whether I could adjust to living with another person. I like being able to pick up and go where I want, when I want, without having to ask anyone or think about caring for anyone. But there’s a tradeoff: I sleep alone, eat most of my meals alone, and spend a lot of my leisure time alone.”

Singlehood—not living with an intimate partner—has increased in recent years, especially among young adults. For example, the rate of never-married Americans in their twenties has nearly tripled since 1960, to 75 percent of young people. As they move into their thirties, more people marry: By 30 to 34 years of age, about 32 percent remain single. Today, more people marry later or not at all, and divorce has added to the numbers of single adults—slightly more than half when adults of all ages are considered. In view of these trends, it is likely that most Americans will spend a substantial part of their adult lives single, and a growing minority—about 8 to 10 percent—will stay that way (Pew Research Center, 2010a; U.S. Census Bureau, 2012b).

Because they marry later, more young-adult men than women are single. But women are far more likely than men to remain single for many years or their entire life. With age, fewer men are available with characteristics that most women seek in a mate—the same age or older, equally or better educated, and professionally successful. In contrast, men can choose partners from a large pool of younger unmarried women. Because of the tendency for women to “marry up” and men to “marry down,” men with a high school diploma or less and highly educated women in prestigious careers are overrepresented among singles after age 30.

Ethnic differences also exist. For example, the percentage of never-married African Americans is nearly twice as great as that of Caucasian Americans in early adulthood (U.S. Census Bureau, 2012b). As we will see later, high unemployment among

black men interferes with marriage. Many African Americans eventually marry in their late thirties and forties, a period in which black and white marriage rates come closer together.

Singlehood can have a variety of meanings. At one extreme are people who choose it deliberately; at the other those who see themselves as single because of circumstances beyond their control. Most, like Heather, are in the middle—adults who wanted to marry but made choices that took them in a different direction. In interview studies of never-married women, some said they focused on occupational goals instead of marriage. Others reported that they found singlehood preferable to their disappointing intimate relationships. And still others commented that they just did not meet “the right person” (Baumbusch, 2004; Lewis, 2000).

The most commonly mentioned advantages of singlehood are freedom and mobility. But singles also recognize drawbacks—loneliness, the dating grind, limited sexual and social life, reduced sense of security, and feelings of exclusion from the world of married couples. Single men have more physical and mental health problems than single women, who more easily come to terms with their lifestyle, in part because of the greater social support available to women through intimate same-sex friendships (Pinquart, 2003). But overall, people over age 35 who have always been single are content with their lives (DePaulo & Morris, 2005; Lucas et al., 2003). Though not quite as happy as married people, they report feeling considerably happier than people recently widowed or divorced.

Nevertheless, many single people go through a stressful period in their late twenties or early thirties, when most of their friends have married. Widespread veneration of marriage, along with negative stereotyping of singles as socially immature and self-centered, contributes (Morris et al., 2008). The mid-thirties is another trying time, as the biological deadline for pregnancy approaches. Interviews with 28- to 34-year-old single women revealed that they were acutely aware of pressures from family members, the shrinking pool of eligible men, the risks of later childbearing, and a sense of being different (Sharp & Ganong, 2011). A few decide to become parents through artificial insemination or a love affair. And an increasing number are adopting, often from overseas countries.

Cohabitation

Cohabitation refers to the lifestyle of unmarried couples who have a sexually intimate relationship and who share a residence. Until the 1960s, cohabitation in Western nations was largely limited to low-SES adults. Since then, it has increased in all groups, with an especially dramatic rise among well-educated, economically advantaged young people. Today’s young adults are much more likely than those of a generation ago to form their first conjugal union through cohabitation. Among American young people, cohabitation is now the preferred mode of entry into a committed intimate partnership, chosen by over 60 percent of couples (U.S. Census Bureau, 2012b). Cohabitation rates are even higher among adults with failed marriages; about one-third of these households include children.

For some couples, cohabitation serves as *preparation for marriage*—a time to test the relationship and get used to living together. For others, however, it is an *alternative to marriage*, offering the rewards of sexual intimacy and companionship along with the possibility of easy departure if satisfaction declines. It is not surprising, then, that cohabiters vary greatly in the extent to which they share money and possessions and take responsibility for each other's children.

Although Americans are more open to cohabitation than in the past, their attitudes are not as positive as those of Western Europeans. In the Netherlands, Norway, and Sweden, cohabitation is thoroughly integrated into society, with cohabiters having many of the same legal rights and responsibilities as married couples. Between 70 and 90 percent of young people cohabit in their first intimate partnership, and cohabiters are nearly as committed to each other as married people (Fussell & Gauthier, 2005; Perelli-Harris & Gassen, 2012). Whereas about 50 percent of American cohabiting unions break up within two years, only 6 to 16 percent dissolve in Western Europe (Jose, O'Leary, & Moyer, 2010; Kiernan, 2002). When they decide to marry, Dutch, Norwegian, and Swedish cohabiters more often do so to legalize their relationships, especially for the sake of children. American cohabiters typically marry to confirm their love and commitment—sentiments that Western Europeans attach to cohabitation.

Furthermore, U.S. couples who cohabit before they are engaged to be married are more prone to divorce than couples who wait to live together until after they have made a commitment to each other. But this association is less strong or absent in Western European nations (Jose, O'Leary, & Moyer, 2010; Kline et al., 2004; Rhoades, Stanley, & Markman, 2006). U.S. young people who cohabit prior to engagement tend to have less conventional values. They have had more sexual partners and are more politically liberal, less religious, and more androgynous. In addition, a larger number have parents who divorced (Kurdek, 2006).

These personal characteristics may contribute to the negative outcomes associated with cohabitation. But the cohabitation experience itself also plays a role. Cohabiters are less likely than married people to pool finances or jointly own a house. In addition, both preengagement cohabiters and formerly cohabiting married couples have poorer-quality relationships (Cohan & Kleinbaum, 2002; Kline et al., 2004). Perhaps the open-ended nature of the cohabiting relationship reduces motivation to develop effective conflict-resolution skills. When cohabiters carry negative communication into marriage, it undermines marital satisfaction. Finally, a history of parental divorce may increase cohabiters' willingness to dissolve a union when it becomes less satisfying.

Certain couples, however, are exceptions to the trends just described. People who cohabit after separation or divorce often test a new relationship carefully to prevent another failure, especially when children are involved. As a result, they cohabit longer and are less likely to move toward marriage. Similarly, cohabitation is often an alternative to marriage among low-SES couples (Pew Research Center, 2010a). Many regard their earn-

Among U.S. couples, making a long-term commitment by becoming engaged before cohabiting predicts an enduring marriage. U.S. young people who cohabit prior to engagement are at increased risk for divorce.

ing power as too uncertain for marriage and continue living together, sometimes giving birth to children and marrying when their financial status improves.

Finally, cohabiting gay and lesbian couples report strong relationship commitment (Kurdek, 2006). When their relationships become difficult, they end more often than those of heterosexual cohabiters and married couples because of fewer barriers to separating. For example, in 37 U.S. states, same-sex cohabiters cannot plan to legalize their relationship because of laws or constitutional provisions that limit marriage to a man and a woman. Furthermore, same-sex cohabiters are less likely to have children in common and more likely to have extended family members who are unsupportive (Lau, 2012; Rothblum, Balsam, & Solomon, 2011). In a study in which same-sex couples in Vermont were followed over three years, cohabiters were more likely than couples in civil unions to have ended their relationships (Balsam et al., 2008). Civil unions were as stable as heterosexual marriages.

For people not ready for marriage, cohabitation combines the rewards of a close relationship with the opportunity to avoid the legal obligations of marriage. But cohabiting couples can encounter difficulties precisely because they do not have these obligations. Bitter fights over property, money, rental contracts, and responsibility for children are the rule rather than the exception when unmarried couples split up.

Childlessness

At work, Sharese got to know Beatrice and Daniel. Married for seven years and in their mid-thirties, they did not have children and were not planning any. To Sharese, their relationship seemed especially caring and affectionate. "At first, we were open to becoming parents," Beatrice explained, "but eventually we decided to focus on our marriage."

Childlessness in the United States has increased steadily, from 9 percent of women between ages 20 and 44 in 1975 to

about 20 percent today, with similar trends occurring in other Western nations (Livingston & Cohn, 2010). Some people are *involuntarily childless* because they did not find a partner with whom to share parenthood or their efforts at fertility treatments did not succeed. Beatrice and Daniel are in another category—men and women who are *voluntarily childless*. But voluntary childlessness is not always a permanent condition. A few people decide early that they do not want to be parents and stick to their plans. But most, like Beatrice and Daniel, make their decision after they are married and have developed a lifestyle they do not want to give up. Later, some change their minds.

Besides marital satisfaction and freedom from child-care responsibilities, common reasons for not having children include the woman's career and economic security (Amba & Martinez, 2006; Kemkes-Grottenhaler, 2003). Consistent with these motives, the voluntarily childless are usually college-educated, have prestigious occupations, and are highly committed to their work.

Negative stereotypes of nonparenthood—as a sign of self-indulgence and irresponsibility—have weakened in Western nations as people have become more accepting of diverse lifestyles (Dykstra & Hagestad, 2007). Acceptance is greatest among highly educated women, who—while not necessarily embracing childlessness—may be more attuned to the demands of parenthood, which are still borne mostly by women (Koropeckyj-Cox & Pendell, 2007).

In line with this trend, voluntarily childless adults are just as content with their lives as parents who have warm relationships with their children. But adults who cannot overcome infertility are likely to be dissatisfied—some profoundly disappointed, others more ambivalent, depending on compensations in other areas of their lives (Letherby, 2002; Nichols & Pace-Nichols, 2000). Childlessness seems to interfere with adjustment and life satisfaction only when it is beyond a person's control.

Divorce and Remarriage

Divorce rates have stabilized since the mid-1980s, partly because of rising age of marriage, which is linked to greater financial stability and marital satisfaction. In addition, the increase in cohabitation has curtailed divorce: Many relationships that once would have been marriages now break up before marriage. Still, 45 percent of U.S. marriages dissolve (U.S. Census Bureau, 2012b). Because most divorces occur within seven years of marriage, many involve young children. Divorces are also common during the transition to midlife, when people have adolescent children—a period (as noted earlier) of reduced marital satisfaction.

Nearly two-thirds of divorced adults remarry. But marital failure is even greater during the first few years of second marriages—10 percent above that for first marriages. Afterward, the divorce rates for first and second marriages are similar (U.S. Census Bureau, 2012b).

Factors Related to Divorce. Why do so many marriages fail? As Christy and Gary's divorce illustrates, the most obvious reason is a disrupted husband-wife relationship.

Christy and Gary did not argue more than Sharese and Ernie. But their problem-solving style was ineffective, and it weakened their attachment to each other. When Christy raised concerns, Gary reacted with contempt, resentment, defensiveness, and retreat. This demand-withdraw pattern is found in many partners who split up, with women more often insisting on change and men more often retreating (Birditt et al., 2010; Haltzman, Holstein, & Moss, 2007). Another typical style involves little conflict, but partners increasingly lead separate lives because they have different expectations of family life and few shared interests, activities, or friends (Gottman & Levenson, 2000).

What problems underlie these maladaptive communication patterns? In a nine-year longitudinal study, researchers asked a U.S. national sample of 2,000 married people about marital problems and followed up three, six, and nine years later to find out who had separated or divorced (Amato & Rogers, 1997). Wives reported more problems than husbands, with the gender difference largely involving the wife's emotions, such as anger and hurt feelings. Husbands seemed to have difficulty sensing their wife's distress, which contributed to her view of the marriage as unhappy. Regardless of which spouse reported the problem or was judged responsible for it, the strongest predictors of divorce during the following decade were infidelity, spending money foolishly, drinking or using drugs, expressing jealousy, engaging in irritating habits, and moodiness.

Background factors that increase the chances of divorce are younger age at marriage, not attending religious services, being previously divorced, and having parents who had divorced—all of which are linked to marital difficulties. For example, couples who married at younger ages are more likely to report infidelity and jealousy. Low religious involvement subtracts an influential context for instilling positive marital attitudes and behaviors. And research following families over two decades reveals that parental divorce elevates risk of divorce in at least two succeeding generations, in part because it promotes child adjustment problems and reduces commitment to the norm of lifelong marriage (Amato & Cheadle, 2005; Wolfinger, 2005). As a result, when

FREDERICK BASS/GETTY IMAGES

An ineffective problem-solving style can lead to divorce. Partners who split up often follow a pattern in which one partner raises concerns, and the other reacts with resentment, anger, and retreat.

adult children marry, they are more likely to engage in inconsiderate behaviors and to have conflict-ridden relationships and less likely to try to work through these difficulties or (if they do try) to have the skills to do so. Marriage to a caring spouse from a stable family background reduces these negative outcomes.

Poorly educated, economically disadvantaged couples who suffer multiple life stresses are especially likely to split up (Clarke-Stewart & Brentano, 2006). But Christy's case represents another trend—rising marital breakup among well-educated, career-oriented, economically independent women. When a woman's workplace status and income exceed her husband's, the risk of divorce increases—an association explained by differing gender-role beliefs between the spouses (Popenoe, 2006). A husband's lack of support for his wife's career can greatly heighten her unhappiness and, therefore, the chances that she will end the marriage. Overall, women are twice as likely as men to initiate divorce proceedings.

In addition to the relationship factors just described, American individualism—which includes the belief that each person has the right to pursue self-expression and personal happiness—contributes to the unusually high U.S. divorce rate (see page 346 in Chapter 10) (Cherlin, 2009). Whether cohabiting or married, Americans partner, split up, and repartner more often than anywhere else in the industrialized world. When people are dissatisfied with their intimate relationship, the cultural value of individualism encourages moving on.

Consequences of Divorce. Divorce involves the loss of a way of life and therefore a part of the self sustained by that way of life. As a result, it provides opportunities for both positive and negative change. Immediately after separation, both men and women experience disrupted social networks, a decline in social support, and increased anxiety, depression, and impulsivity (Amato, 2000). For most, these reactions subside within two years. Nonworking women who organized their identities around their husbands have an especially hard time. And some noncustodial fathers feel disoriented and rootless as a result of decreased contact with their children (Coleman, Ganong, & Leon, 2006). Others distract themselves with a frenzy of social activity.

Finding a new partner contributes most to the life satisfaction of divorced adults (Forste & Heaton, 2004; Wang & Amato, 2000). But it is more crucial for men, who adjust less well than women to living on their own. Despite loneliness and a drop in income (see Chapter 10), women tend to bounce back more easily from divorce. Christy, for example, developed new friendships and a gratifying sense of self-reliance. However, a few women—especially those who are anxious and fearful, who remain strongly attached to their ex-spouses, or who lack education and job skills—experience a drop in self-esteem and persistent depression (Amato, 2000; Coleman, Ganong, & Leon, 2006). Job training, continued education, career advancement, and social support from family and friends play vital roles in the economic and psychological well-being of many divorced women.

Remarriage. On average, people remarry within four years of divorce, men somewhat faster than women. As noted earlier, remarriages are especially vulnerable to breakup, for several reasons. First, practical matters—financial security, help in rearing children, relief from loneliness, and social acceptance—figure more heavily into a second marriage than a first. These concerns do not provide a sound footing for a lasting partnership. Second, some people transfer the negative patterns of interaction learned in their first marriage to the second. Third, people with a failed marriage behind them are even more likely to view divorce as an acceptable solution when marital difficulties resurface. Finally, remarried couples experience more stress from stepfamily situations (Coleman, Ganong, & Leon, 2006). As we will see, stepparent–stepchild ties are powerful predictors of marital happiness.

Blended families generally take three to five years to develop the connectedness and comfort of intact biological families. Family life education, couples counseling, and group therapy can help divorced and remarried adults adapt to the complexities of their new circumstances (Whiteside, 2006).

Varied Styles of Parenthood

Diverse family forms result in varied styles of parenthood. Each type of family—blended, never-married, gay or lesbian, among others—presents unique challenges to parenting competence and adult psychological well-being.

Stepparents. Whether stepchildren live in the household or visit only occasionally, stepparents are in a difficult position. Stepparents enter the family as outsiders and, too often, move into their new parental role too quickly. Lacking a warm attachment bond to build on, their discipline is usually ineffective. Stepparents frequently criticize the biological parent for being too lenient, while the biological parent may view the stepparent as too harsh (Ganong & Coleman, 2004). Compared with first-marriage parents, remarried parents typically report higher levels of tension and disagreement, most centering on child-rearing issues. When both adults have children from prior marriages, rather than only one, more opportunities for conflict exist and relationship quality is poorer.

Stepmothers are especially likely to experience conflict. Those who have not previously been married and had children may have an idealized image of family life, which is quickly shattered. Expected to be in charge of family relationships, stepmothers quickly find that stepparent–stepchild ties do not develop instantly. After divorce, biological mothers are frequently jealous, uncooperative, and possessive of their children. Even when their husbands do not have custody, stepmothers feel stressed. As stepchildren go in and out of the home, stepmothers find life easier without resistant children and then may feel guilty about their “unmaternal” feelings (Church, 2004; MacDonald & DeMaris, 1996). No matter how hard a stepmother tries to build a close parent–child bond, her efforts are probably doomed to failure in the short run.

Stepfathers with children of their own tend to establish positive bonds with stepchildren relatively quickly, perhaps because they are experienced in building warm parent–child ties and feel less pressure than stepmothers to plunge into parenting (Ganong et al., 1999). But stepfathers without biological children (like their stepmother counterparts) can have unrealistic expectations. Or their wives may push them into the father role, sparking negativity from children. After making several overtures that are ignored or rebuffed, these stepfathers frequently withdraw from parenting (Hetherington & Clingempeel, 1992).

In interviews in which young-adult stepchildren provided retrospective accounts of their stepparent relationships, the quality of these ties varied widely, from warm and loving, to ambivalent, to coexisting, to critical and rejecting. A caring husband–wife bond, sensitive relationship-building behaviors by the stepparent, cooperation from the biological parent, and supportive extended family members all affected the development of stepparent–stepchild ties. Over time, many couples built a coparenting partnership that improved interactions with stepchildren (Ganong, Coleman, & Jamison, 2011). But because stepparent–stepchild bonds are hard to establish, the divorce rate is higher for remarried couples with stepchildren than for those without them.

Never-Married Single Parents. Over the past several decades, births to unmarried mothers in industrialized nations have increased dramatically. Today, about 40 percent of U.S. births are to single mothers, more than double the percentage in 1980. Whereas teenage parenthood has declined (see page 378 in Chapter 11), unwed parenthood among mothers in their twenties and older has risen. About 11 percent of U.S. children live with a single mother who has never married (U.S. Census Bureau, 2012b). In recent years, more single women over age 30 in high-status occupations have become parents. But they are still few in number, and little is known about how they and their children fare.

In the United States, African-American young women make up the largest group of never-married parents. About 64 percent of births to black mothers in their twenties are to women without a partner, compared with 28 percent of births to white women (U.S. Census Bureau, 2012b). African-American women postpone marriage more and childbirth less than women in other U.S. ethnic groups. Job loss, persisting unemployment, and consequent inability of many black men to support a family have contributed to the number of African-American never-married, single-mother families.

Never-married African-American mothers tap the extended family, especially their own mothers and sometimes male relatives, for help in rearing their children (Gasden, 1999; Jayakody & Kalil, 2002). For about one-third, marriage—not necessarily to the child’s biological father—occurs within nine years after birth of the first child (Wu, Bumpass, & Musick, 2001). These couples function much like other first-marriage parents. Their children are often unaware that the father is a stepfather, and

parents do not report the child-rearing difficulties typical of blended families (Ganong & Coleman, 1994).

Still, for low-SES women, never-married parenthood generally increases financial hardship; about half live in poverty (Mather, 2010). Nearly 50 percent of white mothers and 60 percent of black mothers have a second child while unmarried. And they are far less likely than divorced mothers to receive paternal child support payments, although child support enforcement both reduces financial stress and increases father involvement (Huang, 2006).

Children of never-married mothers who lack father involvement achieve less well in school and display more antisocial behavior than children in low-SES, first-marriage families—problems that make life more difficult for mothers (Waldfogel, Craigie, & Brooks-Gunn, 2010). But marriage to the child’s biological father benefits children only when the father is a reliable source of economic and emotional support. For example, adolescents who feel close to their nonresident father fare better in school performance and emotional and social adjustment than do those in two-parent homes where a close father tie is lacking (Booth, Scott, & King, 2009).

Unfortunately, most unwed fathers—who usually have no more than a modest education and are doing poorly financially—gradually spend less and less time with their children (Lerman, 2010). Strengthening parenting skills, social support, education, and employment opportunities for low-SES parents would greatly enhance the well-being of unmarried mothers and their children.

Gay and Lesbian Parents. According to recent estimates, about 20 to 35 percent of lesbian couples and 5 to 15 percent of gay couples are parents, most through previous heterosexual

Gay and lesbian parents are as committed to and effective at child rearing as heterosexual parents. Overall, families headed by same-sex partners can be distinguished from other families only by issues related to living in a nonsupportive society.

marriages, some through adoption, and a growing number through reproductive technologies (Gates et al., 2007; Goldberg, 2010; Patterson & Riskind, 2010). In the past, because of laws assuming that homosexuals could not be adequate parents, those who divorced a heterosexual partner lost custody of their children. Today, some U.S. states hold that sexual orientation by itself is irrelevant to custody. A few U.S. states, however, ban gay and lesbian couples from adopting children. Among other countries, gay and lesbian adoptions are legal in Argentina, Belgium, Brazil, Canada, Iceland, Mexico, the Netherlands, Norway, South Africa, Spain, Sweden, the United Kingdom, and Uruguay.

Most research on homosexual parents and children is limited to volunteer samples. Findings indicate that gay and lesbian parents are as committed to and effective at child rearing as heterosexual parents and sometimes more so (Bos, van Balen, & van den Boom, 2007; Tasker, 2005). Also, whether born to or adopted by their parents or conceived through donor insemination, children in gay and lesbian families did not differ from the children of heterosexuals in mental health, peer relations, or gender-role behavior (Allen & Burrell, 1996; Bos & Sandfort, 2010; Farr, Forssell, & Patterson, 2010; Goldberg, 2010). Two additional studies, which surmounted the potential bias associated with a volunteer sample by including all lesbian-mother families who had conceived children at a fertility clinic, also reported that children were developing favorably (Brewaeys et al., 1997; Chan, Raboy, & Patterson, 1998). Likewise, among participants drawn from a representative sample of British mothers and their 7-year-olds, children reared in lesbian-mother families did not differ from children reared in heterosexual families in adjustment and gender-role preferences (Golombok et al., 2003).

Furthermore, children of gay and lesbian parents are similar to other children in sexual orientation; the large majority are heterosexual (Tasker, 2005). But some evidence suggests that more adolescents from homosexual families experiment for a time with partners of both sexes, perhaps as a result of being reared in families and communities especially tolerant of non-conformity and difference (Bos, van Dalen, & Van den Boom, 2004; Stacey & Biblarz, 2001).

When extended-family members withhold acceptance, homosexual mothers and fathers often build “families of choice” through friends, who assume the roles of relatives. Usually, however, parents of gays and lesbians cannot endure a permanent rift (Fisher, Easterly, & Lazear, 2008). With time, interactions between homosexual parents and their families of origin become more positive and supportive.

A major concern of gay and lesbian parents is that their children will be stigmatized by their parents’ sexual orientation. Most studies indicate that incidents of teasing or bullying are rare because parents and children carefully manage the information they reveal to others (Tasker, 2005). Overall, families headed by homosexuals can be distinguished from other families only by issues related to living in a nonsupportive society.

ASK YOURSELF

REVIEW Why is never-married single parenthood especially high among African Americans? What conditions affect parent and child well-being in these families?

Career Development

Besides family life, vocational life is a vital domain of social development in early adulthood. After choosing an occupation, young people must learn how to perform its tasks well, get along with co-workers, respond to authority, and protect their own interests. When work experiences go well, adults develop new competencies, feel a sense of personal accomplishment, make new friends, and become financially independent and secure. And as we have seen, especially for women but also for men who support their partner’s career development, aspirations and accomplishments in the workplace and the family are interwoven.

Establishing a Career

Our discussion earlier in this chapter highlighted diverse paths and timetables for career development. **TAKE A MOMENT...** Consider, once again, the wide variations among Sharese, Ernie, Christy, and Gary. Notice that Sharese and Christy, like many women, had *discontinuous* career paths—ones that were interrupted or deferred by child rearing and other family needs (Huang & Sverke, 2007; Moen & Roehling, 2005). Furthermore, not all people embark on the vocation of their dreams. As noted in our consideration of emerging adulthood, the late-2000s recession greatly increased the number of young people in jobs that do not match their educational preparation.

Over half of adults in their twenties with bachelor’s or graduate degrees do manage to enter their chosen field. Even so, initial experiences can be discouraging. At the health department, Sharese discovered that paperwork consumed much of her day. Because each project had a deadline, the pressure of productivity weighed heavily on her. Adjusting to unanticipated disappointments in salary, supervisors, and co-workers is difficult.

As new employees become aware of the gap between their expectations and reality, resignations are common. Furthermore, in careers with opportunities for promotion, high aspirations must often be revised downward because the structure of most work settings resembles a pyramid, with fewer management and supervisory jobs. For these reasons—in addition to layoffs due to financial exigencies—workers in their twenties change jobs often; five or six changes are not unusual.

Recall from our discussion of Levinson's theory that career progress often depends on the quality of a mentoring relationship. Access to an effective mentor—a person with advanced experience and knowledge who is invested in the junior person's career success and who fosters a bond of trust—is jointly affected by the availability of willing people and the individual's capacity to select an appropriate individual (Ramaswami & Dreher, 2007). The best mentors are seldom top executives, who tend to be preoccupied and therefore less helpful and sympathetic. Usually, young adults fare better with mentors who are just above them in experience and advancement or who are members of their professional associations (Allen & Finkelstein, 2003). Furthermore, mentoring early in a worker's career increases the likelihood of mentoring later on (Bozionelos et al., 2011). The professional and personal benefits of mentoring induce employees to provide it to others and to seek it again for themselves.

Women and Ethnic Minorities

Women and ethnic minorities have penetrated nearly all professions, but their talents often are not developed to the fullest. Women, especially those who are members of economically disadvantaged minorities, remain concentrated in occupations that offer little opportunity for advancement, and they are underrepresented in executive and managerial roles (see Chapter 13, page 457). And although the overall difference between men's and women's earnings is smaller today than 30 years ago, it remains considerable in all industrialized countries (Rampell, 2010). U.S. government surveys following 9,000 U.S. college-educated workers for a decade revealed that a year after receiving their bachelor's degrees, women working full time earned just 80 percent as much as men. The difference was largely (but not entirely) due to gender differences in college majors: Women more often chose education and service fields, men higher-paying scientific and technical fields. Ten years after graduation, the gender pay gap had widened: Women's pay was only 69 percent of men's, and in no profession did women's earnings equal men's (Dey & Hill, 2007). Gender disparities in career development accounted for about 90 percent of the gap, with the remaining 10 percent attributed to on-the-job discrimination.

Especially for women in traditionally feminine occupations, career planning is often short-term and subject to change. Unlike the continuous career lives of most well-educated men, many women enter and exit the labor market several times, or reduce their work hours from full-time to part-time as they give birth to and rear children (Furchtgott-Roth, 2009; Lips, 2013). Time away from a career greatly hinders advancement—a major reason that women in prestigious, male-dominated careers tend to delay or

avoid childbearing (Blair-Loy & DeHart, 2003). Yet an increasing number of accomplished professional women are leaving their jobs to devote themselves full-time to child rearing—a trend that has generated mistaken, gender-stereotyped interpretations of their “choice.” Interviews with such women reveal that the decision to leave their careers is almost always agonizing (Rubin & Wooten, 2007; Stone & Lovejoy, 2004). The most common reason given was a high-pressured, inflexible work environment that offered no leeway for work–family life balance.

In addition, low self-efficacy with respect to male-dominated fields limits women's career progress. Women who pursue nontraditional careers usually have “masculine” traits—high achievement orientation, self-reliance, and belief that their efforts will result in success. But even those with high self-efficacy are less certain than their male counterparts that they can overcome barriers to career success. In a study of women scientists on university faculties, those reporting a sexist work climate (sexual harassment or discrimination in salary, promotion, or resources) were less satisfied with their jobs and less productive (Settles et al., 2006).

Gender-stereotyped images of women as followers rather than leaders slow advancement into top-level management positions. And because men dominate high-status fields, they must be willing to mentor women into leadership positions and take time from their work responsibilities to do so. Mentoring by a senior-male executive predicts progress into management roles and pay gains more strongly for women in male-dominated industries than for men (Ramaswami et al., 2010). When a powerful male leader *sponsors* the advancement of a talented woman, designating her as having the qualities to succeed, senior-level decision makers are far more likely to take notice.

Despite laws guaranteeing equality of opportunity, racial and ethnic bias in career opportunities remains strong (Smith, Brief, & Colella, 2010). In one study, researchers recruited two three-member teams consisting of a white, a black, and a Hispanic male job applicant, each 22 to 26 years old and matched

© NOEL HENDRICKSON/GETTY IMAGES/DIGITAL VISION

Women in male-dominated fields, such as this scientist, usually have “masculine” traits, such as high achievement orientation and self-reliance. Nevertheless, many encounter workplace barriers to career success.

FIGURE 14.5 Relationship of job applicant race/ethnicity to employer callbacks and job offers. The white applicant received slightly more positive responses from employers than did the Hispanic applicant, both of whom greatly exceeded the black applicant, though all three submitted the same résumé and had been matched on verbal and interpersonal skills and physical attractiveness. (From D. Pager, B. Western, & B. Bonikowski, “Discrimination in a Low-Wage Labor Market: A Field Experiment,” *American Sociological Review*, 74, p. 785, copyright © 2009, American Sociological Association. Adapted by permission of SAGE Publications.)

on verbal and interpersonal skills and physical attractiveness. The applicants were assigned identical fictitious résumés (with the exception that the résumé of the white member of the second team disclosed a criminal record) and sent out to apply for 170 entry-level jobs in New York City (Pager, Western, & Bonikowski, 2009). As Figure 14.5 shows, the white applicant received callbacks or job offers from employers slightly more often than the Hispanic applicant, with the black applicant trailing far behind. When the experiment was repeated with the second team, the white felon remained slightly preferred over both minority applicants, despite their clean records.

In another similar investigation, which varied applicant qualifications within résumés, white men and women with high-quality résumés received substantially more employer callbacks than those with low-quality résumés. In contrast, having a high-quality résumé made little difference for blacks. As the researchers noted, “Discrimination appears to bite twice, making it harder for African Americans to find a job and to improve their employability” (Bertrand & Mullainathan, 2004, p. 3). Consistent with this conclusion, African Americans spend more time searching for work, experience less stable employment, and acquire less work experience than Caucasian Americans with equivalent job qualifications (Pager & Shepherd, 2008).

Ethnic minority women often must surmount combined gender and racial discrimination to realize their career potential. Those who succeed frequently display an unusually high sense of self-efficacy, attacking problems head-on despite repeated obstacles to achievement. In interviews with African-American women who had become leaders in diverse fields, all reported intense persistence, fueled by supportive relationships with other

women, including teachers and peers. Many described their mothers as inspiring role models who had set high standards for them (Richie et al., 1997). Others felt empowered by a deep sense of connection to their African-American communities.

Despite obstacles to success, women who have developed rewarding careers generally report higher levels of psychological well-being and life satisfaction (Erdogan et al., 2012). This finding suggests that some of the discontent frequently expressed by married women may not be due to marriage per se but, rather, to lack of a gratifying work life. Consistent with this idea, most women prefer to blend work and family (Barnett & Hyde, 2001). And those in financially stressed families must do so.

Combining Work and Family

The majority of women with children are in the work force (see page 350 in Chapter 10), most in dual-earner marriages or cohabiting relationships. More women than men report moderate to high levels of stress in trying to meet both work and family responsibilities (Higgins, Duxbury, & Lyons, 2010; Zhao, Settles, & Sheng, 2011).

TAKE A MOMENT... Think about a dual-earner family you know well. What are the main sources of strain? When Sharese returned to her job after her children were born, she felt a sense of *role overload*, or conflict between the demands of work and family responsibilities. In addition to a challenging career, she also (like most employed women) shouldered more household and child-care tasks. And both Sharese and Ernie felt torn between the desire to excel at their jobs and the desire to spend more time with each other, their children, and their friends and relatives. Role overload is linked to increased psychological stress, physical health problems, poorer marital relations, less effective parenting, child behavior problems, and poorer job performance (Perry-Jenkins, Repetti, & Crouter, 2000; Saginak & Saginak, 2005; ten Brummelhuis et al., 2012).

Role overload is magnified for women in low-status work roles with rigid schedules and little autonomy (Marshall, 1997).

Time-flexible policies enabling employees to work from home help parents adjust work roles to meet family needs. As a result, employees work harder, take less time off, and feel more committed to their jobs.

Applying What We Know

Strategies That Help Dual-Earner Couples Combine Work and Family Roles

Strategy	Description
Devise a plan for sharing household tasks.	As soon as possible in the relationship, discuss relative commitment to work and family and division of household responsibilities. Decide who does a particular chore on the basis of who has the needed skill and time, not on the basis of gender. Schedule regular times to rediscuss your plan.
Begin sharing child care right after the baby's arrival.	For fathers, strive to spend equal time with the baby early. For mothers, refrain from imposing your standards on your partner. Instead, share the role of "child-rearing expert" by discussing parenting values and concerns often. Attend a parent education course together.
Talk over conflicts about decision making and responsibilities.	Face conflict through communication. Clarify your feelings and needs and express them to your partner. Listen and try to understand your partner's point of view. Then be willing to negotiate and compromise.
Establish a balance between work and family.	Critically evaluate the time you devote to work in view of your family values and priorities. If it is too much, cut back.
Make sure your relationship receives regular loving care.	See Applying What We Know on page 475.
Press for workplace and public policies that assist dual-earner-family roles.	Difficulties faced by dual-earner couples are partly due to lack of workplace and societal supports. Encourage your employer to provide benefits that help combine work and family, such as flexible work hours, parental leave with pay, and on-site high-quality, affordable child care. Communicate with lawmakers and other citizens about improving public policies for children and families.

Couples in prestigious careers have more control over both work and family domains. For example, Sharese and Ernie devised ways to spend more time with their children. They picked them up at child care early one day a week, compensating by doing certain occupational tasks on evenings and weekends. But in a Canadian study of more than 3,000 individuals in dual-earner families who were employed full-time, most coped with role overload by scaling back at home (leaving things undone) or restructuring family roles (taking over responsibilities for each other, as needed), with women doing more of this than men (Higgins, Duxbury, & Lyons, 2010). Overall, couples expected family life to accommodate to work demands. They seldom adjusted work roles to meet family needs. Although some had little flexibility at work, others simply prioritized work over family life.

Workplace supports can greatly reduce role overload, yielding substantial payoffs for employers. Among a large, nationally representative sample of U.S. working adults, the greater the number of time-flexible policies available in their work settings (for example, time off to care for a sick child, choice in start and stop times, and opportunities to work from home), the better their work performance (Halpern, 2005a). Employees with several time-flexible options missed fewer days of work, less often arrived at work late or left early, felt more committed to their employer, and worked harder. They also reported fewer stress-related health symptoms.

LOOK AND LISTEN

Talk with one or more dual-earner couples about workplace supports for good parenting. Which policies are available? Which additional ones would they find especially helpful? ●

Effectively balancing work and family brings many benefits—a better standard of living, improved work productivity, enhanced psychological well-being, greater self-fulfillment, and happier marriages. Ernie took great pride in Sharese's dedication to both family life and career. And the skills, maturity, and self-esteem each derived from coping successfully with challenges at home strengthened their capacity to surmount difficulties at work (Graves, Ohlott, & Ruderman, 2007). Applying What We Know above lists strategies that help dual-earner couples attain mastery and pleasure in both spheres of life.

ASK YOURSELF

REVIEW Why do professionally accomplished women, especially those who are members of economically disadvantaged minorities, typically display high self-efficacy?

CONNECT Generate a list of capacities and skills derived from high commitment to family roles (both partner and parent) that could enhance work performance and satisfaction.

APPLY Write an essay aimed at convincing a company executive that family-friendly policies are "win-win" situations for both workers and employers.

REFLECT Ask someone who has succeeded in a career of interest to you to describe mentoring relationships that aided his or her progress.

SUMMARY

A Gradual Transition: Emerging Adulthood (p. 464)

What is emerging adulthood, and how has cultural change contributed to it?

- In **emerging adulthood**, young adults from about age 18 to 25 have not yet taken on adult responsibilities and do not view themselves as fully adult. Instead, those with economic resources engage in extended exploration of alternatives in education, work, and personal values. Identity development extends into the college years, with young people exploring possibilities in breadth and depth.

© STRACUSE NEWSPAPERS/
PETER CHEN/THE IMAGE WORKS

- During the late teens and early twenties, religious attendance drops to its lowest level, though women and ethnic minority young people express greater religiosity. Regardless of whether they participate in organized religion, many emerging adults begin to construct an individualized faith. They are also committed to improving their world, often engaging in community service.
- Increased education required for entry-level positions in many fields, gains in economic prosperity, and reduced need for young people's labor in industrialized nations have prompted the appearance of emerging adulthood. But because of its strong association with SES and higher education, some researchers do not view emerging adulthood as a distinct period of development.
- In exploring possibilities, emerging adults must adjust to disappointments in love and work, and their explorations may extend risky behaviors of adolescence. A wide array of personal attributes and social supports foster resilience. Relationships with parents are especially influential: A secure, affectionate bond that balances connection and separation predicts many aspects of adaptive functioning.

Erikson's Theory: Intimacy versus Isolation (p. 469)

According to Erikson, what personality changes take place during early adulthood?

- In Erikson's theory, young adults must resolve the conflict of **intimacy versus isolation** as they form a close relationship with a partner. The negative outcome is loneliness and self-absorption.
- Young people also focus on aspects of generativity, including parenting and contributions to society through work and community service.

Other Theories of Adult Psychosocial Development (p. 470)

Describe and evaluate Levinson's and Vaillant's psychosocial theories of adult personality development.

- Expanding Erikson's stage approach, Levinson described a series of eras in which people revise their life structure. Young adults usually construct a dream, typically involving career for men and both marriage and career for women, and form a relationship with a mentor. In their thirties, men tend to settle down, whereas many women remain unsettled into middle adulthood.
- Also in the tradition of Erikson, Vaillant portrayed the twenties as devoted to intimacy, the thirties to career consolidation, the forties to generativity, and the fifties and sixties to passing on cultural values.
- Young adults' development is far more variable today than Levinson's and Vaillant's theories depict.

What is the social clock, and how does it affect personality in adulthood?

- Following a **social clock**—age-graded expectations for major life events—grants confidence to young adults. Deviating from it can bring psychological distress.
- As age-graded expectations for appropriate behavior have become increasingly flexible, departures from social-clock life events are common and can create intergenerational tensions.

Close Relationships (p. 472)

Describe factors affecting mate selection and the role of romantic love in the young adult's quest for intimacy.

- Romantic partners tend to resemble each other in age, education level, ethnicity, religion, and various personal and physical attributes.
- According to an evolutionary perspective, women seek a mate with traits that help ensure children's survival, while men look for characteristics signaling sexual pleasure and ability to bear offspring. From a social learning perspective, gender roles profoundly influence criteria for mate selection. Research suggests that both biological and social forces are involved.
- According to Sternberg's **triangular theory of love**, the balance among intimacy, passion, and commitment changes as romantic relationships move from **passionate love** toward **companionate love**. The Western emphasis on romantic love in mate selection does not characterize all cultures.

Describe adult friendships and sibling relationships, and the role of loneliness in adult development.

- Adult friendships, like earlier friendships, are based on trust, intimacy, and loyalty. Women's same-sex friendships tend to be more intimate than men's. After marriage, other-sex friendships decline with age for men but increase for women, who tend to form them in the workplace. When family experiences have been positive, adult sibling relationships often resemble friendships.

ROB LANG/GETTY IMAGES

- Young adults are vulnerable to **loneliness**, which peaks in the late teens and early twenties. Loneliness that is not overwhelming can encourage young people to reach out to others and better understand themselves.

The Family Life Cycle (p. 478)

Trace phases of the family life cycle that are prominent in early adulthood, and cite factors that influence these phases today.

- Wide variations exist in the sequence and timing of the **family life cycle**. A trend toward later home-leaving has occurred in most industrialized nations. Departures generally occur earlier for education than for full-time work or marriage; role transitions may prompt a move back. Parents of young adults living at home are usually highly committed to helping their children move into adult roles.
- The average age of first marriage in the United States and Western Europe has risen. Many countries and a growing number of U.S. states recognize same-sex marriages.
- Both **traditional marriages** and **egalitarian marriages** are affected by women's participation in the work force. Women in Western nations spend nearly twice as much time as men on housework, although men participate much more in child care than in the past. Women feel particularly dissatisfied when the combined demands of work and family roles are overwhelming. Partners who hold overly positive (but still realistic) biases concerning each other's attributes express greater relationship satisfaction.
- Although most couples in industrialized nations become parents, they do so later and have fewer children than in the past. The arrival of a child brings increased responsibilities, often prompting a shift to more traditional roles. After the birth of a second child, this may reverse. Gratifying marriages tend to remain so after childbirth, but troubled marriages usually become more distressed. Shared caregiving predicts greater parental happiness and positive parent–infant interaction.
- Couples with young children face challenges of clarifying and implementing child-rearing values. Those who engage in effective coparenting are more likely to gain in warm marital interaction, use effective child-rearing practices, and have children who are developing well.
- Parents of adolescents must establish revised relationships with their increasingly autonomous teenagers, blending guidance with freedom and gradually loosening control. Marital satisfaction often declines in this phase.

The Diversity of Adult Lifestyles (p. 486)

Discuss the diversity of adult lifestyles, focusing on singlehood, cohabitation, and childlessness.

- Postponement of marriage and a high divorce rate have contributed to a rise in singlehood. Despite an array of drawbacks, singles typically appreciate their freedom and mobility.
- **Cohabitation** among U.S. couples has increased, becoming the preferred mode of entry into a committed intimate partnership for young people. Compared with their Western European counterparts, Americans who cohabit before marriage tend to be less conventional in values and less committed to their partner, and their subsequent marriages are more likely to fail. But gay and lesbian couples who cohabit because they cannot legally marry report commitment equal to that of married couples.

© TAMPA BAY TIMES/VE EDLHEIT/
THE IMAGE WORKS

- Voluntarily childless adults tend to be college-educated, career-oriented, and content with their lives. But involuntary childlessness interferes with adjustment and life satisfaction.

Cite factors that contribute to today's high rates of divorce and remarriage.

- Almost half of U.S. marriages dissolve. Although nearly two-thirds of divorced people remarry, many divorce again. Maladaptive communication patterns, younger ages at marriage, a family history of divorce, poverty, the changing status of women, and American individualism all contribute to divorce.
- Remarriages are especially vulnerable to breakup. Reasons include the prominence of practical concerns in the decision to remarry, the persistence of negative styles of communication, the acceptance of divorce as a solution to marital difficulties, and problems adjusting to a stepfamily.

Discuss the challenges associated with varied styles of parenthood, including stepparents, never-married parents, and gay and lesbian parents.

- Establishing stepparent–stepchild ties is difficult, especially for stepmothers and for stepfathers without children of their own. A caring husband–wife bond that includes a coparenting partnership, cooperation from the biological parent, and extended-family support promote positive stepparent–stepchild ties.
- Never-married single parenthood is especially high among African-American women in their twenties. Unemployment among black men contributes to this trend. Even with help from extended family members, these mothers find it difficult to overcome poverty.
- Gay and lesbian parents are as effective at child rearing as heterosexual parents, and their children are as well-adjusted as those reared by heterosexual parents.

Career Development (p. 492)

Discuss patterns of career development, and cite difficulties faced by women, ethnic minorities, and couples seeking to combine work and family.

- Men's career paths are usually continuous, whereas women's are often interrupted by family needs. Once young adults settle into an occupation, their progress is affected by opportunities for promotion, the broader economic environment, and access to an effective mentor.
- Women and ethnic minorities have penetrated most professions, but their career advancement has been hampered by time away from the labor market, low self-efficacy, lack of mentoring, and gender stereotypes. Racial and ethnic bias remains strong. Ethnic minority women who succeed display an unusually high sense of self-efficacy.
- Couples in dual-earner marriages often experience role overload. Effectively balancing work and family enhances standard of living, psychological well-being, marital happiness, and work performance.

Physical and Cognitive Development in Middle Adulthood

On a snowy December evening, Devin and Trisha sat down to read the holiday cards piled high on the kitchen counter. Devin's 55th birthday had just passed; Trisha would turn 48 in a few weeks. During the past year, they had celebrated their 24th wedding anniversary.

These milestones, along with the annual updates they received from friends, brought the changes of midlife into bold relief.

Instead of new births, children starting school, or a first promotion at work, holiday cards and letters sounded new themes. Jewel's recap of the past year reflected growing awareness of a finite lifespan, one in which time had become more precious. She wrote:

My mood has been lighter ever since my birthday. There was some burden I laid down by turning 49. My mother passed away when she was 48, so it all feels like a gift now. Blessed be!

George and Anya reported on their son's graduation from law school and their daughter Michelle's first year of university:

Anya is filling the gap created by the children's departure by returning to college for a nursing degree. After enrolling this fall, she was surprised to find herself in the same psychology class as Michelle. At first, Anya worried about handling the academic work, but after a semester of success, she's feeling more confident.

Tim's message reflected continuing robust health, acceptance of physical changes, and a new burden: caring for aging parents—a firm reminder of the limits of the lifespan:

I used to be a good basketball player in college, but recently I noticed that my 20-year-old nephew, Brent, can dribble and shoot circles around me. It must be my age! But I ran our city marathon in September and came in seventh in the over-50 division. Brent ran, too, but he opted out a few miles short of the finish line to get some pizza while I pressed on. That must be my age, too!

Vocational Life and Cognitive Development

Adult Learners: Becoming a Student in Midlife

Characteristics of Returning Students • Supporting Returning Students

The saddest news is that my dad had a bad stroke. His mind is clear, but his body is partially paralyzed. It's really upsetting because he was getting to enjoy the computer I gave him, and it was so upbeat to talk with him about it in the months before the stroke.

Middle adulthood, which begins around age 40 and ends at about 65, is marked by narrowing life options and a shrinking future as children leave home and career paths become more determined. In other ways, middle age is hard to define because wide variations in attitudes and behaviors exist. Some individuals seem physically and mentally young at age 65—active and optimistic, with a sense of serenity and stability. Others feel old at age 40—as if their lives had peaked and were on a downhill course.

Another reason middle adulthood eludes definition is that it is a contemporary phenomenon. Before the twentieth century, only a brief interval separated the tasks of early adulthood from those of old age. Women were often widows by their mid-fifties, before their youngest child left home. And harsh living conditions led people to accept a ravaged body as a natural part of life. As life expectancy—and, with it, health and vigor—increased over the past century, adults became more aware of their own aging and mortality.

In this chapter, we trace physical and cognitive development in midlife. In both domains, we will encounter not just progressive declines but also sustained performance and compensating gains. As in earlier chapters, we will see that change occurs in manifold ways. Besides heredity and biological aging, our personal approach to passing years combines with family, community, and cultural contexts to affect the way we age. ●

PHYSICAL DEVELOPMENT

Physical development in middle adulthood is a continuation of the gradual changes under way in early adulthood. Even the most vigorous adults notice an older body when looking in the mirror or at family photos. Hair grays and thins, new lines appear on the face, and a fuller, less youthful body shape is evident. During midlife, most individuals begin to experience life-threatening health episodes—if not in themselves, then in their partners and friends. And a change in time orientation, from “years since birth” to “years left to live,” adds to consciousness of aging (Neugarten, 1968b).

These factors lead to a revised physical self-image, with somewhat less emphasis on hoped-for gains and more on feared declines (Bybee & Wells, 2003; Frazier, Barreto, & Newman, 2012). Prominent concerns of 40- to 65-year-olds include get-

ting a fatal disease, being too ill to maintain independence, and losing mental capacities. Unfortunately, many middle-aged adults fail to embrace realistic alternatives—becoming more physically fit and developing into healthy, energetic older adults. Although certain aspects of aging cannot be controlled, people can do much to promote physical vigor and good health in midlife.

Physical Changes

As she dressed for work one morning, Trisha remarked jokingly to Devin, “I think I’ll leave the dust on the mirror so I can’t see the wrinkles and gray hairs.” Catching sight of her image, she continued in a more serious tone. “And look at this fat—it just doesn’t want to go! I need to fit some regular exercise into my life.” In response, Devin glanced soberly at his own enlarged midriff.

At breakfast, Devin took his glasses on and off and squinted while reading the paper. “Trish—what’s the eye doctor’s phone number? I’ve got to get these bifocals adjusted again.” As they conversed between the kitchen and the adjoining den, Devin sometimes asked Trisha to repeat herself. And he kept turning up the radio and TV volume. “Does it need to be that loud?” Trisha would ask. Apparently Devin couldn’t hear as clearly as before.

In the following sections, we look closely at the major physical changes of midlife. As we do so, you may find it helpful to refer back to Table 13.1 on page 435, which provides a summary.

Vision

By the forties, difficulty reading small print is common, due to thickening of the lens combined with weakening of the muscle that enables the eye to *accommodate* (adjust its focus) to nearby objects. As new fibers appear on the surface of the lens, they compress older fibers toward the center, creating a thicker, denser, less pliable structure that eventually cannot be transformed at all. By age 50, the accommodative ability of the lens is one-sixth of what it was at age 20. Around age 60, the lens loses its capacity to adjust to objects at varying distances entirely, a condition called **presbyopia** (literally, “old eyes”). As the lens enlarges, the eye rapidly becomes more farsighted between ages 40 and 60 (Charman, 2008). Corrective lenses—or, for nearsighted people, bifocals—ease reading problems.

A second set of changes limits ability to see in dim light, which declines at twice the rate of daylight vision (Jackson & Owsley, 2000). Throughout adulthood, the size of the pupil shrinks and the lens yellows. In addition, starting at age 40, the *vitreous* (transparent gelatin-like substance that fills the eye) develops opaque areas, reducing the amount of light reaching the retina. Changes in the lens and vitreous also cause light to scatter within the eye, increasing sensitivity to glare. Devin had always enjoyed driving at night, but now he sometimes had

trouble making out signs and moving objects (Owsley, 2011). And his vision was more disrupted by bright light sources, such as headlights of oncoming cars. Yellowing of the lens and increasing density of the vitreous also limit color discrimination, especially at the green–blue–violet end of the spectrum (Paramei, 2012). Occasionally, Devin had to ask whether his sport coat, tie, and socks matched.

Besides structural changes in the eye, neural changes in the visual system occur. Gradual loss of rods and cones (light- and color-receptor cells) in the retina and of neurons in the optic nerve (the pathway between the retina and the cerebral cortex) contributes to visual declines. By midlife, half the *rods* (which enable vision in dim light) are lost (Owsley, 2011). And because rods secrete substances necessary for survival of *cones* (which enable daylight and color vision), gradual loss of cones follows.

Middle-aged adults are at increased risk of **glaucoma**, a disease in which poor fluid drainage leads to a buildup of pressure within the eye, damaging the optic nerve. Glaucoma affects nearly 2 percent of people over age 40, more often women than men. It typically progresses without noticeable symptoms and is a leading cause of blindness. Heredity contributes to glaucoma, which runs in families: Siblings of people with the disease have a tenfold increased risk, and it occurs three to four times as often in African Americans and Hispanics as in Caucasians (Guedes, Tsai, & Loewen, 2011; Kwon et al., 2009). Starting in midlife, eye exams should include a glaucoma test. Drugs that promote release of fluid and surgery to open blocked drainage channels prevent vision loss.

Hearing

An estimated 14 percent of Americans between ages 45 and 64 suffer from hearing loss, often resulting from adult-onset hearing impairments (Center for Hearing and Communication, 2012). Although some conditions run in families and may be hereditary, most are age-related, a condition called **presbycusis** (“old hearing”).

As we age, inner-ear structures that transform mechanical sound waves into neural impulses deteriorate through natural cell death or reduced blood supply caused by atherosclerosis. Processing of neural messages in the auditory cortex also declines. Age-related cognitive changes—in processing speed, attention, and memory—that we will take up shortly are also associated with hearing loss (Lin et al., 2011). The first sign, around age 50, is a noticeable decline in sensitivity to high-frequency sounds, which gradually extends to all frequencies. Late in life, human speech becomes more difficult to make out, especially rapid speech and speech against a background of voices (Humes et al., 2012). Still, throughout middle adulthood, most people hear reasonably well across a wide frequency range. And African tribal peoples display little age-related hearing loss (Jarvis & van Heerden, 1967; Rosen, Bergman, & Plester, 1962). These findings suggest factors other than biological aging are involved.

Men’s hearing tends to decline earlier and more rapidly than women’s, a difference associated with cigarette smoking,

THOMAS BARWICK/STONE/GETTY IMAGES
A worker uses a grinder to smooth a metal surface in a steel manufacturing facility. Men’s hearing declines more rapidly than women’s, a difference associated with several factors, including intense noise in some male-dominated occupations.

intense noise and chemical pollutants in some male-dominated occupations, and (at older ages) high blood pressure and cerebrovascular disease, or strokes that damage brain tissue (Heltzner et al., 2005; Van Eyken, Van Camp, & Van Laer, 2007). Government regulations requiring industries to implement such safeguards as noise monitoring, provision of earplugs, pollution control, and regular hearing tests have greatly reduced hearing damage, but some employers do not comply fully (Daniell et al., 2006; Ohlemiller, 2008).

Most middle-aged and elderly people with hearing difficulties benefit from sound amplification with hearing aids. When perception of the human voice is affected, speaking to the person patiently, clearly, and with good eye contact, in an environment with reduced background noise, aids understanding.

Skin

Our skin consists of three layers: (1) the *epidermis*, or outer protective layer, where new skin cells are constantly produced; (2) the *dermis*, or middle supportive layer, consisting of connective tissue that stretches and bounces back, giving the skin flexibility; and (3) the *hypodermis*, an inner fatty layer that adds to the soft lines and shape of the skin. As we age, the epidermis becomes less firmly attached to the dermis, fibers in the dermis thin, cells in both the epidermis and dermis decline in water content, and fat in the hypodermis diminishes, leading the skin to wrinkle, loosen, and feel dry.

In the thirties, lines develop on the forehead as a result of smiling, frowning the brow, and other facial expressions. In the forties, these become more pronounced, and “crow’s-feet” appear around the eyes. Gradually, the skin loses elasticity and begins to sag, especially on the face, arms, and legs (Khavkin & Ellis, 2011). After age 50, “age spots,” collections of pigment under the skin, increase. Blood vessels in the skin become more visible as the fatty layer thins.

Because sun exposure hastens wrinkling and spotting, individuals who have spent much time outdoors without proper skin protection look older than their contemporaries. And partly because the dermis of women is not as thick as that of men, women's skin ages more quickly (Makrantonaki & Xouboulis, 2007).

Muscle–Fat Makeup

As Trisha and Devin make clear, weight gain—“middle-age spread”—is a concern for both men and women. A common pattern of change is an increase in body fat and a loss of lean body mass (muscle and bone). The rise in fat largely affects the torso and occurs as fatty deposits within the body cavity; as noted earlier, fat beneath the skin on the limbs declines. On average, size of the abdomen increases 7 to 14 percent. Although a large portion is due to weight gain, age-related changes in muscle–fat makeup also contribute (Stevens, Katz, & Huxley, 2010). In addition, sex differences in fat distribution appear. Men accumulate more on the back and upper abdomen, women around the waist and upper arms (Sowers et al., 2007). Muscle mass declines very gradually in the forties and fifties, largely due to atrophy of fast-twitch fibers, responsible for speed and explosive strength.

Yet, as indicated in Chapter 13, large weight gain and loss of muscle power are not inevitable. With age, people must gradually reduce caloric intake to adjust for the age-related decline in basal metabolic rate (see page 440). In a longitudinal study of nearly 30,000 U.S. 50- to 79-year-old women diverse in SES and ethnicity, a low-fat diet involving increased consumption of vegetables, fruits, and grains was associated with greater initial weight loss and success at maintaining that loss over a seven-year period (Howard et al., 2006). In nonhuman animals, dietary restraint dramatically increases longevity while sustaining health and vitality. Currently, researchers are identifying the biological mechanisms involved and studying their relevance to humans (see the Biology and Environment box on the following page).

Furthermore, weight-bearing exercise that includes resistance training (placing a moderately stressful load on the muscles) can offset both excess weight and muscle loss. Within the same individual, strength varies between often-used and little-used muscles (Macaluso & De Vito, 2004; Rivlin, 2007). Consider Devin's 57-year-old friend Tim, who for years has ridden his bike to and from work and jogged on weekends, averaging an hour of vigorous activity per day. Like many endurance athletes, he maintained the same weight and muscular physique throughout early and middle adulthood.

Skeleton

As new cells accumulate on their outer layers, the bones broaden, but their mineral content declines, so they become more porous. This leads to a gradual loss in bone density that begins around age 40 and accelerates in the fifties, especially among women (Clarke & Khosla, 2010). Women's reserve of

bone minerals is lower than men's to begin with. And following menopause, the favorable impact of estrogen on bone mineral absorption is lost. Reduction in bone density during adulthood is substantial—about 8 to 12 percent in men and 20 to 30 percent in women (Seeman, 2008).

Loss of bone strength causes the disks in the spinal column to collapse. Consequently, height may drop by as much as 1 inch by age 60, a change that will hasten thereafter. In addition, the weakened bones cannot support as much load: They fracture more easily and heal more slowly. A healthy lifestyle—including weight-bearing exercise, adequate calcium and vitamin D intake, and avoidance of smoking and heavy alcohol consumption—can slow bone loss in postmenopausal women by as much as 30 to 50 percent (Cooper et al., 2009).

When bone loss is very great, it leads to a debilitating disorder called *osteoporosis*. We will take up this condition shortly when we consider illness and disability.

Reproductive System

The midlife transition in which fertility declines is called the **climacteric**. In women, it brings an end to reproductive capacity; in men, by contrast, fertility diminishes but is retained.

Reproductive Changes in Women. The changes involved in women's climacteric occur gradually over a 10-year period, during which the production of estrogen drops. As a result, the number of days in a woman's monthly cycle shortens from about 28 in her twenties and thirties to perhaps 23 by her late forties, and her cycles become more irregular. In some, ova are not released; when they are, more are defective (see Chapter 2, page 53). The climacteric concludes with **menopause**, the end of menstruation and reproductive capacity. This occurs, on average, in the early fifties among North American, European, and East Asian women, although the age range extends from the late thirties to the late fifties (Avis, Crawford, & Johannes, 2002; Rossi, 2005). Women who smoke or who have not borne children tend to reach menopause earlier.

Following menopause, estrogen declines further, causing the reproductive organs to shrink in size, the genitals to be less easily stimulated, and the vagina to lubricate more slowly during arousal. As a result, complaints about sexual functioning increase, with about 35 to 40 percent of women reporting difficulties, especially among those with health problems or whose partners have sexual performance difficulties (Lindau et al., 2007; Walsh & Berman, 2004). The drop in estrogen also contributes to decreased elasticity of the skin and loss of bone mass. Also lost is estrogen's ability to help protect against accumulation of plaque on the walls of the arteries, by boosting “good cholesterol” (high-density lipoprotein).

The period leading up to and following menopause is often accompanied by emotional and physical symptoms, including mood fluctuations and *hot flashes*—sensations of warmth accompanied by a rise in body temperature and redness in the face, neck, and chest, followed by sweating. Hot flashes—which may occur during the day and also, as *night*

Biology and Environment

Anti-Aging Effects of Dietary Calorie Restriction

For nearly 70 years, scientists have known that dietary calorie restriction in nonprimate animals slows aging while maintaining good health and body functions. Rats and mice fed 30 to 40 percent fewer calories than they would freely eat beginning in early life show various physiological health benefits, lower incidence of chronic diseases, and a 60 percent increase in length of life (Fontana, 2009). Mild to moderate calorie restriction begun after rodents reach physical maturity also slows aging and extends longevity, though to a lesser extent. Other studies reveal similar dietary-restriction effects in mice, fleas, spiders, worms, fish, and yeast.

Nonhuman Primate Research

Would primates, especially humans, also benefit from a restricted diet? Researchers have been tracking health indicators in rhesus monkeys after placing some on regimens of 30 percent reduced calories at young, middle, and older ages. More than two decades of longitudinal findings revealed that, compared with freely eating controls, dietary-restricted monkeys were smaller but not overly thin. They accumulated body fat differently—less on the torso, a type of fat distribution that reduces middle-aged humans' risk of heart disease.

Calorie-restricted monkeys also had a lower body temperature and basal metabolic rate—changes that suggest they shifted physiological processes away from growth to life-maintaining functions. Consequently, like calorie-restricted rodents, they seemed better able to withstand severe physical stress, such as surgery and infectious disease (Weindruch et al., 2001).

Among physiological processes mediating these benefits, two seem most powerful. First, calorie restriction inhibited production of free radicals, thereby limiting cellular deterioration, which contributes to many diseases of aging (see page 433 in Chapter 13) (Carter et al., 2007; Yu, 2006). Second, calorie

restriction reduced blood glucose and improved insulin sensitivity, offering protection against diabetes and cardiovascular disease. Lower blood pressure and cholesterol and a high ratio of “good” to “bad” cholesterol in calorie-restricted primates strengthened these effects (Fontana, 2008).

Nevertheless, long-term tracking of the monkeys' age of death revealed no difference in length of survival between the calorie-restricted and control groups, regardless of the age at which restriction began. Limiting food intake delayed the onset of age-related diseases, including cancer, cardiovascular disease, and arthritis, but it did not extend the monkeys' longevity (Mattison et al., 2012). In sum, the calorie-restricted monkeys benefited from more years of healthy life, not from an extended lifespan.

Human Research

Prior to World War II, residents of the island of Okinawa consumed an average of 20 percent fewer calories (while maintaining a healthy diet) than mainland Japanese citizens. Their restricted diet was associated with a 60 to 70 percent reduction in incidence of deaths due to cancer and cardiovascular disease. Recent generations of Okinawans no longer show these health and longevity advantages (Gavrilova & Gavrilov, 2012). The reason, some researchers speculate, is the introduction of Westernized food, including fast food, to Okinawa.

Similarly, normal-weight and overweight people who have engaged in self-imposed calorie restriction for 1 to 12 years display health benefits—reduced blood glucose, cholesterol, and blood pressure and a stronger immune-system response than individuals eating a typical Western diet (Fontana et al., 2004, 2010; Redman et al., 2008). Furthermore, in the first experiment involving random assignment of human participants to calorie-restricted and nonrestricted conditions, the restricted group again displayed

© CHRIS WILLSON/ALAMY

An Okinawan grandfather and grandson enjoy an afternoon of kite flying. Before World War II, residents of Okinawa consumed a restricted diet that was associated with health benefits and longer life. Recent generations no longer show these advantages, possibly due to the introduction of Westernized food to Okinawa.

improved cardiovascular and other health indicators, suggesting reduced risk of age-related disease (Redman & Ravussin, 2011).

Because nonhuman primates (unlike nonprimate animals) show no gains in length of life, researchers believe that calorie restriction is also unlikely to prolong human longevity. But the health benefits that accrue from limiting calorie intake are now well-established. They seem to result from a physiological response to food scarcity that evolved to increase the body's capacity to survive adversity.

Nevertheless, very few people would be willing to maintain a substantially reduced diet for most of their lifespan. As a result, scientists have begun to explore *calorie-restriction mimetics*—agents such as natural food substances, herbs, and vigorous exercise regimens—that might yield the same health effects as calorie restriction, without dieting (Rizvi & Jha, 2011). These investigations are still in their early stages.

sweats, during sleep—affect more than 50 percent of women in Western industrialized nations (Nelson, 2008). Typically, they are not severe: Only about 1 in 12 women experiences them every day.

Although menopausal women tend to report increased irritability and less satisfying sleep, research using EEG and other neurobiological measures finds no links between menopause and changes in quantity or quality of sleep (Lamberg, 2007; Young et al., 2002). Also, most studies reveal no association between menopause and depression in the general population (Soares, 2007; Vesco et al., 2007; Woods et al., 2008). Rather, women who have a previous history of depression, are physically inactive, or are experiencing highly stressful life events are more likely to experience depressive episodes during the climacteric. In view of these findings, sleep difficulties or depression should not be dismissed as temporary byproducts of menopause: These problems merit serious evaluation and treatment.

As Figure 15.1 illustrates, compared with North American, European, African, and Middle Eastern women, Asian women report fewer menopausal complaints, including hot flashes (Obermeyer, 2000). Asian diets, which are low in fat and high in soy-based foods (a rich source of plant estrogen) may be involved.

Hormone Therapy. To reduce the physical discomforts of menopause, doctors may prescribe **hormone therapy**, or low daily doses of estrogen. Hormone therapy comes in two types: (1) estrogen alone, or *estrogen replacement therapy (ERT)*, for women who have had hysterectomies (surgical removal of the uterus); and (2) estrogen plus progesterone, or *hormone replacement therapy (HRT)*, for other women. Combining estrogen

FIGURE 15.1 Percentage of menopausal women in different regions of the world reporting hot flashes. Findings are derived from interviews with large samples in each region. Women in Asian nations, especially Japanese women, are less likely to suffer from hot flashes, perhaps because they eat soy-based foods, a rich source of plant estrogen. See the Cultural Influences box on page 508 for additional evidence on the low rates of menopausal symptoms among Japanese women. (Adapted from Obermeyer, 2000; Shea, 2006.)

with progesterone lessens the risk of cancer of the endometrium (lining of the uterus), which has long been known as a serious side effect of hormone therapy.

Hormone therapy is highly successful at counteracting hot flashes and vaginal dryness. It also offers some protection against bone deterioration. Nevertheless, more than twenty experiments, in which nearly 43,000 peri- or postmenopausal women had been randomly assigned to take hormone therapy (ERT or HRT) or a sugar pill for at least one year and were followed for an average of seven years, revealed an array of negative consequences. Hormone therapy was associated with an increase in heart attack, stroke, blood clots, breast cancer, gallbladder disease, and deaths from lung cancer. ERT, when compared with HRT, intensified the risk of blood clots, stroke, and gallbladder disease. And women age 65 and older taking HRT showed an elevated risk of Alzheimer's disease and other dementias (Marjoribanks et al., 2012).

On the basis of available evidence, women and their doctors should make decisions about hormone therapy carefully. Women with family histories of cardiovascular disease or breast cancer are advised against it. Fortunately, the number of alternative treatments is increasing. A relatively safe migraine-headache medication, gabapentin, substantially reduces hot flashes, perhaps by acting on the brain's temperature regulation center. At high doses, which still appear safe, gabapentin is nearly as effective as hormone therapy. Several antidepressant drugs and black cohosh, an herbal medication, are helpful as well (Guttuso, 2012; Thacker, 2011). Alternative medications are also available to protect the bones, although their long-term safety is not yet clear.

Women's Psychological Reactions to Menopause.

How do women react to menopause—a clear-cut signal that their childbearing years are over? The answer lies in how they interpret the event in relation to their past and future lives.

For Jewel, who had wanted marriage and family but never attained these goals, menopause was traumatic. Her sense of physical competence was still bound up with the ability to have children. Physical symptoms can also make menopause a difficult time (Elavsky & McAuley, 2007). And in a society that values a youthful appearance, some women respond to the climacteric with disappointment about a loss of sex appeal (Howell & Beth, 2002).

Many women, however, find menopause to be little or no trouble, regard it as a new beginning, and report improved quality of life (George, 2002; Mishra & Kuh, 2006). When more than 2,000 U.S. women were asked what their feelings were about no longer menstruating, nearly 50 percent of those currently experiencing changes in their menstrual cycles, and 60 percent of those whose periods had ceased, said they felt relieved (Rossi, 2005). Most do not want more children and are thankful to be freed from worry about birth control. And highly educated women usually have more positive attitudes toward menopause than those with less education (Pitkin, 2010).

Compared with previous generations, the baby-boom generation seems more accepting of menopause (Avis & Crawford,

African-American women, who generally view menopause as normal, inevitable, even welcome, experience less irritability and moodiness during this transition than Caucasian-American women.

2006). Their strong desire to cast aside old, gender-stereotyped views (such as menopause as a sign of decay and disease), their more active approach to seeking health information, and their greater willingness to openly discuss sexual topics may contribute to their generally positive adaptation.

Other research suggests that African-American and Mexican-American women hold especially favorable views. In several studies, African-American women experienced less irritability and moodiness than Caucasian Americans (Melby, Lock, & Kaufert, 2005). They rarely spoke of menopause in terms of physical aging but, instead, regarded it as normal, inevitable, and even welcome (Sampsel et al., 2002, p. 359). Several African Americans expressed exasperation at society's readiness to label as "crazy" middle-aged women's authentic reactions to work- or family-based stressors that often coincide with menopause. Among Mexican-American women who have not yet adopted the language (and perhaps certain beliefs) of the larger society, attitudes toward menopause are especially positive (Bell, 1995). And in an investigation of more than 13,000 40- to 55-year-old U.S. women diverse in ethnicity, other factors—SES, physical health, lifestyle factors (smoking, diet, exercise, weight gain), and especially psychological stress—overshadowed menopausal status and three common symptoms (hot flashes, night sweats, and vaginal dryness) in impact on self-rated quality of life (Avis et al., 2004).

The wide variation in physical symptoms and attitudes indicates that menopause is not just a hormonal event; it is also affected by cultural beliefs and practices. The Cultural

Influences box on page 508 provides a cross-cultural look at women's experience of menopause.

Reproductive Changes in Men. Although men also experience a climacteric, no male counterpart to menopause exists. Both quantity and motility of sperm decrease from the twenties on, and quantity of semen diminishes after age 40, negatively affecting fertility in middle age (Sloter et al., 2006). Still, sperm production continues throughout life, and men in their nineties have fathered children. Testosterone production also declines with age, but the change is minimal in healthy men who continue to engage in sexual activity, which stimulates cells that release testosterone.

Nevertheless, because of reduced blood flow to and changes in connective tissue in the penis, more stimulation is required for an erection, and it may be harder to maintain. The inability to attain an erection when desired can occur at any age, but it becomes more common in midlife, affecting about 34 percent of U.S. men by age 60 (Shaer & Shaer, 2012).

An episode or two of impotence is not serious, but frequent bouts can lead some men to fear that their sex life is over and undermine their self-image. Viagra and other drugs that increase blood flow to the penis offer temporary relief from erectile dysfunction. Publicity surrounding these drugs has prompted open discussion of erectile dysfunction and encouraged more men to seek treatment (Berner et al., 2008). But those taking the medications are often not adequately screened for the host of factors besides declining testosterone that contribute to impotence, including disorders of the nervous, circulatory, and endocrine systems; anxiety and depression; pelvic injury; and loss of interest in one's sexual partner (Montorsi, 2005). Although drugs for impotence are generally safe, a few users have experienced serious vision loss (O'Malley, 2006). In men with high blood pressure or atherosclerosis, the medications heighten the risk of constricting blood vessels in the optic nerve, permanently damaging it.

ASK YOURSELF

REVIEW Describe cultural influences on the experience of menopause.

CONNECT Compare ethnic variations in attitudes toward menopause with ethnic variations in reactions to menarche and early pubertal timing (pages 368 and 370 in Chapter 11). Did you find similarities? Explain.

APPLY Between ages 40 and 50, Nancy gained 20 pounds. She also began to have trouble opening tightly closed jars, and her calf muscles ached after climbing a flight of stairs. "Exchanging muscle for fat must be an inevitable part of aging," Nancy thought. Is she correct? Why or why not?

REFLECT In view of the benefits and risks of hormone therapy, what factors would you consider, or advise others to consider, before taking such medication?

Cultural Influences

Menopause as a Biocultural Event

Biology and culture join forces to influence women's response to menopause, making it a *biocultural event*. In Western industrialized nations, menopause is "medicalized"—assumed to be a syndrome requiring treatment. Many women experience physical and emotional symptoms (Chrisler, 2008; Houck, 2006). The more symptoms they report, the more negative their attitude toward menopause tends to be.

Yet change the circumstances in which menopause is evaluated, and attitudes change as well. In one study, nearly 600 men and women between ages 19 and 85 described their view of menopause in one of three contexts—as a medical problem, as a life transition, or as a symbol of aging (Gannon & Ekstrom, 1993). The medical context evoked many more negative statements than the other contexts.

Research in non-Western cultures reveals that middle-aged women's social status also affects the experience of menopause. In societies where older women are respected and the mother-in-law and grandmother roles bring new privileges and responsibilities, complaints about menopausal symptoms are rare (Fuh et al., 2005). Perhaps in part for this reason, women in Asian nations report fewer discomforts (Shea, 2006). And their symptoms usually differ from those of Western women.

Though they rarely complain of hot flashes, the most frequent symptoms of Asian women are back, shoulder, and joint pain, a possible biological variation from other ethnic groups (Haines et al., 2005; Huang, 2010). In midlife, women in Asian cultures attain peak respect and responsi-

bility. Typically their days are filled with monitoring the household economy, attending to grandchildren, caring for dependent parents-in-law, and employment. Asian women seem to interpret menopausal distress in light of these socially valued commitments. In Japan, neither women nor their doctors consider menopause to be a significant marker of female middle age. Rather, midlife is viewed as an extended period of "socially recognized, productive maturity" (Menon, 2001, p. 58).

A comparison of rural Mayan women of the Yucatán with rural Greek women on the island of Evia reveals additional biocultural influences on the menopausal experience (Beyene, 1992; Beyene & Martin, 2001; Mahady et al., 2008). In both societies, old age is a time of increased status, and menopause brings release from child rearing and more time for leisure activities. Otherwise, Mayan and Greek women differ greatly.

Mayan women marry as teenagers. By 35 to 40, they have given birth to many children but rarely menstruated because of repeated pregnancies and breastfeeding. They also experience menopause up to 10 years earlier than their counterparts in developed nations, perhaps because of additional physical stressors, such as poor nutrition and heavy physical work. Eager for childbearing to end, they welcome menopause, describing it with such phrases as "being happy" and "free like a young girl again." None report hot flashes or any other symptoms.

© CHRIS HAIGH/ALAMY

For these rural Mayan women of the Yucatán, menopause brings freedom. After decades of childbearing, Mayan women welcome menopause, describing it as "being happy" and "free like a young girl again."

Like North Americans, rural Greek women use birth control to limit family size, and most report hot flashes and sweating at menopause. But they regard these as temporary discomforts that will stop on their own, not as medical symptoms requiring treatment. When asked what they do about hot flashes, the Greek women reply, "Pay no attention," "Go outside for fresh air," and "Throw off the covers at night."

Does frequency of childbearing affect menopausal symptoms, as this contrast between Mayan and Greek women suggests? More research is needed to be sure. At the same time, the difference between North American and Greek women in attitudes toward and management of hot flashes is striking (Melby, Lock, & Kaufert, 2005). This—along with other cross-cultural findings—highlights the combined impact of biology and culture on menopausal experiences.

Health and Fitness

In midlife, nearly 85 percent of Americans rate their health as either "excellent" or "good"—still a large majority, but lower than the 95 percent figure in early adulthood (U.S. Department of Health and Human Services, 2012c). Whereas younger

people usually attribute health complaints to temporary infections, middle-aged adults more often point to chronic diseases. As we will see, among those who rate their health unfavorably, men are more likely to suffer from fatal illnesses, women from nonfatal, limiting health problems.

In addition to typical negative indicators—major diseases and disabling conditions—our discussion takes up sexuality as

a positive indicator of health. Before we begin, it is important to note that our understanding of health in middle and late adulthood is limited by insufficient research on women and ethnic minorities. Most studies of illness risk factors, prevention, and treatment have been carried out on men. Fortunately, this situation is changing. For example, the Women's Health Initiative (WHI)—a commitment by the U.S. federal government, extending from 1993 to 2005, to study the impact of various lifestyle and medical prevention strategies on the health of nearly 162,000 postmenopausal women of all ethnic groups and SES levels—has led to important findings, including health risks associated with hormone therapy, discussed earlier. Two five-year extensions, involving annual health updates from 115,000 WHI participants in 2005–2010, and 94,000 participants in 2010–2015, continue to yield vital information.

Sexuality

Frequency of sexual activity among married couples tends to decline in middle adulthood, but for most, the drop is slight. In the National Social Life, Health, and Aging Project, a nationally representative sample of 3,000 U.S. middle-aged and older adults was surveyed about their sex lives. Even in the latter years of midlife (ages 57 to 64), the overwhelming majority of married and cohabiting adults were sexually active (90 percent of men and 80 percent of women) (Waite et al., 2009). About two-thirds reported having sex several times a month, one-third once or twice a week.

Longitudinal research reveals that stability of sexual activity is far more typical than dramatic change. Couples who have sex often in early adulthood continue to do so in midlife (Dennerstein & Leher, 2004; Walsh & Berman, 2004). And the best predictor of sexual frequency is marital happiness, an association that is probably bidirectional (DeLamater, 2012). Sex is more likely to occur in the context of a good marriage, and couples who have sex often probably view their relationship more positively.

Nevertheless, *intensity* of sexual response diminishes in midlife due to physical changes of the climacteric. Both men and women take longer to feel aroused and to reach orgasm (Bartlik & Goldstein, 2001; Walsh & Berman, 2004). If partners perceive each other as less attractive, this may contribute to a drop in sexual desire. Yet in the context of a positive outlook, sexual activity can become more satisfying. Devin and Trisha, for example, viewed each other's aging bodies with acceptance and affection—as a sign of their enduring and deepening relationship. And with greater freedom from the demands of work and family, their sex life became more spontaneous. The majority of married people over age 50 say that their sex life is an important component of their relationship (Waite et al., 2009). And most find ways to overcome difficulties with sexual functioning. One happily married 52-year-old woman commented, “We know what we are doing, we've had plenty of practice (laughs), and I would never have believed that it gets better as you get older, but it does” (Gott & Hinchliff, 2003, p. 1625; Kingsberg, 2002).

When surveys include both married and unmarried people, a striking gender difference in age-related sexual activity appears. The proportion of U.S. men with no sexual partners in the previous year increases only slightly, from 8 percent in the thirties to 12 percent in the late fifties. In contrast, the rise for women is dramatic, from 9 percent to 40 percent—a gender gap that becomes even greater in late adulthood (Laumann & Mahay, 2002; Lindau et al., 2007; Waite et al., 2009). A higher male mortality rate and the value women place on affection and continuity in sexual relations make partners less available to them. Taken as a whole, the evidence reveals that sexual activity in midlife, as in earlier periods, is the combined result of biological, psychological, and social forces.

Illness and Disability

As Figure 15.2 shows, cancer and cardiovascular disease are the leading causes of U.S. deaths in middle age. Unintentional injuries, though still a major health threat, occur at a lower rate than in early adulthood, largely because motor vehicle collisions decline. Despite a rise in vision problems, older adults' many years of driving experience and greater cautiousness may reduce these deaths. In contrast, falls resulting in bone fractures and death nearly double from early to middle adulthood (U.S. Census Bureau, 2012).

As in earlier decades, economic disadvantage is a strong predictor of poor health and premature death, with SES differences widening in midlife (Smith & Infurna, 2011). And largely because of more severe poverty and lack of universal health insurance, the United States continues to exceed most other industrialized nations in death rates from major causes (OECD, 2012). Furthermore, men are more vulnerable than women to most health problems. Among middle-aged men, cancer deaths exceed cardiovascular disease deaths by a small margin; among

FIGURE 15.2 Leading causes of death among people age 45 to 64 in the United States. Men are more vulnerable than women to each leading cause of death. Cancer is the leading killer of both sexes, by a far smaller margin over cardiovascular disease for men than for women. (Adapted from U.S. Census Bureau, 2012.)

FIGURE 15.3 Incidence of 10 leading cancer types among men and women in the United States, 2012.

(From R. Siegel, D. Naishadham, & A. Jemal, 2012, "Cancer Statistics, 2012," *CA: A Cancer Journal for Clinicians*, 62, p. 13. Copyright © 2012 American Cancer Society, Inc. Reproduced with permission of Wiley Inc.)

women, cancer is by far the leading cause of death (refer again to Figure 15.2). Finally, as we take a closer look at illness and disability in the following sections, we will encounter yet another familiar theme: the close connection between psychological and physical well-being. Personality traits that magnify stress—especially hostility and anger—are serious threats to health in midlife.

Cancer. From early to middle adulthood, the death rate due to cancer multiplies tenfold, accounting for about one-third of all midlife deaths in the United States. Although the incidence of many types of cancer is currently leveling off or declining, cancer mortality was on the rise for many decades, largely because of a dramatic increase in lung cancer due to cigarette smoking. Lung cancer is the most common cause of cancer deaths in both genders, worldwide. In the past two decades, its incidence dropped in men; 50 percent fewer smoke today than in the 1950s. In contrast, lung cancer has just begun to decrease in women after a long period of increase, due to large numbers of women taking up smoking in the decades after World War II (American Cancer Society, 2012).

Cancer occurs when a cell's genetic program is disrupted, leading to uncontrolled growth and spread of abnormal cells that crowd out normal tissues and organs. Why does this happen? Mutations of three main kinds contribute to cancer. Some result in *oncogenes* (cancer genes) that directly undergo abnormal cell duplication. Others interfere with the activity of *tumor suppressor genes* so they fail to keep oncogenes from multiplying. And a third type of mutation disrupts the activity of *stability genes*, which normally keep genetic alterations to a minimum by repairing subtle DNA mistakes that occur either during normal cell duplication or as a result of environmental agents (Ewald & Ewald, 2012). When stability genes do not function, mutations in many other genes occur at a higher rate.

Each of these cancer-linked mutations can be either *germline* (due to an inherited predisposition) or *somatic* (occurring in a single cell, which then multiplies) (see page 52 in Chapter 2

to review). Recall from Chapter 13 that according to one theory, error in DNA duplication increases with age, either occurring spontaneously or resulting from the release of free radicals or breakdown of the immune system. Environmental toxins may initiate or intensify this process.

Figure 15.3 shows the incidence of the most common types of cancer. For cancers that affect both sexes, men are generally more vulnerable than women. The difference may be due to genetic makeup, exposure to cancer-causing agents as a result of lifestyle or occupation, and men's greater tendency to delay going to the doctor. Although the relationship of SES to cancer varies with site (for example, lung and stomach cancers are linked to lower SES, breast and prostate cancers to higher SES), cancer death rates increase sharply as SES decreases and are especially high among low-income ethnic minorities (Clegg et al., 2009). Poorer medical care and reduced ability to fight the disease, due to inadequate diet and high life stress, underlie this trend.

Overall, a complex interaction of heredity, biological aging, and environment contributes to cancer. For example, many patients with familial breast cancer who respond poorly to treatment have defective forms of particular tumor-suppressor genes (either BRCA1 or BRCA2). Women with these mutations are especially likely to develop early-onset breast cancer, before age 30 (Ripperger et al., 2009). But their risk remains elevated throughout middle and late adulthood, when breast cancer rises among women in general. Genetic screening is available, permitting prevention efforts to begin early. Nevertheless, breast cancer susceptibility genes account for only 5 to 10 percent of all cases; most women with breast cancer do not have a family history (American Cancer Society, 2012). Other genes and lifestyle factors—including alcohol consumption, overweight, physical inactivity, never having had children, use of oral contraceptives, and hormone therapy to treat menopausal symptoms—heighten their risk.

People often fear cancer because they believe it is incurable. Yet nearly 60 percent of affected individuals are cured—free of the disease for five years or longer. Survival rates, however, vary

Applying What We Know

Reducing Cancer Incidence and Deaths

Intervention	Description
Know the seven warning signs of cancer.	The signs are change in bowel or bladder habits, sore that does not heal, unusual bleeding or discharge, thickening or lump in a breast or elsewhere in your body, indigestion or swallowing difficulty, obvious change in a wart or mole, nagging cough or hoarseness. If you have any of these signs, consult your doctor immediately.
Schedule regular medical checkups and cancer-screening tests.	Women should have a mammogram and Pap test every one to two years. Beginning at age 50, men should have an annual prostate screening test. Both men and women should be screened periodically for colon cancer, as recommended by their doctor.
Avoid tobacco.	Cigarette smoking causes 90 percent of lung cancer deaths and 30 percent of all cancer deaths. Smokeless (chewing) tobacco increases risk of cancers of the mouth, larynx, throat, and esophagus.
Limit alcohol consumption.	Consuming more than one drink per day for women or two drinks per day for men increases risk of cancers of the breast, kidney, liver, head, and neck.
Avoid excessive sun exposure.	Sun exposure causes many cases of skin cancer. When in the sun for an extended time, wear sunglasses, use sunscreen that protects against both UVA and UVB rays, and cover exposed skin.
Avoid unnecessary X-ray exposure.	Excessive exposure to X-rays increases risk of many cancers. Most medical X-rays are adjusted to deliver the lowest possible dose but should not be used unnecessarily.
Avoid exposure to industrial chemicals and other pollutants.	Exposure to nickel, chromate, asbestos, vinyl chloride, radon, and other pollutants increases risk of various cancers.
Weigh the benefits versus risks of hormone therapy.	Because estrogen replacement increases risk of uterine and breast cancers, carefully consider hormone therapy with your doctor.
Maintain a healthy diet.	Eating vegetables, fruits, and whole grains, while avoiding excess dietary fat and salt-cured, smoked, and nitrite-cured foods, reduces risk of colon and rectal cancers.
Avoid excessive weight gain.	Overweight and obesity increase risk of cancers of the breast, colon, esophagus, uterus, and kidney.
Adopt a physically active lifestyle.	Physical activity offers protection against cancers at all body sites except the skin, with the strongest evidence for cancers of the breast, rectum, and colon.

Source: American Cancer Society, 2012.

widely with type of cancer (Siegel, Naishadham, & Jemal, 2012). For example, they are relatively high for breast and prostate cancers, intermediate for cervical and colon cancers, and low for lung and pancreatic cancers.

Breast cancer is the leading malignancy for women, prostate cancer for men. Lung cancer ranks second for both sexes; it causes more deaths (largely preventable through avoiding tobacco) than any other cancer type. It is followed closely in incidence by colon and rectal cancer. Scheduling annual medical checkups that screen for these and other forms of cancer and taking the additional steps listed in Applying What We Know above can reduce cancer illness and death rates considerably. An increasing number of cancer-promoting mutations are being identified, and promising new therapies targeting these genes are being tested.

Surviving cancer is a triumph, but it also brings emotional challenges. During cancer treatment, relationships focus on the illness. Afterward, they must refocus on health and full participation in daily life. Unfortunately, stigmas associated with

cancer exist (Daher, 2012). Friends, family, and co-workers may need reminders that cancer is not contagious and that with patience and support from supervisors and co-workers, cancer survivors regain their on-the-job productivity.

Cardiovascular Disease. Despite a decline over the last few decades (see Chapter 13), each year about 25 percent of middle-aged Americans who die succumb to cardiovascular disease (U.S. Department of Health and Human Services, 2012c). We associate cardiovascular disease with heart attacks, but Devin, like many middle-aged and older adults, learned of the condition during an annual checkup. His doctor detected high blood pressure, high blood cholesterol, and *atherosclerosis*—a buildup of plaque in his coronary arteries, which encircle the heart and provide its muscles with oxygen and nutrients. These indicators of cardiovascular disease are known as “silent killers” because they often have no symptoms.

When symptoms *are* evident, they take different forms. The most extreme is a *heart attack*—blockage of normal blood

Applying What We Know

Reducing the Risk of Heart Attack

Intervention	Risk Reduction
Quit smoking.	Five years after quitting, greatly reduces risk compared to current smokers. Chemicals in tobacco smoke damage the heart and blood vessels and greatly increase the risk of atherosclerosis.
Reduce blood cholesterol level.	Reductions in cholesterol average 10 percent with transition to a healthy diet.
Treat high blood pressure.	Places added force against the artery walls, which can damage the arteries over time. Combination of healthy diet and drug therapy can lower blood pressure substantially.
Maintain ideal weight.	Greatly reduced risk for people who maintain ideal body weight compared to those who are obese.
Exercise regularly.	Greatly reduced risk for people who maintain an active rather than a sedentary lifestyle. In addition to contributing to healthy weight, lowers cholesterol and blood pressure and helps prevent type 2 diabetes, which is strongly linked to heart disease.
Drink an occasional glass of wine or beer. ^a	Modestly reduced risk for people who consume small-to-moderate amounts of alcohol. Believed to promote high-density lipoproteins (a form of “good cholesterol” that lowers “bad cholesterol”) and to prevent clot formation.
If medically recommended, take low-dose aspirin.	Modestly reduced risk for people with a previous heart attack or stroke, by lowering the likelihood of blood clots (should be doctor advised; long-term use can have serious side effects).
Reduce hostility and other forms of psychological stress.	People under stress are more likely to engage in high-risk behaviors, such as overeating and smoking, and to display high-risk symptoms, such as high blood pressure.

^aRecall from Chapter 13 that heavy alcohol use increases the risk of cardiovascular disease as well as many other diseases.

Source: Go et al., 2013.

supply to an area of the heart, usually brought on by a blood clot in one or more plaque-filled coronary arteries. Intense pain results as muscle in the affected region dies. A heart attack is a medical emergency; over 50 percent of victims die before reaching the hospital, another 15 percent during treatment, and an additional 15 percent over the next few years (Go et al., 2013). Among other, less extreme symptoms of cardiovascular disease are *arrhythmia*, or irregular heartbeat. When it persists, it can prevent the heart from pumping enough blood and result in faintness. It can also allow clots to form within the heart’s chambers, which may break loose and travel to the brain. In some individuals, indigestion-like pain or crushing chest pain, called *angina pectoris*, reveals an oxygen-deprived heart.

Today, cardiovascular disease can be treated in many ways—including coronary bypass surgery, medication, and pacemakers to regulate heart rhythm. To relieve arterial blockage, Devin had *angioplasty*, a procedure in which a surgeon threaded a needle-thin catheter into his arteries and inflated a balloon at its tip, which flattened fatty deposits to allow blood to flow more freely. Unless Devin took other measures to reduce his risk, his doctor warned, the arteries would clog again within a year. As Applying What We Know above indicates, adults can do much to prevent heart disease or slow its progress.

Some risks, such as heredity, advanced age, and being male, cannot be changed. But cardiovascular disease is so disabling and deadly that people must be alert for it where they least expect it—for example, in women. Because men account for

over 70 percent of cases in middle adulthood, doctors often view a heart condition as a “male problem” and frequently overlook women’s symptoms, which tend to be milder, more often taking the form of angina than a heart attack (Go et al., 2013). In follow-ups of victims of heart attacks, women—especially African-American women, who are at increased risk—were less likely to be offered drugs to treat blood clots and costly, invasive therapies, such as angioplasty and bypass surgery (Lawton, 2011; Mosca, Conner, & Wenger, 2012; Poon et al., 2012). As a result, treatment outcomes—including rehospitalization and death—tend to be worse for women, particularly black women.

Osteoporosis. When age-related bone loss is severe, a condition called **osteoporosis** develops. The disorder, affecting about 10 million U.S. adults, 80 percent of whom are women, greatly magnifies the risk of bone fractures. An estimated 55 percent of people over age 50 are at risk for osteoporosis because they have bone density levels low enough to be of concern, and 12 percent have been diagnosed with it (American Academy of Orthopaedic Surgeons, 2009). After age 70, osteoporosis affects the majority of people of both sexes. Although we associate it with a slumped-over posture, a shuffling gait, and a “dowager’s hump” in the upper back, this extreme is rare. Because the bones gradually become more porous over many years, osteoporosis may not be evident until fractures—typically in the spine, hips, and wrist—occur or are discovered through X-rays.

© JEFF GREENBERG/PHOTOEDIT

Physical inactivity increases the chances of osteoporosis. More than half of people over age 50, mostly women, are at risk. Weight-bearing exercise and strength training are recommended for both prevention and treatment.

A major factor related to osteoporosis is the decline in estrogen associated with menopause. In middle and late adulthood, women lose about 50 percent of their bone mass, about half of it in the first 10 years following menopause—a decline that, by the late sixties, is two to five times greater than in men (Bonnick, 2008). The earlier a woman reaches menopause, the greater her chances of developing osteoporosis related to estrogen loss. In men, the age-related decrease in testosterone—though much more gradual than estrogen loss in women—contributes to bone loss because the body converts some to estrogen.

Heredity plays an important role. A family history of osteoporosis increases risk, with identical twins more likely than fraternal twins to share the disorder (Ralston & Uitterlinden, 2010). People with thin, small-framed bodies are more likely to be affected because they typically attain a lower peak bone mass in adolescence. In contrast, higher bone density makes African Americans less susceptible than Asian Americans, Caucasians, Hispanics, and Native Americans (Cauley, 2011). An unhealthy lifestyle also contributes: A diet deficient in calcium and vitamin D (essential for calcium absorption), excess intake of sodium and caffeine, and physical inactivity reduce bone mass. Cigarette smoking and alcohol consumption are also harmful because they interfere with replacement of bone cells (Body et al., 2011; Langsetmo et al., 2012).

When major bone fractures (such as the hip) occur, 10 to 20 percent of patients die within a year (Marks, 2010). Osteoporosis usually develops earlier in women than in men, so it has become known as a “women’s disease.” Men are far less likely to be screened and treated for it, even after a hip fracture. Compared with women, men with hip fractures tend to be older and to lack a history of interventions aimed at preserving bone density. Probably for these reasons, the one-year mortality rate after hip fracture is nearly twice as great for men as for women—a gap that widens with age (Haentjens et al., 2010).

To treat osteoporosis, doctors recommend a diet enriched with calcium and vitamin D, weight-bearing exercise (walking rather than swimming), resistance training, and bone-strengthening medications (American Academy of Orthopaedic Surgeons, 2009). A better way to reduce lifelong risk is through early prevention: maximizing peak bone density by increasing calcium and vitamin D intake and engaging in regular exercise in childhood, adolescence, and early adulthood.

Hostility and Anger

Whenever Trisha’s sister Dottie called, she seemed like a powder keg ready to explode. Dottie was critical of her boss at work and dissatisfied with the way Trisha, a lawyer, had handled the family’s affairs after their father died. Inevitably, Dottie’s anger surfaced, exploding in hurtful remarks: “Any lawyer knows that, Trisha. How could you be so stupid! I should have called a *real* lawyer.” “You and Devin are so stuck in your privileged lives that you can’t think of anyone else. You don’t know what work *is*.”

After listening as long as she could bear, Trisha would warn, “Dottie, if you continue, I’m going to hang up. . . . Dottie, I’m ending this right now!”

At age 53, Dottie had high blood pressure, difficulty sleeping, and back pain. In the past five years, she had been hospitalized five times—twice for treatment of digestive problems, twice for an irregular heartbeat, and once for a benign tumor on her thyroid gland. Trisha often wondered whether Dottie’s personal style was partly responsible for her health problems.

That hostility and anger might have negative effects on health is a centuries-old idea. Several decades ago, researchers first tested this notion by identifying 35- to 59-year-old men who displayed the **Type A behavior pattern**—extreme competitiveness, ambition, impatience, hostility, angry outbursts, and a sense of time pressure. They found that within the next eight years, Type As were more than twice as likely as Type Bs (people with a more relaxed disposition) to develop heart disease (Rosenman et al., 1975).

Later studies, however, often failed to confirm these results. Type A is actually a mix of behaviors, only one or two of which affect health. Current evidence pinpoints hostility as a “toxic” ingredient of Type A, since isolating it from global Type A consistently predicts heart disease and other health problems in both men and women (Aldwin et al., 2001; Eaker et al., 2004; Matthews et al., 2004; Smith et al., 2004). The risks of high blood pressure, atherosclerosis, and stroke are several times greater in adults scoring high on hostility measures than in those scoring low (Räikkönen et al., 2004; Williams et al., 2002; Yan et al., 2003).

Expressed hostility in particular—frequent angry outbursts; rude, disagreeable behavior; critical and condescending nonverbal cues during social interaction, including glares; and expressions of contempt and disgust—predicts greater cardiovascular arousal, coronary artery plaque buildup, and heart disease (Haukkala et al., 2010; Julkunen & Ahlström, 2006; Smith & Cundiff, 2011; Smith et al., 2012). As people get angry, heart

rate, blood pressure, and stress hormones escalate until the body's response is extreme.

Of course, people who are repeatedly enraged are more likely to be depressed and dissatisfied with their lives, to lack social supports, and to engage in unhealthy behaviors. But hostility predicts health problems even after such factors as smoking, alcohol consumption, overweight, general unhappiness, and negative life events are controlled (Smith & Mackenzie, 2006).

Another unhealthy feature of the Type A pattern, which also predicts heart disease, is a socially dominant style, evident in rapid, loud, insistent speech and a tendency to cut off and talk over others (Smith, 2006; Smith, Gallo, & Ruiz, 2003). And because men score higher in hostility and dominance than women (Dottie is an exception), emotional style may contribute to the sex differences in heart disease described earlier.

Can Dottie preserve her health by bottling up her hostility instead of expressing it? Repeatedly suppressing overt anger or ruminating about past anger-provoking events is also associated with high blood pressure and heart disease (Eaker et al., 2007; Hogan & Linden, 2004). A better alternative, as we will see, is to develop effective ways of handling stress and conflict.

Adapting to the Physical Challenges of Midlife

Middle adulthood is often a productive time of life, when people attain their greatest accomplishments and satisfactions. Nevertheless, it takes considerable stamina to cope with the full array of changes this period can bring. Devin responded to his expanding waistline and cardiovascular symptoms by leaving his desk twice a week to attend a low-impact aerobics class and by reducing job-related stress through daily 10-minute meditation sessions. Aware of her sister Dottie's difficulties, Trisha resolved to handle her own hostile feelings more adaptively. And her generally optimistic outlook enabled her to cope successfully with the physical changes of midlife, the pressures of her legal career, and Devin's cardiovascular disease.

Stress Management

TAKE A MOMENT... Turn back to Chapter 13, pages 449–450, and review the negative consequences of psychological stress on the cardiovascular, immune, and gastrointestinal systems. As adults encounter problems at home and at work, daily hassles can add up to a serious stress load. Stress management is important at any age, but in middle adulthood it can limit the age-related rise in illness and, when disease strikes, reduce its severity.

Applying What We Know on the following page summarizes effective ways to reduce stress. Even when stressors cannot be eliminated, people can change how they handle some and view others. At work, Trisha focused on problems she could control—not on her boss's irritability but on ways to delegate routine tasks to her staff so she could focus on challenges that required her knowledge and skills. When Dottie phoned, Trisha

learned to distinguish normal emotional reactions from unreasonable self-blame. Instead of interpreting Dottie's anger as a sign of her own incompetence, she reminded herself of Dottie's difficult temperament and hard life. And greater life experience helped her accept change as inevitable, so that she was better-equipped to deal with the jolt of sudden events, such as Devin's hospitalization for treatment of heart disease.

Notice how Trisha called on two general strategies for coping with stress, discussed in Chapter 10: (1) *problem-centered coping*, in which she appraised the situation as changeable, identified the difficulty, and decided what to do about it; and (2) *emotion-centered coping*, which is internal, private, and aimed at controlling distress when little can be done about a situation. Longitudinal research shows that adults who effectively reduce stress move flexibly between problem-centered and emotion-centered techniques, depending on the situation (Zakowski et al., 2001). Their approach is deliberate, thoughtful, and respectful of both themselves and others.

Notice, also, that problem-focused and emotion-focused coping, though they have different immediate goals, facilitate each other. Effective problem-focused coping reduces emotional distress, while effective emotion-focused coping helps people face problems more calmly and, thus, generate better solutions. Ineffective coping, in contrast, is largely emotion-centered and self-blaming, impulsive, or escapist.

Constructive approaches to anger reduction are a vital health intervention (refer again to Applying What We Know). Teaching people to be assertive rather than hostile and to

© JOHNER IMAGES/ALAMY

Stress management in middle adulthood helps limit the age-related rise in illness. This midlifer reduces stress by periodically leaving her high-pressure office environment to work in a tranquil, picturesque setting.

Applying What We Know

Managing Stress

Strategy	Description
Reevaluate the situation.	Learn to differentiate normal reactions from those based on irrational beliefs.
Focus on events you can control.	Don't worry about things you cannot change or that may never happen; focus on strategies for handling events under your control.
View life as fluid.	Expect change and accept it as inevitable; then many unanticipated changes will have less emotional impact.
Consider alternatives.	Don't rush into action; think before you act.
Set reasonable goals for yourself.	Aim high, but be realistic about your capacities, motivation, and the situation.
Exercise regularly.	A physically fit person can better handle stress, both physically and emotionally.
Master relaxation techniques.	Relaxation helps refocus energies and reduce the physical discomfort of stress. Classes and self-help books teach these techniques.
Use constructive approaches to anger reduction.	Delay responding ("Let me check into that and get back to you"); use mentally distracting behaviors (counting to 10 backwards) and self-instruction (a covert "Stop!") to control anger arousal; then engage in calm, self-controlled problem solving ("I should call him rather than confront him personally").
Seek social support.	Friends, family members, co-workers, and organized support groups can offer information, assistance, and suggestions for coping with stressful situations.

negotiate rather than explode interrupts the intense physiological response that intervenes between psychological stress and illness. Sometimes it is best to delay responding by simply leaving a provocative situation, as Trisha did when she told Dottie that she would hang up after one more insult.

As noted in Chapter 13, people tend to cope with stress more effectively as they move from early to middle adulthood. They may become more realistic about their ability to change situations and more skilled at anticipating stressful events and at preparing to manage them (Aldwin, Yancura, & Boeninger, 2010). Furthermore, when middle-aged adults surmount a highly stressful experience, they often report lasting personal benefits as they look back with amazement at what they were able to accomplish under extremely trying conditions. A serious illness and brush with death commonly brings changes in values and perspectives, such as clearer life priorities, a greater sense of personal strength, and closer ties to others. Interpreting trauma as growth-promoting is related to more effective coping with current stressors and with increased physical and mental health years later (Aldwin & Yancura, 2011; Carver, 2011). In this way, managing intense stress can serve as a context for positive development.

But for people who do have difficulty handling midlife's challenges, communities provide fewer social supports than for young adults or senior citizens. For example, Jewel had little knowledge of what to expect during the climacteric. "It would have helped to have a support group so I could have learned about menopause and dealt with it more easily," she told Trisha. Community programs addressing typical midlife concerns,

such as those of adult learners returning to college and caregivers of elderly parents, can reduce stress during this period.

LOOK AND LISTEN

Interview a middle-aged adult who has overcome a highly stressful experience, such as a serious illness, about how he or she coped. Inquire about any resulting changes in outlook on life. Do the adult's responses fit with research findings? ●

Exercise

Regular exercise, as noted in Chapter 13, has a range of physical and psychological benefits—among them, equipping adults to handle stress more effectively and reducing the risk of many diseases. Heading for his first aerobics class, Devin wondered, Can starting to exercise at age 50 counteract years of physical inactivity? His question is important: Nearly 70 percent of U.S. middle-aged adults are sedentary, and half of those who begin an exercise program discontinue it within the first six months. Even among those who stay active, fewer than 20 percent exercise at levels that lead to health benefits (U.S. Department of Health and Human Services, 2011c).

A person beginning to exercise in midlife must overcome initial barriers and ongoing obstacles—lack of time and energy, inconvenience, work conflicts, and health factors (such as overweight). *Self-efficacy*—belief in one's ability to succeed—is just as vital in adopting, maintaining, and exerting oneself in an exercise regimen as it is in career progress (see Chapter 14). An

In cities across the United States, barriers to physical activity are being overcome through the creation of attractive, safe parks and trails. But low-SES adults need greater access to convenient, pleasant exercise environments.

important outcome of starting an exercise program is that sedentary adults gain in self-efficacy, which further promotes physical activity (McAuley & Elavsky, 2008; Wilbur et al., 2005). Enhanced physical fitness, in turn, prompts middle-aged adults to feel better about their physical selves. Over time, their physical self-esteem—sense of body conditioning and attractiveness—rises (Elavsky & McAuley, 2007; Gothe et al., 2011).

The exercise format that works best depends on the beginning exerciser's characteristics. Normal-weight adults are more likely to stick with group classes than are overweight adults, who may feel embarrassed and struggle to keep up with the pace. Overweight people do better with an individualized, home-based routine planned by a consultant (King, 2001). However, adults with highly stressful lives are more likely to persist in group classes, which offer a regular schedule and the face-to-face support of others (King et al., 1997). Yet when stressed people do manage to sustain a home-based program, it substantially reduces stress—more so than the group format (King, Taylor, & Haskell, 1993). Perhaps succeeding on their own helps stressed adults gain better control over their lives. A small digital monitor that tracks physical activity and gives feedback motivates inactive middle-aged adults to increase their activity levels (King et al., 2008). And most say they enjoy using the device.

Accessible, attractive, and safe exercise environments—parks, walking and biking trails, and community recreation centers—and frequent opportunities to observe others using them also promote physical activity. Besides health problems

and daily stressors, low-SES adults often mention inconvenient access to facilities, expense, unsafe neighborhoods, and unclean streets as barriers to exercise—important reasons that activity level declines sharply with SES (Taylor et al., 2007; Wilbur et al., 2003). Interventions aimed at increasing physical activity among low-SES adults must address these issues in addition to lifestyle and motivational factors.

An Optimistic Outlook

What type of individual is likely to cope adaptively with stress brought on by the inevitable changes of life? Researchers interested in this question have identified a set of three personal qualities—control, commitment, and challenge—that, together, they call **hardiness** (Maddi, 2005, 2007, 2011).

Trisha fit the pattern of a hardy individual. First, she regarded most experiences as *controllable*. “You can’t stop all bad things from happening,” she advised Jewel after hearing about her menopausal symptoms, “but you can try to do something about them.” Second, Trisha displayed a *committed*, involved approach to daily activities, finding interest and meaning in almost all of them. Finally, she viewed change as a *challenge*—a normal, welcome, even exciting part of life.

Hardiness influences the extent to which people appraise stressful situations as manageable, interesting, and enjoyable. These optimistic appraisals, in turn, predict health-promoting behaviors, tendency to seek social support, reduced physiological arousal to stress, and fewer physical and emotional symptoms (Maddi, 2006; Maruta et al., 2002; Rääkkönen et al., 1999; Smith, Young, & Lee, 2004). Furthermore, high-hardy individuals are likely to use active, problem-centered coping strategies in situations they can control. In contrast, low-hardy people more often use emotion-centered and avoidant coping strategies—for example, saying, “I wish I could change how I feel,” denying that the stressful event occurred, or eating and drinking to forget about it (Maddi, 2007; Soderstrom et al., 2000).

In this and previous chapters, we have seen that many factors act as stress-resistant resources—among them heredity, diet, exercise, social support, and coping strategies. Research on hardiness adds yet another ingredient: a generally optimistic outlook and zest for life.

Gender and Aging: A Double Standard

Negative stereotypes of aging, which lead many middle-aged adults to fear physical changes, are more likely to be applied to women than to men, yielding a double standard (Antonucci, Blieszner, & Denmark, 2010). Though many women in midlife say they have “hit their stride”—feel assertive, confident, versatile, and capable of resolving life’s problems—people often rate them as less attractive and as having more negative personality characteristics than middle-aged men (Canetto, Kaminski, & Felicio, 1995; Denmark & Klara, 2007; Kite et al., 2005).

These effects appear more often when people rate photos as opposed to verbal descriptions of men and women. The ideal of a sexually attractive woman—smooth skin, good muscle tone,

lustrous hair—may be at the heart of the double standard of aging. Some evidence suggests that the end of a woman's ability to bear children contributes to negative judgments of physical appearance, especially by men (Marcus-Newhall, Thompson, & Thomas, 2001). Yet societal forces exaggerate this view. For example, middle-aged people in media ads are usually male executives, fathers, and grandfathers—handsome images of competence and security. And many more cosmetic products designed to hide signs of aging are offered for women than for men.

At one time in our evolutionary history, this double standard may have been adaptive. Today, as many couples limit childbearing and devote more time to career and leisure pursuits, it has become irrelevant. Some recent surveys suggest that the double standard is declining—that more people are viewing middle age as a potentially upbeat, satisfying time for both genders, sometimes even more so for women than for men (Menon, 2001; Narayan, 2008). Models of older women with lives full of intimacy, accomplishment, hope, and imagination are promoting acceptance of physical aging and a new vision of growing older—one that emphasizes gracefulness, fulfillment, and inner strength.

ASK YOURSELF

REVIEW Cite evidence that biological aging, individual heredity, and environmental factors contribute to osteoporosis.

CONNECT According to the lifespan perspective, development is multidimensional—affected by biological, psychological, and social forces. Provide examples of how this assumption characterizes health at midlife.

APPLY During a routine physical exam, Dr. Furrow gave 55-year-old Bill a battery of tests for cardiovascular disease but did not assess his bone density. In contrast, when 60-year-old Cara complained of chest pains, Dr. Furrow opted to “wait and see” before initiating further testing. What might account for Dr. Furrow's different approaches to Cara and Bill?

REFLECT Which midlife health problem is of greatest personal concern to you? What steps can you take now to help prevent it?

COGNITIVE DEVELOPMENT

In middle adulthood, the cognitive demands of everyday life extend to new and sometimes more challenging situations. Consider a typical day in the lives of Devin and Trisha. Recently appointed dean of faculty at a small college, Devin was at his desk by 7:00 A.M. In between strategic-planning meetings, he reviewed files of applicants for new positions, worked on the coming year's budget, and spoke at an alumni luncheon. Meanwhile, Trisha prepared for a civil trial, participated in jury selection, and then joined the other top lawyers at her firm for

a conference about management issues. That evening, Trisha and Devin advised their 20-year-old son, Mark, who had dropped by to discuss his uncertainty over whether to change his college major. By 7:30 P.M., Trisha was off to an evening meeting of the local school board. And Devin left for a biweekly gathering of an amateur quartet in which he played the cello.

Middle adulthood is a time of expanding responsibilities—on the job, in the community, and at home. To juggle diverse roles effectively, Devin and Trisha called on a wide array of intellectual abilities, including accumulated knowledge, verbal fluency, memory, rapid analysis of information, reasoning, problem solving, and expertise in their areas of specialization. What changes in thinking take place in middle adulthood? How does vocational life—a major arena in which cognition is expressed—influence intellectual skills? And what can be done to support the rising tide of adults who are returning to higher education in hopes of enhancing their knowledge and quality of life?

Changes in Mental Abilities

At age 50, when he occasionally couldn't recall a name or had to pause in the middle of a lecture or speech to think about what to say next, Devin wondered, Are these signs of an aging mind? Twenty years earlier, he had taken little notice of the same events. His questioning stems from widely held stereotypes of older adults as forgetful and confused. Most cognitive aging research has focused on deficits while neglecting cognitive stability and gains.

As we examine changes in thinking in middle adulthood, we will revisit the theme of diversity in development. Different aspects of cognitive functioning show different patterns of change. Although declines occur in some areas, most people display cognitive competence, especially in familiar contexts, and some attain outstanding accomplishment. As we will see, certain apparent decrements in cognitive aging result from weaknesses in the research itself! Overall, the evidence supports an optimistic view of adult cognitive potential.

The research we are about to consider illustrates core assumptions of the lifespan perspective: development as *multidimensional*, or the combined result of biological, psychological, and social forces; development as *multidirectional*, or the joint expression of growth and decline, with the precise mix varying across abilities and individuals; and development as *plastic*, or open to change, depending on how a person's biological and environmental history combines with current life conditions. You may find it helpful to return to pages 9–10 in Chapter 1 to review these ideas.

Cohort Effects

Research using intelligence tests sheds light on the widely held belief that intelligence inevitably declines in middle and late adulthood as the brain deteriorates. Many early cross-sectional

FIGURE 15.4 Cross-sectional and longitudinal trends in verbal ability, illustrating cohort effects. The steep cross-sectional decline is largely due to better health and education in younger generations. When adults are followed longitudinally, their verbal scores rise during early and middle adulthood and gradually decline during later years. However, this longitudinal trend does not hold for all abilities. (From K. W. Schaie, 1988, “Variability in Cognitive Functioning in the Elderly,” in M. A. Bender, R. C. Leonard, & A. D. Woodhead [Eds.], *Phenotypic Variation in Populations*, p. 201. Adapted with kind permission from Springer Science+Business Media B. V. and K. W. Schaie.)

studies showed this pattern—a peak in performance at age 35 followed by a steep drop into old age. But widespread testing of college students and soldiers in the 1920s provided a convenient opportunity to conduct longitudinal research, retesting participants in middle adulthood. These findings revealed an age-related increase! To explain this contradiction, K. Warner Schaie (1998, 2005) used a sequential design, combining longitudinal and cross-sectional approaches (see page 38 in Chapter 1) in the Seattle Longitudinal Study.

In 1956, people ranging in age from 22 to 70 were tested cross-sectionally. Then, at regular intervals, longitudinal follow-ups were conducted and new samples added, yielding a total of 5,000 participants, five cross-sectional comparisons, and longitudinal data spanning more than 60 years. Findings on five mental abilities showed the typical cross-sectional drop after the mid-thirties. But longitudinal trends for those abilities revealed modest gains in midlife, sustained into the fifties and the early sixties, after which performance decreased gradually.

Figure 15.4 illustrates Schaie’s cross-sectional and longitudinal outcomes for just one intellectual factor: verbal ability. How can we explain the seeming contradiction in findings? *Cohort effects* are largely responsible for this difference. In cross-sectional research, each new generation experienced better health and education than the one before it (Schaie, 2011). Also, the tests given may tap abilities less often used by older individuals, whose lives no longer require that they learn information for its own sake but, instead, skillfully solve real-world problems.

Crystallized and Fluid Intelligence

A close look at diverse mental abilities shows that only certain ones follow the longitudinal pattern identified in Figure 15.4. To appreciate this variation, let’s consider two broad mental abilities, each of which includes an array of specific intellectual factors.

The first of these broad abilities, **crystallized intelligence**, refers to skills that depend on accumulated knowledge and experience, good judgment, and mastery of social conventions—abilities acquired because they are valued by the individual’s culture. Devin made use of crystallized intelligence when he expressed himself articulately at the alumni luncheon and suggested effective ways to save money in budget planning. On intelligence tests, vocabulary, general information, verbal comprehension, and logical reasoning items measure crystallized intelligence.

In contrast, **fluid intelligence** depends more heavily on basic information-processing skills—ability to detect relationships among visual stimuli, speed of analyzing information, and capacity of working memory. Though fluid intelligence often combines with crystallized intelligence to support effective reasoning and problem solving, it is believed to be influenced less by culture than by conditions in the brain and by learning unique to the individual (Horn & Noll, 1997). Intelligence test items reflecting fluid abilities include spatial visualization, digit span, letter–number sequencing, and symbol search. (Refer to page 302 in Chapter 9 for examples.)

Many cross-sectional studies show that crystallized intelligence increases steadily through middle adulthood, whereas fluid intelligence begins to decline in the twenties. These trends have been found repeatedly in investigations in which younger and older participants had similar education and general health status, largely correcting for cohort effects (Horn, Donaldson,

AP IMAGES/THE ARIZONA DAILY SUN, JAKE BACON

Don Clarke, who flew attack helicopters in the U.S. army, fulfilled a long-held dream when he became an emergency medical service helicopter pilot. Flying search-and-rescue missions requires Clarke, now in his early sixties, to make use of complex mental abilities that are at their peak in midlife.

& Engstrom, 1981; Kaufman & Horn, 1996; Park et al., 2002). In one such investigation, including nearly 2,500 mentally and physically healthy 16- to 85-year-olds, verbal (crystallized) IQ peaked between ages 45 and 54 and did not decline until the eighties! Nonverbal (fluid) IQ, in contrast, dropped steadily over the entire age range (Kaufman, 2001).

The midlife rise in crystallized abilities makes sense because adults are constantly adding to their knowledge and skills at work, at home, and in leisure activities. In addition, many crystallized skills are practiced almost daily. But does longitudinal evidence confirm the progressive falloff in fluid intelligence? And if so, how can we explain it?

Schaie’s Seattle Longitudinal Study. Figure 15.5 shows Schaie’s longitudinal findings in detail. The five factors that gained in early and middle adulthood—verbal ability, inductive reasoning, verbal memory, spatial orientation, and numeric ability—include both crystallized and fluid skills. Their paths of change confirm that midlife is a time when some of the most complex mental abilities are at their peak (Willis & Schaie, 1999). According to these findings, middle-aged adults are intellectually “in their prime,” not—as stereotypes would have it—“over the hill.”

Figure 15.5 also shows a sixth ability, *perceptual speed*—a fluid skill in which participants must, for example, identify

within a time limit which of five shapes is identical to a model or whether pairs of multidigit numbers are the same or different. Perceptual speed decreased from the twenties to the late eighties—a pattern that fits with a wealth of research indicating that cognitive processing slows as people get older (Schaie, 1998, 2005). Also notice in Figure 15.5 how, late in life, fluid factors (spatial orientation, numeric ability, and perceptual speed) show greater decrements than crystallized factors (verbal ability, inductive reasoning, and verbal memory). These trends have been confirmed in short-term longitudinal follow-ups of individuals varying widely in age (McArdle et al., 2002).

Explaining Changes in Mental Abilities. Some theorists believe that a general slowing of central nervous system functioning underlies nearly all age-related declines in cognitive performance (Salthouse, 1996, 2006). Many studies offer at least partial support for this idea. For example, Kaufman (2001) reported that scores on speeded tasks mirror the regular, age-related decline in fluid-task performance. Researchers have also identified other important changes in information processing, some of which may be triggered by declines in speed.

Before we turn to this evidence, let’s clarify why research reveals gains followed by stability in crystallized abilities, despite a much earlier decline in fluid intelligence, or basic information-processing skills. First, the decrease in basic processing, while substantial after age 45, may not be great enough to affect many well-practiced performances until quite late in life. Second, as we will see, adults can often compensate for cognitive limitations by drawing on their cognitive strengths. Finally, as people discover that they are no longer as good as they once were at certain tasks, they accommodate, shifting to activities that depend less on cognitive efficiency and more on accumulated knowledge. Thus, the basketball player becomes a coach, the once quick-witted salesperson a manager.

Individual and Group Differences

The age trends just described mask large individual differences. Some adults, because of illness or unfavorable environments, decline intellectually much earlier than others. And others sustain high functioning, even in fluid abilities, at advanced ages.

Adults who use their intellectual skills seem to maintain them longer. In the Seattle Longitudinal Study, declines were delayed for people with above-average education; complex, self-directed occupations; and stimulating leisure pursuits that included reading, traveling, attending cultural events, and participating in clubs and professional organizations. People with flexible personalities, lasting marriages (especially to a cognitively high-functioning partner), and absence of cardiovascular and other chronic diseases were also likely to maintain mental abilities well into late adulthood (Schaie, 1996, 2000, 2011; Yu et al., 2009). And being economically well-off was linked to favorable cognitive development, undoubtedly because SES is associated with many of the factors just mentioned.

FIGURE 15.5 Longitudinal trends in six mental abilities, from the Seattle Longitudinal Study. In five abilities, modest gains occurred into the fifties and early sixties, followed by gradual declines. The sixth ability—perceptual speed—decreased steadily from the twenties to the late eighties. And late in life, fluid factors (spatial orientation, numeric ability, and perceptual speed) showed greater decrements than crystallized factors (verbal ability, inductive reasoning, and verbal memory). (From K. W. Schaie, 1994, “The Course of Adult Intellectual Development,” *American Psychologist*, 49, p. 308. Copyright © 1994 by the American Psychological Association. Reprinted with permission of American Psychological Association.)

Several sex differences also emerged, consistent with those found in childhood and adolescence. In early and middle adulthood, women outperformed men on verbal tasks and perceptual speed, while men excelled at spatial skills (Maitland et al., 2000). Overall, however, changes in mental abilities over the adult years were remarkably similar for the two sexes, defying the stereotype that older women are less competent than older men.

Furthermore, when the baby-boom generation, now middle-aged, was compared with the previous generation at the same age, cohort effects were evident. On verbal memory, inductive reasoning, and spatial orientation, baby boomers performed substantially better, reflecting generational advances in education, technology, environmental stimulation, and health care (Schaie, 2011; Willis & Schaie, 1999). These gains are expected to continue: Today's children, adolescents, and adults of all ages attain substantially higher mental test scores than same-age individuals born just a decade or two earlier—differences that are largest for fluid-ability tasks (Flynn, 2007, 2011; Zelinski & Kennison, 2007).

Finally, adults who maintained higher levels of perceptual speed tended to be advantaged in other cognitive capacities. As we turn to information processing in midlife, we will pay special attention to the impact of processing speed on other aspects of cognitive functioning.

Information Processing

Many studies confirm that as processing speed slows, certain basic aspects of executive function, including attention and working memory, decline. Yet midlife is also a time of great expansion in cognitive competence as adults apply their vast knowledge and life experience to problem solving in the everyday world.

Speed of Processing

Devin watched with fascination as his 20-year-old son, Mark, played a computer game, responding to multiple on-screen cues in rapid-fire fashion. When Devin tried it, though he practiced over several days, his performance remained well behind Mark's. Similarly, on a family holiday in Australia, Mark adjusted quickly to driving on the left side of the road, but after a week, Trisha and Devin still felt confused at intersections, where rapid responses were needed.

These real-life experiences fit with laboratory findings. On both simple reaction-time tasks (pushing a button in response to a light) and complex ones (pushing a left-hand button to a blue light, a right-hand button to a yellow light), response time increases steadily from the early twenties into the nineties. The more complex the situation, the more disadvantaged older adults are. Although the decline in speed is gradual and quite small—less than 1 second in most studies—it is nevertheless of practical significance (Der & Deary, 2006; Dykiert et al., 2012).

What causes this age-related slowing of cognitive processing? Researchers agree that changes in the brain are responsible but disagree on the precise explanation (Hartley, 2006; Salthouse & Cava, 2000). According to the **neural network view**, as neurons in the brain die, breaks in neural networks occur. The brain adapts by forming bypasses—new synaptic connections that go around the breaks but are less efficient (Cerella, 1990). In support of this hypothesis, aging is accompanied by withering of the myelin coating on neural fibers within the cerebral cortex, especially in the frontal lobes and the corpus callosum. Reduced myelination appears as small, high-intensity bright spots within fMRIs (Raz et al., 2007). The bright spots, a sign of deteriorating neuronal connections, are believed to be caused by reduced cerebral blood flow (often associated with high blood pressure and atherosclerosis). Extent of myelin breakdown, however, does not consistently predict decrements in reaction time or other cognitive functions (Rodrigue & Kennedy, 2011).

Another approach to age-related cognitive slowing, the **information-loss view**, suggests that older adults experience greater loss of information as it moves through the cognitive system. As a result, the whole system must slow down to inspect and interpret the information. Imagine making a photocopy, then using it to make another copy. Each subsequent copy is less clear. Similarly, with each step of thinking, information degrades. The older the adult, the more exaggerated this effect (Myerson et al., 1990). Complex tasks, which have more processing steps, are more affected by information loss. Possibly, multiple neural changes that vary across individuals underlie such information loss and associated declines in processing speed (Hartley, 2006; Salthouse, 2011).

What is clear is that processing speed predicts adults' performance on many tests of complex abilities. The slower their reaction time, the lower people's scores on tests of memory, reasoning, and problem solving, with relationships greater for fluid- than crystallized-ability items (Finkel et al., 2007; Salthouse, 2006). Indeed, as adults get older, correlations between processing speed and other cognitive performances strengthen (see Figure 15.6). This suggests that processing speed contributes broadly to declines in cognitive functioning, which become more widespread and pronounced with aging (Li et al., 2004).

Yet as Figure 15.6 shows, processing speed correlates only moderately with older adults' performances, including fluid-ability tasks. And it is not the only major predictor of age-related cognitive changes. Other factors—declines in vision and hearing and in attentional resources, inhibition, working-memory capacity, and use of memory strategies—also predict diverse age-related cognitive performances (Hartley, 2006; Luo & Craik, 2008). Nevertheless, processing speed, as we will see in the following sections, does contribute to the decrements in attention and memory just mentioned (Levitt, Fugelsang, & Crossley, 2006). But disagreement persists over whether age-related cognitive changes have just one common cause, best represented by processing speed, or multiple independent causes.

Furthermore, processing speed is a weak predictor of the skill with which older adults perform complex, familiar tasks in

FIGURE 15.6 Age-related changes in correlations of processing speed with measures of fluid and crystallized intelligence. Correlations are higher at younger and at older ages. During childhood, gains in processing speed support development of other abilities and are related to mental test performance (see Chapter 9, page 302). As people age, declines in processing speed limit many abilities, but more so for fluid than crystallized skills. Note, however, that even at the oldest ages, correlations between processing speed and other abilities are moderate. (From S.-C. Li et al., 2004, “Transformations in the Couplings Among Intellectual Abilities and Constituent Cognitive Processes Across the Life Span,” *Psychological Science*, 15, p. 160. Copyright © 2004, Sage Publications. Reprinted by Permission of SAGE Publications.)

everyday life, which they continue to do with considerable proficiency. Devin, for example, played a Mozart quartet on his cello with great speed and dexterity, keeping up with three other players 10 years his junior. How did he manage? Compared with the others, he more often looked ahead in the score (Krampe & Charness, 2007). Using this compensatory approach, he could prepare a response in advance, thereby minimizing the importance of speed. In one study, researchers asked 19- to 72-year-olds to perform a variety of typing tasks and also tested their reaction time. Although reaction time slowed with age, typing speed did not change (Salthouse, 1984). Like Devin, older typists look further ahead in the material to be typed, anticipating their next keystrokes. Knowledge and experience can also compensate for impairments in processing speed. Devin’s many years of playing the cello undoubtedly supported his ability to play swiftly and fluidly.

Because older adults find ways to compensate for cognitive slowing on familiar tasks, their reaction time is considerably better on verbal items (indicating as quickly as possible whether a string of letters forms a word) than on nonverbal items (responding to a light or other signal) (Hultsch, MacDonald, & Dixon, 2002; Verhaeghen & Cerella, 2008). Finally, as we will see in Chapter 17, older adults’ processing speed can be improved through training, though age differences remain.

Attention

Studies of attention focus on how much information adults can take into their mental systems at once; the extent to which they can attend selectively, ignoring irrelevant information; and the ease with which they can adapt their attention, switching from one task to another as the situation demands. When Dottie telephoned, Trisha sometimes tried to prepare dinner or check her e-mail inbox while talking on the phone. But with age, she found it harder to engage in the two activities simultaneously.

Consistent with Trisha’s experience, laboratory research reveals that sustaining two tasks at once, when at least one of the tasks is complex, becomes more challenging with age. Older adults have difficulty even when they have recently engaged in extensive practice of one of the activities and it is therefore expected to be automatic (Maquestiaux et al., 2010). An age-related decrement also occurs in the ability to focus on relevant information and to switch back and forth between mental operations, such as judging one of a pair of numbers as “odd or even” on some trials, “more or less” on others (Kramer & Kray, 2006; Verhaeghen & Cerella, 2008).

These declines in attention might be due to the slowdown in information processing described earlier, which limits the amount of information a person can focus on at once (Allen, Ruthruff, & Lien, 2007; Verhaeghen, 2012). Reduced processing speed may also contribute to a related finding: a decrement with age in the ability to combine many pieces of visual information into a meaningful pattern. When the mind inspects stimuli slowly, they are more likely to remain disconnected (Pilz, Bennett, & Sekuler, 2010; Plude & Doussard-Roosevelt, 1989). This problem, in turn, can intensify attentional difficulties.

As adults get older, *inhibition*—resistance to interference from irrelevant information—is also harder (Gazzaley et al., 2005; Hasher, Lustig, & Zacks, 2007). On *continuous performance tasks*, in which participants are shown a series of stimuli on a computer screen and asked to press the space bar only after a particular sequence occurs (for example, the letter *K* immediately followed by the letter *A*), performance declines steadily from the thirties into old age, with older adults making more errors of commission (pressing the space bar in response to incorrect letter sequences). And when extraneous noise is introduced, errors of omission (not pressing the space bar after a *K-A* sequence) also rise with age (Mani, Bedwell, & Miller, 2005). In everyday life, inhibitory difficulties cause older adults to appear distractible—inappropriately diverted from the task at hand by a thought or a feature of the environment.

Again, adults can compensate for these changes. People highly experienced in attending to critical information and performing several tasks at once, such as air traffic controllers and pilots, know exactly what to look for. As a result, they show smaller age-related attentional declines (Tsang & Shaner, 1998). Similarly, older adults focus on relevant information and handle two tasks proficiently when they have extensively practiced those activities over their lifetimes (Kramer & Madden, 2008).

© ELLIOTT FRANKS/ARENA/PAL/TOPIAM/THE IMAGE WORKS

Conductors and teachers must focus on relevant information within a complex field of stimulation and divide their attention among competing tasks—well-practiced skills that may help slow age-related declines in attention.

Finally, practice can improve the ability to divide attention between two tasks, selectively focus on relevant information, and switch back and forth between mental operations. When older adults receive training in these skills, their performance improves as much as that of younger adults, although training does not close the gap between age groups (Bherer et al., 2006; Erickson et al., 2007; Kramer, Hahn, & Gopher, 1998).

Memory

Memory is crucial for all aspects of information processing—an important reason that we place great value on a good memory in middle and late adulthood. From the twenties into the sixties, the amount of information people can retain in working memory diminishes. Whether given lists of words or digits (verbal tasks) or serial location stimuli (spatial tasks involving retaining each location on a screen of a series of stimuli), middle-aged and older adults recall less than young adults, although verbal memory suffers much less than spatial memory (Hale et al., 2011; Old & Naveh-Benjamin, 2008a). Verbal memory may be better preserved because the older adults tested have previously formed and often used verbal representations of the to-be-learned information (Kalpouzos & Nyberg, 2012). The necessary spatial representations, in contrast, are far less familiar.

These changes are affected by a decline in use of memory strategies. Older individuals rehearse less than younger individuals—a difference believed to be due to a slower rate of thinking (Salthouse, 1996). Older people cannot repeat new information to themselves as quickly as younger people. A reduction in basic working-memory capacity is another influence, leading to difficulties in retaining to-be-remembered items and processing them at the same time (Basak & Verhaeghen, 2011).

Memory strategies of organization and elaboration, which require people to link incoming information with already stored information, are also applied less often and less effectively with age (Dunlosky & Hertzog, 2001; Troyer et al., 2006). An additional reason older adults are less likely to use these techniques is that they find it harder to retrieve information from long-term memory that would help them recall. For example, given a list of words containing *parrot* and *blue jay*, they don't immediately access the category "bird," even though they know it well (Hultsch et al., 1998). Why does this happen? Greater difficulty keeping one's attention on relevant information seems to be involved (Hasher, Lustig, & Zacks, 2007). As irrelevant stimuli take up space in working memory, less is available for the memory task at hand.

But keep in mind that the memory tasks given by researchers require strategies that many adults seldom use and may not be motivated to use, since most are not in school (see Chapter 9, page 306). When a word list has a strong category-based structure, older adults organize as well as younger adults do (Naveh-Benjamin, 2000; Naveh-Benjamin et al., 2005). And when given training in strategic memorizing, middle-aged and older people use strategies willingly, and they show improved performance over long periods, though age differences remain (Derwinger, Neely, & Bäckman, 2005).

Furthermore, tasks can be designed to help older people compensate for age-related declines in working memory—for example, by slowing the pace at which information is presented or cuing the link between new and previously stored information ("To learn these words, try thinking of the category 'bird'") (Hay & Jacoby, 1999). In one study, adults ranging in age from 19 to 68 were shown a video and immediately tested on its content (a pressured, classroomlike condition). Then they were given a packet of information on the same topic as the video to study at their leisure and told to return three days later to be tested (a self-paced condition) (Beier & Ackerman, 2005). Performance declined with age only in the pressured condition, not in the self-paced condition. And although topic-relevant knowledge predicted better recall in both conditions, it did so more strongly in the self-paced condition, which granted participants ample time to retrieve and apply what they already knew.

LOOK AND LISTEN

Ask several adults in their fifties or early sixties to list their top three everyday memory challenges and to explain what they do to enhance recall. How knowledgeable are these midlifers about effective memory strategies? ●

As these findings illustrate, assessing older adults in highly structured, constrained conditions substantially underestimates what they can remember when given opportunities to pace and direct their own learning. (Refer to the Social Issues: Education box on the following page for a "dramatic" illustration.) When we consider the variety of memory skills we call on in daily life, the decrements just described are limited in scope. General *factual knowledge* (such as historical events), *procedural*

Social Issues: Education

The Art of Acting Improves Memory in Older Adults

Actors face a daunting task: They must memorize massive quantities of dialogue and then reproduce it accurately and spontaneously, as if they genuinely mean what they say. No wonder the most common question asked of actors is, “How did you learn all those lines?”

Interviews with professional actors reveal that most don’t memorize lines in the way students typically learn a historic speech or a poem in school—by rote, or rehearsing the lines many times. Instead, they focus on the meaning of the words, an approach that produces much better recall. First, they analyze the script for the character’s intentions, breaking it down into what they call “beats”—small, goal-directed chunks of dialogue. Then they represent the role as a sequence of goals, one leading to the next. When actors recall this chain of goals, lines become easier to remember (Noice & Noice, 2006). For example, one actor divided a half-page of dialogue into three beats: “to put [the other character] at ease,” “to start a conversation with him,” “to flatter/draw him out.”

To create a beat sequence, actors engage in extensive elaboration of dialogue segments. For example, to the line, “Perhaps he’s in love with me but doesn’t know it,” an actor might create a visual image of an uncertain lover, relate the material to a past love affair of her own, and match her own mood to feeling tone of the statement. Deep

elaborative processing of the dialogue segment, along with analysis of its beat goal, yields substantial verbatim recall without rote memorization.

Actors’ script learning is so successful that on stage, they are free to “live in the moment,” focusing on communicating authentic meaning through action, emotion, and utterance while speaking verbatim lines. This intermodal integration of spoken word with facial expression, tone of voice, and body language contributes further to script retention.

Can aging adults benefit from exercises that teach the essence of acting—thorough mastery of a script, enabling complete immersion in performance? To find out, researchers gave middle-aged and older adults nine 90-minute cognitively demanding group sessions of theater training over a month’s time. Each session required them to analyze the goals of brief scenes so they could become fully engrossed in acting out their meaning (Noice, Noice, & Staines, 2004). Compared with no-intervention controls, theater-training participants showed greater gains on tests of working-memory capacity, word recall, and problem solving—improvements still evident four months after the intervention ended.

The theater training required highly effortful intermodal processing, which may explain its cognitive benefits. fMRI research

These community-theater actors master their lines through deep, elaborate processing of goal-oriented segments of dialogue. Teaching these script-learning techniques to aging adults yields lasting gains in memory performance.

indicates that deeply processing verbal meanings strongly activates certain areas in the frontal lobes of the cerebral cortex in middle-aged adults, restoring them to patterns close to those of young adults (Park, 2002). These findings lend neurobiological support to the power of acting, with its challenging intermodal processing of meaning, to enhance human memory.

knowledge (such as how to drive a car or solve a math problem), and knowledge related to one’s occupation either remain unchanged or increase into midlife.

Furthermore, middle-aged people who have trouble recalling something often draw on decades of accumulated *metacognitive knowledge* about how to maximize memory—reviewing major points before an important presentation, organizing notes and files so information can be found quickly, and parking the car in the same area of the parking lot each day. Research confirms that aging has little impact on metacognitive knowledge and the ability to apply such knowledge to improve learning (Hertzog & Dunlosky 2011; Schwartz & Frazier, 2005).

In sum, age-related changes in memory vary widely across tasks and individuals as people use their cognitive capacities to meet the requirements of their everyday worlds. **TAKE A MOMENT...** Does this remind you of Sternberg’s *theory of successful intelligence*, described in Chapter 9—in particular, his notion of *practical intelligence* (see page 311)? Intelligent people adapt their information-processing skills to fit with their personal desires and the demands of their environments. Therefore, to understand memory development (and other aspects of cognition) in adulthood, we must view it in context. As we turn to problem solving, expertise, and creativity, we will encounter this theme again.

Practical Problem Solving and Expertise

One evening, as Devin and Trisha sat in the balcony of the Chicago Opera House awaiting curtain time, the announcement came that 67-year-old Ardis Krainik, the opera company's general director and "life force," had died. After a shocked hush, members of the audience began turning to one another, asking about the woman who had made the opera company into one of the world's greatest.

Starting as a chorus singer and clerk typist, Ardis rose rapidly through the ranks, becoming assistant to the director and developing a reputation for tireless work and unmatched organizational skill. When the opera company fell deeply in debt, Ardis—now the newly appointed general director—erased the deficit within a year and restored the company's sagging reputation. She charmed donors into making large contributions, attracted world-class singers, and filled the house to near capacity.

Ardis's story is a dramatic one, but all middle-aged adults encounter opportunities to display continued cognitive growth in the realm of **practical problem solving**, which requires people to size up real-world situations and analyze how best to achieve goals that have a high degree of uncertainty. Gains in *expertise*—an extensive, highly organized, and integrated knowledge base that can be used to support a high level of performance—help us understand why practical problem solving takes this leap forward.

The development of expertise is under way in early adulthood and reaches its height in midlife, leading to highly efficient and effective approaches to solving problems that are organized around abstract principles and intuitive judgments. Saturated with experience, the expert intuitively feels when an approach to a problem will work and when it will not. This rapid, implicit application of knowledge is the result of years of learning, experience, and effortful practice (Birney & Sternberg, 2006; Krampe & Charness, 2007). It cannot be assessed by laboratory tasks or mental tests that do not call on this knowledge.

Expertise is not just the province of the highly educated and of those who rise to the top of administrative ladders. In a study of food service workers, researchers identified the diverse ingredients of expert performance in terms of physical skills (strength and dexterity); technical knowledge (of menu items, ordering, and food presentation); organizational skills (setting priorities, anticipating customer needs); and social skills (confident presentation and a pleasant, polished manner). Next, 20- to 60-year-olds with fewer than two to more than ten years of experience were evaluated on these qualities. Although physical strength and dexterity declined with age, job knowledge and organizational and social skills increased (Perlmutter, Kaplan, & Nyquist, 1990). Compared to younger adults with similar years of experience, middle-aged employees performed more competently, serving customers in especially adept, attentive ways.

Age-related advantages are also evident in solutions to everyday problems (Denney, 1990; Denney & Pearce, 1989).

TAKE A MOMENT... Consider the following dilemma:

What would you do if you had a landlord who refused to make some expensive repairs you want done because he or she thinks they are too costly?

- a. Try to make the repairs yourself.
- b. Try to understand your landlord's view and decide whether they are necessary repairs.
- c. Try to get someone to settle the dispute between you and your landlord.
- d. Accept the situation and don't dwell on it. (Cornelius & Caspi, 1987, p. 146)

In this example, the preferred choice is (b), a problem-centered approach that involves seeking information and using it to guide action. From middle age on, adults place greater emphasis on thinking through a practical problem with multiple potential solutions—trying to understand it better, interpreting it from different perspectives, and solving it through logical analysis. On such tasks, middle-aged and older adults select strategies that (as rated by independent judges) are at least as good as and sometimes better than those of young adults (Kim & Hasher, 2005; Mienaltowski, 2011). Perhaps for this reason, they are more rational decision makers—less likely than young adults to select attractive-looking options that, on further reflection, are not the best.

Creativity

As noted in Chapter 13, creative accomplishment tends to peak in the late thirties or early forties and then decline, but with considerable variation across individuals and disciplines. Some people produce highly creative works in later decades: In her early sixties, Martha Graham choreographed *Clytemnestra*, recognized as one of the great full-length modern-dance dramas. Igor Stravinsky composed his last major musical work at age 84. Charles Darwin finished *On the Origin of Species* at age 50 and continued to write groundbreaking books and papers in his sixties and seventies. Harold Gregor, who painted the dazzling image on the cover of this book, continues to invent new styles and to be a highly productive artist at age 83. And as with problem solving, the *quality* of creativity may change with advancing age—in at least three ways.

First, youthful creativity in literature and the arts is often spontaneous and intensely emotional, while creative works produced after age 40 often appear more deliberately thoughtful (Lubart & Sternberg, 1998). Perhaps for this reason, poets produce their most frequently cited works at younger ages than do authors of fiction and nonfiction (Cohen-Shalev, 1986). Poetry depends more on language play and "hot" expression of feelings, whereas story- and book-length works require extensive planning and molding.

Second, with age, many creators shift from generating unusual products to combining extensive knowledge and exper-

© BRIANA ORR

In midlife, creativity often shifts to more altruistic goals. Author Masha Hamilton's travels to northeastern Kenya to research her novel, *The Camel Bookmobile*, led her to help organize the Camel Book Drive. It has funded the purchase of camels, books, and equipment for nomadic schools in the area.

rience into unique ways of thinking (Abra, 1989; Sasser-Coen, 1993). Creative works by older adults more often sum up or integrate ideas. Mature academics typically devote less energy to new discoveries in favor of writing memoirs, histories of their field, and other reflective works. And in older creators' novels, scholarly writings, and commentaries about their paintings and musical compositions, learning from life experience and living with old age are common themes (Beckerman, 1990; Lindauer, Orwoll, & Kelley, 1997; Sternberg & Lubart, 2001).

Finally, creativity in middle adulthood frequently reflects a transition from a largely egocentric concern with self-expression to more altruistic goals (Tahir & Gruber, 2003). As the middle-aged person overcomes the youthful illusion that life is eternal, the desire to give to humanity and enrich the lives of others increases.

Taken together, these changes may contribute to an overall decline in creative output in later decades. In reality, however, creativity takes new forms.

Information Processing in Context

Cognitive gains in middle adulthood are especially likely in areas involving experience-based buildup and transformation of knowledge and skills. As the evidence just reviewed confirms, processing speed varies with the situation. When given challenging real-world problems related to their expertise, middle-aged adults are likely to win out in both efficiency and excellence of thinking. Furthermore, on tasks and test items relevant to their real-life endeavors, intelligent, cognitively active midlifers respond as competently and nearly as quickly as their younger counterparts do!

By middle age, people's past and current experiences vary enormously—more so than in previous decades—and thinking is characterized by an increase in specialization as people branch out in various directions. Yet to reach their cognitive potential, adults must have opportunities for continued growth. Let's see how vocational and educational environments can support cognition in midlife.

ASK YOURSELF

REVIEW How do slowing of cognitive processing, reduced working-memory capacity, and difficulties with inhibition affect memory in midlife? What can older adults do to compensate for these declines?

CONNECT In which aspects of cognition did Devin decline, and in which did he gain? How do changes in Devin's thinking reflect assumptions of the lifespan perspective?

APPLY Asked about hiring middle-aged sales personnel, a department store manager replied, "They're my best employees!" Why does this manager find older employees desirable, despite age-related declines in processing speed, attention, and working memory?

Vocational Life and Cognitive Development

Vocational settings are vital contexts for maintaining previously acquired skills and learning new ones. Yet work environments vary in the degree to which they are cognitively stimulating and promote autonomy. And inaccurate, negative stereotypes of age-related problem-solving and decision-making skills can result in older employees being assigned less challenging work.

Recall from Chapter 13 that cognitive and personality characteristics affect occupational choice. Once a person is immersed in a job, it influences cognition. In a study of a large sample of U.S. men in diverse occupations, researchers asked about the complexity and self-direction of their jobs. During the interview, they also assessed cognitive flexibility, based on logical reasoning, awareness of both sides of an issue, and independence of judgment. Two decades later, the job and cognitive variables were remeasured, permitting a look at their effects on each other (Schooler, Mulatu, & Oates, 2004). Findings revealed that complex work augmented later cognitive flexibility more than cognitive flexibility influenced preference for complex work.

Similar findings emerged in large-scale studies carried out in Japan and Poland—cultures quite different from the United States (Kohn, 2006; Kohn et al., 1990; Kohn & Slomczynski, 1990). In each nation, having a stimulating, nonroutine job helped explain the relationship between SES and flexible, abstract thinking. Furthermore, people in their fifties and early

sixties benefit cognitively from challenging work just as much as those in their twenties and thirties (Avolio & Sosik, 1999; Miller, Slomczynski, & Kohn, 1985).

Mentally stimulating work requires middle-aged and older adults to grapple with novel situations. Research suggests that continuously confronting complex, novel tasks contributes importantly to cognitive development, predicting gains in cognitive flexibility and reducing the age-related decline in fluid abilities (Bowen, Noack, & Staudinger, 2011). Once again, we are reminded of the plasticity of development. Cognitive flexibility is responsive to work experiences well into middle adulthood and perhaps beyond. Designing jobs to promote intellectual stimulation and challenge may be a powerful means of fostering higher cognitive functioning later in the lifespan.

Adult Learners: Becoming a Student in Midlife

Adults are returning to undergraduate and graduate study in record numbers. During the past three decades, students age 25 and older in U.S. colleges and universities increased from 27 to 39 percent of total enrollment, with an especially sharp rise in those over age 35 (U.S. Department of Education, 2012). Life transitions often trigger a return to formal education, as with Devin and Trisha's friend Anya, who entered a nursing program after her last child left home. Early marriage (which often disrupts women's educational pathways), divorce, widowhood, a job layoff, a family move, a youngest child reaching school age, older children entering college, and rapid changes in the job market are other events that commonly precede reentry (Hostetler, Sweet, & Moen, 2007; Moen & Roehling, 2005). Among a sample of African-American women, additional motivations included serving as a role model for children and enriching their ethnic community as a whole (Coker, 2003).

AP IMAGES/NANCY PALMIERI

This 50-year-old, a full-time undergraduate at Mount Holyoke College, is one of many nontraditional students in U.S. colleges and universities. Appropriate academic advising and encouragement from family members, friends, and faculty help middle-aged learners succeed.

Characteristics of Returning Students

About 60 percent of adult learners are women (U.S. Department of Education, 2012). As Anya's fear of not being able to handle class work suggests (see page 501), reentry women report feeling especially self-conscious, inadequate, and hesitant to talk in class (Compton, Cox, & Laanan, 2006). Their anxiety stems partly from not having practiced academic learning for many years and partly from negative aging and gender stereotypes—erroneous beliefs that traditional-age students are smarter or that men are more logical and therefore more academically capable. And for minority students, ethnic stereotypes about ability to learn and prejudicial treatment are also factors (Coker, 2003).

Role demands outside of school—from children, spouses, other family members, friends, and employers—pull many returning women in conflicting directions. Those reporting high psychological stress typically are single parents with limited financial resources, or married women with high career aspirations, young children, and nonsupportive partners (Deutsch & Schmertz, 2011; Padula & Miller, 1999). When couples fail to rework divisions of household and child-care responsibilities to accommodate the woman's return to school, marital satisfaction declines (Sweet & Moen, 2007). As a classmate remarked to Anya, "I tried keeping the book open and reading, cooking, and talking to the kids. It didn't work. So I had to say to Bill, 'Can't you put in a load of laundry once in a while, get home earlier on just some nights?' He forgets—I went through his going to graduate school!"

Because of multiple demands on their time, mature-age women tend to take fewer credits, experience more interruptions in their academic programs, and progress at a slower pace than mature-age men. Role overload is the most common reason for not completing their degrees (Jacobs & King, 2002). But many express high motivation to work through those difficulties, referring to the excitement of learning, to the fulfillment academic success brings, and to their hope that a college education will improve both their work and family lives (Kinser & Deitchman, 2007).

LOOK AND LISTEN

Interview a nontraditional student on your campus about the personal challenges and rewards of working toward a degree at a later age. ●

Supporting Returning Students

As these findings suggest, social supports for returning students can make the difference between continuing in school and dropping out. Adult students need family members and friends who encourage their efforts and enable them to find time for uninterrupted study. Anya's classmate explained, "My doubts subsided when one day, Bill volunteered, 'You take your books and do what you need to do. I can cook dinner and do the laundry.'" Institutional services for returning students are also essential. Personal relationships with faculty, peer networks enabling adults to build a social community with other non-

Applying What We Know

Facilitating Adult Reentry to College

Sources of Support	Description
Partner and children	Value and encourage educational efforts. Help with household tasks to permit time for uninterrupted study.
Extended family and friends	Value and encourage educational efforts.
Educational institution	Provide orientation programs and literature that inform adult students about services and social supports. Provide counseling and intervention addressing academic weaknesses, self-doubts about success, and matching courses to career goals. Facilitate peer networks through regular meetings, phone, and online contacts. Promote personal relationships with faculty. Encourage active engagement and discussion in classes and integration of course content with real-life experiences. Offer evening, Saturday, and off-campus classes and online courses. Provide financial aid for part-time students. Initiate campaigns to recruit returning students, including those from low-income families and ethnic minority groups. Help students with young children find child-care arrangements and provide on-campus child care.
Workplace	Value and encourage educational efforts. Offer flexible work schedules to make possible coordination of work, class, and family responsibilities.

traditional students who understand their daily struggles, conveniently scheduled evening and Saturday classes, online courses, and financial aid for part-time students increase the chances of academic success.

Although nontraditional students rarely require assistance in settling on career goals, they report a strong desire for help in choosing the most appropriate courses and for small, discussion-based classes that meet their learning and relationship needs. Academic advising and professional internship opportunities are vital. Students from low-SES backgrounds often need special assistance, such as academic tutoring, sessions in confidence building and assertiveness, and—in the case of ethnic minorities—help adjusting to styles of learning that are at odds with their cultural background.

Applying What We Know above suggests ways to facilitate adult reentry to college. When support systems are in place, most returning students reap great personal benefits and do well academically. Succeeding at coordinating education, family, and work demands leads to gains in self-efficacy and admiration from family members, friends, and co-workers (Chao & Good, 2004). Nontraditional students especially value forming new relationships, sharing opinions and experiences, and relating subject matter to their own lives. Their greater ability to integrate knowledge results in an enhanced appreciation of classroom experiences and assignments. And their presence in college classes provides valuable intergenerational contact. As younger students observe the capacities and talents of older classmates, unfavorable stereotypes of aging decline.

After finishing her degree, Anya secured a position as a parish nurse with creative opportunities to counsel members of

a large congregation about health concerns. Education granted her new life options, financial rewards, and higher self-esteem as she reevaluated her own competencies. Sometimes (though not in Anya's case) these revised values and increased self-reliance can spark other changes, such as a divorce or a new intimate partnership (Esterberg, Moen, & Dempster-McClain, 1994). In middle adulthood as in earlier years, education transforms development, often profoundly reshaping the life course.

ASK YOURSELF

REVIEW In view of the impact of vocational and educational experiences on midlife cognitive development, evaluate the saying “You can’t teach an old dog new tricks.”

CONNECT Most high-level government and corporate positions are held by middle-aged and older adults rather than by young adults. What cognitive capacities enable mature adults to perform these jobs well?

APPLY Marcella completed one year of college in her twenties. Now, at age 42, she has returned to earn a degree. Plan a set of experiences for Marcella's first semester that will increase her chances of success.

REFLECT What range of services does your institution offer to support returning students? What additional supports would you recommend?

SUMMARY

PHYSICAL DEVELOPMENT

Physical Changes (p. 502)

Describe the physical changes of middle adulthood, paying special attention to vision, hearing, the skin, muscle-fat makeup, and the skeleton.

- The gradual physical changes begun in early adulthood continue in midlife, contributing to a revised physical self-image, with less emphasis on hoped-for gains and more on feared declines.
- Vision is affected by **presbyopia** (loss of the accommodative ability of the lens), reduced vision in dim light, increased sensitivity to glare, and diminished color discrimination. After age 40, risk of **glaucoma**, a buildup of pressure in the eye that damages the optic nerve, increases.
- Age-related hearing loss, or **presbycusis**, begins with a decline in detection of high frequencies and then spreads to other tones. Eventually, human speech becomes harder to decipher.

THOMAS BARWICK/STONE/GETTY IMAGES

- The skin wrinkles, loosens, and dries. Age spots develop, especially in women and in people exposed to the sun.
- Muscle mass declines and fat deposits increase, with notable sex differences in fat distribution. A low-fat diet and regular exercise, including resistance training, can offset both excess weight and muscle loss.
- Bone density declines, especially in women after menopause. Height loss and bone fractures can result.

Describe reproductive changes in both sexes during middle adulthood.

- The **climacteric** in women, which occurs gradually as estrogen production drops, concludes with **menopause**, often accompanied by emotional and physical symptoms. These reactions, however, vary widely with ethnicity, SES, physical health, psychological stress, and other factors.
- **Hormone therapy** can reduce the discomforts of menopause, but its use increases the risk of cardiovascular disease, certain cancers, and cognitive declines.
- Although sperm production continues throughout life, quantity of semen diminishes and erections become harder to attain and maintain. Drugs are available to combat impotence.

Health and Fitness (p. 508)

Discuss sexuality in middle adulthood and its association with psychological well-being.

- Frequency of sexual activity among married couples declines only slightly in middle adulthood. Intensity of sexual response diminishes due to physical changes of the climacteric. Most married people over age 50 find ways to overcome difficulties with sexual functioning.

Discuss cancer, cardiovascular disease, and osteoporosis, noting risk factors and interventions.

- The death rate from cancer multiplies tenfold from early to middle adulthood. A complex interaction of heredity, biological aging, and environment contributes to cancer. Today, nearly 60 percent of affected individuals are cured. Regular screenings and various preventive steps can reduce the incidence of cancer and cancer deaths.
- Despite a decline in recent decades, cardiovascular disease remains a major cause of death in middle adulthood, especially among men. Symptoms include high blood pressure, high blood cholesterol, atherosclerosis, heart attack, arrhythmia, and angina pectoris. Quitting smoking, reducing blood cholesterol, exercising, and reducing stress can decrease risk and aid in treatment.

- **Osteoporosis** affects 12 percent of people over age 50; most are postmenopausal women. Adequate calcium and vitamin D, weight-bearing exercise, resistance training, and bone-strengthening medications can help prevent and treat osteoporosis.

Discuss the association of hostility and anger with heart disease and other health problems.

- Expressed hostility, a component of the **Type A behavior pattern**, predicts heart disease and other health problems, largely due to physiological arousal associated with anger. Anger suppression is also related to health problems; a better alternative is to develop effective ways of handling stress and conflict.

Adapting to the Physical Challenges of Midlife (p. 514)

Discuss the benefits of stress management, exercise, and an optimistic outlook in dealing effectively with the physical challenges of midlife.

- Effective stress management includes both problem-centered and emotion-centered coping, depending on the situation; constructive approaches to anger reduction; and social support. In middle adulthood, people tend to cope with stress more effectively, often reporting lasting personal benefits.
- Regular exercise offers physical and psychological advantages, making it worthwhile for sedentary middle-aged people to begin exercising. Developing a sense of self-efficacy, choosing an appropriate exercise format, and having access to accessible, attractive, and safe exercise environments promote physical activity.

© BLEND IMAGES/ALAMY

- **Hardiness** is made up of three personal qualities: control, commitment, and challenge. By inducing a generally optimistic outlook, hardiness helps people cope with stress adaptively.

Explain the double standard of aging.

- Although negative stereotypes of aging discourage both men and women, middle-aged women are more likely to be viewed unfavorably, especially by men. New surveys suggest that this double standard is declining.

COGNITIVE DEVELOPMENT**Changes in Mental Abilities**

(p. 517)

Describe cohort effects on intelligence revealed by Schaie's Seattle Longitudinal Study.

- Early cross-sectional research showed a peak in intelligence test performance at age 35 followed by a steep decline, whereas longitudinal evidence revealed modest gains in midlife. Using a sequential design, Schaie found that the cross-sectional, steep drop-off largely resulted from cohort effects, as each new generation experienced better health and education.

Describe changes in crystallized and fluid intelligence in middle adulthood, and discuss individual and group differences in intellectual development.

- **Crystallized intelligence**, which depends on accumulated knowledge and experience, gains steadily through middle adulthood. In contrast, **fluid intelligence**, which depends more on basic information-processing skills, begins to decline in the twenties.
- In the Seattle Longitudinal Study, perceptual speed shows steady, continuous decline. But other fluid skills, in addition to crystallized abilities, increase through middle adulthood, confirming that midlife is a time of peak performance on a variety of complex abilities.
- Large individual differences among middle-aged adults remind us that intellectual development is multidimensional, multidirectional, and plastic. Illness and unfavorable environments are linked to intellectual declines; stimulating occupations and leisure pursuits, flexible personalities, lasting marriages, good health, and economic advantage predict favorable cognitive development.

- Women outperform men on verbal tasks and perceptual speed, whereas men excel at spatial skills. Gains in certain intellectual skills by the baby boomers relative to the previous generation reflect advances in education, technology, environmental stimulation, and health care.

Information Processing

(p. 520)

How does information processing change in midlife?

- Speed of cognitive processing slows with age. According to the **neural network view**, as neuronal connections deteriorate, the brain adapts by forming new, less efficient synaptic connections. The **information-loss view** states that older adults experience greater loss of information as it moves through the cognitive system, resulting in slower processing to interpret the information.
- As processing speed slows, people perform less well on memory, reasoning, and problem-solving tasks, especially fluid-ability items. But other factors also predict age-related cognitive performances.
- Middle-aged people show declines in ability to divide their attention, focus on relevant stimuli, and switch from one task to another as the situation demands. Inhibition becomes harder, at times prompting distractibility.

© ELLIOTT FRANKS/ARENA/PAL/ TOPHAM/THE IMAGE WORKS

- Adults in midlife retain less information in working memory, largely due to a decline in use of memory strategies. But training, improved design of tasks, and metacognitive knowledge enable older adults to compensate for age-related decrements.

Discuss the development of practical problem solving, expertise, and creativity in middle adulthood.

- Middle-aged adults display continued growth in **practical problem solving**, largely due to gains in expertise. Creativity becomes more deliberately thoughtful and often shifts from generating unusual products to integrating ideas, and from concern with self-expression to more altruistic goals.

Vocational Life and Cognitive Development

(p. 525)

Describe the relationship between vocational life and cognitive development.

- Well into middle adulthood, stimulating, complex work augments flexible, abstract thinking. It also reduces the age-related decline in fluid abilities.

Adult Learners: Becoming a Student in Midlife (p. 526)**Discuss the challenges that adults face in returning to college, ways to support returning students, and benefits of earning a degree in midlife.**

- Adults are returning to college and graduate school in record numbers. The majority are women, often motivated by life transitions. Returning students must cope with a lack of recent practice at academic work, stereotypes of aging and ethnicity, and demands of multiple roles.
- Social support from family and friends and institutional services suited to their needs can help returning students succeed. Further education results in enhanced competencies, new relationships, intergenerational contact, and reshaped life paths.

Midlife is a time of increased generativity—giving to and guiding younger generations. Charles Callis, director of New Zealand's Olympic Museum, shows visiting schoolchildren how to throw a discus. His enthusiastic demonstration conveys the deep sense of satisfaction he derives from generative activities.

Emotional and Social Development in Middle Adulthood

One weekend when Devin, Trisha, and their 24-year-old son, Mark, were vacationing together, the two middle-aged parents knocked on Mark's hotel room door. "Your dad and I are going off to see a crafts exhibit," Trisha explained. "Feel free to stay behind," she offered, recalling Mark's antipathy toward attending such events as an adolescent.

"We'll be back around noon for lunch."

"That exhibit sounds great!" Mark replied. "I'll meet you in the lobby."

"Sometimes I forget he's an adult!" exclaimed Trisha as she and Devin returned to their room to grab their coats. "It's been great to have Mark with us—like spending time with a good friend."

PHOTO/ODILON DIMIER/GETTY IMAGES

In their forties and fifties, Trisha and Devin built on earlier strengths and intensified their commitment to leaving a legacy for those who would come after them. When Mark faced a difficult job market after graduating from college, he returned home to live with Trisha and Devin and remained there for several years. With their support, he took graduate courses while working part-time, found steady employment in his late twenties, fell in love, and married in his mid-thirties. With each milestone, Trisha and Devin felt a sense of pride at having escorted a member of the next generation into responsible adult roles. Family activities, which had declined during Mark's adolescent and college years, increased as Trisha and Devin related to their son as an enjoyable adult companion. Challenging careers and more time for community involvement, leisure pursuits, and each other contributed to a richly diverse and gratifying time of life.

The midlife years were not as smooth for two of Trisha and Devin's friends. Fearing that she might grow old alone, Jewel frantically pursued her quest for an intimate partner. She attended singles events, registered with dating services, and traveled in hopes of meeting a like-minded companion. "I can't stand the thought of turning 50," she lamented in a letter to Trisha. Jewel also had compensating satisfactions—friendships that had grown more meaningful, a warm relationship with a nephew and niece, and a successful consulting business.

Tim, Devin's best friend from graduate school, had been divorced for over five years. Recently, he had met Elena and had come to love her deeply. But Elena was in the midst of major life changes. In addition to her own divorce, she was dealing with a troubled daughter, a career change, and a move away from the city that served as a

constant reminder of her unhappy past. Whereas Tim had reached the peak of his career and was ready to enjoy life, Elena wanted to recapture much of what she had missed in earlier decades, including opportunities to realize her talents. “I don’t know where I fit into Elena’s plans,” Tim wondered aloud on the phone with Trisha.

With the arrival of middle adulthood, half or more of the lifespan is over. Increasing awareness of limited time ahead prompts adults to reevaluate the meaning of their lives, refine and strengthen their identities, and reach out to future generations. Most middle-aged people make modest adjustments in their outlook, goals, and daily lives. But a few experience profound inner turbulence and initiate major changes, often in an effort to make up for lost time. Together with advancing years, family and work transitions contribute greatly to emotional and social development.

More midlifers are addressing these tasks than ever before, now that the baby boomers have reached their forties, fifties, and sixties (see page 12 in Chapter 1 to review how baby boomers have reshaped the life course). Indeed, 45- to 54-year-olds are currently the largest age sector of the U.S. population, and they are healthier, better educated, and—despite the late-2000s recession—more financially secure than any previous midlife cohort (U.S. Census Bureau, 2012b; Whitbourne & Willis, 2006). As our discussion will reveal, they have brought increased self-confidence, social consciousness, and vitality—along with great developmental diversity—to this period of the lifespan.

A monumental survey called *Midlife Development in the United States (MIDUS)*, conducted in the mid-1990s, has contributed enormously to our understanding of midlife emotional and social development. Conceived by a team of researchers spanning diverse fields, including psychology, sociology, anthropology, and medicine, the aim of MIDUS was to generate new knowledge on the challenges faced by middle-aged adults. Its nationally representative sample included over 7,000 U.S. 25- to 75-year-olds, enabling those in the middle years to be compared with younger and older individuals. Through telephone interviews and self-administered questionnaires, participants responded to over 1,100 items addressing wide-ranging psychological, health, and background factors, yielding unprecedented breadth of information in a single study (Brim, Ryff, & Kessler, 2005). The research endeavor also included “satellite” studies, in which subsamples of respondents were questioned in greater depth on key topics. And it has been extended longitudinally, with 75 percent of the sample recontacted at first follow-up, in the mid-2000s (Radler & Ryff, 2010).

MIDUS has greatly expanded our knowledge of the *multidimensional* and *multidirectional* nature of midlife change, and it promises to be a rich source of information about middle adulthood and beyond for many years to come. Hence, our discussion repeatedly draws on MIDUS, at times delving into its findings, at other times citing them alongside those of other investigations. Let’s turn now to Erikson’s theory and related research, to which MIDUS has contributed. ●

Erikson’s Theory: Generativity versus Stagnation

Erikson’s psychological conflict of midlife is called **generativity versus stagnation**. Generativity involves reaching out to others in ways that give to and guide the next generation. Recall from Chapter 14 that generativity is under way in early adulthood through work, community service, and childbearing and child rearing. Generativity expands greatly in midlife, when adults focus more intently on extending commitments beyond oneself (identity) and one’s life partner (intimacy) to a larger group—family, community, or society. The generative adult combines the need for self-expression with the need for communion,

integrating personal goals with the welfare of the larger social world (McAdams & Logan, 2004). The resulting strength is the capacity to care for others in a broader way than previously.

Erikson (1950) selected the term *generativity* to encompass everything generated that can outlive the self and ensure society's continuity and improvement: children, ideas, products, works of art. Although parenting is a major means of realizing generativity, it is not the only means: Adults can be generative in other family relationships (as Jewel was with her nephew and niece), as mentors in the workplace, in volunteer endeavors, and through many forms of productivity and creativity.

Notice, from what we have said so far, that generativity brings together personal desires and cultural demands. On the personal side, middle-aged adults feel a need to be needed—to attain symbolic immortality by making a contribution that will survive their death (Kotre, 1999; McAdams, Hart, & Maruna, 1998). This desire may stem from a deep-seated evolutionary urge to protect and advance the next generation. On the cultural side, society imposes a social clock for generativity in midlife, requiring adults to take responsibility for the next generation through their roles as parents, teachers, mentors, leaders, and coordinators (McAdams & Logan, 2004). And according to Erikson, a culture's "belief in the species"—the conviction that life is good and worthwhile, even in the face of human destructiveness and deprivation—is a major motivator of generative action. Without this optimistic worldview, people would have no hope of improving humanity.

The negative outcome of this stage is stagnation: Once people attain certain life goals, such as marriage, children, and career success, they may become self-centered and self-indulgent. Adults with a sense of stagnation express their self-absorption in many ways—through lack of interest in young people (including their own children), through a focus on what they can get from others rather than what they can give, and through taking little interest in being productive at work, developing their talents, or bettering the world in other ways.

Some researchers study generativity by asking people to rate themselves on generative characteristics, such as feelings of duty to help others in need or obligation to be an involved citizen. Others ask open-ended questions about life goals, major high points, and most satisfying activities, rating people's responses for generative references. And still others look for generative themes in people's narrative descriptions of themselves (Keyes & Ryff, 1998a, 1998b; McAdams, 2006, 2011; Newton & Stewart, 2010; Rossi, 2001, 2004). Whichever method is used, generativity tends to increase in midlife. For example, in longitudinal and cross-sectional studies of college-educated women, and in an investigation of middle-aged adults diverse in SES, self-rated generativity rose throughout middle adulthood (see Figure 16.1). At the same time, participants expressed greater concern about aging, increased security with their identities, and a stronger sense of competence (Miner-Rubino, Winter, & Stewart, 2004; Stewart, Ostrove, & Helson, 2001; Zucker, Ostrove, & Stewart, 2002). As the Social Issues: Health box on page 534 illustrates, generativity is also a major unifying theme in middle-aged adults' life stories.

FIGURE 16.1 Age-related changes in self-rated generativity, concern about aging, identity security, and sense of competence. In a longitudinal study of over 300 college-educated women, self-rated generativity increased from the thirties to the fifties, as did concern about aging. The rise in generativity was accompanied by other indicators of psychological health—greater security with one's identity and sense of competence. (Adapted from Stewart, Ostrove, & Helson, 2001.)

Just as Erikson's theory suggests, highly generative people appear especially well-adjusted—low in anxiety and depression; high in autonomy, self-acceptance, and life satisfaction; and more likely to have successful marriages and close friends (Ackerman, Zuroff, & Moskowitz, 2000; An & Cooney, 2006; Grossbaum & Bates, 2002; Westermeyer, 2004). They are also more open to differing viewpoints, possess leadership qualities, desire more from work than financial rewards, and care greatly about the welfare of their children, their partner, their aging parents, and the wider society (Peterson, 2002; Peterson, Smirles, & Wentworth, 1997). Furthermore, generativity is associated with more effective child rearing—higher valuing of trust, open communication, transmission of generative values to children, and an authoritative style (Peterson, 2006; Peterson & Duncan, 2007; Pratt et al., 2008). Generative midlifers are also more involved in political activities, including voting, campaigning, and contacting public officials (Cole & Stewart, 1996).

Although these findings characterize adults of all backgrounds, individual differences in contexts for generativity exist. Having children seems to foster generative development in both men and women. In several studies, including the MIDUS survey, fathers scored higher in generativity than childless men (Marks, Bumpass, & Jun, 2004; McAdams & de St. Aubin, 1992; Snarey et al., 1987). Similarly, in an investigation of well-educated women from ages 43 to 63, those with family commitments (with or without a career) expressed greater generative concerns than childless women who were solely focused on their careers (Newton & Stewart, 2010). Parenting seems to spur especially tender, caring attitudes toward succeeding generations.

For low-SES men with troubled pasts as sons, students, workers, and intimate partners, fatherhood can provide a context for highly generative, positive life change (Roy & Lucas, 2006). At times, these fathers express this generativity as a

Social Issues: Health

Generative Adults Tell Their Life Stories

In research aimed at understanding how highly generative adults make sense of their lives, Dan McAdams and his colleagues interviewed two groups of midlifers: those who often behave generatively and those who seldom do. Participants were asked to relate their life stories, including a high point, a low point, a turning point, and important scenes from childhood, adolescence, and adulthood (McAdams, 2006, 2011; McAdams et al., 2001). Analyses of story lines and themes revealed that adults high and low in generativity reconstruct their past and anticipate their future in strikingly different ways.

Narratives of highly generative people usually contained an orderly sequence of events that the researchers called a commitment story, in which adults give to others as a means of giving back to family, community, and society (McAdams, 2006). The generative storyteller typically describes an early special advantage (such as a good family or a talent), along with early awareness of the suffering of others. This clash between blessing and suffering motivates the person to view the self as “called,” or committed, to being good to others. In commitment stories, the theme of redemption is prominent. Highly generative adults frequently describe scenes in which extremely negative life events, involving frustration, failure, loss, or death, are redeemed, or made better, by good outcomes—personal renewal, improvement, and enlightenment.

Consider a story related by Diana, a 49-year-old fourth-grade teacher. Born in a small town to a minister and his wife, Diana was a favorite among the parishioners, who showered her with attention and love. When she was 8, however, her life hit its lowest point: As she looked on in horror, her younger brother ran into the street and was hit by a car; he died later that day. Afterward, Diana, sensing her father’s anguish, tried—unsuccessfully—to be the

“son” he had lost. But the scene ends on an upbeat note, with Diana marrying a man who forged a warm bond with her father and who became accepted “as his own son.” One of Diana’s life goals was to improve her teaching, because “I’d like to give something back . . . to grow and help others grow” (McAdams et al., 1997, p. 689). Her interview overflowed with expressions of generative commitment.

Whereas highly generative adults tell stories in which bad scenes turn good, less generative adults relate stories with themes of contamination, in which good scenes turn bad. For example, a good first year of college turns sour when a professor grades unfairly. A young woman loses weight and looks good but can’t overcome her low self-esteem.

Why is generativity connected to life-story redemption events? First, some adults may view their generative activities as a way to redeem negative aspects of their lives. In a study of the life stories of ex-convicts who turned away from crime, many spoke of a strong desire to do good works as penance for their transgressions (Maruna, 2001; Maruna, LeBel, & Lanier, 2004). Second, generativity seems to entail the conviction that the imperfections of today can be transformed into a better tomorrow. Through guiding and giving to the next generation, mature adults increase the chances that the mistakes of the past will not happen again. Finally, interpreting one’s own life in terms of redemption offers hope that hard work will lead to

future benefits—an expectation that may sustain generative efforts of all kinds, from rearing children to advancing communities and societies.

Life stories offer insight into how people imbue their lives with meaning and purpose. Adults high and low in generativity do not differ in the number of positive and negative events included in their narratives. Rather, they interpret those events differently. Commitment stories, filled with redemption, involve a way of thinking about the self that fosters a caring, compassionate approach to others (McAdams & Logan, 2004). Such stories help people realize that although their own personal story will someday end, other stories will follow, due in part to their own generative efforts.

The more redemptive events adults include in their life stories, the higher their self-esteem, life satisfaction, and certainty that the challenges of life are meaningful, manageable, and rewarding (Lilgendahl & McAdams, 2011; McAdams, 2001). Researchers still have much to learn about factors that lead people to view good as emerging from adversity.

refusal to pass on their own history of suffering. As one former gang member, who earned an associate's degree and struggled to keep his teenage sons off the streets, explained, "I came through the depths of hell to try to be a father. I let my sons know, 'You're never without a daddy, don't you let anybody tell you that.' I tell them that if me and your mother separate, I make sure that wherever I go, I build something for you to come to" (p. 153).

Finally, compared with Caucasians, African Americans more often engage in certain types of generativity. They are more involved in religious groups and activities, offer more social support to members of their community, and are more likely to view themselves as role models and sources of wisdom for their children (Hart et al., 2001). A life history of strong support from church and extended family may strengthen these generative values and actions. Among Caucasian Americans, religiosity and spirituality are also linked to greater generative activity (Dillon & Wink, 2004; Son & Wilson, 2011; Wink & Dillon, 2008). Highly generative middle-aged adults often indicate that as children and adolescents, they internalized moral values rooted in a religious tradition and sustained their commitment to those values, which provided lifelong encouragement for generative action (McAdams, 2006). Especially in individualistic societies, belonging to a religious community or believing in a higher being may help preserve generative commitments.

Other Theories of Psychosocial Development in Midlife

Erikson's broad sketch of psychosocial change in midlife has been extended by Levinson and Vaillant. Let's revisit their theories, which were introduced in Chapter 14.

Levinson's Seasons of Life

Return to page 470 to review Levinson's eras (seasons of life). His interviews with adults revealed that middle adulthood begins with a transition, during which people evaluate their success in meeting early adulthood goals. Realizing that from now on, more time will lie behind than ahead, they regard the remaining years as increasingly precious. Consequently, some make drastic revisions in their life structure: divorcing, remarrying, changing careers, or displaying enhanced creativity. Others make smaller changes in the context of marital and occupational stability.

Whether these years bring a gust of wind or a storm, most people turn inward for a time, focusing on personally meaningful living (Neugarten, 1968b). According to Levinson, to reassess and rebuild their life structure, middle-aged adults must confront four developmental tasks. Each requires the individual to reconcile two opposing tendencies within the self, attaining greater internal harmony.

- *Young-old*: The middle-age person must seek new ways of being both young and old. This means giving up certain youthful qualities, transforming others, and finding positive meaning in being older. Perhaps because of the double standard of aging (see pages 516–517 in Chapter 15), most middle-aged women express concern about appearing less attractive as they grow older (Rossi, 2005). But middle-aged men—particularly non-college-educated men, who often hold blue-collar jobs requiring physical strength and stamina—are also highly sensitive to physical aging. In one study, they were more concerned about physical changes than both college- and non-college-educated women, who exceeded college-educated men (Miner-Rubino, Winter, & Stewart, 2004).

Compared with previous midlife cohorts, U.S. baby boomers are especially interested in controlling physical changes—a desire that has helped energize a huge industry of anti-aging cosmetic products and medical procedures (Jones, Whitbourne, & Skultety, 2006; Lachman, 2004). And sustaining a youthful *subjective age* (feeling younger than one's actual age) is more strongly related to self-esteem and psychological well-being among American than Western-European middle-aged and older adults (Westerhof & Barrett, 2005; Westerhof, Whitbourne, & Freeman, 2012). In the more individualistic U.S. context, a youthful self-image seems more important for viewing oneself as self-reliant and capable of planning for an active, fulfilling late adulthood.

- *Destruction–creation*: With greater awareness of mortality, the middle-aged person focuses on ways he or she has acted destructively. Past hurtful acts toward parents, intimate partners, children, friends, and co-workers are countered by a strong desire to participate in activities that advance human welfare and leave a legacy for future generations. The image of a legacy can be satisfied in many ways—through charitable gifts, creative products, volunteer service, or mentoring young people.
- *Masculinity–femininity*: The middle-aged person must create a better balance between masculine and feminine parts of the self. For men, this means greater acceptance of “feminine” traits of nurturance and caring, which enhance close relationships and compassionate exercise of authority in the workplace. For women, it generally means being more open to “masculine” characteristics of autonomy and assertiveness. Recall from Chapter 8 that people who combine masculine and feminine traits have an androgynous gender identity. Later we will see that androgyny is associated with favorable personality traits and adjustment.
- *Engagement–separateness*: The middle-aged person must forge a better balance between engagement with the external world and separateness. For many men, and for women who have had successful careers, this may mean reducing concern with ambition and achievement and attending more fully to oneself. But women who have been devoted to child rearing or an unfulfilling job often feel compelled

to move in the other direction (Levinson, 1996). At age 48, Elena left her position as a reporter for a small-town newspaper, pursued an advanced degree in creative writing, accepted a college teaching position, and began writing a novel. Tim, in contrast, recognized his overwhelming desire for a gratifying romantic partnership. By scaling back his own career, he realized he could grant Elena the time and space she needed to build a rewarding work life—and that doing so might deepen their attachment to each other.

People who flexibly modify their identities in response to age-related changes yet maintain a sense of self-continuity are more aware of their own thoughts and feelings and are higher in self-esteem and life satisfaction (Jones, Whitbourne, & Skultety, 2006; Sneed et al., 2012). But adjusting one's life structure to incorporate the effects of aging requires supportive social contexts. When poverty, unemployment, and lack of a respected place in society dominate the life course, energies are directed toward survival rather than realistically approaching age-related changes. And even adults whose jobs are secure and who live in pleasant neighborhoods may find that employment conditions restrict possibilities for growth by placing too much emphasis on productivity and profit and too little on the meaning of work. In her early forties, Trisha left a large law firm, where she felt constant pressure to bring in high-fee clients and received little acknowledgment of her efforts, for a small practice.

Opportunities for advancement ease the transition to middle adulthood. Yet these are far less available to women than to men. Individuals of both sexes in blue-collar jobs also have few possibilities for promotion. Consequently, they make whatever vocational adjustments they can—becoming active union members, shop stewards, or mentors of younger workers (Christensen & Larsen, 2008; Levinson, 1978). Many men find compensating rewards in moving to the senior generation of their families.

Vaillant's Adaptation to Life

Whereas Levinson interviewed 35- to 45-year-olds, Vaillant (1977, 2002)—in his longitudinal research on well-educated men and women—followed participants past the half-century mark. Recall from Chapter 14 how adults in their late fifties and sixties extend their generativity, becoming “keepers of meaning,” or guardians of their culture (see page 471). Vaillant reported that the most-successful and best-adjusted entered a calmer, quieter time of life. “Passing the torch”—concern that the positive aspects of their culture survive—became a major preoccupation.

In societies around the world, older people are guardians of traditions, laws, and cultural values. This stabilizing force holds in check too-rapid change sparked by the questioning and challenging of adolescents and young adults. As people approach the end of middle age, they focus on longer-term, less-personal goals, such as the state of human relations in their society. And they become more philosophical, accepting the fact that not all problems can be solved in their lifetime.

Is There a Midlife Crisis?

Levinson (1978, 1996) reported that most men and women in his samples experienced substantial inner turmoil during the transition to middle adulthood. Yet Vaillant (1977, 2002) saw few examples of crisis but, rather, slow and steady change. These contrasting findings raise the question of how much personal upheaval actually accompanies entry to midlife. Are self-doubt and stress especially great during the forties, and do they prompt major restructuring of the personality, as the term **midlife crisis** implies?

Consider the reactions of Trisha, Devin, Jewel, Tim, and Elena to middle adulthood. Trisha and Devin moved easily into this period, whereas Jewel, Tim, and Elena engaged in greater questioning of their situations and sought alternative life paths. Clearly, wide individual differences exist in response to midlife. **TAKE A MOMENT...** Now ask several individuals in their twenties and thirties whether they expect to encounter a midlife crisis between ages 40 and 50. You are likely to find that Americans often anticipate it, perhaps because of culturally induced apprehension of aging (Wethington, Kessler, & Pixley, 2004). Yet little evidence supports this view of middle age as a turbulent time.

When MIDUS participants were asked to describe “turning points” (major changes in the way they felt about an important aspect of their lives) that had occurred during the past five years, most of the ones reported concerned work. Women's work-related turning points peaked in early adulthood, when many adjusted their work lives to accommodate marriage and childrearing (see Chapter 14). The peak for men, in contrast, came at midlife, a time of increased career responsibility

AP IMAGES/THE REPORTER, KEITH VANDERVORT

Like many midlifers, elementary school teacher Jaime Malwitz modified his career in ways that resemble a turning point, not a crisis. He designed a scientist-in-residence program for elementary schools. Here he serves as a resident physicist, discussing a density experiment with a fifth grader.

and advancement. Other common turning points in early and middle adulthood were positive: They involved fulfilling a dream and learning something good about oneself (Wethington, Kessler, & Pixley, 2004). Overall, turning points rarely resembled midlife crises. Even negative work-related turning points generally led to personal growth—for example, a layoff that sparked a positive career change or a shift in energy from career to personal life.

Asked directly if they had ever experienced something they would consider a midlife crisis, only one-fourth of the MIDUS respondents said yes. And they defined such events much more loosely than researchers do. Some reported a crisis well before age 40, others well after age 50. And most attributed it not to age but rather to challenging life events (Wethington, 2000). Consistent with this view, Elena had considered both a divorce and a new career long before she initiated these changes. In her thirties, she separated from her husband; later she reconciled with him and told him that she desired to return to school, which he firmly opposed. She put her own life on hold because of her daughter's academic and emotional difficulties and her husband's resistance.

Another way of exploring midlife questioning is to ask adults about life regrets—attractive opportunities for career or other life-changing activities they did not pursue or lifestyle changes they did not make. In two investigations of women in their early forties, those who acknowledged regret without making life changes, compared to those who modified their lives, reported less favorable psychological well-being and poorer physical health over time (Landman et al., 1995; Stewart & Vandewater, 1999). The two groups did not differ in social or financial resources available to effect change. Rather, they differed in personality: Those who made changes were higher in confidence and assertiveness.

By late midlife, with less time ahead to make life changes, people's interpretation of regrets plays a major role in their well-being. Mature, contented adults acknowledge a past characterized by some losses, have thought deeply about them, and feel stronger because of them. At the same time, they are able to disengage from them, investing in current, personally rewarding goals (King & Hicks, 2007). Among a sample of several hundred 60- to 65-year-olds diverse in SES, about half expressed at least one regret. Compared to those who had not resolved their disappointments, those who had come to terms with them (accepted and identified some eventual benefits) or had “put the best face on things” (identified benefits but still had some lingering regret) reported better physical health and greater life satisfaction (Torges, Stewart, & Miner-Rubino, 2005).

In sum, life evaluation is common during middle age. Most people make changes that are best described as turning points rather than drastic alterations of their lives. Those who cannot modify their life paths often look for the “silver lining” in life's difficulties (King & Hicks, 2007; Wethington, Kessler, & Pixley, 2004). The few midlifers who are in crisis typically have had early adulthoods in which gender roles, family pressures, or low income and poverty severely limited their ability to fulfill personal needs and goals, at home or in the wider world.

Stage or Life Events Approach

That crisis and major restructuring in midlife are rare raises, once again, a question we considered in Chapter 14: Can adult psychosocial changes can be organized into stages, as Erikson's, Levinson's, and Vaillant's theories indicate? A growing number of researchers believe the midadult transition is not stagelike (Freund & Ritter, 2009; McCrae & Costa, 2003; Srivastava et al., 2003). Some regard it as simply an adaptation to normative life events, such as children growing up, reaching the crest of a career, and impending retirement.

Yet recall from earlier chapters that life events are no longer as age-graded as they were in the past. Their timing is so variable that they cannot be the sole cause of midlife change. Furthermore, in several studies, people were asked to trace their thoughts, feelings, attitudes, and hopes during early and middle adulthood. Psychosocial change, in terms of personal disruption followed by reassessment, coincided with both family life cycle events and chronological age. For this reason, most experts regard adaptation during midlife as the combined result of growing older and social experiences (Lachman, 2004; Sneed, Whitbourne, & Culang, 2006). **TAKE A MOMENT...** Return to our discussion of generativity and the midlife transition on page 533, and notice how both factors are involved.

Finally, in describing their lives, the large majority of middle-aged people report troubling moments that prompt new understandings and goals. As we look closely at emotional and social development in middle adulthood, we will see that this period, like others, is characterized by both continuity and change. Debate persists over whether midlife psychosocial changes are stagelike. With this in mind, let's turn to the diverse inner concerns and outer experiences that contribute to psychological well-being and decision making in midlife.

ASK YOURSELF

REVIEW What personal and cultural forces motivate generativity? Why does it increase and contribute vitally to favorable adjustment in midlife?

CONNECT How might the approach of many middle-aged adults to handling life regrets prevent the occurrence of midlife crises?

APPLY After years of experiencing little personal growth at work, 42-year-old Mel looked for a new job and received an attractive offer in another city. Although he felt torn between leaving close friends and pursuing a long-awaited career opportunity, after several weeks of soul searching, he took the new job. Was Mel's dilemma a midlife crisis? Why or why not?

REFLECT Think of a middle-aged adult whom you admire. Describe the various ways that individual expresses generativity.

Stability and Change in Self-Concept and Personality

Midlife changes in self-concept and personality reflect growing awareness of a finite lifespan, longer life experience, and generative concerns. Yet certain aspects of personality remain stable, revealing the persistence of individual differences established during earlier periods.

Possible Selves

On a business trip, Jewel found a spare afternoon to visit Trisha. Sitting in a coffee shop, the two women reminisced about the past and thought aloud about the future. “It’s been tough living on my own and building the business,” Jewel said. “What I hope for is to become better at my work, to be more community-oriented, and to stay healthy and available to my friends. Of course, I would rather not grow old alone, but if I don’t find that special person, I suppose I can take comfort in the fact that I’ll never have to face divorce or widowhood.”

Jewel is discussing **possible selves**, future-oriented representations of what one hopes to become and what one is afraid of becoming. Possible selves are the temporal dimension of self-concept—what the individual is striving for and attempting to avoid. To lifespan researchers, these hopes and fears are just as vital in explaining behavior as people’s views of their current characteristics. Indeed, possible selves may be an especially strong motivator of action in midlife, as adults attach increased meaning to time (Frazier & Hooker, 2006). As we age, we may rely less on social comparisons in judging our self-worth and more on temporal comparisons—how well we are doing in relation to what we had planned.

Throughout adulthood, the personality traits people assign to their current selves show considerable stability. A 30-year-old who says he is cooperative, competent, outgoing, or successful is likely to report a similar picture at a later age. But reports of possible selves change greatly. Adults in their early twenties mention many possible selves, and their visions are lofty and idealistic—being “perfectly happy,” “rich and famous,” “healthy throughout life,” and not being “down and out” or “a person who does nothing important.” With age, possible selves become fewer in number and more modest and concrete. Most middle-aged people no longer desire to be the best or the most successful. Instead, they are largely concerned with performance of roles and responsibilities already begun—“being competent at work,” “being a good husband and father,” “putting my children through the colleges of their choice,” “staying healthy,” and not being “a burden to my family” or “without enough money to meet my daily needs” (Bybee & Wells, 2003; Cross & Markus, 1991; Ryff, 1991).

What explains these shifts in possible selves? Because the future no longer holds limitless opportunities, adults preserve

mental health by adjusting their hopes and fears. To stay motivated, they must maintain a sense of unachieved possibility, yet they must still manage to feel good about themselves and their lives despite disappointments (Lachman & Bertrand, 2002). For example, Jewel no longer desired to be an executive in a large company, as she had in her twenties. Instead, she wanted to grow in her current occupation. And although she feared loneliness in old age, she reminded herself that marriage can lead to equally negative outcomes, such as divorce and widowhood—possibilities that made not having attained an important interpersonal goal easier to bear.

Unlike current self-concept, which is constantly responsive to others’ feedback, possible selves (though influenced by others) can be defined and redefined by the individual, as needed. Consequently, they permit affirmation of the self, even when things are not going well (Bolkan & Hooker, 2012). Researchers believe that possible selves may be the key to continued well-being in adulthood, as people revise these future images to achieve a better match between desired and achieved goals. Many studies reveal that the self-esteem of middle-aged and older individuals equals or surpasses that of younger people, perhaps because of the protective role of possible selves (Robins & Trzesniewski, 2005).

Self-Acceptance, Autonomy, and Environmental Mastery

An evolving mix of competencies and experiences leads to changes in certain aspects of personality during middle adulthood. In Chapter 15, we noted that midlife brings gains in expertise and practical problem solving. Middle-aged adults also offer more complex, integrated descriptions of themselves than do younger and older individuals (Labouvie-Vief, 2003). Furthermore, midlife is typically a period in which the number of social roles peaks—spouse, parent, worker, and engaged community member. And status at work and in the community typically rises, as adults take advantage of opportunities for leadership and other complex responsibilities (Helson, Soto, & Cate, 2006).

These changes in cognition and breadth of roles undoubtedly contribute to other gains in personal functioning. In research on adults ranging in age from the late teens into the seventies, and in cultures as distinct as the United States and Japan, three qualities increased from early to middle adulthood:

- *Self-acceptance*: More than young adults, middle-aged people acknowledged and accepted both their good and bad qualities and felt positively about themselves and life.
- *Autonomy*: Middle-aged adults saw themselves as less concerned about others’ expectations and evaluations and more concerned with following self-chosen standards.
- *Environmental mastery*: Middle-aged people saw themselves as capable of managing a complex array of tasks easily and effectively (Karasawa et al., 2011; Ryff & Keyes, 1995).

As these findings indicate, midlife is generally a time of increased comfort with the self, independence, assertiveness, commitment to personal values, and life satisfaction (Helson, Jones, & Kwan, 2002; Keyes, Shmotkin, & Ryff, 2002; Stone et al., 2010). Perhaps because of this rise in overall psychological well-being, middle age is sometimes referred to as “the prime of life.”

At the same time, factors contributing to psychological well-being differ substantially among cohorts, as self-reports gathered from 25- to 65-year-old MIDUS survey respondents reveal (Carr, 2004). Among women who were born during the baby-boom years or later, and who thus benefited from the women’s movement, balancing career with family predicted greater self-acceptance and environmental mastery. But also consider that women born before or during World War II who sacrificed career to focus on child rearing—expected of young mothers in the 1950s and 1960s—were similarly advantaged in self-acceptance. Likewise, men who were in step with prevailing social expectations scored higher in well-being. Baby-boom and younger men who modified their work schedules to make room for family responsibilities—who fit their cohort’s image of the “good father”—were more self-accepting. But older men who made this accommodation scored much lower in self-acceptance than those who focused on work and thus conformed to the “good provider” ideal of their times. (See the Biology and Environment box on pages 540–541 for additional influences on midlife psychological well-being.)

Notions of happiness, however, vary among cultures. In comparisons of Japanese and Korean adults with same-age U.S. MIDUS participants, the Japanese and Koreans reported lower levels of psychological well-being, largely because they were less willing than the Americans to endorse individualistic traits, such as self-acceptance and autonomy, as characteristic of themselves (Karasawa et al., 2011; Keyes & Ryff, 1998b). Consistent with their collectivist orientation, Japanese and Koreans’ highest well-being scores were on positive relations with others. The Korean participants clarified that they viewed personal fulfillment as achieved through family, especially the success of children. Americans also regarded family relations as relevant to well-being but placed greater emphasis on their own traits and accomplishments than on their children’s.

Coping with Daily Stressors

In Chapter 15, we discussed the importance of stress management in preventing illness. It is also vital for psychological well-being. In a MIDUS satellite study in which more than 1,000 participants were interviewed on eight consecutive evenings, researchers found an early- to mid-adulthood plateau in frequency of daily stressors, followed by a decline as work and family responsibilities ease and leisure time increases (see Figure 16.2) (Almeida & Horn, 2004). Women reported more frequent role overload (conflict among roles of employee, spouse, parent, and caregiver of an aging parent) and family-network and child-related stressors, men more work-related stressors, but both

FIGURE 16.2 Age-related changes in daily stressors among men and women. In a MIDUS satellite study, researchers interviewed more than 1,000 adults on eight consecutive evenings. Findings revealed an early- to mid-adulthood plateau, followed by a decline as work and family responsibilities ease and leisure time increases. (From D. M. Almeida & M. C. Horn, 2004, “Is Daily Life More Stressful During Middle Adulthood?” in O. G. Brim, C. D. Ruff, and R. C. Kessler [Eds.], *How Healthy Are We? A National Study of Well-Being at Midlife*. Chicago: The University of Chicago Press, p. 438. Adapted by permission of The University of Chicago Press.)

genders experienced all varieties. Compared with older people, young and midlife adults also perceived their stressors as more disruptive and unpleasant, perhaps because they often experienced several at once, and many involved financial risks and children.

But recall, also, from Chapter 15 that midlife brings an increase in effective coping strategies. Middle-aged individuals are more likely to identify the positive side of difficult situations, postpone action to permit evaluation of alternatives, anticipate and plan ways to handle future discomforts, and use humor to express ideas and feelings without offending others (Diehl, Coyle, & Labouvie-Vief, 1996). Notice how these efforts flexibly draw on both problem-centered and emotion-centered strategies.

Why might effective coping increase in middle adulthood? Other personality changes seem to support it. Complex, integrated, coherent self-descriptions—which increase in midlife, indicating an improved ability to blend strengths and weaknesses into an organized picture—predict a stronger sense of personal control over outcomes and good coping strategies (Hay & Diehl, 2010; Labouvie-Vief & Diehl, 2000). Midlife gains in emotional stability and confidence in handling life’s problems may also contribute (Roberts et al., 2007; Roberts & Mroczek, 2008). These attributes predict work and relationship effectiveness—outcomes that reflect the sophisticated, flexible coping of middle age.

Biology and Environment

What Factors Promote Psychological Well-Being in Midlife?

For Trisha and Devin, midlife brought contentment and high life satisfaction. But the road to happiness was rockier for Jewel, Tim, and Elena. What factors contribute to individual differences in psychological well-being at midlife? Consistent with the lifespan perspective, biological, psychological, and social forces are involved, and their effects are interwoven.

Good Health and Exercise

Good health affects energy and zest for life at any age. But during middle and late adulthood, taking steps to improve health and prevent disability becomes a better predictor of psychological well-being. Many studies confirm that engaging in regular exercise—walking, dancing, jogging, or swimming—is more strongly associated with self-rated health and a positive outlook in older than in younger adults (Bherer, 2012). Middle-aged people who maintain an exercise regimen are likely to perceive themselves as particularly active for their age and, therefore, to feel a special sense of accomplishment (Netz et al., 2005). In addition, physical activity enhances self-

efficacy and effective stress management (see page 515 in Chapter 15).

Sense of Control and Personal Life Investment

Middle-aged adults who report a high sense of control over events in various aspects of their lives—health, family, and work—also report more favorable psychological well-being. Sense of control contributes further to self-efficacy. It also predicts use of more effective coping strategies, including seeking of social support, and thereby helps sustain a positive outlook in the face of health, family, and work difficulties (Lachman, Neupert, & Agrigoroaei, 2011).

Personal life investment—firm commitment to goals and involvement in pursuit of those goals—also adds to mental health and life satisfaction (Staudinger & Bowen, 2010). According to Mihaly Csikszentmihalyi, a vital wellspring of

These yoga students express a sense of purpose and accomplishment. Maintaining an exercise regimen contributes greatly to midlife psychological well-being.

happiness is *flow*—the psychological state of being so engrossed in a demanding, meaningful activity that one loses all sense of time and self-awareness. People describe flow as the height of enjoyment, even as an ecstatic state. The more people experience flow, the more they judge their lives to be gratifying (Nakamura & Csikszentmihalyi, 2009). Although flow is common in people engaged in creative endeavors, many others report it—students who love studying, employees who like their jobs, adults involved in challenging leisure pursuits, and

Gender Identity

In her forties and early fifties, Trisha appeared more assertive at work. She spoke out more freely at meetings and took a leadership role when a team of lawyers worked on an especially complex case. She was also more dominant in family relationships, expressing her opinions to her husband and son more readily than she had 10 or 15 years earlier. In contrast, Devin's sense of empathy and caring became more apparent, and he was less assertive and more accommodating to Trisha's wishes than before.

Many studies report an increase in “masculine” traits in women and “feminine” traits in men across middle age (Huyck, 1990; James et al., 1995). Women become more confident, self-sufficient, and forceful, men more emotionally sensitive, caring, considerate, and dependent. These trends appear in cross-sectional and longitudinal research, in people varying in SES,

and in diverse cultures—not just Western industrialized nations but also village societies such as the Maya of Guatemala, the Navajo of the United States, and the Druze of the Middle East (Fry, 1985; Gutmann, 1977; Turner, 1982). Consistent with Levinson's theory, gender identity in midlife becomes more androgynous—a mixture of “masculine” and “feminine” characteristics.

Although the existence of these changes is well-accepted, explanations for them are controversial. A well-known evolutionary view, **parental imperative theory**, holds that identification with traditional gender roles is maintained during the active parenting years to help ensure the survival of children. Men become more goal-oriented, while women emphasize nurturance (Gutmann & Huyck, 1994). After children reach adulthood, parents are free to express the “other-gender” side of their personalities.

parents and grandparents engaged in pleasurable learning activities with children. Flow depends on perseverance and skill at complex endeavors that offer potential for growth. These qualities are well-developed in middle adulthood.

Positive Social Relationships

Developing gratifying social ties is closely linked to midlife psychological well-being. In a survey of college alumni, those who preferred occupational prestige and high income to close friends were twice as likely as other respondents to describe themselves as “fairly” or “very” unhappy (Perkins, 1991, as cited by Myers, 2000).

Supportive relationships, especially with friends and relatives, improve mental health by promoting positive emotions and protecting against stress (Fiori, Antonucci, & Cortina, 2006; Powdthavee, 2008). Enjoyable social ties can even strengthen the impact of an exercise regimen on well-being. Among an ethnically diverse sample of women using a private gym or an African Caribbean community center, exercising with likeminded companions contributed to their happiness and life satisfaction (Wray, 2007). The social side of going to the gym appeared especially important to minority women, who were less concerned with physical-appearance benefits than their Caucasian agemates.

But this biological account has been criticized. As we discussed in earlier chapters, parents need both warmth and assertiveness (in the form of firmness and consistency) to rear children effectively. And although children’s departure from the home is related to men’s openness to the “feminine” side of their personalities, the link to a rise in “masculine” traits among women is less apparent (Huyck, 1996, 1998). In longitudinal research, college-educated women in the labor force became more independent by their early forties, regardless of whether they had children; those who were homemakers did not. Women attaining high status at work gained most in dominance, assertiveness, and outspokenness by their early fifties (Helson & Picano, 1990; Wink & Helson, 1993). Furthermore, cohort effects can contribute to this trend: In one study, middle-aged women of the baby-boom generation—who experienced new career opportunities as a result of the women’s

A Good Marriage

Although friendships are important, a good marriage boosts psychological well-being even more. The role of marriage in mental health increases with age, becoming a powerful predictor by late midlife (Marks, Bumpass, & Jun, 2004; Marks & Greenfield, 2009).

Longitudinal studies tracking people as they move in and out of intimate relationships suggest that marriage actually brings about well-being. For example, when interviews with over 13,000 U.S. adults were repeated five years later, people who remained married reported greater happiness than those who remained single. Those who separated or divorced became less happy, reporting considerable depression (Marks & Lambert, 1998). Couples who married for the first time experienced a sharp increase in happiness, those who entered their second marriage a modest increase.

Although not everyone is better off married, the link between marriage and well-being is similar in many nations, suggesting that marriage changes people’s behavior in ways that make them better off (Diener et al., 2000; Lansford et al., 2005). Married partners monitor each other’s health and offer care in times of illness. They also earn and save more money than single people,

and higher income is modestly linked to psychological well-being (Myers, 2000; Waite, 1999). Furthermore, sexual satisfaction predicts mental health, and married couples have more satisfying sex lives than singles (see Chapter 13).

Mastery of Multiple Roles

Success in handling multiple roles—spouse, parent, worker, community volunteer—is linked to psychological well-being. In the MIDUS survey, as role involvement increased, both men and women reported greater environmental mastery, more rewarding social relationships, heightened sense of purpose in life, and more positive emotion. Furthermore, adults who occupied multiple roles and who also reported high control (suggesting effective role management) scored especially high in well-being—an outcome that was stronger for less-educated adults (Ahrens & Ryff, 2006). Control over roles may be vital for individuals with lower educational attainment, whose role combinations may be particularly stressful and who have fewer economic resources.

Finally, among nonfamily roles, community volunteering in the latter part of midlife contributes uniquely to psychological well-being (Choi & Kim, 2011; Ryff et al., 2012). It may do so by strengthening self-efficacy, generativity, and altruism.

movement—more often described themselves as having masculine and androgynous traits than did older women (Strough et al., 2007).

Additional demands of midlife may prompt a more androgynous orientation. For example, among men, a need to enrich a marital relationship after children have departed, along with reduced chances for career advancement, may be involved in the awakening of emotionally sensitive traits. Compared with men, women are far more likely to face economic and social disadvantages. A greater number remain divorced, are widowed, and encounter discrimination in the workplace. Self-reliance and assertiveness are vital for coping with these circumstances.

In sum, androgyny in midlife results from a complex combination of social roles and life conditions. In Chapter 8, we noted that androgyny predicts high self-esteem. In adulthood,

In middle age, gender identity becomes more androgynous for both sexes. Men tend to show an increase in “feminine” traits, becoming more emotionally sensitive, caring, considerate, and dependent.

it is also associated with cognitive flexibility, creativity, advanced moral reasoning, and psychosocial maturity (Prager & Bailey, 1985; Runco, Cramond, & Pagnani, 2010; Waterman & Whitbourne, 1982). People who integrate the masculine and feminine sides of their personalities tend to be psychologically healthier, perhaps because they are able to adapt more easily to the challenges of aging.

Individual Differences in Personality Traits

Although Trisha and Jewel both became more self-assured and assertive in midlife, in other respects they differed. Trisha had always been more organized and hard-working, Jewel more gregarious and fun-loving. Once, the two women traveled together. At the end of each day, Trisha was disappointed if she had not kept to a schedule and visited every tourist attraction. Jewel liked to “play it by ear”—wandering through streets and stopping to talk with shopkeepers and residents.

In previous sections, we considered personality changes common to many middle-aged adults, but stable individual differences also exist. Through factor analysis of self-report ratings, the hundreds of personality traits on which people differ have been reduced to five basic factors, often referred to as the “**big five**” personality traits: neuroticism, extroversion, openness to experience, agreeableness, and conscientiousness. Table 16.1 provides a description of each. Notice that Trisha is high in conscientiousness, whereas Jewel is high in extroversion.

Longitudinal and cross-sectional studies of U.S. men and women reveal that agreeableness and conscientiousness increase from the teenage years through middle age, whereas neuroticism declines, and extroversion and openness to experience do not change or decrease slightly—changes that reflect “settling down” and greater maturity. Similar trends have been identified in more than fifty countries varying widely in cultural traditions, including Canada, Germany, Italy, Japan, Russia, and South Korea (McCrae & Costa, 2006; Roberts, Walton, & Viechtbauer, 2006; Schmitt et al., 2007; Soto et al., 2011; Srivastava et al., 2003). The consistency of these cross-cultural findings has led some researchers to conclude that adult personality change is genetically influenced. They note that individual differences in the “big five” traits are large and highly stable: A person who scores high or low at one age is likely to do the same at another, over intervals ranging from 3 to 30 years (McCrae & Costa, 2006).

How can there be high stability in personality traits, yet significant changes in aspects of personality discussed earlier? Studies of the “big five” traits include very large samples and typically do not examine the impact of a host of contextual factors—including life events, the social clock, and cultural values—that shape aspirations, goals, and expectations for appropriate behavior (Caspi & Roberts, 2001). Look closely at the traits in Table 16.1, and you will see that they differ from the attributes considered in previous sections: They do not take into account motivations, preferred tasks, and coping styles, nor do they consider how certain aspects of personality, such as masculinity and femininity, are integrated. Theorists concerned

TABLE 16.1 The “Big Five” Personality Traits

TRAIT	DESCRIPTION
Neuroticism	Individuals who are high on this trait are worrying, temperamental, self-pitying, self-conscious, emotional, and vulnerable. Individuals who are low are calm, even-tempered, self-content, comfortable, unemotional, and hardy.
Extroversion	Individuals who are high on this trait are affectionate, talkative, active, fun-loving, and passionate. Individuals who are low are reserved, quiet, passive, sober, and emotionally unreactive.
Openness to experience	Individuals who are high on this trait are imaginative, creative, original, curious, and liberal. Individuals who are low are down-to-earth, uncreative, conventional, uncurious, and conservative.
Agreeableness	Individuals who are high on this trait are soft-hearted, trusting, generous, acquiescent, lenient, and good-natured. Individuals who are low are ruthless, suspicious, stingy, antagonistic, critical, and irritable.
Conscientiousness	Individuals who are high on this trait are conscientious, hard-working, well-organized, punctual, ambitious, and persevering. Individuals who are low are negligent, lazy, disorganized, late, aimless, and nonpersistent.

Source: McCrae, 2011; McCrae & Costa, 2006.

with change due to experience focus on how personal needs and life events induce new strategies and goals; their interest is in “the human being as a complex adaptive system” (Block, 1995, 2011, p. 19). In contrast, those who emphasize stability due to heredity measure personality traits on which individuals can easily be compared and that are present at any time of life.

To resolve this apparent contradiction, we can think of adults as changing in overall organization and integration of personality but doing so on a foundation of basic, enduring dispositions that support a coherent sense of self as people adapt to changing life circumstances. When more than 2,000 individuals in their forties were asked to reflect on their personalities during the previous six years, 52 percent said they had “stayed the same,” 39 percent said they had “changed a little,” and 9 percent said they had “changed a lot” (Herbst et al., 2000). Again, these findings contradict a view of middle adulthood as a period of great turmoil and change. But they also underscore that personality remains an “open system,” responsive to the pressures of life experiences. Indeed, certain midlife personality changes may strengthen trait consistency! Improved self-understanding, self-acceptance, and skill at handling challenging situations may result in less need to modify basic personality dispositions over time.

ASK YOURSELF

REVIEW Summarize personality changes at midlife. How can these changes be reconciled with increasing stability of the “big five” personality traits?

CONNECT List cognitive gains that typically occur during middle adulthood. (See Chapter 15, pages 518–519 and 524–525.) How might they support midlife personality changes?

APPLY Jeff, age 46, suggested to his wife, Julia, that they set aside time once a year to discuss their relationship—both positive aspects and ways to improve. Julia was surprised because Jeff had never before expressed interest in working on their marriage. What midlife developments probably fostered this new concern?

REFLECT List your hoped-for and feared possible selves. Then ask family members in early and middle adulthood to do the same. Are their reports consistent with age-related research findings? Explain.

Relationships at Midlife

The emotional and social changes of midlife take place within a complex web of family relationships and friendships and an intensified personal focus on generative concerns. Although some middle-aged people live alone, the vast majority—87 percent in the United States—live in families, most with a spouse

(U.S. Census Bureau, 2012b). Partly because they have ties to older and younger generations in their families and partly because their friendships are well-established, people tend to have a larger number of close relationships during midlife than at any other period (Antonucci, Akiyama, & Takahashi, 2004).

The middle adulthood phase of the family life cycle is often referred to as “launching children and moving on.” In the past, it was called the “empty nest,” but this phrase implies a negative transition, especially for women who have devoted themselves entirely to their children and for whom the end of active parenting can trigger feelings of emptiness and regret. But for most people, middle adulthood is a liberating time, offering a sense of completion and opportunities to strengthen social ties and rekindle interests.

As our discussion in Chapter 14 revealed, increasing numbers of young adults are living at home because of tight job markets and financial challenges, yielding launch–return–relaunch patterns for many middle-aged parents. Still, a declining birthrate and longer life expectancy mean that many contemporary parents do launch children a decade or more before retirement and then turn to other rewarding activities. As adult children depart and marry, middle-aged parents must adapt to new roles of parent-in-law and grandparent. At the same time, they must establish a different type of relationship with their aging parents, who may become ill or infirm and die.

Middle adulthood is marked by the greatest number of exits and entries of family members. Let’s see how ties within and beyond the family change during this time of life.

Marriage and Divorce

Although not all couples are financially comfortable, middle-aged households are well-off economically compared with other age groups. Americans between 45 and 54 have the highest average annual income. And the baby boomers—more of whom have earned college and postgraduate degrees and live in dual-earner families—are financially better off than previous midlife generations (Eggebeen & Sturgeon, 2006; U.S. Census Bureau, 2012b). Partly because of increased education and financial security, the contemporary social view of marriage in midlife is one of expansion and new horizons.

These forces strengthen the need to review and adjust the marital relationship. For Devin and Trisha, this shift was gradual. By middle age, their marriage had permitted satisfaction of family and individual needs, endured many changes, and culminated in deeper feelings of love. Elena’s marriage, in contrast, became more conflict-ridden as her teenage daughter’s problems introduced added strains and as departure of children made marital difficulties more obvious. Tim’s failed marriage revealed yet another pattern. With passing years, the number of problems declined, but so did the love expressed (Rokach, Cohen, & Dreman, 2004). As less happened in the relationship, good or bad, the couple had little to keep them together.

As the Biology and Environment box on pages 540–541 revealed, marital satisfaction is a strong predictor of midlife psychological well-being. Middle-aged men who have focused

LORI ADAMSKI PEEK/WORKBOOK STOCK/GETTY IMAGES

For many middle-aged couples, having forged a relationship that permits satisfaction of both family and individual needs results in deep feelings of love.

only on career often realize the limited nature of their pursuits. At the same time, women may insist on a more gratifying relationship. And children fully engaged in adult roles remind middle-aged parents that they are in the latter part of their lives, prompting many to decide that the time for improving their marriages is now (Berman & Napier, 2000).

As in early adulthood, divorce is one way of resolving an unsatisfactory marriage in midlife. The divorce rate of U.S. 50- to 65-year-olds has doubled over the past two decades (Brown & Lin, 2012). Divorce at any age takes a heavy psychological toll, but midlifers seem to adapt more easily than younger people. A survey of more than 13,000 Americans revealed that following divorce, middle-aged men and women reported less decline in psychological well-being than their younger counterparts (Marks & Lambert, 1998). Midlife gains in practical problem solving and effective coping strategies may reduce the stressful impact of divorce.

Because the divorce rate is more than twice as great among remarried couples as among those in first marriages, about half of midlife divorces involve people who have had one or more previous unsuccessful marriages. Highly educated middle-aged adults are more likely to divorce, probably because their more comfortable economic circumstances make it easier to leave an unhappy marriage (Skaff, 2006). Nevertheless, for many women, marital breakup—especially when it is repeated—severely reduces standard of living (see page 347 in Chapter 10). For this reason, in midlife and earlier, it is a strong contributor to the **feminization of poverty**—a trend in which women who support themselves or their families have become the majority

of the adult population living in poverty, regardless of age and ethnic group. Because of weak public policies safeguarding families (see Chapter 2), the gender gap in poverty is higher in the United States than in other Western industrialized nations (U.S. Census Bureau, 2012b).

What do recently divorced middle-aged people say about why their marriages ended? Women frequently mention communication problems, inequality in the relationship, adultery, gradual distancing, substance abuse, physical and verbal abuse, or their own desire for autonomy. Men also bring up poor communication and sometimes admit that their “workaholic” lifestyle or emotional inattentiveness played a major role in their marital failure. Women are more likely than men to initiate divorce, and those who do fare somewhat better in psychological well-being. Men who initiate a split often already have another romantic involvement to turn to (Rokach, Cohen, & Dreman, 2004; Sakraida, 2005; Schneller & Arditti, 2004).

Longitudinal evidence reveals that middle-aged women who weather divorce successfully tend to become more tolerant, comfortable with uncertainty, nonconforming, and self-reliant in personality—factors believed to be fostered by divorce-forced independence. And both men and women reevaluate what they consider important in a healthy relationship, placing greater weight on equal friendship and less on passionate love than they had the first time. As in earlier periods, divorce represents both a time of trauma and a time of growth (Baum, Rahav, & Sharon, 2005; Schneller & Arditti, 2004). Little is known about long-term adjustment following divorce among middle-aged men, perhaps because most enter new relationships and remarry within a short time.

Changing Parent–Child Relationships

Parents’ positive relationships with their grown children are the result of a gradual process of “letting go,” starting in childhood, gaining momentum in adolescence, and culminating in children’s independent living. As noted earlier, most parents “launch” adult children sometime in midlife. But because more people are delaying having children to their thirties and even forties (see page 438 in Chapter 13), the age at which midlifers experience their children’s departure varies widely. Most parents adjust well; only a minority have difficulty (Mitchell & Lovegreen, 2009). Investment in nonparental relationships and roles, children’s characteristics, parents’ marital and economic circumstances, and cultural forces affect the extent to which this transition is expansive and rewarding or sad and distressing.

After their son Mark secured a career-entry job and moved out of the family home permanently, Devin and Trisha felt a twinge of nostalgia combined with a sense of pride in their grown son’s maturity and success. Beyond this, they returned to rewarding careers and community participation and delighted in having more time for each other. Parents who have developed gratifying alternative activities typically welcome their children’s adult status (Mitchell & Lovegreen, 2009). A strong work orientation, especially, predicts gains in life satisfaction after children depart from the home (Silverberg, 1996).

Wide cultural variations exist in the social clock for children's departure. Recall from Chapter 13 that many young people from low-SES homes and with cultural traditions of extended-family living do not leave home early. In the Southern European countries of Greece, Italy, and Spain, parents often actively delay their children's leaving. In Italy, for example, parents believe that moving out without a "justified" reason signifies that something is wrong in the family. Hence, many more Italian young adults reside with their parents until marriage than in other Western nations. At the same time, Italian adults grant their grown children extensive freedom within the parental home (Rusconi, 2004). Parent–adult-child relationships are usually positive, making living with parents attractive.

With the end of parent–child coresidence comes a substantial decline in parental authority. Devin and Trisha no longer knew of Mark's daily comings and goings or expected him to inform them. Nevertheless, Mark telephoned at regular intervals to report on events in his life and seek advice about major decisions. Although the parental role changes, its continuation is important to middle-aged adults. Departure of children is a relatively minor event as long as parent–child contact and affection are sustained (Mitchell & Lovegreen, 2009). When it results in little or no communication, parents' psychological well-being declines.

Whether or not they reside with parents, adolescent and young-adult children who are "off-time" in development—who deviate from parental expectations about how the path to adult responsibilities should unfold—can prompt parental strain (Pillemer & Sutor, 2002; Settersten, 2003). Consider Elena, whose daughter was doing poorly in her college courses and in danger of not graduating. The need for extensive parental guidance, at a time when she expected her daughter to be more responsible and independent, caused anxiety and unhappiness for Elena, who was ready to reduce time devoted to active parenting.

In one study, researchers asked a large sample of 40- to 60-year-old parents to report on their grown children's problems and successes along with their own psychological well-being. Consistent with the familiar saying, "parents are only as happy as their least happy child," having even one problematic child dampened parents' well-being, but having a successful child did not have a compensating positive effect. The more grown children with problems, the poorer parents' well-being. In contrast, it took multiple successful grown children to sway parents' well-being in a favorable direction (Fingerman et al., 2012a). As with marriages, negative, conflict-ridden experiences with grown children are particularly salient, profoundly affecting midlife parents' psychological states.

Throughout middle adulthood, parents continue to give more assistance to children than they receive, especially while children are unmarried or when they face difficulties, such as marital breakup or unemployment (Ploeg et al., 2004; Zarit & Eggebeen, 2002). Support in Western countries typically flows "downstream": Although ethnic variations exist, most middle-aged parents provide more financial, practical, emotional, and social support to their offspring than to their aging parents,

unless a parent has an urgent need (declining health or other crises) (Fingerman & Birditt, 2011; Fingerman et al., 2011a). In explaining their generous support of adult children, parents usually mention the importance of the relationship. And providing adult children with assistance enhances midlife psychological well-being (Marks & Greenfield, 2009). Clearly, middle-aged adults remain invested in their adult children's development and continue to reap deep personal rewards from the parental role.

When children marry, parents must adjust to an enlarged family network that includes in-laws. Difficulties occur when parents do not approve of their child's partner or when the young couple adopts a way of life inconsistent with parents' values. Parents who take steps to forge a positive tie with a future daughter- or son-in-law generally experience a closer relationship after the couple marries (Fingerman et al., 2012b). And when warm, supportive relationships endure, intimacy between parents and children increases over the adult years, with great benefits for parents' life satisfaction (Ryff, Singer, & Seltzer, 2002). Members of the middle generation, especially mothers, usually take on the role of **kinkeeper**, gathering the family for celebrations and making sure everyone stays in touch.

Parents of adult children expect a mature relationship, marked by tranquility and contentment. Yet many factors—on both the child's and the parent's side—affect whether that goal is achieved. Applying What We Know on page 546 suggests ways middle-aged parents can increase the chances that bonds with adult children will be loving and rewarding and serve as contexts for personal growth.

Grandparenthood

Two years after Mark married, Devin and Trisha were thrilled to learn that a granddaughter was on the way. Although the stereotypical image of grandparents as elderly persists, today the average age of becoming a grandparent is 50 years for American women, 52 for American men (Legacy Project, 2012). A longer life expectancy means that many adults will spend one-third or more of their lifespan in the grandparent role.

Meanings of Grandparenthood. Middle-aged adults typically rate grandparenthood as highly important, following closely behind the roles of parent and spouse but ahead of worker, son or daughter, and sibling (Reitzes & Mutran, 2002). Why did Trisha and Devin, like many others their age, greet the announcement of a grandchild with such enthusiasm? Most people experience grandparenthood as a significant milestone, mentioning one or more of the following gratifications:

- *Valued elder*—being perceived as a wise, helpful person
- *Immortality through descendants*—leaving behind not just one but two generations after death
- *Reinvolvement with personal past*—being able to pass family history and values to a new generation
- *Indulgence*—having fun with children without major child-rearing responsibilities (AARP, 2002; Hebblethwaite & Norris, 2011)

Applying What We Know

Ways Middle-Aged Parents Can Promote Positive Ties with Their Adult Children

Suggestion	Description
Emphasize positive communication.	Let adult children and their intimate partners know of your respect, support, and interest. This not only communicates affection but also permits conflict to be handled in a constructive context.
Avoid unnecessary comments that are a holdover from childhood.	Adult children, like younger children, appreciate an age-appropriate relationship. Comments that have to do with safety, eating, and self-care (“Be careful on the freeway,” “Don’t eat those foods,” “Make sure you wear a sweater—it’s cold out today”) annoy adult children and can stifle communication.
Accept the possibility that some cultural values and practices and aspects of lifestyle will be modified in the next generation.	In constructing a personal identity, most adult children have gone through a process of evaluating the meaning of cultural values and practices for their own lives. Traditions and lifestyles cannot be imposed on adult children.
When an adult child encounters difficulties, resist the urge to “fix” things.	Accept the fact that no meaningful change can take place without the willing cooperation of the adult child. Stepping in and taking over communicates a lack of confidence and respect. Find out whether the adult child wants your help, advice, and decision-making skills.
Be clear about your own needs and preferences.	When it is difficult to arrange for a visit, babysit, or provide other assistance, say so and negotiate a reasonable compromise rather than letting resentment build.

Grandparent–Grandchild Relationships. Grandparents’ styles of relating to grandchildren vary as widely as the meanings they derive from their new role. The grandparent’s and grandchild’s age and sex make a difference. When their granddaughter was young, Trisha and Devin enjoyed an affectionate, playful relationship with her. As she got older, she looked to them for information and advice in addition to warmth and caring. By the time their granddaughter reached adolescence,

Trisha and Devin had become role models, family historians, and conveyers of social, vocational, and religious values.

Living nearby is the strongest predictor of frequent, face-to-face interaction with young grandchildren. Despite high family mobility in Western industrialized nations, most grandparents live close enough to at least one grandchild to enable regular visits. But because time and resources are limited, number of “grandchild sets” (households with grandchildren) reduces grandparent visits (Uhlenberg & Hammill, 1998). A strong desire to affect the development of grandchildren can motivate grandparents’ involvement. As grandchildren get older, distance becomes less influential and relationship quality more so: The extent to which adolescent or young-adult grandchildren believe their grandparent values contact is a good predictor of a close bond (Brussoni & Boon, 1998).

As Figure 16.3 shows, maternal grandmothers report more frequent visits with grandchildren than do paternal grandmothers, who are slightly advantaged over both maternal and paternal grandfathers (Uhlenberg & Hammill, 1998). Typically, relationships are closer between grandparents and grandchildren of the same sex and, especially, between maternal grandmothers and granddaughters—a pattern found in many countries (Brown & Rodin, 2004). Grandmothers also report higher satisfaction with the grandparent role than grandfathers, perhaps because grandmothers are more likely to participate in recreational, religious, and family activities with grandchildren (Reitzes & Mutran, 2004; Silverstein & Marengo, 2001). The grandparent role may be a vital means through which women satisfy their kinkeeping function.

SES and ethnicity also influence grandparent–grandchild ties. In higher-income families, where the grandparent role is not central to family maintenance and survival, it is fairly

Many grandparents derive great joy from an affectionate, playful relationship with young grandchildren. As this grandchild gets older, he may look to his grandfather for advice, as a role model, and for family history in addition to warmth and caring.

FIGURE 16.3 Influence of grandparent sex and lineage on frequent visiting of grandchildren. When a nationally representative sample of 4,600 U.S. grandparents were asked how often they visited a particular set of grandchildren, maternal grandmothers were especially likely to report visiting frequently (at least once a week). Paternal grandmothers slightly exceeded both maternal and paternal grandfathers. (From P. Uhlenberg & B. G. Hammill, 1998, "Frequency of Grandparent Contact with Grandchild Sets: Six Factors That Make a Difference," *Gerontologist*, 38, p. 281. Copyright © 1998 The Gerontological Society of America. Reprinted by permission of Oxford University Press and Peter Uhlenberg.)

unstructured and takes many forms. In low-income families, by contrast, grandparents often perform essential activities. For example, many single parents live with their families of origin and depend on grandparents' financial and caregiving assistance to reduce the impact of poverty. Compared with grandchildren in intact families, grandchildren in single-parent and stepparent families report engaging in more diverse, higher-quality activities with their grandparents (Kennedy & Kennedy, 1993). As children experience the stress of family transition, bonds with grandparents take on increasing importance.

In some cultures, grandparents are absorbed into an extended-family household and become actively involved in child rearing. When a Chinese, Korean, or Mexican-American maternal grandmother is a homemaker, she is the preferred caregiver while parents of young children are at work (Kamo, 1998; Williams & Torrez, 1998). Similarly, involvement in child care is high among Native-American grandparents. In the absence of a biological grandparent, an unrelated aging adult may be integrated into the family to serve as a mentor and disciplinarian for children (Werner, 1991). (See Chapter 2, page 66, for a description of the grandmother's role in the African-American extended family.)

Increasingly, grandparents have stepped in as primary caregivers in the face of serious family problems. As the Social Issues: Health box on page 548 reveals, a rising number of American children live apart from their parents in grandparent-headed households. Despite their willingness to help and their competence at child rearing, grandparents who take full responsibility for young children experience considerable emotional

and financial strain. They need more assistance from community and government agencies than is currently available.

Because parents usually serve as gatekeepers of grandparents' contact with grandchildren, relationships between grandparents and their daughter-in-law or son-in-law strongly affect the closeness of grandparent-grandchild ties. A positive bond with a daughter-in-law seems particularly important in the relationship between grandparents and their son's children (Fingerman, 2004). And after a marital breakup, grandparents who are related to the custodial parent (typically the mother) have more frequent contact with grandchildren.

When family relationships are positive, grandparenthood provides an important means of fulfilling personal and societal needs in midlife and beyond. Typically, grandparents are a frequent source of pleasure, support, and knowledge for children, adolescents, and young adults. They also provide the young with firsthand experience in how older people think and function. In return, grandchildren become deeply attached to grandparents and keep them abreast of social change. Clearly, grandparenthood is a vital context for sharing between generations.

Middle-Aged Children and Their Aging Parents

The percentage of middle-aged Americans with living parents has risen dramatically—from 10 percent in 1900 to over 50 percent in the first decade of the twenty-first century (U.S. Census Bureau, 2012b). A longer life expectancy means that adult children and their parents are increasingly likely to grow old together. What are middle-aged children's relationships with their aging parents like? And how does life change for adult children when an aging parent's health declines?

Frequency and Quality of Contact. A widespread myth is that adults of past generations were more devoted to their aging parents than are today's adults. Although adult children spend less time in physical proximity to their parents, the reason is not neglect or isolation. Because of a desire to be independent, made possible by gains in health and financial security, fewer aging adults live with younger generations now than in the past. Nevertheless, approximately two-thirds of older adults in the United States live close to at least one of their children, and frequency of contact is high through both visits and telephone calls (U.S. Census Bureau, 2012b). Proximity increases with age: Aging adults who move usually do so in the direction of kin, and younger people tend to move in the direction of their aging parents.

Middle age is a time when adults reassess relationships with their parents, just as they rethink other close ties. Many adult children become more appreciative of their parents' strengths and generosity and mention positive changes in the quality of the relationship, even after parents show physical declines. A warm, enjoyable relationship contributes to both parent and adult-child well-being (Fingerman et al., 2007, 2008; Pudrovska, 2009). Trisha, for example, felt closer to her parents and often asked them to tell her more about their earlier lives.

Social Issues: Health

Grandparents Rearing Grandchildren: The Skipped-Generation Family

Nearly 2.4 million U.S. children—4 to 5 percent of the child population—live with grandparents but apart from parents, in **skipped-generation families** (U.S. Census Bureau, 2012b). The number of grandparents rearing grandchildren has increased over the past two decades. The arrangement occurs in all ethnic groups, though more often in African-American, Hispanic, and Native-American families than in Caucasian families. Although grandparent caregivers are more likely to be women than men, many grandfathers participate (Fuller-Thomson & Minkler, 2005, 2007; Minkler & Fuller-Thomson, 2005). Grandparents generally step in when parents' troubled lives—as a result of substance abuse, child abuse and neglect, family violence, or physical or mental illness—threaten children's well-being (Langosch, 2012). Often these families take in two or more children.

As a result, grandparents usually assume the parenting role under highly stressful life circumstances. Unfavorable child-rearing experiences have left their mark on the children, who show high rates of learning difficulties, depression, and antisocial behavior. Absent parents' adjustment difficulties strain family relationships. Parents may interfere by violating the grandparents' behavioral limits, taking grandchildren away without permission, or making promises to children that they do not keep. These youngsters also introduce financial burdens into households that often are already low-income (Mills, Gomez-Smith, & De Leon, 2005; Williamson, Softas-Nall, & Miller, 2003). All these factors heighten grandparents' emotional distress.

Grandparents struggle with daily dilemmas—wanting to be grandparents, not parents; wanting the parent to be present in the child's life but fearing for the child's well-being if the parent returns and does not provide good care (Templeton, 2011). And grandparent caregivers, at a time when they anticipated having more time for spouses, friends, and leisure, instead have less. Many report feeling emotionally drained, depressed, and worried about what will happen to the children if their own health fails (Hayslip & Kaminski, 2005; Langosch, 2012). Some families are extremely burdened. Native-American caregiving grandparents are especially likely to be unemployed, to have a disability, to be caring for several grandchildren, and to be living in extreme poverty (Fuller-Thomson & Minkler, 2005).

Despite great hardship, these grandparents seem to realize their widespread image as “silent saviors,” often forging close emotional bonds with their grandchildren and using effective child-rearing practices (Fuller-Thomson & Minkler, 2000; Gibson, 2005). Compared with children in divorced, single-parent families, blended families, or foster families, children reared by grandparents fare better in adjustment (Rubin et al., 2008; Solomon & Marx, 1995).

Skipped-generation families have a tremendous need for social and financial support and intervention services for troubled children. Custodial grandparents describe support groups—both for themselves and for their grandchildren—as especially

© JIM WEST PHOTOGRAPHY

A custodial grandmother helps her 8-year-old granddaughter with homework. Although grandparents usually assume the parenting role under highly stressful circumstances, most find compensating rewards in rearing grandchildren.

helpful, yet only a minority make use of such interventions (Smith, Rodriguez, & Palmieri, 2010). This suggests that grandparents need special help in finding out about and accessing support services.

Although their everyday lives are often stressful, caregiving grandparents—even those rearing children with serious problems—report as much fulfillment in the grandparent role as typical grandparents do (Hayslip et al., 2002). The warmer the grandparent–grandchild bond, the greater grandparents' long-term life satisfaction (Goodman, 2012). Many grandparents mention joy from sharing children's lives and feelings of pride at children's progress, which help compensate for difficult circumstances. And some grandparents view the rearing of grandchildren as a “second chance”—an opportunity to make up for earlier, unfavorable parenting experiences and “do it right” (Dolbin-MacNab, 2006).

Research indicates that middle-aged daughters forge closer, more supportive relationships with aging parents, especially mothers, than do middle-aged sons (Fingerman, 2003). But this gender difference may be declining. Sons report closer ties and greater assistance to aging parents in recent than in previous studies (Fingerman et al., 2007, 2008). Changing gender roles

are likely responsible. Because the majority of contemporary middle-aged women are employed, they face many competing demands on their time and energy. Consequently, men are becoming more involved in family responsibilities, including with aging parents (Fingerman & Birditt, 2011). Despite this shift, women's investment continues to exceed men's.

SOLLINA IMAGES/THE IMAGE BANK/GETTY IMAGES

In midlife, many adults develop warmer, more supportive relationships with their aging parents. At a birthday party for her mother, this daughter expresses love and appreciation for her mother's strengths and generosity.

In collectivist cultures, older adults most often live with their married children. For example, traditionally, Chinese, Japanese, and Korean seniors moved in with a son and his wife and children; today, many live with a daughter and her family, too. This tradition of coresidence, however, is declining in some parts of Asia and in the United States, as more Asian and Asian-American aging adults choose to live on their own (Davey & Takagi, 2013; Zhan & Montgomery, 2003; Zhang, 2004). In African-American and Hispanic families as well, coresidence is common. Regardless of whether coresidence and daily contact are typical, relationship quality usually reflects patterns established earlier: Positive parent-child ties generally remain so, as do conflict-ridden interactions.

Help exchanged between adult children and their aging parents is responsive to past and current family circumstances. The more positive the history of the parent-child tie, the more help given and received. Also, aging parents give more help to unmarried adult children and to those with disabilities. Similarly, adult children give more to elderly parents who are widowed or in poor health—usually emotional support and practical help, less often financial assistance. At the same time, middle-aged parents do what they can to maximize the overall quantity of help offered, as needed: While continuing to provide generous assistance to their children because of the priority placed on the parent-child tie (see page 545), middle-aged adults augment the aid they give to elderly parents as parental health problems increase (Kunemund, Motel-Klingebiel, & Kohli, 2005; Stephens et al., 2009).

Even when parent-child relationships have been emotionally distant, adult children offer more support as parents age, out of a sense of altruism and family duty (Silverstein et al., 2002).

And although the baby-boom generation is often described as self-absorbed, baby-boom midlifers actually express a stronger commitment to caring for their aging parents than the preceding middle-aged generation (Gans & Silverstein, 2006).

In sum, as long as multiple roles are manageable and the experiences within each are high in quality, midlife intergenerational assistance as family members (aging parents) have increased needs is best characterized as *resource expansion* rather than as merely conflicting demands that inevitably drain energy and detract from psychological well-being (Grundy & Henretta, 2006; Stephens et al., 2009). Recall from the Biology and Environment box on pages 540–541 that midlifers derive great personal benefits from successfully managing multiple roles. Their enhanced self-esteem, mastery, and sense of meaning and purpose expand their motivation and energy to handle added family-role demands, from which they reap additional personal rewards.

Caring for Aging Parents. About 25 percent of U.S. adult children provide unpaid care to an aging adult (MetLife, 2011). The burden of caring for aging parents can be great. In Chapter 2, we noted that as birthrates have declined, the family structure has become increasingly “top-heavy,” with more generations alive but fewer younger members. Consequently, more than one older family member is likely to need assistance, with fewer younger adults available to provide it.

The term **sandwich generation** is widely used to refer to the idea that middle-aged adults must care for multiple generations above and below them at the same time (Riley & Bowen, 2005). Although only a minority of contemporary middle-aged adults who care for aging parents have children younger than age 18 at home, many are providing assistance to young-adult children and to grandchildren—obligations that, when combined with work and community responsibilities, can lead middle-aged caregivers to feel “sandwiched,” or squeezed, between the pressures of older and younger generations. As more baby boomers move into late adulthood and as their adult children continue to delay childbearing, the number of midlifers who are working, rearing young children, and caring for aging parents will increase.

Middle-aged adults living far from aging parents who are in poor health often substitute financial help for direct care, if they have the means. But when parents live nearby and have no spouse to meet their needs, adult children usually engage in direct care. Regardless of family income level, African-American, Asian-American, and Hispanic adults give aging parents more direct care and financial help than Caucasian-American adults do (Shuey & Hardy, 2003). Compared with their white counterparts, African Americans and Hispanics express a stronger sense of obligation, and find it more personally rewarding, to support their aging parents (Fingerman et al., 2011b; Swartz, 2009). And African Americans often draw on close, family-like relationships with friends and neighbors for caregiving assistance.

In all ethnic groups, responsibility for providing care to aging parents falls more on daughters than on sons. Why are

Caring for an aging parent with a chronic illness or disability is highly stressful. But social support reduces physical and emotional strain, enabling adult children to find satisfactions and rewards in tending to parents' needs.

women usually the principal caregivers? Families turn to the person who seems most available—living nearby and with fewer commitments that might interfere with the ability to assist. These unstated rules, in addition to parents' preference for same-sex caregivers (aging mothers live longer), lead more women to fill the role (see Figure 16.4). Daughters also feel more obligated than sons to care for aging parents (Gans & Silverstein, 2006; Stein, 2009). And although couples strive to be fair to both sides of the family, they tend to provide more direct care for the wife's parents. This bias, however, is weaker in ethnic minority families and is nonexistent in Asian nations where cultural norms specify that daughters-in-law provide care to their husband's parents (Shuey & Hardy, 2003; Zhan & Montgomery, 2003).

As Figure 16.4 shows, nearly one-fourth of American working women are caregivers; others quit their jobs to provide care. And the time they devote to caring for a disabled aging parent is substantial, averaging 10 to 20 hours per week (MetLife, 2011; Takamura & Williams, 2004). Nevertheless, men—although doing less than women—do contribute. In one investigation, employed men spent an average of 7½ hours per week caring for parents or parents-in-law (Neal & Hammer, 2007). Tim, for example, looked in on his father, a recent stroke victim, every evening, reading to him, running errands, making household repairs, and taking care of finances. His sister, however, provided more hands-on care—cooking, feeding, bathing, managing medication, and doing laundry. The care sons and daughters provide tends to be divided along gender-role lines. About 10 percent of the time—generally when no other family member

can do so—sons become primary caregivers, heavily involved in basic-care tasks (Harris, 1998; Pinguart & Sörensen, 2006).

As adults move from early to later middle age, the sex difference in parental caregiving declines. Perhaps as men reduce their vocational commitments and feel less need to conform to a “masculine” gender role, they grow more able and willing to provide basic care (Marks, 1996; MetLife, 2011). At the same time, parental caregiving may contribute to men's greater openness to the “feminine” side of their personalities. A man who cared for his mother, severely impaired by Alzheimer's disease, commented on how the experience altered his outlook: “It was so difficult to do these tasks; things a man, a son, is not supposed to do. I have definitely modified my views on conventional expectations” (Hirsch, 1996, p. 112).

Although most adult children help willingly, caring for a chronically ill or disabled parent is highly stressful. Over time, the parent usually gets worse, and the caregiving task escalates. As Tim explained to Devin and Trisha, “One of the hardest aspects is the emotional strain of seeing my father's physical and mental decline up close.”

Caregivers who share a household with ill parents—about 23 percent of U.S. adult children—experience the most stress. When a parent and child who have lived separately for years must move in together, conflicts generally arise over routines and lifestyles. But the greatest source of stress is problem behavior, especially for caregivers of parents who have deteriorated mentally (Alzheimer's Association, 2012b). Tim's sister reported that their father would wake during the night, ask repetitive questions, follow her around the house, and become agitated and combative.

FIGURE 16.4 Baby boomers, by work status and gender, who provide basic personal care to an aging parent in poor health. A survey of a nationally representative sample of 1,100 U.S. men and women over age 50 with at least one parent living revealed that more nonworking than working adults engaged in basic personal care (assistance with such activities as dressing, feeding, and bathing). Regardless of work status, many more women than men were caregivers. (Adapted from *The MetLife Study of Caregiving Costs to Working Caregivers: Double Jeopardy for Baby Boomers Caring for Their Parents*, June 2011, Figure 3. Applying What We Know

Relieving the Stress of Caring for an Aging Parent

Strategy	Description
Use effective coping strategies.	Use problem-centered coping to manage the parent's behavior and caregiving tasks. Delegate responsibilities to other family members, seek assistance from friends and neighbors, and recognize the parent's limits while calling on capacities the parent does have. Use emotion-centered coping to reinterpret the situation in a positive way, such as emphasizing the opportunity it offers for personal growth and for giving to parents in the last years of their lives. Avoid denial of anger, depression, and anxiety in response to the caregiving burden, which heightens stress.
Seek social support.	Confide in family members and friends about the stress of caregiving, seeking their encouragement and help. So far as possible, avoid quitting work to care for an ill parent; doing so is associated with social isolation and loss of financial resources.
Make use of community resources.	Contact community organizations to seek information and assistance, in the form of caregiver support groups, in-home respite help, home-delivered meals, transportation, and adult day care.
Press for workplace and public policies that relieve the emotional and financial burdens of caring for an aging parent.	Encourage your employer to provide care benefits, such as flexible work hours and employment leave for caregiving. Communicate with lawmakers and other citizens about the need for additional government funding to help pay for caregiving. Emphasize the need for improved health insurance plans that reduce the financial strain of caring for an aging parent on middle- and low-income families.

Parental caregiving often has emotional, physical, and financial consequences. It leads to role overload, high job absenteeism, exhaustion, inability to concentrate, feelings of hostility, anxiety about aging, and high rates of depression, with women more profoundly affected than men (Neal & Hammer, 2007; Pinquart & Sörensen, 2006). Caregivers who must reduce their employment hours or leave the labor force to provide care (mostly women) face not just lost wages but also diminished retirement benefits. Despite having more time to care for an ill parent, women who quit work fare especially poorly in adjustment, probably because of social isolation and financial strain (Bookman & Kimbrel, 2011). Positive experiences at work can actually reduce the stress of parental care as caregivers bring a favorable self-evaluation and a positive mood home with them.

In cultures and subcultures where adult children feel an especially strong sense of obligation to care for aging parents, the emotional toll is also high (Knight & Sayegh, 2010). In research on Korean, Korean-American, and Caucasian-American caregivers of parents with mental disabilities, the Koreans and Korean Americans reported higher levels of family obligation and care burden—and also higher levels of anxiety and depression—than the Caucasian Americans (Lee & Farran, 2004; Youn et al., 1999). And among African-American caregivers, women who strongly endorsed cultural reasons for providing care (“It’s what my people have always done”) fared less well in mental health two years later than women who moderately endorsed cultural reasons (Dilworth-Anderson, Goodwin, & Williams, 2004).

Social support is highly effective in reducing caregiver stress. Tim’s encouragement, assistance, and willingness to listen

helped his sister cope with in-home care of their father so that she could find satisfactions in it. When caregiving becomes a team effort with multiple family members trading off, caregivers cope more effectively. Under these conditions, despite being demanding and stressful, it can enhance psychological well-being (Roberto & Jarrott, 2008). Adult children feel gratified at having helped and gain in self-understanding, problem solving, and sense of competence.

LOOK AND LISTEN

Ask a middle-aged adult caring for an aging parent in declining health to describe both the stressful and rewarding aspects of caregiving. What strategies does he or she use to reduce stress? To what extent does the caregiver share caregiving burdens with family members and enlist the support of community organizations? ●

In Denmark, Sweden, and Japan, a government-sponsored home helper system eases the burden of parental care by making specially trained nonfamily caregivers available, based on seniors’ needs (Saito, Auestad, & Waerness, 2010). In the United States, in-home care by a nonfamily caregiver is too costly for most families; only 10 to 20 percent arrange it (Family Caregiver Alliance, 2009). And unless they must, few people want to place their parents in formal care, such as nursing homes, which also are expensive. Applying What We Know above summarizes ways to relieve the stress of caring for an aging parent—at the individual, family, community, and societal levels. We will address additional care options, along with interventions for caregivers, in Chapter 17.

Siblings

As Tim's relationship with his sister reveals, siblings are ideally suited to provide social support. Nevertheless, a survey of a large sample of ethnically diverse Americans revealed that sibling contact and support decline from early to middle adulthood, rebounding only after age 70 for siblings living near each other (White, 2001). Decreased midlife contact is probably due to the demands of middle-aged adults' diverse roles. However, most adult siblings report getting together or talking on the phone at least monthly (Antonucci, Akiyama, & Merline, 2002).

Despite reduced contact, many siblings feel closer in midlife, often in response to major life events (Stewart et al., 2001). Launching and marriage of children seem to prompt siblings to think more about each other. As Tim commented, "It helped our relationship when my sister's children were out of the house and married. I'm sure she cared about me. I think she just didn't have time!" When a parent becomes seriously ill, brothers and sisters who previously had little to do with one another may find themselves in touch about parental care. And when parents die, adult children realize they have become the oldest generation and must look to each other to sustain family ties.

Not all sibling bonds improve, of course. Recall Trisha's negative encounters with her sister, Dottie (see page 513 in Chapter 15). Dottie's difficult temperament had made her hard to get along with since childhood, and her temper flared when their father died and problems arose over family finances. Large inequities in division of labor in parental caregiving can also unleash intense sibling conflict (Silverstein & Giarrusso, 2010). As siblings grow older, good relationships often get better and poor relationships get worse.

As in early adulthood, sister-sister relationships are closer than sister-brother and brother-brother ties, a difference apparent in many industrialized nations (Cicirelli, 1995; Fowler, 2009). But a comparison of middle-aged men of the baby-boom generation with those of the preceding cohort revealed warmer, more expressive ties between baby-boom brothers (Bedford &

© JEFF GREENBERG/THE IMAGE WORKS

These brothers, both in their fifties, express their mutual affection at a family reunion. Even when they have only limited contact, siblings often feel closer in midlife.

Avioli, 2006). A contributing factor may be baby boomers' more flexible gender-role attitudes.

In industrialized nations, sibling relationships are voluntary. In village societies, they are generally involuntary and basic to family functioning. For example, among Asian Pacific Islanders, family social life is organized around strong brother-sister attachments. A brother-sister pair is often treated as a unit in exchange marriages with another family. After marriage, brothers are expected to protect sisters, and sisters serve as spiritual mentors to brothers. Families not only include biological siblings but bestow on other relatives, such as cousins, the status of brother or sister, creating an unusually large network of lifelong sibling support (Cicirelli, 1995). Cultural norms reduce sibling conflict, thereby ensuring family cooperation. In industrialized nations, promoting positive sibling ties in childhood is vital for warm sibling bonds in later years.

Friendships

As family responsibilities declined in middle age, Devin found he had more time to spend with friends. On Friday afternoons, he met several male friends at a coffee house, and they chatted for a couple of hours. But most of Devin's friendships were couple-based—relationships he shared with Trisha. Compared with Devin, Trisha more often got together with friends on her own.

Middle-aged friendships reflect the same trends discussed in Chapter 14. At all ages, men's friendships are less intimate than women's. Men tend to talk about sports, politics, and business, whereas women focus on feelings and life problems. Women report a greater number of close friends and say they both receive and provide their friends with more emotional support (Antonucci, Akiyama, & Takahashi, 2004).

Over the past decade, the average number of friendships rose among U.S. midlifers, perhaps because of ease of keeping in touch through social media (Wang & Wellman, 2010). Though falling short of young adults' use, connecting regularly with friends through Facebook or other social networking sites has risen rapidly among middle-aged adults (see Figure 16.5) (Brenner, 2013; Hampton et al., 2011). As in early adulthood, women are more active users. And users have more offline close relationships, sometimes using Facebook to revive "dormant" friendships.

Still, for both sexes, number of friends declines from middle to late adulthood, probably because people become less willing to invest in nonfamily ties unless they are very rewarding. As selectivity of friendship increases, older adults try harder to get along with friends (Antonucci & Akiyama, 1995). Having chosen a friend, middle-aged people attach great value to the relationship and take extra steps to protect it.

LOOK AND LISTEN

Ask a middle-aged couple you know well to describe the number and quality of their friendships today compared with their friendships in early adulthood. Does their report match research findings? Explain. ●

FIGURE 16.5 Gains in use of social networking sites by age group from 2005 to 2012. Repeated surveys of large representative samples of U.S. adults who use the Internet revealed that social networking site use increased substantially for all age groups. Though not as avid users as young adults, most middle-aged adults use social networking sites, primarily Facebook. (From J. Brenner, 2013, “Pew Internet: Social Networking.” Pew Research Center’s Internet & American Life Project, Washington, D.C. February 14, 2013, www.pewinternet.org. Adapted by permission.)

By midlife, family relationships and friendships support different aspects of psychological well-being. Family ties protect against serious threats and losses, offering security within a long-term timeframe. In contrast, friendships serve as current sources of pleasure and satisfaction, with women benefiting somewhat more than men (Levitt & Cici-Gokaltun, 2011). As middle-aged couples renew their sense of companionship, they may combine the best of family and friendship.

ASK YOURSELF

REVIEW How do age, sex, proximity, and culture affect grandparent–grandchild ties?

CONNECT Cite evidence that early family relationships affect middle-aged adults’ bonds with adult children, aging parents, and siblings.

APPLY Raylene and her brother Walter live in the same city as their aging mother, Elsie. When Elsie could no longer live independently, Raylene took primary responsibility for her care. What factors probably contributed to Raylene’s involvement in caregiving and Walter’s lesser role?

REFLECT Ask one of your parents for his or her view of how the parent–child relationship changed as you transitioned to new adult roles, such as college student, career-entry worker, married partner, or parent. Do you agree?

Vocational Life

As we have seen, the midlife transition typically involves vocational adjustments. For Devin, it resulted in a move up the career ladder to a demanding administrative post as college dean. Trisha reoriented her career from a large to a small law firm, where she felt her efforts were appreciated. Recall from Chapter 15 that after her oldest child left home, Anya earned a college degree and entered the work force for the first time. Jewel strengthened her commitment to an already successful business, while Elena changed careers. Finally, Tim reduced his career obligations as he prepared for retirement.

Work continues to be a salient aspect of identity and self-esteem in middle adulthood. More so than in earlier or later years, people attempt to increase the personal meaning and self-direction of their vocational lives. At the same time, certain aspects of job performance improve. Middle-aged employees have lower rates of absenteeism, turnover, and accidents. They are also more effective workplace citizens—more often helping colleagues and trying to improve group performance and less often complaining about trivial issues. And because of their greater knowledge and experience, their work productivity typically equals or exceeds that of younger workers (Ng & Feldman, 2008). Consequently, an older employee ought to be as valuable as a younger employee, and possibly more so.

The large tide of baby boomers currently moving through midlife and (as we will see in Chapter 18) the desire of most to work longer than the previous generation means that the number of older workers will rise dramatically over the next few decades (Leonesio et al., 2012). Yet a favorable transition from adult worker to older worker is hindered by negative stereotypes of aging—incorrect assumptions of limited learning capacity, slower decision making, and resistance to change and supervision (Posthuma & Campion, 2009). Furthermore, gender discrimination continues to restrict the career attainments of many women. Let’s take a close look at middle-aged work life.

Job Satisfaction

Job satisfaction has both psychological and economic significance. If people are dissatisfied at work, the consequences include absenteeism, turnover, grievances, and strikes, all of which are costly to employers.

Research shows that job satisfaction increases in midlife in diverse nations and at all occupational levels, from executives to hourly workers (see Figure 16.6 on page 554). The relationship is weaker for women than for men, probably because women’s reduced chances for advancement result in a sense of unfairness. It is also weaker for blue-collar than for white-collar workers, perhaps because blue-collar workers have less control over their own work schedules and activities (Avolio & Sosik, 1999). When different aspects of jobs are considered, intrinsic

FIGURE 16.6 Age-related changes in job satisfaction. In this study of more than 2,000 university employees at all levels, from secretary to university president, job satisfaction dropped slightly in early adulthood as people encountered some discouraging experiences (see Chapter 14). In middle age, job satisfaction showed a steady rise. (From W. A. Hochwarter et al., 2001, “A Note on the Nonlinearity of the Age–Job–Satisfaction Relationship,” *Journal of Applied Social Psychology*, 31, p. 1232. Copyright © 2001, John Wiley and Sons. Reproduced with permission of Wiley Inc.)

satisfaction—happiness with the work itself—shows a strong age-related gain. Extrinsic satisfaction—contentment with supervision, pay, and promotions—changes very little (Barnes-Farrell & Matthews, 2007).

What explains the rise in job satisfaction during middle adulthood? An improved capacity to cope effectively with difficult situations and a broader time perspective probably contribute. “When I first started teaching, I complained about a lot of things,” remarked Devin. “From my current vantage point, I can tell a big problem from a trivial one.” Moving out of unrewarding work roles, as Trisha did, can also boost morale. Key characteristics that predict job well-being include involvement in decision making, reasonable workloads, and good physical working conditions. Older people may have greater access to jobs that are attractive in these ways. Furthermore, having fewer alternative positions into which they can move, older workers generally reduce their career aspirations (Barnes-Farrell & Matthews, 2007). As the perceived gap between actual and possible achievements narrows, job involvement—importance of one’s work to self-esteem—increases (Warr, 2001).

Although emotional engagement with work is usually seen as psychologically healthy, it can also result in **burnout**—a condition in which long-term job stress leads to mental exhaustion, a sense of loss of personal control, and feelings of reduced accomplishment. Burnout occurs more often in the helping professions, including health care, human services, and teaching, which place high emotional demands on employees. Although people in interpersonally demanding jobs are as psychologi-

cally healthy as other people, sometimes a worker’s dedication exceeds his or her coping skills, especially in an unsupportive work environment (Schmidt, Neubach, & Heuer, 2007). Burnout is associated with excessive work assignments for available time and lack of encouragement and feedback from supervisors. It tends to occur more often in the United States than in Western Europe, perhaps because of Americans’ greater achievement orientation (Maslach, Schaufeli, & Leiter, 2001).

Burnout is a serious occupational hazard, linked to impaired attention and memory, severe depression, on-the-job injuries, physical illnesses, poor job performance, absenteeism, and turnover (Sandström et al., 2005; Wang, 2005). To prevent burnout, employers can make sure workloads are reasonable, provide opportunities for workers to take time out from stressful situations, limit hours of stressful work, and offer social support. Interventions that enlist employees’ participation in designing higher-quality work environments show promise for increasing work engagement and effectiveness and reducing burnout (Leiter, Gascón, & Martínez-Jarreta, 2010). And provisions for working at home may respond to the needs of some people for a calmer, quieter work atmosphere.

Career Development

After several years as a parish nurse, Anya felt a need for additional training to do her job better. Trisha appreciated her firm’s generous support of workshop and course attendance, which helped her keep abreast of new legal developments. And as college dean, Devin took a summer seminar each year on management effectiveness. As these experiences reveal, career development is vital throughout work life.

Job Training. Anya’s 35-year-old supervisor, Roy, was surprised when she asked for time off to upgrade her skills. “You’re in your fifties,” he replied. “What’re you going to do with so much new information at this point in your life?”

Roy’s insensitive, narrow-minded response, though usually unspoken, is all too common among managers—even some who are older themselves! Research suggests that training and on-the-job career counseling are less available to older workers. And when career development activities are offered, older employees may be less likely to volunteer for them (Barnes-Farrell & Matthews, 2007; Hedge, Borman, & Lammlein, 2006). What influences willingness to engage in job training and updating?

Personal characteristics are important: With age, growth needs give way somewhat to security needs. Consequently, learning and challenge may have less intrinsic value to many older workers. Perhaps for this reason, older employees depend more on co-worker and supervisor encouragement for vocational development. Yet as we have seen, they are less likely to have supportive supervisors. Furthermore, negative stereotypes of aging reduce older workers’ self-efficacy, or confidence that they can get better at their jobs (Maurer, 2001; Maurer,

Wrenn, & Weiss, 2003). Self-efficacy is a powerful predictor of employees' efforts to renew and expand career-relevant skills.

Workplace characteristics matter, too. An employee given work that requires new learning must pursue that learning to complete the assignment. Unfortunately, older workers sometimes receive more routine tasks than younger workers. Therefore, some of their reduced motivation to engage in career-relevant learning may be due to the type of assignments they receive. In companies with a more favorable *age climate* (view of older workers), mature employees participate frequently in further education and report greater self-efficacy and commitment to the organization (Bowen, Noack, & Staudinger, 2011).

Gender and Ethnicity: The Glass Ceiling. In her thirties, Jewel became a company president by starting her own business. Having concluded that, as a woman, she had little chance of rising to a top executive position in a large corporation, she didn't even try. Although women and ethnic minorities have gradually gained in access to managerial careers, they remain a long distance from gender and ethnic equality (Huffman, 2012). From career entry on, inequalities in promotion between men and women and between whites and blacks become more pronounced over time—findings still evident after education, work skills, and work productivity have been controlled (Barreto, Ryan, & Schmitt, 2009; Maume, 2004). Women who are promoted usually get stuck in mid-level positions. When the most prestigious high-level management jobs are considered, white men are overwhelmingly advantaged: They account for 70 percent of chief executive officers at large corporations and 93 percent at Fortune 500 companies (U.S. Census Bureau, 2012b).

Women and ethnic minorities face a **glass ceiling**, or invisible barrier to advancement up the corporate ladder. Why is this so? Management is an art and skill that must be taught. Yet women and ethnic minorities have less access to mentors, role models, and informal networks that serve as training routes (Baumgartner & Schneider, 2010). And stereotyped doubts about women's career commitment and ability to become strong managers (especially women with children) also contribute, leading supervisors to underrate their competence and not to recommend them for formal management training programs (Hoobler, Lemmon, & Wayne, 2011). Furthermore, challenging, high-risk, high-visibility assignments that require leadership and open the door to advancement, such as startup ventures, international experience, and troubleshooting, are less often granted to both women and minorities.

Finally, women who demonstrate qualities linked to leadership and advancement—assertiveness, confidence, forcefulness, and ambition—encounter prejudice because they deviate from traditional gender roles, even though they more often combine these traits with a democratic, collaborative style of leading than do men (Cheung & Halpern, 2010; Eagly & Carli, 2007). To overcome this bias, women in line for top positions must demonstrate greater competence than their male counterparts. In an investigation of several hundred senior managers at a multinational financial services corporation, promoted female managers had earned higher performance ratings than promoted male managers (Lyness & Heilman, 2006). In contrast, no gender difference existed in performance of managers not selected for promotion.

Like Jewel, many women have dealt with the glass ceiling by going around it, leaving the corporate environment and going into business for themselves. Today, more than half of all startup businesses in the United States are owned and operated by women. The large majority are successful entrepreneurs and leaders, meeting or exceeding their expansion and earnings goals (Ahuja, 2005; U.S. Census Bureau, 2012b). But when women and ethnic minorities leave the corporate world to further their careers, companies not only lose valuable talent but also fail to address the leadership needs of an increasingly diverse work force.

Career Change at Midlife

Although most people remain in the same vocation through middle age, career change does occur, as with Elena's shift from journalism to teaching and creative writing. Recall that circumstances at home and at work motivated Elena's decision to pursue a new vocation. Like other career changers, she wanted a more satisfying life—a goal she attained by ending an unhappy marriage and initiating a long-awaited vocational move at the same time.

As noted earlier, midlife career changes are seldom radical; they typically involve leaving one line of work for a related one. Elena sought a more stimulating, involving job. But other people

After many years as a professor of ancient Greek philosophy, Abe Schoener found himself at a dead end in his career. In his mid-forties, he decided to transform his passion for winemaking into a new vocation as a vintner—a radical shift that prompted the breakup of his marriage but ultimately led to a more satisfying life.

Unemployment

As companies downsize, eliminating jobs, the majority of people affected are middle-aged and older. Although unemployment is difficult at any time, middle-aged adults show a sharper decline in physical and mental health than their younger counterparts. Those who perceive a company's layoff process as unfair and inconsiderate—for example, giving them little time to prepare—often experience the event as highly traumatic (Breslin & Mustard, 2003; McKee-Ryan et al., 2009). Older workers affected by layoffs remain jobless longer, suffering substantial income loss. In addition, people over age 40 who must reestablish occupational security find themselves “off-time” in terms of the social clock. Consequently, job loss can disrupt major tasks of midlife, including generativity and reappraisal of life goals and accomplishments. Finally, having been more involved in and committed to an occupation, the older unemployed worker has also lost something of greater value.

People who lose their jobs in midlife, whether executives or blue-collar workers, seldom duplicate the status and pay of their previous positions. As they search, they encounter age discrimination and find that they are overqualified for many openings. Those also facing financial difficulties are at risk for deepening depression and physical health declines over time (Gallo et al., 2006; McKee-Ryan, 2011). Counseling that focuses on financial planning, reducing feelings of humiliation due to the stigma of unemployment, and encouraging personal flexibility can help people implement effective problem-centered coping strategies in their search for alternative work roles.

move in the reverse direction—to careers that are more relaxing, free of painful decisions, and less demanding (Juntunen, Wegner, & Matthews, 2002). The decision to change is often difficult. The individual must weigh years invested in one set of skills, current income, and job security against present frustrations and hoped-for gains.

An extreme career shift, by contrast, usually signals a personal crisis (Young & Rodgers, 1997). In a study of professionals who abandoned their well-paid, prestigious positions for routine, poorly paid, semiskilled work, nonwork problems contributed to radical change. An eminent 55-year-old TV producer became a school bus driver, a New York banker a waiter in a ski resort (Sarason, 1977). Each was responding to feelings of personal meaninglessness—escaping from family conflict, difficult relationships with colleagues, and work that had become unsatisfying to a less burdensome life.

Among blue-collar workers—those in such occupations as construction, manufacturing, mining, maintenance, or food-service work—midlife career shifts are seldom freely chosen. In one investigation, researchers followed a large sample of blue-collar men in their fifties over a seven-year period; all were employed by Alcoa, the world's largest producer of aluminum. One-third had highly physically taxing jobs. Of the small minority who transitioned to less physically demanding work, an injury usually preceded the change (Modrek & Cullen, 2012). Transitioners appeared to change jobs to stay in the workforce, rather than being forced to retire early, at less than full pension benefits, because of their disability.

Yet opportunities to shift to less physically demanding work are limited, particularly in the late-2000s recession aftermath. A strong predictor of middle-aged workers' eligibility for such jobs is education—at least a high school diploma (Blau & Goldstein, 2007). Less educated workers with a physical disability face greatly reduced chances of remaining in the labor force.

Planning for Retirement

One evening, Devin and Trisha met Anya and her husband, George, for dinner. Halfway through the meal, Devin inquired, “George, tell us what you and Anya are going to do about retirement. Are you planning to close down your business or work part-time? Do you think you'll stay here or move out of town?”

Three or four generations ago, the two couples would not have had this conversation. In 1900, about 70 percent of American men age 65 and over were in the labor force. By 1970, however, the figure had dropped to 27 percent, and in the early twenty-first century it declined to 16 percent (U.S. Census Bureau, 2012b). Because of government-sponsored retirement benefits (begun in the United States in 1935), retirement is no longer a privilege reserved for the wealthy. The federal government pays Social Security to the majority of the aged, and others are covered by employer-based private pension plans.

As the trend just noted suggests, the average age of retirement has declined over the past several decades. Currently, it is age 63 in the United States and hovers between 60 and 63 in other Western nations (U.S. Census Bureau, 2012b). The recent recession led to an increase in the number of Americans at

Applying What We Know

Ingredients of Effective Retirement Planning

Issue	Description
Finances	Ideally, financial planning for retirement should start with the first paycheck; at a minimum, it should begin 10 to 15 years before retirement.
Fitness	Starting a fitness program in middle age is important because good health is crucial for well-being in retirement.
Role adjustment	Retirement is harder for people who strongly identify with their work role. Preparing for a radical role adjustment reduces stress.
Where to live	The pros and cons of moving should be considered carefully because where one lives affects access to health care, friends, family, recreation, entertainment, and part-time employment.
Leisure and volunteer activities	A retiree typically gains an additional 50 hours per week of free time. Careful planning of what to do with that time has a major impact on psychological well-being.
Health insurance	Finding out about government-sponsored health insurance options helps protect quality of life after retirement.
Legal affairs	The preretirement period is an excellent time to finalize a will and begin estate planning.

risk for being unable to sustain their preretirement standard of living after leaving the workforce. Consequently, a survey of a large, nationally representative sample of baby boomers revealed that the majority expect to delay retirement (Jones, 2012). But current estimates indicate that most will need to work just a few extra years to be financially ready to retire (Munnell et al., 2012). For the healthy, active, long-lived baby-boom generation, up to one-fourth of their lives may lie ahead after they leave their jobs.

Retirement is a lengthy, complex process that begins as soon as the middle-aged person first thinks about it (Kim & Moen, 2002b). Planning is important because retirement leads to a loss of two important work-related rewards—income and status—and to a change in many other aspects of life. Like other life transitions, retirement can be stressful.

Nearly half of middle-aged people engage in no concrete retirement planning, yet research consistently shows that clarifying goals for the future and acquiring financial-planning knowledge result in better retirement savings, adjustment, and satisfaction (Hershey et al., 2007; Jacobs-Lawson, Hershey, & Neukam, 2004).

LOOK AND LISTEN

Contact the human resources division of a company or institution in your community, and inquire about the retirement planning services it offers. How comprehensive are those services, and what percentage of its recent retirees made use of them? ●

Applying What We Know above lists the variety of issues addressed in a typical retirement preparation program. Financial planning is especially vital in the United States where (unlike

Western European nations) the federal government does not offer a pension system that guarantees an adequate standard of living (see page 68 in Chapter 2). Hence, U.S. retirees' income typically drops by 50 percent. But although more people engage in financial planning than in other forms of preparation, even those who attend financial education programs often fail to look closely at their financial well-being and to make wise decisions (Keller & Lusardi, 2012). Many could benefit from an expert's financial analysis and counsel.

Retirement leads to ways of spending time that are largely guided by one's interests rather than one's obligations. Individuals who have not thought carefully about how to fill this time may find their sense of purpose in life seriously threatened. Research reveals that planning for an active life has an even greater impact on happiness after retirement than financial planning. Participation in activities promotes many factors essential for psychological well-being, including a structured time schedule, social contact, and self-esteem (Schlossberg, 2004). Carefully considering whether or not to relocate at retirement is related to an active life, since it affects access to health care, friends, family, recreation, entertainment, and part-time work.

Devin retired at age 62, George at age 66. Though several years younger, Trisha and Anya—like many married women—coordinated their retirements with those of their husbands. In contrast, Jewel—in good health but without an intimate partner to share her life—kept her consulting business going until age 75. Tim took early retirement and moved to be near Elena, where he devoted himself to public service—tutoring second graders in a public school, transporting inner-city children to museums, and coaching after-school and weekend youth sports. For Tim, retirement offered a new opportunity to give generously to his community.

Unfortunately, less well-educated people with lower lifetime earnings are least likely to attend retirement preparation programs—yet they stand to benefit the most. And compared with men, women do less planning for retirement, instead relying on their husband's preparations. This gender gap seems to be narrowing, however, as women increasingly contribute to family income (Adams & Rau, 2011). Employers must take extra steps to encourage lower-paid workers and women to participate in planning activities. In addition, enhancing retirement adjustment among the economically disadvantaged depends on access to better vocational training, jobs, and health care at early ages. Clearly, a lifetime of opportunities and experiences affects the transition to retirement. In Chapter 18, we will consider the decision to retire and retirement adjustment in greater detail.

ASK YOURSELF

REVIEW What factors contribute to the rise in job satisfaction with age?

CONNECT Supervisors sometimes assign the more routine tasks to older workers, believing that they can no longer handle complex assignments. Cite evidence from this and the previous chapter indicating that this assumption is incorrect.

APPLY An executive wonders how his large corporation can foster advancement of women and ethnic minorities to upper management positions. What strategies would you recommend?

SUMMARY

Erikson's Theory: Generativity versus Stagnation (p. 532)

According to Erikson, how does personality change in middle age?

- Generativity expands as middle-aged adults face Erikson's psychological conflict of **generativity versus stagnation**. Personal desires and cultural demands jointly shape adults' generative activities.
- Highly generative people, who contribute to society through parenthood, other family relationships, the workplace, and volunteer endeavors, appear especially well-adjusted. Stagnation occurs when people become self-centered and self-indulgent in midlife.

Other Theories of Psychosocial Development in Midlife (p. 535)

Describe Levinson's and Vaillant's views of psychosocial development in middle adulthood, and discuss similarities and differences between men and women.

- According to Levinson, middle-aged adults confront four developmental tasks, each requiring them to reconcile two opposing tendencies within the self: young–old, destruction–creation, masculinity–femininity, and engagement–separateness.
- Middle-aged men show greater acceptance of “feminine” traits of nurturance and caring, while women are more open to “masculine” characteristics of autonomy and assertiveness. Men and successful career-oriented women may reduce their concern with ambition and

achievement, but women who have devoted themselves to child rearing or an unfulfilling job often seek rewarding work or community engagement.

- Vaillant found that adults in their late forties and fifties become guardians of their culture, seeking to “pass the torch” to later generations.

Does the term midlife crisis reflect most people's experience of middle adulthood, and is middle adulthood accurately characterized as a stage?

- Most people respond to midlife with changes that are better described as “turning points” than as a crisis. Only a minority experience a **midlife crisis** characterized by intense self-doubt and stress that lead to drastic life alterations.
- Some midlife changes are adaptations to life events that are less age-graded than in the past. Most middle-aged adults also report troubling moments that prompt new understandings and goals, but debate persists over whether these psychosocial changes are stagelike.

Stability and Change in Self-Concept and Personality (p. 538)

Describe changes in self-concept, personality, and gender identity in middle adulthood.

- Middle-aged individuals maintain self-esteem and stay motivated by revising their **possible selves**, which become fewer in number as well as more modest and concrete as people adjust their hopes and fears to their life circumstances.

- Midlife typically brings enhanced psychological well-being, through greater self-acceptance, autonomy, and environmental mastery. Factors contributing to well-being, however, vary widely among cohorts and cultures.
- Daily stressors plateau in early to mid-adulthood, and then decline as work and family responsibilities ease. Midlife gains in emotional stability and confidence in handling life's problems lead to increased effectiveness in coping with stressors.
- Both men and women become more androgynous in middle adulthood. Biological explanations, such as **parental imperative theory**, are controversial. A combination of social roles and life conditions is more likely responsible.

RAMIRO OLACREGUI/GETTY IMAGES

Discuss stability and change in the “big five” personality traits in adulthood.

- Among the **“big five” personality traits**, agreeableness and conscientiousness increase into middle age, while neuroticism declines, and extroversion and openness to experience do not change or decrease slightly. Individual differences are large and highly stable: Although adults change in overall organization and integration of personality, they do so on a foundation of basic, enduring dispositions.

Relationships at Midlife

(p. 543)

Describe the middle adulthood phase of the family life cycle.

- “Launching children and moving on” is the midlife phase of the family life cycle. Adults must adapt to many entries and exits of family members as their children launch–return–relaunch, marry, and produce grandchildren, and as their own parents age and die.
- When divorce occurs, middle-aged adults seem to adapt more easily than younger people. For women, midlife marital breakup often severely reduces standard of living, contributing to the **feminization of poverty**.
- Most middle-aged parents adjust well to launching adult children, especially if positive parent–child relationships are sustained, but adult children who are “off-time” in development can prompt parental strain. As children marry, middle-aged parents, especially mothers, often become **kinkeepers**.
- Grandparents’ contact and closeness with grandchildren depend on proximity, number of grandchild sets, sex of grandparent and grandchild, and in-law relationships. In low-income families and in some ethnic groups, grandparents provide essential financial and child-care assistance. When serious family problems exist, grandparents may become primary caregivers in **skipped-generation families**.

© BLUE JEAN IMAGES/ALAMY

- Middle-aged adults reassess their relationships with aging parents, often becoming more appreciative. Mother–daughter relationships tend to be closer than other parent–child ties. The more positive the history of the parent–child tie and the greater the need for assistance, the more help exchanged.

- Middle-aged adults, often caught between caring for aging parents, assisting young-adult children and grandchildren, and meeting work and community responsibilities, are called the **sandwich generation**. The burden of caring for ill or frail parents falls most heavily on adult daughters, though the sex difference declines in later middle age.
- Parental caregiving has emotional and health consequences, especially in cultures and subcultures where adult children feel a particularly strong obligation to provide care. Social support is highly effective in reducing caregiver stress and helping adult children derive benefits from caregiving.

Describe midlife sibling relationships and friendships.

- Sibling contact and support decline from early to middle adulthood, probably because of the demands of diverse roles. But many middle-aged siblings feel closer, often in response to major life events. Sister–sister ties are typically closest in industrialized nations. In nonindustrialized societies, strong brother–sister attachments may be basic to family functioning.
- In midlife, friendships become fewer, more selective, and more deeply valued. Men continue to be less expressive with their friends than women, who have more close friendships. Viewing a spouse as a best friend can contribute greatly to marital happiness.

Vocational Life (p. 553)

Discuss job satisfaction and career development in middle adulthood, with special attention to sex differences and experiences of ethnic minorities.

- Vocational readjustments are common as middle-aged people seek to increase the personal meaning and self-direction of their work lives. Certain aspects of job performance improve. Job satisfaction increases at all occupational levels, more so for men than for women.
- **Burnout** is a serious occupational hazard, especially for those in helping professions. It can be prevented by ensuring reasonable workloads, limiting hours of stressful work, providing workers with social support, and enlisting employees’ participation in designing higher-quality work environments.

- Both personal and workplace characteristics influence the extent to which older workers engage in career development. In companies with a more favorable age climate, mature employees report greater self-efficacy and commitment to the organization.
- Women and ethnic minorities face a **glass ceiling** because of limited access to management training and prejudice against women who demonstrate strong leadership qualities. Many women further their careers by leaving the corporate world, often to start their own businesses.

Discuss career change and unemployment in middle adulthood.

- Midlife career change typically involves leaving one line of work for a related one. Radical career change often signals a personal crisis. Among blue-collar workers, midlife career shifts are seldom freely chosen.

- Unemployment is especially difficult for middle-aged adults, who constitute the majority of workers affected by corporate downsizing and layoffs. Counseling can help them find alternative, gratifying work roles, but these rarely match their previous status and pay.

Discuss the importance of planning for retirement.

- Retirement brings major life changes, including loss of income and status and an increase in free time. Besides financial planning, planning for an active life is vital, with a strong impact on happiness after retirement. Low-paid workers and women need extra encouragement to participate in retirement planning.

milestones

Development in Middle Adulthood

JETTA PRODUCTIONS/
WALTER HODGES/GETTY IMAGES

40–50 years

PHYSICAL

- Accommodative ability of the lens of the eye, ability to see in dim light, and color discrimination decline; sensitivity to glare increases. (502–503)
- Hearing loss at high frequencies occurs. (503)
- Hair grays and thins. (502)
- Lines on the face become more pronounced; skin loses elasticity and begins to sag. (503)
- Weight gain continues, accompanied by a rise in fatty deposits in the torso, while fat beneath the skin declines. (504)
- Loss of lean body mass (muscle and bone) occurs. (504)
- In women, production of estrogen drops, leading to shortening and irregularity of the menstrual cycle. (504)

© JEFF GREENBERG/PHOTODISC

- In men, quantity of semen and sperm declines. (507)
- Intensity of sexual response declines, but frequency of sexual activity drops only slightly. (509)
- Rates of cancer and cardiovascular disease increase. (509–513)

COGNITIVE

- Consciousness of aging increases. (502, 535)
- Crystallized intelligence increases; fluid intelligence declines. (518–519)
- Speed of processing declines, but adults can compensate through experience and practice. (520–521)

© LAURA DOSS/CORBIS

- Ability to attend selectively and to adapt attention—switching from one task to another—declines, but adults can compensate through experience and practice. (521)
- Amount of information retained in working memory declines, in part because of reduced use of memory strategies. (522)
- Retrieving information from long-term memory becomes more difficult. (522)

COMSTOCK/GETTY IMAGES

- General factual knowledge, procedural knowledge, knowledge related to one's occupation, and metacognitive knowledge remain unchanged or may increase. (522–523)
- Practical problem solving and expertise increase. (524)
- Creativity may become more deliberately thoughtful, emphasize integrating ideas, and shift from self-expression to more altruistic goals. (524–525)

© FLORESCO PRODUCTIONS/CORBIS

- If occupation offers challenge and autonomy, may show gains in cognitive flexibility. (525–526)

EMOTIONAL/SOCIAL

- Generativity increases. (532–533)
- Focus shifts toward personally meaningful living. (535)

- Possible selves become fewer in number and more modest and concrete. (538)
- Self-acceptance, autonomy, and environmental mastery increase. (538–539)
- Strategies for coping with stressors become more effective. (539)
- Gender identity becomes more androgynous; “masculine” traits increase in women, “feminine” traits in men. (535, 540–542)
- Agreeableness and conscientiousness increase, while neuroticism declines. (542)
- May launch children. (544–545)
- May become a kinkeeper, especially if a mother. (545)
- May become a parent-in-law and a grandparent. (545–547)
- Becomes more appreciative of parents’ strengths and generosity; quality of relationships with parents increase. (547)
- May care for a parent with a disability or chronic illness. (549–551)
- Siblings may feel closer. (552)

- Number of friends generally declines. (552)
- Intrinsic job satisfaction—happiness with one’s work—typically increases. (553–554)

50–65 years

PHYSICAL

- Lens of the eye loses its capacity to adjust to objects at varying distances entirely. (502)
- Hearing loss gradually extends to all frequencies but remains greatest for high frequencies. (503)
- Skin continues to wrinkle and sag, “age spots” increase, and blood vessels in the skin become more visible. (503)
- In women, menopause occurs; as estrogen declines further, genitals are less easily stimulated, and the vagina lubricates more slowly during arousal. (504)
- In men, inability to attain an erection when desired becomes more common. (507)
- Loss of bone mass continues; rates of osteoporosis rise. (504, 512–513)
- Collapse of disks in the spinal column causes height to drop by as much as 1 inch. (504)
- Rates of cancer and cardiovascular disease continue to increase. (509–513)

COGNITIVE

- Cognitive changes previously listed continue.

EMOTIONAL/SOCIAL

- Emotional and social changes previously listed continue.

- Parent-to-child help-giving declines, and child-to-parent support and practical assistance increase. (548–549)

- May retire. (556–557)

chapter 17

AP IMAGES/KHIN MAUNG WIN

Cultures around the world connect age with wisdom. Older adults' life experience enhances their ability to solve human problems and fill leadership positions. These are endeavors of South African anti-apartheid activist Archbishop Desmond Tutu and Myanmar opposition leader Aung San Suu Kyi. Each is a Nobel Peace laureate.

Physical and Cognitive Development in Late Adulthood

At age 67, Walt gave up his photography business and looked forward to more spare time with 64-year-old Ruth, who retired from her position as a social worker at the same time. For Walt and Ruth, this culminating period of life was filled with volunteer work, golfing three times a week, and joint vacations with Walt's older brother Dick and his wife, Goldie. Walt also took up activities he had always loved but had little time to pursue—writing poems and short stories, attending theater performances, enrolling in a class on world politics, and cultivating a garden that became the envy of the neighborhood. Ruth read voraciously, served on the board of directors of an adoption agency, and had more time to visit her sister Ida in a nearby city.

Over the next 20 years, Walt and Ruth amazed nearly everyone who met them with their energy and vitality. Their warmth, concern for others, and generosity with their time led not just their own children and grandchildren, but also nieces, nephews, children of friends, and former co-workers, to seek them out. On weekends, their home was alive with visitors.

Then, in their early eighties, the couple's lives changed profoundly. Walt had surgery to treat a cancerous prostate gland and within 3 months was hospitalized again after a heart attack. He lingered for 6 weeks with Ruth at his side and then died. Ruth's grieving was interrupted by the need to care for Ida. Alert and spry at age 78, Ida deteriorated mentally in her seventy-ninth year, despite otherwise excellent physical health. Meanwhile, Ruth's arthritis worsened, and her vision and hearing weakened.

As Ruth turned 85, certain activities had become difficult—but not impossible. “It just takes a little adjustment!” Ruth exclaimed in her usual upbeat manner. Reading was harder, so she downloaded audiobooks to her MP3 player. Her gait was slower and her eyesight less reliable, making her hesitant to go out alone. At dinner in a noisy restaurant with her daughter and family, Ruth felt overwhelmed and participated little in the fast-moving conversation. But in one-to-one interactions in a calm environment, she showed the same intelligence, wit, and astute insights that she had displayed all her life.

Late adulthood stretches from age 65 to the end of the lifespan. Unfortunately, popular images fail to capture the quality of these final decades. Instead, many myths prevail—that older people have entered a period of deterioration and dependency, that they are no longer able to learn, and that their families isolate them in nursing

homes. Young people who have little contact with older adults are often surprised that those like Walt and Ruth even exist—active and involved in the world around them.

As we trace physical and cognitive development in late adulthood, we will see that the balance of gains and declines shifts as death approaches. But in industrialized nations, the typical 65-year-old can anticipate nearly two healthy, rewarding decades before this shift affects everyday life. And as Ruth illustrates, even after older adults become frail, many find ways to surmount physical and cognitive challenges.

Late adulthood is best viewed as an extension of earlier periods, not a break with them. As long as social and cultural contexts give older adults support, respect, and purpose in life, these years are a time of continued potential. ●

PHYSICAL DEVELOPMENT

TAKE A MOMENT... Do you know an older person who “seems young” or “seems old” for his or her age? In using these descriptors, we acknowledge that chronological age is an imperfect indicator of **functional age**, or actual competence and performance. Because people age biologically at different rates, some 80-year-olds appear younger than many 65-year-olds. Also, recall from Chapter 13 that within each person, change differs across parts of the body. For example, Ruth became infirm physically but remained active mentally, whereas Ida, though physically fit for her age, found it hard to carry on a conversation, keep appointments, or complete familiar tasks.

So much variation exists between and within individuals that researchers have not yet identified any single biological measure that predicts the overall rate at which a person will age.

Two friends enjoy a stroll in Tokyo, Japan. How old are they? How old do they look and feel? Because people age biologically at different rates, the woman on the right appears younger, though both are in their early eighties.

But we do have estimates of how much longer older adults can expect to live, and our knowledge of factors affecting longevity in late adulthood has increased rapidly.

Life Expectancy

“I wonder how many years I have left,” Ruth asked herself each time a major life event, such as retirement or widowhood, occurred. Dramatic gains in **average life expectancy**—the number of years that an individual born in a particular year can expect to live, starting at any given age—provide powerful support for the multiplicity of factors considered in previous chapters that slow biological aging, including improved nutrition, medical treatment, sanitation, and safety. Recall from Chapter 1 that in 1900, life expectancy was just under 50 years; in the United States today, it is 78.5—nearly 76 for men and 81 for women. A major factor in this extraordinary gain is a steady decline in infant mortality (see Chapter 3), but death rates among adults have decreased as well. For example, heart disease, the leading cause of overall adult death in the United States, has dropped by more than 60 percent in the past 50 years, due to declines in risk factors (such as high blood pressure and cigarette smoking) and, mostly, advances in medical treatment (U.S. Department of Health and Human Services, 2011c).

Variations in Life Expectancy

Consistent group differences in life expectancy underscore the joint contributions of heredity and environment to biological aging. In almost all cultures, women can look forward to 2 to 7 more years of life than men—a life expectancy advantage that characterizes females of most species (Kirkwood, 2010). The protective value of the female’s extra X chromosome (see Chapter 2) is believed to be responsible. Yet since the early 1970s, the gender gap in life expectancy has narrowed in industrialized nations (Leung, Zhang, & Zhang, 2004). Because men are at higher risk for disease and early death, they reap somewhat larger generational gains from positive lifestyle changes and new medical discoveries.

Life expectancy varies substantially with SES, ethnicity, and nationality. As education and income increase, so does length of life (Whitfield, Thorpe, & Szanton, 2011). In the United States, a white child born in 2010 is likely to live 3 to 6 years longer than an African-American child (U.S. Department of Health and Human Services, 2011c). Accounting for this difference are higher rates of infant mortality, unintentional injuries, life-threatening disease, stress, and violent death linked to low SES.

Length of life—and, even more important, *quality of life* in old age—can be predicted by a country’s health care, housing, and social services, along with lifestyle factors. When researchers estimate **average healthy life expectancy**, the number of years a person born in a particular year can expect to live in full health, without disease or injury, Japan ranks first,

© EVERETT KENNEDY BROWN/EPA/CORBIS

In a Japanese seaside city, a spry aging couple practice their local tradition of net fishing. Japan's low rates of obesity and heart disease and favorable health-care policies contribute to its worldwide leading status in healthy life expectancy.

with the United States below the overwhelming majority of industrialized nations (see Figure 17.1). Japan's leading status in this overall measure of population health has been attributed to its low rates of obesity and heart disease, linked to its low-fat diet, along with its favorable health-care policies. Because the United States falls short in these respects, Americans spend somewhat more time disabled and die earlier than older adults in most other developed countries.

In developing nations with widespread poverty, malnutrition, disease, and armed conflict, average life expectancy hovers around 55 years. And healthy life expectancy is reduced by three to four decades compared with the industrialized world—for example, for males, 69 years in Japan, 67 years in Sweden, 65 years in the United States, but only 48 in Afghanistan, 47 in Sierra Leone, and 28 in Haiti, where overall health recently declined because of the 2010 catastrophic earthquake (Salomon et al., 2012).

Life Expectancy in Late Adulthood

Although poverty-stricken groups lag behind the economically advantaged, the proportion of older adults has risen dramatically in the industrialized world. From 1900 to 2010, people age 65 and older increased from 4 percent to 13 percent of the U.S. population. Because of aging baby boomers, older adults are projected to rise to nearly 20 percent by 2030. Among older Americans, the fastest-growing segment is the 85-and-older group, which has increased by 30 percent during the past decade and currently makes up nearly 3.5 percent of the U.S. population. By 2050, they are expected to swell to over three times their current number (U.S. Census Bureau, 2012b).

Americans reaching age 65 in the early twenty-first century can look forward, on average, to 19 more years of life. As at earlier ages, life expectancy is greater for older women than for men. Today, the 65- to 69-year age group includes 117 women

FIGURE 17.1 Average healthy life expectancy at birth in 30 nations, ranked on basis of measures for women. Japan ranks first, the United States a disappointing thirtieth. In each nation, women's healthy life expectancy is about 2 to 3 years longer than men's. (From Salomon et al., 2012.)

for every 100 men; for people age 85 and older, this number climbs to 210 (U.S. Census Bureau, 2012b). Similar discrepancies exist throughout the world, with the exception of a few developing countries where death rates of women during child-birth are high or women experience severe discrimination and deprivation.

Although women outnumber men by a greater margin as older adults advance in age, differences in average life expectancy between the sexes are declining. An American newborn girl can expect to live about 5 years longer than a newborn boy. At age 65, the difference narrows to just under 3 years; at age 85, to just over 1 year. Over age 100, the gender gap in life expectancy disappears (U.S. Census Bureau, 2012b). Similarly,

Biology and Environment

What Can We Learn About Aging from Centenarians?

Jeanne Louise Calment, listed in *Guinness World Records* as the longest-lived person whose age could be documented, was born in Arles, France, in 1875 and died there in 1997, 122 years later. Heredity undoubtedly contributed to her longevity: Her father lived to age 94, her mother to 86. Her family was middle-SES, and in her twenties, she married a prosperous merchant (Robine & Allard, 1999). As a young woman, she was healthy and energetic; she bicycled, swam, roller-skated, played tennis, and ran up the steps of the cathedral to attend daily Mass.

Jeanne attributed her longevity to a diet rich in olive oil and an occasional glass of port wine. Others credit her easy-going disposition and resistance to stress. “If you can’t do anything about it,” she once said, “don’t worry about it.” Jeanne took up fencing at age 85 and rode a bicycle until age 100. Shortly thereafter, she moved into assisted living (see page 589), where she blossomed, becoming a celebrity because of both her age and her charming personality. Alert and quick-witted until her final

year, she recommended laughter as the best recipe for long life. Asked once about the effects of aging, she quipped, “I’ve only one wrinkle, and I am sitting on it.”

Because of stereotypes of aging, we tend to picture the most older people as extremely frail. Yet the past 30 years have seen a 65 percent increase in centenarians in the industrialized world. Currently, American centenarians, though still rare (a fraction of one percent of the population), number about 53,000 (Meyer, 2012). But the proportion of centenarians in the United States is smaller than in most other developed nations.

Among centenarians, women outnumber men by five to one. About 60 to 70 percent have physical and mental impairments that interfere with independent functioning. But the rest lead active, autonomous lives (Perls & Terry, 2003). These robust centenarians are of special interest because they represent the ultimate potential of the human species. What are they like? Results of several longitudinal studies reveal that they are diverse in years of education (none to postgraduate),

© PASCAL PARROT/CORBIS SYGMA

Jeanne Louise Calment, shown here at age 121, took up fencing at age 85, rode a bicycle until age 100, and maintained a quick wit until her final year. The longest-lived person on record, she died at age 122.

economic well-being (very poor to very rich), and ethnicity. At the same time, their physical condition and life stories reveal common threads.

differences in rates of chronic illness and in life expectancy between higher-SES whites and low-SES ethnic minorities decline with age. Around age 87, a *life expectancy crossover* occurs—surviving members of low-SES ethnic minority groups live longer than members of the white majority (Herd, Robert, & House, 2011; Masters, 2012; Sautter et al., 2012). Researchers speculate that among males and members of low-SES groups, only the biologically sturdiest survive into very old age.

Throughout this book, we have seen that genetic and environmental factors jointly affect aging. With respect to heredity, identical twins typically die within 3 years of each other, whereas fraternal twins of the same sex differ by more than 6 years. Also, longevity runs in families. When both parents survive to age 70 or older, the chances that their children will live to 90 or 100 are double that of the general population (Cevenini et al., 2008; Hayflick, 1994; Mitchell et al., 2001). At the same time, evidence from twin studies suggests that once people pass 75 to 80 years, the contribution of heredity to length of life decreases in favor of environmental factors—a healthy diet;

normal body weight; regular exercise; little or no tobacco, alcohol, and drug use; an optimistic outlook; low psychological stress; and social support (Yates et al., 2008; Zaretsky, 2003). As the Biology and Environment box above reveals, the study of centenarians—people who cross the 100-year mark—offers special insights into how biological, psychological, and social influences work together to promote a long, satisfying life.

Maximum Lifespan

Finally, perhaps you are wondering: For humans, what is the **maximum lifespan**, or species-specific biological limit to length of life (in years), corresponding to the age at which the oldest known individual died? As the Biology and Environment box indicates, the oldest verified age is 122 years.

Does this figure actually reflect the upper bound of human longevity, or can it be extended? Some scientists believe that 122 years is close to the maximum, and 85 to 90 years is as much as most humans can expect. They point out that gains in average

Health

Centenarians usually have grandparents, parents, and siblings who reached very old age, indicating a genetically based survival advantage. Likewise, their children, who are typically in their seventies and eighties, appear physically young for their age (Coles, 2004; Perls et al., 2002). Some centenarians share with siblings a segment of identical DNA on the fourth chromosome, suggesting that a certain gene, or several genes, may increase the likelihood of exceptionally long life (Perls & Terry, 2003).

Most robust centenarians greatly delay or escape age-related chronic illnesses. Genetic testing reveals a low incidence of genes associated with immune-deficiency disorders, cancer, and Alzheimer's disease. Consistent with these findings, robust centenarians usually have efficiently functioning immune systems, and after-death examinations reveal few brain abnormalities (Silver & Perls, 2000). Others function effectively despite underlying chronic disease—typically atherosclerosis, other cardiovascular problems, and brain pathology (Berzlanovich et al., 2005; Evert et al., 2003). Compared with the general population, about four times as many centenarian women gave birth to healthy children after

age 40 (Perls et al., 2000). Late childbearing may indicate that the body, including the reproductive system, is aging slowly.

As a group, robust centenarians are of average or slender build and practice moderation in eating. Many have most or all of their own teeth—another sign of unusual physical health. The large majority report having never smoked, engaging in no more than moderate wine consumption, and sustaining a lifelong pattern of physical activity past age 100 (Hagberg & Samuelson, 2008; Kropf & Pugh, 1995).

Personality

In personality, these very senior citizens appear highly optimistic (Jopp & Rott, 2006). In a study in which robust centenarians retook personality tests after 18 months, they reported more fatigue and depression, perhaps in response to increased frailty at the very end of their lives. But they also scored higher in toughmindedness, independence, emotional security, and openness to experience—traits that may be vital for surviving beyond 100 (Martin, Long, & Poon, 2002). An important contributor to their favorable mental health and longevity is social support, especially close family bonds and a long and happy marriage

(Margrett et al., 2011; Velkoff, 2000). An unusually large percentage of centenarian men—about one-fourth—are still married.

Activities

Robust centenarians have a history of community involvement—working for just causes that are central to their growth and happiness. Their past and current activities often include stimulating work, leisure pursuits, and learning, which may help sustain their good cognition and life satisfaction (Antonini et al., 2008). Writing letters, poems, plays, and memoirs; making speeches; teaching music lessons and Sunday school; nursing the sick; chopping wood; selling merchandise, bonds, and insurance; painting; practicing medicine; and preaching sermons are among robust centenarians' varied involvements. In several cases, illiterate centenarians learned to read and write.

In sum, robust centenarians illustrate typical development at its best. These independent, mentally alert, happy 100-year-olds reveal how a healthy lifestyle, personal resourcefulness, and close ties to family and community can build on biological strengths, thereby pushing the limits of an active, fulfilling life.

life expectancy are largely the result of reducing health risks in the first 20 or 30 years—especially, the harmful behavioral and environmental conditions linked to poverty, limited education, and weak access to health care (Olshansky, 2011). For people age 65 and older, life expectancy has increased very little—only about 5 months—over the past decade. And although the number of centenarians is rising (see the Biology and Environment box), the odds of becoming a centenarian have been extremely low throughout human history and remain so today—in the U.S. population, just 1.7 for every 10,000 people, with most centenarians dying by age 103 (Carnes, Olshansky, & Hayflick, 2013). Nevertheless, other researchers remain convinced that we can add to human maximum lifespan.

This controversy raises another issue: *Should* maximum lifespan be increased as far as possible? **TAKE A MOMENT...** How would you answer this question? Many people respond that the important goal is not just quantity of life, but quality—that is, doing everything possible to extend healthy life expectancy. Most experts agree that only after reducing the high rates

of preventable illness and disability among low-SES individuals and wiping out age-related diseases should we invest in lengthening the maximum lifespan.

Physical Changes

The programmed effects of specific genes and the random cellular events believed to underlie biological aging (see Chapter 13) make physical declines more apparent in late adulthood. The majority of people age 65 and older are capable of living active, independent lives, but with age, growing numbers need assistance. After age 75, about 9 percent of Americans have difficulty carrying out **activities of daily living (ADLs)**—basic self-care tasks required to live on one's own, such as bathing, dressing, getting in and out of bed or a chair, or eating. And about 17 percent cannot carry out **instrumental activities of daily living (IADLs)**—tasks necessary to conduct the business of daily life and also requiring some cognitive competence, such

as telephoning, shopping, food preparation, housekeeping, and paying bills. The proportion of older adults with these limitations rises sharply with age (U.S. Department of Health and Human Services, 2011c). Nevertheless, most body structures can last into our eighties and beyond, if we take good care of them. For an overview of the physical changes we are about to discuss, return to Table 13.1 on page 435.

Nervous System

On a routine office visit, 80-year-old Ruth's doctor asked her how she was getting along. "I think I might be losing my mind," Ruth replied anxiously. "Yesterday, I forgot the name of the family who just moved in next door. And the day before, I had trouble finding the right words to explain to a delivery service how to get to my house."

"Ruth, everyone forgets those sorts of things from time to time," Dr. Wiley reassured her. "When we were young and had a memory lapse, we reprimanded ourselves for being scatterbrained and thought no more about it. Now, when we do the same thing, we attribute it to having 'a senior moment,' and we worry."

Ruth also wondered why extremes of hot and cold weather felt more uncomfortable than in earlier years. And she needed more time to coordinate a series of movements and had become less sure of her balance.

Aging of the central nervous system affects a wide range of complex activities. Although brain weight declines throughout adulthood, brain-imaging research and after-death autopsies reveal that the loss becomes greater starting in the sixties and may amount to as much as 5 to 10 percent by age 80, due to withering of the myelin coating on neural fibers, loss of synaptic connections, death of neurons, and enlargement of ventricles (spaces) within the brain (Rodrigue & Kennedy, 2011; Zelazo & Lee, 2010).

Neuron loss occurs throughout the cerebral cortex but at different rates among different regions and often inconsistently within parts of those regions. In longitudinal studies, the frontal lobes, especially the prefrontal cortex (responsible for inhibition, integration of information, strategic thinking, and other aspects of executive function), and the corpus callosum (which connects the two cortical hemispheres) tended to show greater shrinkage than the parietal and temporal lobes, with the occipital lobes changing little (see page 124 in Chapter 4 for a visual image of these regions) (Fabiani, 2012; Smith et al., 2007). The cerebellum (which controls balance and coordination and supports cognitive processes) also loses neurons—in all, about 25 percent. And EEG measures reveal gradual slowing and reduced intensity of brain waves—signs of diminished efficiency of the central nervous system (Kramer, Fabiani, & Colcombe, 2006).

But brain-imaging research reveals wide individual differences in the extent of these losses, which are moderately associated with cognitive functioning (Raz et al., 2010). And the brain can overcome some decline. In several studies, growth of neural fibers in the brains of older adults unaffected by illness took place at the same rate as in middle-aged people. Aging neurons established new synapses after other neurons had degenerated

(Flood & Coleman, 1988). Furthermore, the aging cerebral cortex can, to a limited degree, generate new neurons (Gould, 2007; Snyder & Cameron, 2012). And fMRI evidence reveals that compared with younger adults, older people who do well on memory and other cognitive tasks show more widely distributed activity across areas of the cerebral cortex, particularly in the prefrontal cortex and in regions mirroring typically active sites but located in the opposite hemisphere (Fabiani, 2012; Reuter-Lorenz & Cappell, 2008). This suggests that one way older adults compensate for neuron loss is to call on additional brain regions to support cognitive processing.

The autonomic nervous system, involved in many life-support functions, also performs less well, putting the older adults at risk during heat waves and cold spells. For example, Ruth's reduced tolerance for hot weather was due to decreased sweating. And her body found it harder to raise its core temperature during cold exposure. However, among physically fit older people who are free of disease, these declines are mild (Blatteis, 2012). The autonomic nervous system also releases higher levels of stress hormones into the bloodstream than it did earlier, perhaps to arouse body tissues that have become less responsive to these hormones over the years (Whitbourne, 2002). As we will see, this change may contribute to decreased immunity and to sleep problems.

Sensory Systems

Changes in sensory functioning become increasingly noticeable in late life. Older adults see and hear less well, and their taste, smell, and touch sensitivity may also decline. As Figure 17.2

FIGURE 17.2 Rates of visual and hearing impairments among U.S. men and women by age. Among a large, nationally representative sample, those reporting that they had trouble seeing, even when wearing glasses or contact lenses, were judged visually impaired; those reporting “a lot of trouble” hearing were judged hearing impaired. Women report more visual impairments; men report more hearing impairments, a gap that widens considerably in late adulthood. In late life, hearing impairments become more common than visual impairments. (Adapted from U.S. Department of Health and Human Services, 2012d.)

shows, in late life, hearing impairments are more common than visual impairments. Extending trends in middle adulthood, more women than men report being visually impaired, more men than women hearing impaired.

Vision. In Chapter 15 (see pages 502–503), we noted that structural changes in the eye make it harder to focus on nearby objects, see in dim light, and perceive color. In late adulthood, vision diminishes further. The cornea (clear covering of the eye) becomes more translucent and scatters light, which blurs images and increases sensitivity to glare. The lens continues to yellow, leading to further impairment in color discrimination. The number of individuals with **cataracts**—cloudy areas in the lens, resulting in foggy vision and (without surgery) eventual blindness—increases tenfold from middle to late adulthood, affecting 25 percent of people in their seventies and 50 percent of those in their eighties (Owsley, 2011; U.S. Census Bureau, 2012b). Besides biological aging, heredity, sun exposure, cigarette smoking, alcohol consumption, and certain diseases (such as hypertension and diabetes) increase the risk of cataracts (Sacca et al., 2009). Fortunately, removal of the lens and replacement with an artificial lens implant is highly successful in restoring vision.

Impaired eyesight in late adulthood largely results from a reduction in light reaching the retina (caused by yellowing of the lens, shrinking of the pupil, and clouding of the vitreous) and from cell loss in the retina and optic nerve (refer again to Chapter 15). Dark adaptation—moving from a brightly lit to a dim environment, such as a movie theater—becomes harder. A decline in binocular vision (the brain’s ability to combine images received from both eyes) makes depth perception less reliable. And visual acuity (fineness of discrimination) worsens, dropping sharply after age 70 (Owsley, 2011).

When light-sensitive cells in the macula, or central region of the retina, break down, older adults may develop **macular degeneration**, in which central vision blurs and gradually is lost. Macular degeneration is the leading cause of blindness among older adults. About 10 percent of 65- to 74-year-olds, and 30 percent of 75- to 85-year-olds, have symptoms. If diagnosed early, macular degeneration can sometimes be treated with laser therapy. As with cataracts, heredity (including several identified genes) increases risk, especially when combined with cigarette smoking or obesity (Chu et al., 2008; Rhone & Basu, 2008; Wysong, Lee, & Sloan, 2009). Atherosclerosis also contributes by constricting blood flow to the retina. Protective factors—believed to exert their effects by shielding cells in the macula from free-radical damage—include regular, brisk physical activity and a diet rich in green, leafy vegetables, which are excellent sources of vitamins A, C, E, and carotenoids (yellow and red plant pigments) (Feret et al., 2007).

Visual difficulties have a profound impact on older people’s self-confidence and everyday behavior. As she approached age 80, Ruth gave up driving, and she worried about Walt, who found it hard to shift focus between the road and the dashboard or to make out pedestrians at dusk and at night. On foot, problems with depth perception and dark adaptation increase older adults’ chances of stumbling.

When vision loss is extensive, it can affect leisure pursuits and be very isolating. Because of her poor vision, Ruth could no longer enjoy museums, movies, playing bridge, or working crossword puzzles, and she depended on others for help with housekeeping and shopping. But even among people age 85 and older, only 30 percent experience visual impairment severe enough to interfere with daily living (U.S. Department of Health and Human Services, 2011c). For many, however, reduced vision goes undetected. Treatment is vital for sustaining quality of life.

Hearing. “Mom, I’d like you to meet Joe’s cousin Leona,” said Ruth’s daughter Sybil at a Thanksgiving gathering. But in the clamor of boisterous children, television sounds, and nearby conversations, 85-year-old Ruth didn’t catch Leona’s name or her relationship to Sybil’s husband, Joe.

“Tell me your name again?” Ruth asked, adding, “Let’s go into the other room, where it’s quieter, so we can speak a bit.”

Reduced blood supply and natural cell death in the inner ear and auditory cortex, discussed in Chapter 15, along with stiffening of membranes (such as the eardrum), cause hearing to decline in late adulthood. Decrements are greatest at high frequencies, although detection of soft sounds diminishes throughout the frequency range (see page 503). In addition, responsiveness to startling noises lessens, and discriminating complex tone patterns becomes harder (Hietanen et al., 2004; Kidd & Bao, 2012).

Although hearing loss has less impact on self-care than vision loss, it affects safety and enjoyment of life. In the din of city traffic, 80-year-old Ruth didn’t always correctly interpret warnings, whether spoken (“Watch it, don’t step out yet”) or nonspeaking (the beep of a horn). And when she turned up the radio or television volume, she sometimes missed the ring of the telephone or a knock at the door.

As hearing declines, older people report lower self-efficacy, more loneliness and depressive symptoms, and a smaller social

This adult son’s patient guidance helps his father feel included at a boisterous family reunion. Declines in hearing make it difficult for older adults to socialize in noisy settings.

network than their normally hearing peers (Kramer et al., 2002). Of all hearing difficulties, the age-related decline in speech perception has the greatest impact on life satisfaction. After age 70, ability to detect the content and emotionally expressive features of conversation declines, especially in noisy settings (Gosselin & Gagne, 2011).

Although Ruth used problem-centered coping to increase her chances of hearing conversation, she wasn't always successful. At the family's Thanksgiving reunion, fewer relatives took time to talk with Ruth, and she felt some pangs of loneliness. And sometimes people were inconsiderate. On a dinner outing, when Ruth asked Joe to repeat himself, he turned to Sybil and said loudly, "Be honest, Syb, Ruth's going deaf, isn't she?" In one study, older adults' adoption of such negative stereotypes of aging predicted greater hearing loss over a three-year period (Levy, Slade, & Gill, 2006).

Most older adults do not suffer from hearing loss great enough to disrupt their daily lives until after age 85. For those who do, compensating with a hearing aid is helpful. Furthermore, recall from Chapter 4 (pages 145–146) that beginning at birth, our perception is *intermodal* (combines information from more than one sensory system). By attending to facial expressions, gestures, and lip movements, older adults can use vision to help interpret the spoken word. Finally, when family members and others speak in quiet environments, older people are far more likely to convey an image of alertness and competence than of reduced sensitivity to the surrounding world.

Taste and Smell. Walt's brother Dick was a heavy smoker. In his sixties, he poured salt and pepper over his food and asked for "extra hot" in Mexican and Indian restaurants.

Dick's reduced sensitivity to the four basic tastes—sweet, salty, sour, and bitter—is evident in many adults after age 60. Older adults also have greater difficulty recognizing familiar foods by taste alone (Fukunaga, Uematsu, & Sugimoto, 2005; Methven et al., 2012). But no change in the number or distribution of taste buds occurs late in life, so this drop in taste sensitivity may be due to factors other than aging. Cigarette smoking, dentures, medications, and environmental pollutants can affect taste perception (Drewnowski & Shultz, 2001). When taste is harder to detect, food is less enjoyable, increasing the likelihood of dietary deficiencies. Flavor additives can help make food more attractive.

Besides enhancing food enjoyment, smell has a self-protective function. An aging person who has difficulty detecting rancid food, gas fumes, or smoke may be in a life-threatening situation. A decrease in the number of smell receptors after age 60 contributes to declines in odor sensitivity (Seiberling & Conley, 2004). Researchers believe that odor perception not only wanes but becomes distorted, a change that may promote complaints that "food no longer smells and tastes right." But older adults experiencing greater difficulty with verbal recall, including retrieval of odor labels, have greater difficulty with odor recognition tasks (Larsson, Öberg, & Bäckman, 2005). So cognitive changes may make the decline in odor perception appear greater than it actually is.

Touch. Object recognition through touch occurs many times each day, as adults identify common objects after manually exploring them—keys or credit card in a pocket, corkscrew at the back of a drawer—within 2 to 3 seconds. Touch sensitivity is especially crucial for certain adults, such as the severely visually impaired reading Braille and people making fine judgments about texture—for example, in art and handicraft activities. In later life, capacity to discriminate detailed surface properties and identify unfamiliar objects by touch declines. Waning of touch perception on the hands, especially the fingertips—believed to be due to loss of touch receptors in certain regions of the skin and slowing of blood circulation to the extremities—contributes (Stevens & Cruz, 1996). In addition, decrements in fluid abilities, especially spatial orientation, are influential (see page 519 in Chapter 15) (Kalisch et al., 2012). Fluid skills are strongly correlated with older adults' tactile performance.

Compared to their sighted counterparts, blind Braille readers retain high touch sensitivity well into old age (Legge et al., 2008). Years of experience in picking up detailed tactile information seem to protect their tactile discrimination skills.

Cardiovascular and Respiratory Systems

Aging of the cardiovascular and respiratory systems proceeds gradually and usually unnoticed in early and middle adulthood. In late adulthood, changes become more apparent. In their sixties, Ruth and Walt noticed that they felt more physically stressed after running to catch a bus or to cross a street before the light changed.

As the years pass, the heart muscle becomes more rigid, and some of its cells die while others enlarge, leading the walls of the left ventricle (the largest heart chamber, from which blood is pumped to the body) to thicken. In addition, artery walls stiffen

© JUICE IMAGES/LAMY

These mountain hikers need frequent rests to catch their breath and regain their energy. With aging of the cardiovascular and respiratory systems, sufficient oxygen may not be delivered to body tissues during physical exertion.

and accumulate some plaque (cholesterol and fats) due to normal aging (much more in those with atherosclerosis). Finally, the heart muscle becomes less responsive to signals from pacemaker cells within the heart, which initiate each contraction (Larsen, 2009; Smith & Cotter, 2008).

As a combined result of these changes, the heart pumps with less force, maximum heart rate decreases, and blood flow throughout the circulatory system slows. This means that sufficient oxygen may not be delivered to body tissues during high physical activity. (Recall from Chapter 13 that a healthy heart supports typical levels of exertion well into old age.)

Changes in the respiratory system compound the effects of reduced oxygenation. Because lung tissue gradually loses its elasticity, vital capacity (amount of air that can be forced in and out of the lungs) is reduced by half between ages 25 and 80. As a result, the lungs fill and empty less efficiently, causing the blood to absorb less oxygen and give off less carbon dioxide. This explains why older people increase their breathing rate more and feel more out of breath while exercising.

Cardiovascular and respiratory deficiencies are more extreme in lifelong smokers and in people who have failed to reduce dietary fat or have had many years of exposure to environmental pollutants. As we have seen in previous chapters, exercise is a powerful means of slowing cardiovascular aging (Galetta et al., 2012). Exercise also facilitates respiratory functioning, as we will see later when we discuss health and fitness.

Immune System

As the immune system ages, T cells, which attack antigens (foreign substances) directly, become less effective (see Chapter 13, page 437). In addition, the immune system is more likely to malfunction by turning against normal body tissues in an **autoimmune response**. A less competent immune system can increase the risk of a variety of illnesses, including infectious diseases (such as the flu), cardiovascular disease, certain forms of cancer, and various autoimmune disorders, such as rheumatoid arthritis and diabetes (Larbi, Fülöp, & Pawelec, 2008). But an age-related decline in immune functioning is not the cause of most late-life illnesses. It merely permits disease to progress, whereas a stronger immune reaction would stamp out the disease agent.

Although older adults vary greatly in immunity, most experience some loss, ranging from partial to profound (Ponnappan & Ponnappan, 2011). The strength of the aging person's immune system seems to be a sign of overall physical vigor. Certain immune indicators, such as high T cell activity, predict better physical functioning and survival over the next two years in very old people (Moro-Garcia et al., 2012; Wikby et al., 1998).

Recall from Chapter 13 that stress hormones undermine immunity. With age, the autonomic nervous system releases higher levels of these into the bloodstream (refer back to page 437). As the immune response declines with age, stress-induced susceptibility to infection rises dramatically (Archer et al., 2011). A healthy diet and exercise help protect the immune response in old age, whereas obesity aggravates the age-related decline.

Sleep

When Walt went to bed at night, he usually lay awake for a half-hour to an hour before falling asleep, remaining in a drowsy state longer than when he was younger. During the night, he spent less time in the deepest phase of NREM sleep (see Chapter 3, page 108) and awoke several times—again sometimes lying awake for a half-hour or more before drifting back to sleep.

Older adults require about as much total sleep as younger adults: around 7 hours per night. Yet as people age, they have more difficulty falling asleep, staying asleep, and sleeping deeply. Insomnia affects nearly half of older adults at least a few nights per month. The timing of sleep tends to change as well, toward earlier bedtime and earlier morning waking (Edwards et al., 2010). Changes in brain structures controlling sleep and higher levels of stress hormones in the bloodstream, which have an alerting effect on the central nervous system, are believed to be responsible.

Until age 70 or 80, men experience more sleep disturbances than women, for several reasons. First, enlargement of the prostate gland, which occurs in almost all aging men, constricts the urethra (the tube draining the bladder) and leads to a need to urinate more often, including during the night. Second, men—especially those who are overweight and use alcohol heavily—are more prone to **sleep apnea**, a condition in which breathing ceases for 10 seconds or longer, resulting in many brief awakenings. An estimated 45 to 60 percent of older adults are affected (Edwards et al., 2010).

Poor sleep can feed on itself. Walt's nighttime wakefulness led to daytime fatigue and short naps, which made it harder to fall asleep the following evening. And because Walt expected to have trouble sleeping, he worried about it, which also interfered with sleep. Insomnia in older adults is of special concern because it increases the risk of falls and cognitive impairments (Crowley, 2011). Those who are poor sleepers more often report slower reaction times and attention and memory difficulties.

Fortunately, there are ways to foster restful sleep, such as establishing a consistent bedtime and waking time, exercising regularly, and using the bedroom only for sleep (not for eating, reading, or watching TV) (McCurry et al., 2007). Older adults receive more prescription sedatives for sleep complaints than do people under age 60. Used briefly, these drugs can help relieve temporary insomnia. But long-term medication can make matters worse by increasing the frequency and severity of sleep apnea and by inducing rebound insomnia after the drug is discontinued (Feinsilver, 2003). Finally, discomfort due to an enlarged prostate, including frequent urination at night, can be corrected with laser surgical procedures that relieve symptoms without complications (Zhang et al., 2012).

Physical Appearance and Mobility

In earlier chapters, we saw that changes leading to an aged appearance are under way as early as the twenties and thirties. Because these occur gradually, older adults may not notice that they look older until changes have become obvious. Each year

Aging brings changes in appearance, evident in these portraits of Jimmy Carter, former U.S. president, at ages 52, 63, and 88. The skin creases and sags, “age spots” increase, the nose and ears broaden, and hair on the head thins.

during their summer travels, Walt and Ruth observed that Dick and Goldie’s skin appeared more wrinkled. Their hair turned from gray to white as all pigment was lost; their bodies grew rounder and their arms and legs thinner. When they returned home, Walt and Ruth also were more aware that they themselves had aged.

Creasing and sagging of the skin, described in Chapter 15, extends into old age. In addition, oil glands that lubricate the skin become less active, leading to dryness and roughness. “Age spots” increase; in some individuals, the arms, backs of the hands, and face may be dotted with these pigmented marks. Blood vessels can be seen beneath the more transparent skin, which has largely lost its layer of fatty support (Whitbourne, 2002). This loss further limits the older adult’s ability to adapt to hot and cold temperatures.

The face is especially likely to show these effects because it is frequently exposed to the sun, which accelerates aging. Other factors that contribute to facial wrinkling and age spots include long-term alcohol use, cigarette smoking, and psychological stress. Additional facial changes occur: The nose and ears broaden as new cells are deposited on the outer layer of the skeleton. And especially in older adults with a history of poor dental care, teeth may be yellowed, cracked, and chipped, and gums may have receded. As hair follicles under the skin’s surface die, hair on the head thins in both sexes, and the scalp may be visible (Whitbourne, 2002). In men with hereditary pattern baldness, follicles do not die but, instead, begin to produce fine, downy hair.

Body build changes as well. Height continues to decline, especially in women, as loss of bone mineral content leads to further collapse of the spinal column. Weight generally drops after age 60 because of additional loss of lean body mass (bone density and muscle), which is heavier than the fat deposits accumulating on the torso.

Several factors affect mobility. The first is muscle strength, which generally declines at a faster rate in late adulthood than in middle age. On average, by 60 to 70 years of age, 10 to 20 percent of muscle power has been lost, a figure that climbs to 30 to 50 percent after age 70 to 80 (Reid & Fielding, 2012). Second, bone strength deteriorates because of reduced bone mass, and tiny cracks in response to stress weaken the bones further. Third, strength and flexibility of the joints and the ligaments and tendons (which connect muscle to bone) diminish. In her eighties, Ruth’s reduced ability to support her body, flex her limbs, and rotate her hips made walking at a steady, moderate pace, climbing stairs, and rising from a chair difficult.

In Chapter 13, we noted that endurance athletes who continue training throughout adulthood retain their muscular physiques and much of their strength into their sixties and seventies. These especially active people, like other aging individuals, lose fast-twitch muscle fibers, but they compensate by strengthening remaining slow-twitch fibers so they work more efficiently. A history of regular physical activity translates into greater mobility in late life (Koster et al., 2007; Patel et al., 2006). At the same time, a carefully planned exercise program can enhance older adults’ joint flexibility and range of movement.

Adapting to Physical Changes of Late Adulthood

Great diversity exists in older adults’ adaptation to the physical changes of aging. People who are more anxious about growing older monitor their physical state more closely and are more concerned about their appearance (Montepare, 2006). Dick and Goldie took advantage of an enormous industry designed to stave off outward signs of old age, including cosmetics, wigs, and plastic surgery, plus various “anti-aging” dietary supplements,

herbal products, and hormonal medications offered by “longevity” clinics—none with any demonstrated benefits and some of them harmful (Olshansky, Hayflick, & Perls, 2004). In contrast, Ruth and Walt were relatively unconcerned about their thinning white hair and wrinkled skin. Their identities were less bound up with their appearance than with their ability to remain actively engaged in their surroundings.

Most older people sustain a favorable *subjective age*—say they feel younger than they look and than they actually are (Kleinspehn-Ammerlahn, Kotter-Grühn, & Smith, 2008; Uotinen et al., 2006; Westerhof, 2008). In several investigations, 75-year-olds reported feeling about 15 years younger! A youthful self-evaluation is linked to satisfaction with growing older—better mental health and psychological well-being (Keyes & Westerhof, 2012).

Clearly, older adults vary in the aspects of physical aging that matter most to them. *Wanting* to be younger (as opposed to *feeling* younger) than one’s actual age is associated with less positive mental health (Keyes & Westerhof, 2012). Compared with Dick and Goldie, Ruth and Walt approached aging with a more positive outlook and greater peace of mind, resolving to intervene in those aspects of physical aging that could be changed and to accept those that could not.

Research shows that the most obvious outward signs of aging—graying hair, facial wrinkles, and baldness—bear no relationship to sensory, cognitive, and motor functioning or to longevity (Schnohr et al., 1998). In contrast, neurological, sensory, cardiovascular, respiratory, immune-system, and skeletal and muscular health are strongly associated with cognitive performance and both quality and length of later life (Bergman, Blomberg, & Almkvist, 2007; Lin et al., 2011; Reyes-Ortiz et al., 2005; Schäfer, Huxhold, & Lindenberger, 2006). Furthermore, people can do more to prevent declines in the functioning of these internal body systems than they can do to prevent gray hair and baldness!

Effective Coping Strategies. Think back to our discussion of problem-centered and emotion-centered coping in Chapter 15. It applies here as well. As Walt and Ruth prevented and compensated for age-related changes through diet, exercise, environmental adjustments, and an active, stimulating lifestyle, they felt a sense of personal control over their fates. This prompted additional active coping and improved physical functioning.

Older people who report a high sense of personal control usually deal with physical changes through problem-centered coping strategies. A 75-year-old who lost sight in one eye consulted an occupational therapist for advice and, to compensate for reduced depth perception and visual field, trained himself to use more side-to-side head movements. In contrast, older adults who consider age-related declines inevitable and uncontrollable tend to be passive when faced with them and to report more physical and psychological adjustment difficulties (Kempen et al., 2006; Lachman, Neupert, & Agrigoroaei, 2011).

Sense of control varies across cultures: U.S. individualistic values emphasize the power of one’s own action and choices.

Consequently, Americans score higher in personal control than adults in Asian nations and in Mexico (Angel, Angel, & Hill, 2009; Yamaguchi et al., 2005). Furthermore, we have seen that the United States is less generous than other industrialized nations in government-supported health care and social security benefits (see pages 67–68 in Chapter 2). In one study, sense of personal control was a much stronger predictor of older adults’ health status in the United States than it was in England, where government policies do more to support good health throughout the lifespan (Clarke & Smith, 2011).

When physical disabilities become severe, sense of control has diminishing returns, no longer having as much impact on health status. Older adults with substantial physical impairments cope more effectively when they acknowledge reduced control and accept the need for caregiver or equipment assistance (Clarke & Smith, 2011; Ross & Sastry, 1999). But doing so may be more difficult for many older Americans, who are accustomed to a “culture of personal control,” than for older people elsewhere in the world.

Assistive Technology. A rapidly expanding **assistive technology**, or array of devices that permit people with disabilities to improve their functioning, is available to help older people cope with physical declines. Computers are the greatest source of these innovative products. People with sensory impairments can use special software to enlarge text or have it read aloud. Phones that can be dialed and answered by voice commands help those with difficulty pushing buttons or getting across a room to answer the phone. And for older people who take multiple medications, a tiny computer chip called a “smart cap” can be placed on medicine bottles. It beeps on a programmed schedule as a reminder to take the drug and tracks how many and at what time pills have been taken.

WILL & DENI MCINTYRE / PHOTO RESEARCHERS/GETTY IMAGES

A physical therapist helps a stroke patient master use of a tool for reaching and gripping small objects. Assistive devices help older adults with disabilities maintain their independence.

Architects have also designed homes that can adapt to changing physical needs—equipping them with movable walls that expand and contract, plumbing that enables a full bathroom to be added on the main floor, and “smart-home” technologies that promote safety and mobility, such as sensors in floors that activate room lights when an older person gets up at night and alarm systems that detect falls. Another remarkable device is a bathroom scale that helps monitor health status. It sends a signal to a control box, which reads the person’s weight aloud. After comparing weight with previous readings, the box asks relevant questions—“Are you more tired than usual?” “Are you having trouble sleeping?”—that can be answered by pressing a “yes” or “no” button. The box also works with equipment that measures blood pressure, activity level, and other health indicators. Data collected are sent electronically to whomever the older adult gives access.

Use of assistive devices slows physical declines and reduces the need for personal caregiving (Hoenig, Taylor, & Sloan, 2003; Wilson et al., 2009). Do older adults with disabilities regard some technologies as invasions of privacy? The overwhelming majority weigh privacy concerns against potential benefits—saying for example, “If this [monitoring system] would keep me independent longer, I wouldn’t mind” (Melenhorst et al., 2004; Rogers & Fisk, 2005). As these findings suggest, sustaining an effective *person–environment fit*, or match between older people’s current capabilities and the demands of their living environments, enhances psychological well-being (Lawton, 1998). Modifying physical and social environments to boost older adults’ ability to perform familiar tasks and master new ones contributes to their sense of competence and the quality of their lives.

At present, U.S. government-sponsored health-care coverage is largely limited to essential medical equipment; smart-home technologies are beyond the means of most older people. Sweden’s health-care system, in contrast, covers many assistive devices that promote function and safety, and its building code requires that new homes include a full bathroom on the main floor (Hooyman & Kiyak, 2011). In this way, Sweden strives to maximize person–environment fit for its older adults, helping them remain as independent as possible.

Overcoming Stereotypes of Aging. Negative stereotypes of late adulthood, which view older adults as weak, boring, and debilitated and “deterioration as inevitable,” are widespread in Western nations (Staudinger & Bowen, 2010). Overcoming this pessimistic picture is vital for helping people adapt favorably to late-life physical changes. In a survey of older adults diverse in SES, many reported experiencing prejudice and discrimination (Palmore, 2001). For example, 30 to 40 percent had been ignored, talked down to, or assumed to be unable to hear or understand well because of their age.

Like gender stereotypes, aging stereotypes often operate automatically, without awareness; people “see” older adults in stereotypical ways, even when they appear otherwise (Kite et al., 2005). As seniors encounter these negative messages, they experience *stereotype threat*, which results in diminished

performance on tasks related to the stereotype (see pages 314–315 in Chapter 9). In several studies, researchers exposed older adults to words associated with either negative aging stereotypes (“decrepit,” “confused”) or positive aging stereotypes (“sage,” “enlightened”). Those in negative-stereotype conditions displayed a more intense physiological response to stress, greater help-seeking and feelings of loneliness, and worse physical performance, recall memory, self-efficacy, and appraisals of their own health (Coudin & Alexopoulos, 2010; Hess & Hinson, 2006; Hess, Hinson, & Statham, 2004; Levy & Leifheit-Limson, 2009; Mazerolle et al., 2012). **TAKE A MOMENT...** How might stereotype threat explain the hearing loss linked to negative stereotypes of aging, mentioned on page 570?

As the findings just reviewed indicate, negative stereotypes have a stressful, disorganizing impact on older adults’ functioning. Positive stereotypes, in contrast, reduce stress and foster physical and mental competence (Bolkan & Hooker, 2012). In a longitudinal investigation, people with positive self-perceptions of aging—who, for example, agreed with such statements as “As I get older, things are better than I thought they’d be”—lived, on average, 7½ years longer than those with negative self-perceptions. This survival advantage remained after gender, SES, loneliness, and physical health status were controlled (Levy et al., 2002). Adults with less education are especially susceptible to the detrimental effects of aging stereotypes, perhaps because they tend to accept those messages uncritically (Andreolletti & Lachman, 2004).

Older adults rarely appear in television programs and, when they do, typically play minor roles. But a positive sign is that negative portrayals of seniors on TV and in other media are rare. TV commercials featuring older people usually depict them in stereotypically positive roles, most commonly as an “adventurous golden ager” (fun-loving, sociable, and active), “perfect grandparent” (family-oriented, kind, and generous), or “productive golden ager” (intelligent, capable, and successful) (Lee, Carpenter, & Meyers, 2006). Still, the products promoted in such ads are mostly medications and medical services and “anti-aging” cosmetics and treatments—images that reinforce negative views of older adults as preoccupied with physical declines and dissatisfied with their appearance.

In cultures where older adults are treated with deference and respect, an aging appearance can be a source of pride. In one study, Chinese adults diverse in age were less likely than Canadian adults to stereotype older people, either positively or negatively (Ryan et al., 2004). In the native language of the Inuit people of Canada, the closest word to “elder” is *isumataq*, or “one who knows things”—a high status that begins when a couple becomes head of the extended family unit. When Inuit older adults were asked for their thoughts on aging well, they mentioned attitudes—a positive approach to life, interest in transmitting cultural knowledge to young people, and community involvement—nearly twice as often as physical health (Collings, 2001).

Japan honors its older citizens with an annual celebration, Respect for the Aged Day. Also, a ritual called *kanreki* recognizes

An Inuit senior of northern Canada teaches a young adult how to make sealskin kamiks, or boots. In Inuit culture, aging is associated with expert knowledge and high status. Hence, changes in physical appearance can be a source of pride.

the older person's new freedoms and competencies and senior place in the family and society. Japanese extended families in the United States often plan the *kanreki* as a surprise sixtieth birthday party, incorporating elements of both the traditional ritual (such as dress) and the Western birthday (a special cake). Cultural valuing of aging prompts a welcoming approach to late adulthood, including some of its physical transitions.

Despite inevitable declines, physical aging can be viewed with either optimism or pessimism. As Walt commented, "You can think of your glass as half full or half empty." As the Cultural Influences box on page 576 makes clear, cultural valuing of older adults greatly increases the likelihood that they will adopt the "half full" alternative.

ASK YOURSELF

REFLECT While watching TV during the coming week, keep a log of portrayals of older adults in commercials. How many images were positive? How many negative? Compare your observations with research findings.

Health, Fitness, and Disability

At Walt and Ruth's fiftieth wedding anniversary, 77-year-old Walt thanked a roomful of well-wishers for joining in the celebration. Then, with emotion, he announced, "I'm so grateful Ruth and I are still healthy enough to give to our family, friends, and community."

As Walt's remarks affirm, health is central to psychological well-being in late life. When researchers ask older adults about possible selves (see Chapter 16, page 538), number of hoped-for physical selves declines with age and number of feared physical selves increases. Nevertheless, because older people compare themselves to same-age peers, the majority rate their health favorably (U.S. Department of Health and Human Services, 2011c). In an investigation of more than 500 70- to 100-year-olds living in Berlin, Germany, subjective ratings of one's own health rose in late life, even though objective assessments by health professionals declined (Baltes & Smith, 2003). As for protecting their health, older adults' sense of self-efficacy is as high as that of young adults and higher than that of middle-aged people (Frazier, 2002).

Self-efficacy and optimism about one's health promote continued health-enhancing behaviors (Kubzansky et al., 2002; Morrison, 2008). Disability need not inevitably lead to further disability and dependency. In several longitudinal studies, 10 to 50 percent of older adults with disabilities showed substantial improvement two to six years later (Johnston et al., 2004; Ostir et al., 1999). Furthermore, good health permits older adults to remain socially active, thereby fostering psychological well-being (Fiori, Smith, & Antonucci, 2007).

As mentioned earlier, SES and ethnic variations in health diminish in late adulthood. Nevertheless, SES continues to predict physical functioning (House, Lantz, & Herd, 2005; Yao & Robert, 2008). African-American and Hispanic older people (one-fifth of whom live in poverty) remain at greater risk for various health problems, including cardiovascular disease, diabetes, and certain cancers. Native-American older adults are even worse off. The majority are poor, and chronic health conditions—including diabetes, kidney disease, liver disease, tuberculosis, and hearing and vision impairments—are so widespread that in the United States, the federal government grants Native Americans special health benefits. These begin as early as age 45, reflecting a much harder and shorter lifespan.

Unfortunately, low-SES older adults are more likely than their higher-SES counterparts to delay seeking medical treatment (Lee, Hasnain-Wynia, & Lau, 2011). Part of the reason is cost: On average, U.S. Medicare beneficiaries devote an estimated one-tenth of their income to out-of-pocket health-care expenses—a proportion that escalates among those with the fewest resources (Johnson & Mommaerts, 2010). Furthermore, low-SES older people often do not comply with doctors' directions because they feel less in control of their health and less optimistic that treatment will work. Their low sense of self-efficacy further impairs their physical condition.

Cultural Influences

Cultural Variations in Sense of Usefulness in Late Life

A wealth of evidence confirms that older adults fare best when they retain social status and opportunities for community participation, even after they become frail (Fry et al., 1997; Rossi, 2004). Yet cultures vary widely in the extent to which they include their oldest members in meaningful social roles.

Consider the Herero, a pastoral people of Botswana, Africa. Older people who are strong and active spend their days just as younger people do, tending the cattle and performing other chores. When older adults decline physically, they retain positions of seniority and are treated with respect. A status hierarchy makes the oldest man and his wife village leaders. They are responsible for preserving the sacred flame of the ancestors, who remain significant family members after death. Children are sent to live in the homes of frail community members to provide care—an assignment that is a source of great pride and prestige.

Old age is also a gratifying time of life in Momence, Illinois, a small, working-class farming and manufacturing town. The population is highly stable, so seniors hold positions of authority because of their length of residence and intimate knowledge of the community. Town, church, and club leaders tend to be older, and past leaders are included in decision making. And because frail older adults are embedded in family, neighborhood, and church networks that have persisted for many years, other community members often inquire about them,

visit them, and monitor their condition.

The Herero and the residents of Momence seldom refer to older adults in terms of their age. Rather, they mention knowledge and social position (Keith et al., 1994). But in most of the Western world, old age is a salient attribute that readily triggers negative stereotypes, including the label “useless.” For example, after a young anthropologist who was studying life at a senior center introduced several of his contemporaries to an 80-year-old man, one remarked, “He has outlived his usefulness. He would be happier dead” (Tsuji, 2005, p. 3). In line with this view, compared with younger and middle-aged adults, older adults typically score lower on measures of sense of purpose in life (Ryff & Singer, 2002).

Yet contributing to making life better for others, as we will see in Chapter 18, is an important component of older adults’ life goals. It also affects their health and survival. Studies in diverse nations—Finland, France, Japan, and the United States—reveal that older people who often felt useless were more likely to display increasing disability and to die in the ensuing 4 to 10 years than those who felt needed, after initial health status, SES, and other relevant factors were controlled (Gruenewald et al.,

Among the Herero people of Botswana, Africa, children are assigned the prestigious responsibility of providing care to older adults who have declined physically. This Herero child helps a senior member of her village drink milk.

2007, 2009; Okamoto & Tanaka, 2004; Pitkala et al., 2004).

Fortunately, only a minority of Western older adults report feeling useless most or all of the time—7 percent in a U.S. sample. But another 34 percent said that they sometimes feel that way (Gruenewald et al., 2009). Providing older people with opportunities to assume important roles readily combats this harmful self-perception. In one instance, seniors with arthritis were trained to become lay leaders, who delivered courses on coping with disease symptoms. Six months later, they reported a changed outlook: They highly valued their newly acquired status, felt more self-confident, better managed their own symptoms, and were more willing “to get on with life” (Hainsworth & Barlow, 2001). As one lay leader remarked, “It’s almost as if I’ve stopped aging and started to get younger!”

The sex differences noted in Chapter 15 extend into late adulthood: Men are more prone to fatal diseases, women to non-life-threatening disabling conditions. By very old age (80 to 85 and beyond), women are more impaired than men because only the sturdiest men have survived (Crimmins, Kim, & Solé-Auró, 2011; Morrison, 2008). In addition, with fewer physical limitations, older men are better able to remain independent and to engage in exercise, hobbies, and involvement in the social world, all of which promote better health.

Widespread health-related optimism among older people suggests that substantial inroads into preventing disability can be made even in the last few decades of life. Ideally, as life expectancy extends, we want the average period of diminished vigor before death—especially, the number of months or years of ill-health and suffering—to decrease. This public health goal is called the **compression of morbidity**. Several large-scale studies indicate that over the past several decades, compression of morbidity has occurred in industrialized nations (Fries,

Bruce, & Chakravarty, 2011). Medical advances in treatment of disease and improved socioeconomic conditions are largely responsible.

In addition, the impact of good health habits on postponement of disability is large. In a longitudinal investigation, researchers followed university alumni from their late sixties over the next two decades. In those who were low risk (no risk factors of smoking, obesity, or lack of exercise), disability was delayed by nearly 5 years compared with those who were moderate risk (had one of these risk factors). Compared to high-risk participants (with two or three risk factors), postponement of disability in the low-risk group exceeded 8 years (see Figure 17.3) (Chakravarty et al., 2012). Those who were obese, sedentary, and addicted to tobacco surged to extremely high levels of disability in the two years before death. And although good health habits lengthened life by about 3½ years, their impact on functional ability was greater.

Consequently, researchers believe that the most promising route to further compression of morbidity in developed countries is to reduce negative lifestyle factors. Progress in this respect, however, has been disappointing. Certain unhealthy conditions—such as a high-fat diet, overweight and obesity, and a sedentary lifestyle—that contribute to earlier onset of disability have been increasing. Without modifying these factors, future gains in compression of morbidity will be hard to achieve. Rather, we may see a trend in the reverse direction: people surviving longer with debilitating illnesses because of new and

improved medical treatments (Crimmins & Beltrán-Sánchez, 2010). As we look closely at health, fitness, and disability in late adulthood, we will add to our discussion of health promotion in earlier chapters, taking up additional routes to this vital objective.

Comprehensive strategies are needed in the developing world, where 70 percent of older people will reside by 2025. In these nations, poverty is rampant, chronic diseases occur earlier, even routine health interventions are unavailable or too costly for all but a few, and most public health programs do not focus on late adulthood (Rinaldo & Ferraro, 2012). As a result, disability rates among older adults are especially high, and as yet, no progress has been made in compression of morbidity.

Nutrition and Exercise

The physical changes of late life lead to an increased need for certain nutrients—calcium and vitamin D to protect the bones; zinc and vitamins B₆, C, and E to protect the immune system; and vitamins A, C, and E to prevent free radicals (see Chapter 13, pages 433–434). Yet declines in physical activity, in the senses of taste and smell, and in ease of chewing (because of deteriorating teeth) can reduce the quantity and quality of food eaten. Furthermore, the aging digestive system has greater difficulty absorbing certain nutrients, such as protein, calcium, and vitamin D. And older adults who live alone may have problems shopping or cooking and may feel less like eating by themselves.

Together, these physical and environmental conditions increase the risk of dietary deficiencies, which are common among U.S. older adults.

Except for calcium and vitamin D, a daily vitamin–mineral supplement is recommended only for older adults suffering from malnutrition. Vitamin–mineral supplements do not reduce the incidence of cardiovascular disease or cancer (Neuhouser et al., 2009). Furthermore, supplemental nutrients and herbs identified as “cognitive enhancers”—including B and E vitamins, folic acid, and ginkgo biloba—do not improve cognitive functioning and neither prevent nor slow the progression of Alzheimer’s disease (Aisen et al., 2008; DeKosky et al., 2008; McDaniel, Maier, & Einstein, 2002). Rather, a diet high in nutrients is most effective in fostering physical and cognitive health in late adulthood. And regularly eating fish high in polyunsaturated fatty acids (which promote vascular health) offers some protection against mental disabilities (Cannella, Savina, & Donini, 2009; Skully & Saleh, 2011).

In addition to a healthy diet, exercise continues to be a powerful health intervention. Sedentary healthy older adults up to age 80 who begin endurance training (walking, cycling, aerobic dance) show gains in vital capacity that compare favorably with those of much younger individuals. And

FIGURE 17.3 Development of disability in older adults with low, moderate, and high risk factors. More than 2,300 university alumni were followed from age 68 over the next two decades. The low-risk group had no risk factors (smoking, obesity, or lack of exercise). The moderate-risk group had one risk factor, and the high-risk group had two or three risk factors. Emergence of disability (at the 0.1 level) in the low-risk group was delayed by nearly 5 years compared to the moderate-risk group, and by more than 8 years compared to the high-risk group. Compression of morbidity occurred among the low-risk participants relative to their higher-risk counterparts, even though all participants were socioeconomically advantaged. (Adapted from E. F. Chakravarty et al., 2012, “Lifestyle Risk Factors Predict Disability and Death in Healthy Aging Adults,” *American Journal of Medicine*, 125, p. 193. Copyright © 2012, Elsevier. This spectacularly fit participant in the Senior Olympics has likely been exercising for most of her life. But even exercise programs begun in late adulthood can promote muscle size and strength and preservation of brain structures and behavioral capacities.

weight-bearing exercise begun in late adulthood—even as late as age 90—promotes muscle size and strength, blood flow to muscles, and ability of muscles to extract oxygen from blood (deJong & Franklin, 2004; Goldberg, Dengel, & Hagberg, 1996; Pyka et al., 1994). This translates into improved walking speed, balance, posture, and ability to carry out everyday activities, such as opening a stubborn jar lid, carrying an armload of groceries, or lifting a 30-pound grandchild.

Exercise also increases blood circulation to the brain, which helps preserve brain structures and behavioral capacities. Brain scans show that physically fit older people experience less tissue loss—in both neurons and glial cells—in diverse areas of the cerebral cortex (Erickson et al., 2010; Miller et al., 2012). And compared with physically inactive age mates, previously sedentary older adults who initiated a program of regular, moderate to vigorous exercise displayed increased activity in areas of the prefrontal cortex governing control of attention, as well as improved attention during mental testing, yielding better performance (Colcombe et al., 2004). They also showed gains in volume of the cerebral cortex—clear biological evidence for the role of physical activity in preserving central nervous system health (Colcombe et al., 2006).

Although good nutrition and physical activity are most beneficial when they are lifelong, it is never too late to change. Beginning in his sixties and until his death at age 94, Walt's Uncle Louie played tennis for an hour on most days and went ballroom dancing three nights a week. Exercise led Louie to

sustain a high sense of physical self-esteem. As a dancer, he dressed nattily and moved gracefully. He often commented on how dance and other sports could transform an older person's appearance from dowdy to elegant, expressing the beauty of the inner self.

Older people who come to value the intrinsic benefits of physical activity—feeling stronger, healthier, and more energetic—are likely to engage in it. Yet about 65 percent of U.S. 65- to 74-year-olds and 75 percent of those over age 75 do not exercise regularly (U.S. Department of Health and Human Services, 2011c). Often, those with chronic disease symptoms think “taking it easy” is the best treatment and believe that exercise actually will do harm. In planning exercise programs for older adults, it is important to instill a sense of control—by stressing the health-enhancing rewards of physical activity and by changing negative beliefs that interfere with sustained effort (Lachman, Neupert, & Agrigoroaei, 2011). Active seniors can serve as positive role models and sources of encouragement.

Sexuality

When Walt turned 60, he asked his 90-year-old Uncle Louie at what age sexual desire and activity cease. Walt's question stemmed from a widely held myth that sex drive disappears in late adulthood. Louie corrected this impression. “My sexual interest has never gone away,” he explained to Walt. “I can't do it as often, and it's a quieter experience than it was in my youth. But Rachella and I have led a happy intimate life, and it's still that way.”

As in other cross-sectional studies, the National Social Life, Health, and Aging Project, which surveyed a large, nationally representative sample of U.S. 57- to 85-year-olds, reported a decline in frequency of sexual activity in late adulthood—especially among women, who are less likely than men to be in

JONATHAN KIRN/GETTY IMAGES

Most healthy older couples report continued, regular sexual enjoyment. In addition to intercourse, feeling sensual, enjoying close companionship, and being loved and wanted are all part of sexuality at the most advanced ages.

FIGURE 17.4 Age-related changes in sexual activity among adults with an intimate partner. In the National Social Life, Health, and Aging Project, which surveyed more than 3,000 U.S. 57- to 85-year-olds, most men and women with an intimate partner reported engaging in sexual activity (usually intercourse) at least two to three times per month. Sexual activity declined during late adulthood. Still, more than half of partnered 75- to 85-year-olds reported regular sexual activity. (Adapted from Waite et al., 2009.)

a marital or other intimate relationship. At the same time, the majority of respondents attributed at least some importance to sex, and those who had been sexually active in the previous year mostly rated sex as “very” or “extremely” important. Consistent with these attitudes, most healthy couples reported continued, regular sexual enjoyment. More than half of the oldest respondents with an intimate partner indicated that they engaged in some type of sexual activity (usually intercourse) at least two to three times per month (see Figure 17.4) (Waite et al., 2009). Note that these trends are probably influenced by cohort effects: A new generation of older adults, accustomed to viewing sexuality positively, will probably be more sexually active.

The same generalization we discussed for midlife applies to late life: Good sex in the past predicts good sex in the future. Furthermore, using intercourse as the only measure of sexual activity promotes a narrow view of pleasurable sex. Even at the most advanced ages, there is more to sexuality than the sex act itself—feeling sensual, enjoying close companionship, and being loved and wanted. Both older men and older women report that the male partner is usually the one who ceases to interact sexually (DeLamater, 2012; DeLamater & Moorman, 2007). In a culture that emphasizes an erection as necessary for being sexual, a man may withdraw from all erotic activity when he finds that erections are harder to achieve and more time must elapse between them.

Disabilities that disrupt blood flow to the penis—most often, disorders of the autonomic nervous system, cardiovascular disease, and diabetes—are largely responsible for dampening sexuality in older men. But as noted in Chapter 15, availability of drug treatments, such as Viagra, has increased men’s willingness to discuss erectile dysfunction with their doctors. Cigarette smoking, excessive alcohol intake, and a variety of prescription medications also lead to diminished sexual performance. Among women, poor health and absence of a partner are major factors that reduce sexual activity (DeLamater, 2012; Huang et al., 2009). Because the sex ratio increasingly favors females, aging heterosexual women have fewer and fewer opportunities for sexual encounters. Older adults who lack partners for an extended time tend to drift into a state of sexual disinterest.

Physical Disabilities

TAKE A MOMENT... Compare the death rates shown in Figure 17.5 with those in Figure 15.2 on page 509. You will see that illness and disability climb as the end of the lifespan approaches. Cardiovascular disease and cancer remain the leading causes of death, increasing dramatically from mid- to late life. As before, death rates from heart disease and cancer are higher for men than for women, although the sex difference declines with advancing age (U.S. Census Bureau, 2012b).

Respiratory diseases, which rise sharply with age, are the third most common cause of death among the aged. Among such diseases is *emphysema*, caused by extreme loss of elasticity in lung tissue, which results in serious breathing difficulty. Although a few cases of emphysema are inherited, most result from long-term cigarette smoking. *Stroke* and *Alzheimer’s disease* follow; both are unique in being more prevalent among women, largely because women live longer. Stroke occurs when

FIGURE 17.5 Leading causes of death among people age 65 and older in the United States. In late adulthood, heart disease is the leading cause of death, followed by cancer. Stroke (unique in being more prevalent among women), chronic respiratory diseases, pneumonia and flu, Alzheimer’s disease, and unintentional injuries also claim the lives of many older adults. (Adapted from U.S. Census Bureau, 2012b.)

a blood clot blocks a blood vessel or a blood vessel hemorrhages in the brain, causing damage to brain tissue. It is a major cause of late-life disability and, after age 75, death. Alzheimer's disease, the leading cause of dementia, also rises sharply with age; we will consider it in-depth shortly.

Other diseases are less frequent killers, but they limit older adults' ability to live fully and independently. We have already noted the increase after age 65 in macular degeneration, which severely impairs vision and leads to blindness (see page 569). Osteoporosis, discussed in Chapter 15, continues to rise in late adulthood; recall that it affects the majority of men and women after age 70. Yet another bone disorder—*arthritis*—adds to the physical limitations of many older people. And *type 2 diabetes* and *unintentional injuries* also multiply in late adulthood. In the following sections, we take up these last three conditions.

Finally, an important point must be kept in mind as we discuss physical and mental disabilities of late adulthood: That these conditions are strongly *related to age* does not mean that they are *entirely caused by aging*. To clarify this distinction, experts distinguish between **primary aging** (another term for *biological aging*), or genetically influenced declines that affect all members of our species and take place even in the context of overall good health, and **secondary aging**, declines due to hereditary defects and negative environmental influences, such as poor diet, lack of exercise, disease, substance abuse, environmental pollution, and psychological stress.

Throughout this book, we have seen that it is difficult to distinguish primary from secondary aging. Undoubtedly you have, at one time or another, encountered a *frail older adult*—a person of extreme infirmity who displays wasted muscle mass and strength, weight loss, severe mobility problems, and perhaps cognitive impairment. **Frailty** involves weakened functioning of diverse organs and body systems, yielding symptoms that profoundly interfere with everyday competence—unintentional weight loss, self-reported exhaustion, muscle weakness, slow walking speed, and low physical activity. Frailty leaves older people highly vulnerable in the face of infection, extremely hot or cold weather, or injury (Masoro, 2011; Walston et al., 2006). Although primary aging contributes to frailty, researchers agree that secondary aging plays a larger role, through genetic disorders, unhealthy lifestyle, and chronic disease (Bergman et al., 2007; Fried et al., 2009). The serious conditions we are about to discuss are major sources of frailty in late adulthood.

Arthritis. Beginning in her late fifties, Ruth felt a slight morning stiffness in her neck, back, hips, and knees. In her sixties, she developed bony lumps on the end joints of her fingers. As the years passed, she experienced periodic joint swelling and some loss of flexibility—changes that affected her ability to move quickly and easily.

Arthritis, a condition of inflamed, painful, stiff, and sometimes swollen joints and muscles, becomes more common in late adulthood. It occurs in several forms. Ruth has **osteoarthritis**, the most common type, which involves deteriorating cartilage on the ends of bones of frequently used joints. Otherwise known

© MONIKA GRAFF/THE IMAGE WORKS

This frail 80-year-old, working with a physical therapist, suffers from wasted muscle mass and strength, weight loss, and severe mobility problems. In addition to biological aging, secondary aging—through genetic disorders, unhealthy lifestyle, and chronic disease—plays a major role in his frailty.

as “wear-and-tear arthritis” or “degenerative joint disease,” it is one of the few age-related disabilities in which years of use make a difference. Although a genetic proneness exists, the disease usually does not appear until the forties or fifties. In frequently used joints, cartilage on the ends of the bones, which reduces friction during movement, gradually deteriorates. Or obesity places abnormal pressure on the joints and damages cartilage. Almost all older adults show some osteoarthritis on X-rays, although wide individual differences in severity exist (Zhang & Jordan, 2010). It is the most common cause of mobility problems and of surgical hip and knee replacements in older adults.

Unlike osteoarthritis, which is limited to certain joints, **rheumatoid arthritis** involves the whole body. An autoimmune response leads to inflammation of connective tissue, particularly the membranes that line the joints, resulting in overall stiffness, inflammation, and aching. Tissue in the cartilage tends to grow, damaging surrounding ligaments, muscles, and bones. The result is deformed joints and often serious loss of mobility. Sometimes other organs, such as the heart and lungs, are affected (Goronzy, Shao, & Weyand, 2010). Worldwide, about ½ to 1 percent of older adults have rheumatoid arthritis.

Overall, disability due to arthritis affects 45 percent of U.S. men over age 65 and rises modestly with age. Among women, the incidence is higher and increases sharply with age: About 50 percent of 65- to 84-year-olds and 70 percent of those over age 85 are affected (U.S. Census Bureau, 2012b). Although rheumatoid arthritis can strike at any age, it rises after age 60. Twin studies support a strong hereditary contribution. Presence of certain genes heightens disease risk, possibly by triggering a

late-life defect in the immune system (Turesson & Matteson, 2006). However, identical twins differ widely in disease severity, indicating that environment makes a difference. So far, cigarette smoking is the only confirmed lifestyle influence, greatly increasing risk in people without a family history of the disease (Klareskog et al., 2006). Early treatment with powerful anti-inflammatory medications helps slow progression of rheumatoid arthritis.

Managing arthritis requires a balance of rest when the disease flares, pain relief, and physical activity. Regular aerobic exercise and strength training lessen pain and improve physical functioning (Semanik, Chang, & Dunlop, 2012). In obese people, weight loss is essential. Although osteoarthritis responds to these interventions more easily than rheumatoid arthritis, the course of each varies greatly. With proper analgesic medication, joint protection, lifestyle changes, and surgery to replace badly damaged hip or knee joints, many people with either form of the illness lead long, productive lives.

Diabetes. After a meal, the body breaks down the food, releasing glucose (the primary energy source for cell activity) into the bloodstream. Insulin, produced by the pancreas, keeps the blood concentration of glucose within set limits by stimulating muscle and fat cells to absorb it. When this balance system fails, either because not enough insulin is produced or because body cells become insensitive to it, *type 2 diabetes* (otherwise known as *diabetes mellitus*) results. Over time, abnormally high blood glucose damages the blood vessels, increasing the risk of heart attack, stroke, circulatory problems in the legs (which impair balance and gait), and injury to the eyes, kidneys, and nerves.

Excessive blood glucose also reduces blood flow to the hippocampus, a brain structure that plays an important role in memory (see page 218 in Chapter 7) (Wu et al., 2008). In several longitudinal studies, diabetes was associated with more rapid cognitive declines in older people and an elevated risk of dementia, especially Alzheimer's disease—an association we will soon revisit when we take up Alzheimer's (Cole, Astell, & Sutherland, 2007; Williams, McNeilly, & Sutherland, 2012). Impaired glucose tolerance accelerates degeneration of neurons and synapses (Petrofsky, Berk, & Al-Nakhli, 2012). Cognitive deficits may even be under way in the prediabetic state, prior to a diabetic diagnosis.

From middle to late adulthood, the incidence of type 2 diabetes nearly doubles; it affects 20 percent of Americans age 65 and older (U.S. Census Bureau, 2012b). Diabetes runs in families, suggesting that heredity is involved. But inactivity and abdominal fat deposits greatly increase the risk. Higher rates of type 2 diabetes—exceeding 30 percent—are found among African-American, Mexican-American, and Native-American seniors for both genetic and environmental reasons, including high-fat diets and obesity associated with poverty.

Treating type 2 diabetes requires lifestyle changes, including a carefully controlled diet, regular exercise, and weight loss (Meneilly, 2006). By promoting glucose absorption and reducing abdominal fat, physical activity lessens disease symptoms.

Unintentional Injuries. At age 65 and older, the death rate from unintentional injuries is at an all-time high—more than twice as great as in adolescence and early adulthood. Motor vehicle collisions and falls are largely responsible.

Motor Vehicle Accidents. Motor vehicle collisions account for only one-fourth of U.S. injury mortality in late life, compared with one-half in middle adulthood. But a look at individual drivers tells a different story. Older adults have higher rates of traffic violations, accidents, and fatalities per mile driven than any other age group, with the exception of drivers under age 25. The high rate of injury persists, even though many older people, especially women, limit their driving after noticing that their ability to drive safely is slipping. Deaths due to injuries—motor vehicle and otherwise—continue to be much higher for men than for women (U.S. Census Bureau, 2012b).

Recall that visual declines led Walt to have difficulty seeing the dashboard and identifying pedestrians at night. The greater older adults' visual processing difficulties, the higher their rate of moving violations and crashes (Friedman et al., 2013). Compared with young drivers, older people are less likely to drive quickly and recklessly but more likely to fail to heed signs, yield the right of way, and turn appropriately. They often try to compensate for their difficulties by being more cautious. Slowed reaction time and indecisiveness pose hazards, too. In Chapter 15, we noted that with age, adults find it harder to attend selectively, engage in two activities at once, and switch back and forth between tasks—skills essential for safe driving (Makishita & Matsunaga, 2008). Hence, they are at high risk for collisions at busy intersections and in other complex traffic situations.

Nevertheless, older people usually try to drive as long as possible. Giving up driving results in loss of freedom, control over one's life, and self-esteem. Specially trained driver rehabilitation consultants—affiliated with hospitals, drivers licensing agencies, or U.S. Area Agencies on Aging (see page 67 in Chapter 2)—can help assess older adults' capacity to continue

Visual processing difficulties, slowed reaction time, and declines in selective attention contribute to the high rates of traffic violations, accidents, and fatalities per mile driven among older people. Still, seniors usually try to drive as long as possible.

driving, provide driver retraining, or counsel them to retire from driving and to arrange other transportation options.

Older adults also make up more than 30 percent of all U.S. pedestrian deaths (U.S. Census Bureau, 2012b). Confusing intersections, especially signals that do not allow older people enough time to cross the street, are often involved.

Falls. One day, Ruth fell down the basement steps and lay there with a broken ankle until Walt arrived home an hour later. Ruth's tumble represents the leading type of accident in late life. About 30 percent of adults over age 65 and 50 percent over age 80 have experienced a fall within the last year. Declines in vision, hearing, mobility, muscle strength, and cognitive functioning; depressed mood; use of medications that affect mental processing; and development of certain chronic illnesses, such as arthritis—all of which make it harder to avoid hazards and keep one's balance—increase the risk of falling (Rubenstein, Stevens, & Scott, 2008). The more of these factors that are present, the greater the risk of falling.

Because of weakened bones and difficulty breaking a fall, serious injury results about 10 percent of the time. Among the most common is hip fracture. It increases fifteenfold from age 65 to 85 and is associated with a 20 percent increase in mortality (Centers for Disease Control and Prevention, 2010). Of those who survive, half never regain the ability to walk without assistance.

Falling can also impair health indirectly, by promoting fear of falling. Almost half of older adults who have fallen admit that they purposefully avoid activities because they are afraid of falling again. In this way, a fall can limit mobility and social contact, undermining both physical and psychological well-being (Painter et al., 2012). Although an active lifestyle may expose older people to more situations that can cause a fall, the health benefits of activity far outweigh the risk of serious injury due to falling.

Preventing Unintentional Injuries. Many steps can be taken to reduce unintentional injury in late adulthood. Designing motor vehicles and street signs to accommodate seniors' visual needs is a goal for the future. Meanwhile, training that enhances visual and cognitive skills essential for safe driving and that helps older adults avoid high-risk situations (such as busy intersections and rush hour) can save lives.

Similarly, efforts to prevent falls must address risks within the person and the environment—through corrective eyewear, strength and balance training, and improved safety in homes and communities. Consult the National Resource Center for Safe Aging, www.safeaging.org, for a wealth of information on senior safety.

Mental Disabilities

Normal age-related cell death in the brain, described earlier, does not lead to loss of ability to engage in everyday activities. But when cell death and structural and chemical abnormalities

are profound, serious deterioration of mental and motor functions occurs.

Dementia refers to a set of disorders occurring almost entirely in old age in which many aspects of thought and behavior are so impaired that everyday activities are disrupted. Dementia strikes 13 percent of adults over age 65. Approximately 2 to 3 percent of people age 65 to 69 are affected; the rate doubles every 5 to 6 years until it reaches about 22 percent among those age 85 to 89 and over half after age 90—trends that apply to the United States and other Western nations (Prince et al., 2013). Beyond age 80, a larger proportion of women than men have dementia, perhaps reflecting the biological sturdiness of the oldest men. Although dementia rates are similar across most ethnic groups, older African Americans have about twice the incidence, and Hispanics about one and one-half times the incidence, as whites (Alzheimer's Association, 2012b). Associated risk factors, not race, are responsible, as we will see shortly.

About a dozen types of dementia have been identified. Some are reversible with proper treatment, but most are irreversible and incurable. A few forms, such as Parkinson's disease,¹ involve deterioration in subcortical brain regions (primitive structures below the cortex) that often extends to the cerebral cortex and, in many instances, results in brain abnormalities resembling Alzheimer's disease. Research suggests that Parkinson's and Alzheimer's are related (Cai et al., 2012). But in the large majority of dementia cases, subcortical brain regions are intact, and progressive damage occurs only to the cerebral cortex. The two most common forms of *cortical dementia* are Alzheimer's disease and cerebrovascular dementia.

Alzheimer's Disease. When Ruth took 79-year-old Ida to the ballet, an occasion the two sisters anticipated eagerly each year, she noticed a change in Ida's behavior. Ida, who had forgotten the engagement, reacted angrily when Ruth arrived unannounced at her door. Driving to the theater, which was in a familiar part of town, Ida got lost—all the while insisting that she knew the way perfectly. As the lights dimmed and the music began, Ida talked loudly and dug noisily in her purse.

"Shhhhhh," responded a dozen voices from surrounding seats.

"It's just the music!" Ida snapped at full volume. "You can talk all you want until the dancing starts." Ruth was astonished and embarrassed at the behavior of her once socially sensitive sister.

Six months later, Ida was diagnosed with **Alzheimer's disease**, the most common form of dementia, in which structural and chemical brain deterioration is associated with gradual loss of many aspects of thought and behavior. Alzheimer's accounts for 60 percent of all dementia cases and, at older ages, for an even higher percentage. Approximately 8 to 10 percent

¹In Parkinson's disease, neurons in the part of the brain that controls muscle movements deteriorate. Symptoms include tremors, shuffling gait, loss of facial expression, rigidity of limbs, difficulty maintaining balance, and stooped posture.

of people over age 65—about 5.2 million Americans—have the disorder. Of those over age 85, close to 45 percent are affected. In 2030, when all baby boomers will have reached late adulthood, the number of Americans with Alzheimer's is expected to rise to 7.7 million—an increase of more than 50 percent. About 5 to 15 percent of all deaths among older adults involve Alzheimer's, making it a significant cause of late-life mortality (Alzheimer's Association, 2012b).

Symptoms and Course of the Disease. The earliest symptoms are often severe memory problems—forgetting names, dates, appointments, familiar routes of travel, or the need to turn off the kitchen stove. At first, recent memory is most impaired, but as serious disorientation sets in, recall of distant events and such basic facts as time, date, and place evaporates. Faulty judgment puts the person in danger. For example, Ida insisted on driving after she was no longer competent to do so. Personality changes occur—loss of spontaneity and sparkle, anxiety in response to uncertainties created by mental problems, aggressive outbursts, reduced initiative, and social withdrawal. Depression often appears in the early phase of Alzheimer's and other forms of dementia and seems to be part of the disease process (Serra et al., 2010; Yaari & Corey-Bloom, 2007). However, depression may worsen as the older adult reacts to disturbing mental changes.

As the disease progresses, skilled and purposeful movements disintegrate. When Ruth took Ida into her home, she had to help her dress, bathe, eat, brush her teeth, and (eventually) walk and use the bathroom. Ida's sleep was disrupted by delusions and imaginary fears. She often awoke in the night and banged on the wall, insisting that it was dinnertime, or cried out that someone was choking her. Over time, Ida lost the ability to comprehend and produce speech. And when her brain ceased to process information, she could no longer recognize objects and familiar people. In the final months, Ida became increasingly vulnerable to infections, lapsed into a coma, and died.

The course of Alzheimer's varies greatly, from a year to as long as 20 years, with those diagnosed in their sixties and early seventies typically surviving longer than those diagnosed at later ages (Brodsky, Seher, & Gibson, 2012; Rait et al., 2010). The average life expectancy for a 70-year-old man with the disease is about 4½ years, for a 70-year-old woman about 8 years.

Brain Deterioration. A diagnosis of Alzheimer's disease is made through exclusion, after ruling out other causes of dementia by a physical examination and psychological testing—an approach that is more than 90 percent accurate. To confirm Alzheimer's, doctors inspect the brain after death for a set of abnormalities that either cause or result from the disease (Hyman et al., 2012). In about 90 percent of cases, however, brain-imaging techniques (MRI and PET), which yield three-dimensional pictures of brain volume and activity, predict whether individuals will receive an after-death confirmation of Alzheimer's (Vitali et al., 2008). Researchers are also tracking changes in the chemical makeup of the blood and cerebrospinal

fluid in an effort to predict Alzheimer's long before cognitive symptoms appear (Sperling et al., 2011). These procedures offer hope of very early diagnosis, opening the door to more successful interventions.

Two major structural changes in the cerebral cortex, especially in memory and reasoning areas, are associated with Alzheimer's. Inside neurons, **neurofibrillary tangles** appear—bundles of twisted threads that are the product of collapsed neural structures and that contain abnormal forms of a protein called *tau*. Outside neurons, **amyloid plaques**, dense deposits of a deteriorated protein called *amyloid*, surrounded by clumps of dead nerve and glial cells, develop. Although some neurofibrillary tangles and amyloid plaques are present in the brains of normal middle-aged and older people and increase with age, they are far more abundant in Alzheimer's victims. A major thrust of current research is understanding exactly how abnormal amyloid and tau damage neurons, so treatments can be developed to slow or block these processes.

Researchers once thought that amyloid plaques contributed to the neuronal damage of Alzheimer's. But recent findings suggest that they reflect the brain's effort to get harmful amyloid away from neurons. Instead, a major culprit seems to be abnormal breakdown of amyloid remaining *within* neurons (National Institute on Aging, 2012). In both Alzheimer's disease and Parkinson's disease, disruptions occur in a key neuronal process responsible for chopping up and disposing of abnormal proteins (Cai et al., 2012). These damaged proteins (including amyloid) build to toxic levels. Studies suggest that abnormal amyloid causes the generation of signals within neurons and their transfer across synapses to malfunction (Kopeikina et al., 2011; Palop et al., 2007). Eventually, damaged

An image of tissue in the Alzheimer's brain reveals amyloid plaques between neurons, and dead and dying neurons containing neurofibrillary tangles. Compare these cell changes with healthy brain cells.

amyloid induces heightened, abnormal electrical activity throughout the brain, contributing to broad neural network malfunctioning.

Abnormal tau in neurofibrillary tangles adds to neuronal breakdown. Tangles disrupt the transport of nutrients and signals from the neuron to its connective fibers, thereby joining with amyloid to block synaptic communication. Furthermore, abnormal tau triggers disintegration of nearby normal tau (de Calignon et al., 2012; Liu et al., 2012). Gradually, tau pathology moves across synapses, spreading from neuron to neuron and, over time, from one brain region to the next—thereby amplifying damage.

As synapses deteriorate, levels of neurotransmitters decline, neurons die in massive numbers, and brain volume shrinks. Destruction of neurons that release the neurotransmitter acetylcholine, involved in transporting messages between distant brain regions, further disrupts neuronal networks. A drop in serotonin, a neurotransmitter that regulates arousal and mood, may contribute to sleep disturbances, aggressive outbursts, and depression (Rothman & Mattson, 2012). These problems may intensify cognitive and motor symptoms.

Risk Factors. Alzheimer's disease comes in two types: *familial*, which runs in families, and *sporadic*, which has no obvious family history. Familial Alzheimer's generally has an early onset—between ages 30 and 60—and progresses more rapidly than the later-appearing sporadic type, which typically appears after age 65. Researchers have identified genes on chromosomes 1, 14, and 21, involved in generation of harmful amyloid, that are related to familial Alzheimer's. In each case, the abnormal gene is dominant; if it is present in only one of the pair of genes inherited from parents, the person will develop early-onset Alzheimer's (Ertekin-Tanner, 2007; National Institute on Aging, 2012). Recall that chromosome 21 is involved in

Down syndrome. Individuals with this chromosomal disorder who live past age 40 almost always have the brain abnormalities and symptoms of Alzheimer's.

Heredity plays a different role in sporadic Alzheimer's, through somatic mutation. About half of people with this form of the disease have an abnormal gene on chromosome 19, which results in excess levels of *ApoE4*, a blood protein that carries cholesterol throughout the body. Researchers believe that a high blood concentration of ApoE4 affects the expression of a gene involved in regulating insulin. Deficient insulin and resulting glucose buildup in the bloodstream (conditions that, when extreme, lead to diabetes) are linked to brain damage, especially in areas regulating memory, and to high buildup of harmful amyloid in brain tissue (Liu et al., 2013; National Institute on Aging, 2012). In line with these findings, individuals with diabetes have a greatly increased risk of developing Alzheimer's.

At present, the abnormal ApoE4 gene is the most commonly known risk factor for sporadic Alzheimer's. But genetic testing has revealed many other genes that seem to make an equal or greater contribution. For example, in older adults with Alzheimer's, genes involved in clearing amyloid from neurons often are altered, enabling excessive amyloid buildup (Weeraratna et al., 2007). And some genes impair nutrient and signal transfer from neurons to connective fibers, without affecting amyloid (Conejero-Goldberg et al., 2011).

Nevertheless, many sporadic Alzheimer's victims show no known genetic marker, and some individuals with the ApoE4 gene do not develop the disease. Evidence is increasing for the role of a variety of other factors in susceptibility to Alzheimer's, including excess dietary fat, physical inactivity, overweight and obesity, smoking, chronic psychological stress, cardiovascular disease, stroke, and (as just noted) diabetes (Kivipelto et al., 2008; Pendlebury & Rothwell, 2009; Whitmer et al., 2008; Yaffe et al., 2011). Moderate to severe head injuries, possibly by accelerating deterioration of amyloid and tau, also increase Alzheimer's risk, especially among people with the ApoE4 gene (Jellinger, 2004). Individuals subjected to repeated instances, such as boxers, football players, and combat veterans, are especially likely to be affected.

Still, some older adults with an abundance of amyloid plaques in their brains never develop Alzheimer's (Rowe et al., 2007). The disease probably results from different combinations of genetic and environmental factors, each leading to a somewhat different course of the disease. The high incidence of Alzheimer's and other forms of dementia among African Americans illustrates the complexity of potential causes.

Compared with African Americans, Yoruba village dwellers of Nigeria show a much lower Alzheimer's incidence and no association between the ApoE4 gene and the disease (Gureje et al., 2006). Some investigators speculate that intermarriage with Caucasians heightened genetic risk among African Americans and that environmental factors translated that risk into reality (Hendrie, 2001). Whereas the Yoruba of Nigeria eat a low-fat diet, the African-American diet is high in fat. Eating

fatty foods may increase the chances that the ApoE4 gene will lead to Alzheimer's. And even for Yoruba and African Americans without the ApoE4 gene, a high-fat diet is risky (Hall et al., 2006). The more fat consumed and the higher the blood level of "bad" cholesterol (low-density lipoproteins), the greater the incidence of Alzheimer's.

Protective Factors. Researchers are testing both drug and nondrug approaches to preventing or slowing the progress of Alzheimer's. Among promising drug therapies is immune globulin, a blood product delivered intravenously that contains naturally occurring antibodies against harmful amyloid (National Institute on Aging, 2012). Preliminary research suggests that it improves cognitive functioning and reduces amyloid buildup in the brain. Insulin therapy, delivered via a nasal spray to the brain, helps regulate neuronal use of glucose (Craft et al., 2012). New findings indicate that it has memory benefits and slows cognitive decline—at least in the short term—among older adults with mild cognitive impairment, which commonly precedes Alzheimer's.

A "Mediterranean diet" emphasizing fish, unsaturated fat (olive oil), and moderate consumption of red wine is linked to a 13 percent reduced incidence of Alzheimer's disease, to slower disease progression in diagnosed individuals, and also to a reduction in cerebrovascular dementia (which we will turn to next) (Scarmeas et al., 2007; Sofi et al., 2008). These foods contain fatty acids, antioxidants, and other substances that help promote the health of the cardiovascular and central nervous systems.

Education and an active lifestyle are beneficial as well. The rate of Alzheimer's is reduced by more than half in older adults with higher education, though this protective effect is not as great for those with the ApoE4 gene (Seeman et al., 2005; Stern, 2009). Some researchers speculate that the complex cognitive activities of better-educated people lead to more synaptic connections, which act as a *cognitive reserve*, giving the aging brain greater tolerance for injury before it crosses the threshold into mental disability. In support of this view, compared to their less educated counterparts, the highly educated display a faster rate of decline following an Alzheimer's diagnosis, suggesting that they show symptoms only after very advanced brain deterioration (Hall et al., 2007). Late-life engagement in cognitively stimulating social and leisure activities also reduces the risk of Alzheimer's and of dementia in general, perhaps by stimulating synaptic growth (Bennett et al., 2006; Hall et al., 2009).

Finally, persistence, intensity, and variety of physical activity are associated with decreased risk of Alzheimer's and cerebrovascular dementia, with larger benefits for older people with the ApoE4 gene. In longitudinal research, exercising regularly in midlife predicted reduced late-life dementia, after many other dementia-linked lifestyle factors were controlled (Ahlskog et al., 2011; Smith et al., 2013). Beginning regular exercise in late life is also protective. In one investigation, older adults with mild cognitive impairment and therefore judged to be at risk for

Alzheimer's were randomly assigned to either a 24-week home-based physical activity program or to a usual home-care control group (Lautenschlager et al., 2008). At a six-month follow-up, those experiencing the intervention continued to engage in regular exercise and showed slight cognitive improvement, whereas controls had declined in cognitive functioning.

Helping Alzheimer's Victims and Their Caregivers. As Ida's Alzheimer's worsened, the doctor prescribed a mild sedative and an antidepressant to help control her behavior. Drugs that increase levels of the neurotransmitters acetylcholine and serotonin show promise in limiting challenging dementia symptoms—especially agitation and disruptiveness, which are particularly stressful for caregivers (National Institute on Aging, 2012). Providing stimulation through engaging activities, exercise, and sensory experiences (touch, music, and videos) also helps reduce inappropriate behaviors (Camp, Cohen-Mansfield, & Capezuti, 2002).

But with no cure available, family interventions ensure the best adjustment possible for the Alzheimer's victim, spouse, and other relatives. Dementia caregivers devote substantially more time to caregiving and experience more stress than do people caring for older adults with physical disabilities (Alzheimer's Association, 2012b). They need assistance and encouragement from extended-family members, friends, and community agencies. The Social Issues: Health box on pages 586–587 describes a variety of helpful interventions for family caregivers. In addition to these strategies, avoiding dramatic changes in living conditions, such as moving to a new location, rearranging furniture, or modifying daily routines, helps people with Alzheimer's disease feel as secure as possible in a cognitive world that is gradually disintegrating.

Investigate formal respite services, providing temporary relief to caregivers of older adults with dementia, in your community. Visit a respite program, and talk to several family caregivers about its impact on the patient's and their own adjustment. ●

Cerebrovascular Dementia. In cerebrovascular dementia, a series of strokes leaves areas of dead brain cells, producing step-by-step degeneration of mental ability, with each step occurring abruptly after a stroke. Approximately 10 to 20 percent of all cases of dementia in Western nations are cerebrovascular, and about 10 percent are due to a combination of Alzheimer's and repeated strokes (Gorelick et al., 2011).

Cerebrovascular dementia results from a combination of genetic and environmental forces. The effects of heredity are indirect, through high blood pressure, cardiovascular disease, and diabetes, each of which increases the risk of stroke. And environmental influences—including cigarette smoking, heavy alcohol use, high salt intake, very low dietary protein, obesity, inactivity, and psychological stress—also heighten stroke risk (Sahathevan, Brodtmann, & Donnan, 2011).

Social Issues: Health

Interventions for Caregivers of Older Adults with Dementia

Margaret, wife and caregiver of a 71-year-old Alzheimer's patient, sent a desperate plea to an advice columnist at her local newspaper: "My husband can't feed or bathe himself, or speak to anyone or ask for assistance. I must constantly anticipate his needs and try to meet them. Please help me. I'm at the end of my rope."

The effects of Alzheimer's disease are devastating not just to victims but also to family members who provide care with little or no outside assistance. Caregiving under these conditions has been called the "36-hour day" because of its constant demands. Although the majority of home caregivers are middle-aged, an estimated nearly 25 percent are older adults caring for a spouse or an aging parent. One-third of them are in poor health themselves, yet the number of hours dedicated to caregiving increases with caregiver age and is especially high among ethnic minority older adults, whose cultures emphasize care as a family obligation (Alzheimer's Association, 2012a).

Family members who exceed their caregiving capacities suffer greatly in physical and mental health and are at risk for early mortality (Sørensen & Pinquart, 2005). Severity of cognitive impairments and behavior problems in care recipients are strong predictors of weakening caregiver health. And the close relationship between

the caregiver and the suffering individual— involving shared memories, experiences, and emotions—seems to heighten caregiver risk for physical and psychological problems (Monin & Schulz, 2009).

Most communities offer interventions designed to support family caregivers, but they need to be expanded and made more cost-effective. Those that work best address multiple needs: knowledge, coping strategies, caregiving skills, and respite.

Knowledge

Virtually all interventions try to enhance knowledge about the disease, caregiving challenges, and available community assistance. Knowledge is usually delivered through classes, but websites with wide-ranging information on caregiving, and online message boards and chat rooms through which caregivers can share information, also exist. Gains in knowledge, however, must be combined with other approaches to improve caregivers' well-being.

This daughter cares for her father, who has Alzheimer's disease. Although the task has compensating rewards, it is physically demanding and emotionally draining. A great need exists for interventions that support caregivers.

Coping Strategies

Many interventions teach caregivers everyday problem-solving strategies for managing the dependent person's behavior, along with techniques for dealing with their own negative thoughts and feelings, such as resentment about having to provide constant care. Modes of delivery include support groups, individual therapy, and "coping with frustration" classes. All yield improvements in caregivers' adjustment and in patients' disturbing behaviors, both immediately and in follow-ups more than a year

Because of their greater susceptibility to cardiovascular disease, more men than women have cerebrovascular dementia (Ruitenberg et al., 2001). The disease also varies among countries. For example, deaths due to stroke are high in Japan. Although a low-fat diet reduces Japanese adults' risk of cardiovascular disease, high intake of alcohol and salt and a diet very low in animal protein increase the risk of stroke. As Japanese consumption of alcohol and salt declined and intake of meat rose in recent decades, rates of cerebrovascular dementia and stroke-caused deaths dropped (Jellinger, 2008; Sekita et al., 2010). However, they remain higher than in other developed nations.

Although Japan presents a unique, contradictory picture (there, cardiovascular disease is low, and stroke is high), in most cases cerebrovascular dementia is caused by atherosclerosis. Prevention is the only effective way to stop the disease. The incidence of cerebrovascular dementia has dropped in the last two decades, largely as a result of the decline in heart disease and more effective stroke prevention methods (U.S. Department of Health and Human Services, 2011c). Signs that a stroke might be coming are weakness, tingling, or numbness in an arm, a leg, or the face; sudden vision loss or double vision; speech difficulty; and severe dizziness and imbalance. Doctors may prescribe drugs to reduce the tendency of the blood to clot.

later (Selwood et al., 2007). Individual approaches are most effective because assistance can be tailored to the specific caregiver–patient situation.

Caregiving Skills

Caregivers benefit from lessons in how to communicate with older adults who can no longer express thoughts and emotions clearly and handle everyday tasks—for example, sustaining good eye contact to convey interest and caring; speaking slowly, with short, simple words; using gestures to reinforce meaning; waiting patiently for a response; refraining from interrupting, correcting, criticizing, or talking about the older adult as if he or she isn't there; and introducing pleasant activities, such as music and slow-paced children's TV programs, that relieve agitation (Alzheimer's Association, 2012a). Interventions that teach communication skills through active practice reduce patients' troublesome behavior and, as a result, lessen caregivers' distress and boost their sense of self-efficacy (Done & Thomas, 2001; Irvine, Ary, & Bourgeois, 2003).

Respite

Caregivers usually say that *respite*—time away from providing care—is the assistance they most desire. But they may be reluctant to accept friends' and relatives' informal offers to help because of guilt, or to use formal services (such as adult day care or temporary placement in a care facility) because of cost or worries about the older

adult's adjustment. Yet respite at least twice a week for several hours improves physical and mental health for most caregivers by enabling them to maintain friendships, engage in enjoyable activities, and sustain a balanced life (Jeon, Brodaty, & Chesterson, 2005; Lund et al., 2010).

For respite to be most effective, caregivers must start using services before they become overwhelmed. Once a rewarding, enjoyable life has been lost, it is difficult to restore. Furthermore, frequent, regular respite is far more helpful than infrequent, irregular use. And planning how best to use respite time is crucial. Caregivers who end up spending respite hours doing housework, shopping, or working usually remain dissatisfied (Lund et al., 2009). Those who engage in activities they had wanted and planned to do gain in psychological well-being.

In addition to time away from the caregiving situation, caregivers benefit from short periods of relief from the unrelenting demands of in-home care. One group of researchers devised a unique tool called Video Respite—a series of videotapes suited to the interests of Alzheimer's patients that provide caregivers with a half-hour to an hour break. On each tape, an actor conducts a slow-paced, simple conversation about familiar experiences, people, and objects, pausing occasionally for the impaired person to respond (Lund et al., 1995). Evaluations show that the videos capture the attention of people with Alzheimer's and reduce problem behaviors, such as wandering, agitation, and aggression.

Intervention Programs

Multifaceted intervention programs that begin early in the caregiving process, that continue for many weeks or months, and that are tailored to caregivers' individual needs greatly reduce stress while helping them find satisfactions in caring for a declining loved one. And such interventions usually delay institutional placement of dementia patients as well.

The Resources for Enhancing Alzheimer's Caregiver Health (REACH) initiative was an evaluation of nine “active” intervention programs, each including some or all of the ingredients just described, versus five “passive” interventions providing only information and referral to community agencies. Among more than 1,200 participating caregivers, those receiving six months of active intervention declined more in self-reported burden. And one program providing family therapy in the home—through a telephone system facilitating frequent communication among therapist, caregiver, family members, and other support systems—substantially reduced caregiver depressive symptoms (Gitlin et al., 2003; Schultz et al., 2003). Caregivers with greater care responsibility—women versus men, lower-SES versus higher-SES, spouses versus non-spouses—benefited most from active intervention. In an additional evaluation with more than 600 participants, REACH active intervention programs enhanced quality of life among caregivers of diverse ethnicities—African American, Caucasian, and Hispanic (Belle et al., 2006).

Once strokes occur, paralysis and loss of speech, vision, coordination, memory, and other mental abilities are common.

Misdiagnosed and Reversible Dementia. Careful diagnosis of dementia is crucial because other disorders can be mistaken for it. And some forms of dementia can be treated and a few reversed.

Depression is the disorder most often misdiagnosed as dementia. The depressed (but not demented) older adult is likely to exaggerate his or her mental difficulties, whereas the demented person minimizes them and is not fully aware of cognitive declines. About 1 to 2 percent of people over age 65

are severely depressed, and another 2 percent are moderately depressed—rates lower than those for young and middle-aged adults (Nordhus, 2008). As we will see in Chapter 18, however, depression rises with age. It is often related to physical illness and pain and can lead to cognitive deterioration. As at younger ages, the support of family members and friends, antidepressant medication, and individual, family, and group therapy can help relieve depression. However, U.S. older adults often do not receive the mental health services they need—partly because Medicare offers reduced coverage for treating mental health problems and partly because doctors rarely refer seniors for mental health services (Robinson, 2010). These circumstances

Depression—often related to physical illness and pain—may be misdiagnosed as dementia. With his therapist's support, this senior has a good chance of avoiding depression during his slow recovery from a leg injury.

increase the chances that depression will deepen and be confused with dementia.

The older we get, the more likely we are to be taking drugs that may have side effects resembling dementia. For example, some medications for coughs, diarrhea, and nausea inhibit the neurotransmitter acetylcholine, leading to Alzheimer's-like symptoms. In addition, some diseases can cause temporary memory loss and mental symptoms, especially among older people, who often become confused and withdrawn when ill (Fong, Tulevaev, & Inouye, 2009). Treatment of the underlying illness relieves the problem. Finally, environmental changes and social isolation can trigger mental declines (Hawton et al., 2011). When supportive ties are restored, cognitive functioning usually bounces back.

Health Care

Health-care professionals and lawmakers in industrialized nations worry about the economic consequences of rapid increase in the older population. Rising government-supported health-care costs and demand for certain health-care services, particularly long-term care, are of greatest concern.

Cost of Health Care for Older Adults. Adults age 65 and older make up just 13 percent of the American population but account for over 40 percent of government health-care spending (U.S. Department of Health and Human Services, 2012d). According to current estimates, the cost of government-sponsored health insurance, or Medicare, for older people will nearly double by 2020 as more baby boomers enter late adulthood and average life expectancy extends further (Centers for Medicare and Medicaid Services, 2012).

Medicare expenses rise steeply with age. People age 75 and older receive, on average, 70 percent more benefits than younger senior citizens. Most of this increase reflects the need for long-term care—in hospitals and nursing homes—resulting from an age-related rise in disabling chronic diseases and acute illnesses. Because Medicare funds only about half of older adults' medical needs, American seniors spend several times as much on health care as their counterparts do in other industrialized nations (OECD, 2012b). And Medicare provides far less support for long-term care than U.S. older people with severe disabilities need.

Long-Term Care. When Ida moved into Ruth's home, Ruth promised never to place Ida in an institution. But as Ida's condition worsened and Ruth faced health problems of her own, she couldn't keep her word. Ida needed round-the-clock monitoring. Reluctantly, Ruth placed her in a nursing home.

Advancing age is strongly associated with use of long-term care services, especially nursing homes. Nearly half of U.S. nursing home residents are age 85 and older (Centers for Disease Control and Prevention, 2012). Among disorders of aging, dementia—especially Alzheimer's disease—most often leads to nursing home placement, followed by arthritis, hip fracture, and stroke (Agüero-Torres et al., 2001). Greater use of nursing homes is also prompted by loss of informal caregiving support through widowhood—which mostly affects women—and aging of adult children and other relatives.

Overall, only 5 percent of Americans age 65 and older are institutionalized, about half the rate in other industrialized nations, such as the Netherlands and Sweden, which provide more generous public financing of institutional care (OECD, 2012b). Unless nursing home placement follows hospitalization for an acute illness, older adults must pay for it until their resources are exhausted. At that point, Medicaid (health insur-

ance for the poor) takes over. Consequently, the largest users of nursing homes in the United States are people with either very low or high incomes. Middle-income seniors and their families are more likely to try to protect their savings from being drained by high nursing home costs.

Nursing home use also varies across ethnic groups. For example, Caucasian Americans are nearly twice as likely as African Americans to be institutionalized. African-American older adults are more likely to have large, close-knit extended families with a strong sense of caregiving responsibility and who care for them at home. Similarly, Asian, Hispanic, and Native-American seniors use nursing homes less often than Caucasian Americans (Andel, Hyer, & Slack, 2007; Yaffe et al., 2002). Overall, families provide at least 60 to 80 percent of all long-term care in Australia, Canada, New Zealand, the United States, and Western Europe. As we have seen, families of diverse ethnic and SES backgrounds willingly step in to care for older people in times of need.

To reduce institutionalized care of older adults and its associated high cost, experts advocate alternatives, such as publicly funded in-home help for family caregivers (see Chapter 16, page 551). Another option that has increased dramatically over the past two decades is **assisted living**—a homelike housing arrangement for seniors who require more care than can be provided at home but less than is usually provided in nursing homes. Assisted living is a cost-effective alternative to nursing homes that prevents unnecessary institutionalization (Stone & Reinhard, 2007). It also can enhance residents' autonomy, social life, community involvement, and life satisfaction—benefits that we will take up in Chapter 18.

In Denmark, the combination of a government-sponsored home-helper system and expansion of assisted-living housing resulted in a 30 percent reduction in the need for nursing home beds over a 15-year period. At the same time, the Danish government saved money: Public expenditures for long-term care

declined by 8 percent (Hastrup, 2007; Stuart & Weinrich, 2001). Strengthening caregiving and health-care services in U.S. assisted-living facilities would result in similarly favorable outcomes, while also enhancing older adults' happiness (Williams & Warren, 2008). The overwhelming majority of residents want to stay in assisted living rather than move to a nursing home.

When nursing home placement is necessary, steps can be taken to improve its quality. For example, the Netherlands has established separate facilities designed to meet the different needs of patients with mental and physical disabilities. And every older person, no matter how disabled, benefits from opportunities to maintain existing strengths and acquire new skills that can compensate for declines. Institutionalized individuals—like older people everywhere—desire a sense of personal control, gratifying social relationships, and meaningful and enjoyable daily activities (Alkema, Wilber, & Enguidanos, 2007). As Chapter 18 will reveal, designing nursing homes to meet these needs promotes both physical and psychological well-being.

ASK YOURSELF

REVIEW Cite evidence that both genetic and environmental factors contribute to Alzheimer's disease and cerebrovascular dementia.

CONNECT Explain how each level of ecological systems theory (Chapter 1, pages 24–25) contributes to caregiver well-being and quality of home care for older adults with dementia.

REFLECT What care and living arrangements have been made for seniors needing assistance in your family? How did culture, personal values, financial means, health, and other factors influence those decisions?

COGNITIVE DEVELOPMENT

Ruth's complaints to her doctor about difficulties with memory and verbal expression reflect common concerns about cognitive functioning in late adulthood. Decline in speed of processing, under way throughout the adult years, is believed to affect many aspects of cognition in old age. In Chapter 15, we noted that reduced efficiency of thinking contributes to (but may not fully explain) decrements in certain basic aspects of executive function, including attention and memory. Declines in working-memory capacity, inhibition of irrelevant information, use of

Older adults can sustain high levels of functioning through selective optimization with compensation. This retired theater teacher has done so by creating a studio at home where he focuses on composing music.

memory strategies, and retrieval from long-term memory continue in the final decades of life, affecting many aspects of cognitive aging.

TAKE A MOMENT... Return to Figure 15.5 on page 519, and note that the more a mental ability depends on fluid intelligence (biologically based information-processing skills), the earlier it starts to decline. In contrast, mental abilities that rely on crystallized intelligence (culturally based knowledge) are sustained longer. But maintenance of crystallized intelligence depends on continued opportunities to enhance cognitive skills. When these are available, crystallized abilities—vocabulary, general information, and expertise in specific endeavors—can offset losses in fluid intelligence.

Look again at Figure 15.5. In advanced old age, decrements in fluid intelligence limit what people can accomplish even with cultural supports, including a rich background of experience, knowledge of how to remember and solve problems, and a stimulating daily life (Berg & Sternberg, 2003; Kaufman, 2001). Consequently, crystallized intelligence shows a modest decline.

Generally, loss outweighs improvement and maintenance as people approach the end of life, but plasticity is still possible: Some individuals display high maintenance and minimal loss at very old ages (Baltes & Smith, 2003; Schaie, 2011). Research reveals greater individual variation in cognitive functioning in late adulthood than at any other time of life (Hultsch, MacDonald, & Dixon, 2002; Riediger & Lindenberger, 2006). Besides fuller expression of genetic and lifestyle influences, increased freedom to pursue self-chosen courses of action—some that enhance and others that undermine cognitive skills—may be responsible.

How can older adults make the most of their cognitive resources? According to one view, those who sustain high levels

of functioning engage in **selective optimization with compensation**: Narrowing their goals, they select personally valued activities to optimize (or maximize) returns from their diminishing energy. They also find new ways to *compensate* for losses (Baltes & Freund, 2003; Baltes, Lindenberger, & Staudinger, 2006).

One day, Ruth and Walt watched a public television rebroadcast of an interview with 80-year-old concert pianist Arthur Rubinstein. Asked how he managed to sustain such extraordinary piano playing at his advanced age, Rubinstein replied that he was *selective*; he played fewer pieces. This enabled him to *optimize* his energy; he could practice each piece more. Finally, he developed new, *compensatory* techniques for a decline in playing speed. For example, before a fast passage, he played extra slowly, so the fast section appeared to his audience to move more quickly.

Research confirms that in late adulthood, personal goals—while still including gains—increasingly focus on maintaining abilities and preventing losses (Freund & Ebner, 2005). In one study, researchers asked people to rate their most important physical and cognitive goals for emphasis on growth (“With this goal, I want to improve something or achieve something new”) and maintenance/prevention of losses (“With this goal, I want to maintain something or prevent a loss”) (Ebner, Freund, & Baltes, 2006). As Figure 17.6 shows, compared with young adults, older adults accentuated maintenance and loss prevention.

FIGURE 17.6 Personal goal orientation toward growth and maintenance/prevention of loss in young and older adults.

Participants were asked to list two physical and two cognitive goals and then to rate each for emphasis on growth and on maintenance or prevention of loss, using an 8-point scale. Older adults—while continuing to pursue growth—placed much greater emphasis on maintenance and loss prevention than did young adults. (From N. C. Ebner, A. M. Freund, & P. B. Baltes, 2006, “Developmental Changes in Personal Goal Orientation from Young to Late Adulthood: From Striving for Gains to Maintenance and Prevention of Losses,” *Psychology and Aging*, 21, p. 671. Adapted by permission of American Psychological Association.)

As we review major changes in memory, language processing, and problem solving, we will consider ways that older adults optimize and compensate in the face of declines. We will also see that certain abilities that depend on extensive life experience, not processing efficiency, are sustained or increase in old age. Last, we take up programs that recognize older people as lifelong learners empowered by new knowledge, just as they were at earlier periods of development.

LOOK AND LISTEN

Interview an older adult about memory and other cognitive challenges, asking for examples. For each instance, invite the older person to describe his or her efforts to optimize cognitive resources and compensate for losses. ●

Memory

As older adults take in information more slowly, retain less in working memory, and find it harder to inhibit irrelevant information, apply strategies, and retrieve relevant knowledge from long-term memory, the chances of memory failure increase (Luo & Craik, 2008; Naveh-Benjamin, 2012; Verhaeghen, 2012). A reduced capacity to hold material in working memory while operating on it means that memory problems are especially evident on complex tasks.

Deliberate versus Automatic Memory

“Ruth, you know that movie we saw—the one with the little 5-year-old boy who did such a wonderful acting job. I’d like to suggest it to Dick and Goldie. But what was it called?” asked Walt.

“I can’t think of it, Walt. We’ve seen a few movies lately. Which theater was it at? Who’d we go with? Tell me more about the little boy—maybe it’ll come to me.”

Although we all occasionally have memory failures like this, difficulties with diverse aspects of *episodic memory*, or recall of everyday experiences, rise substantially in old age. When Ruth and Walt watched the movie, their slower cognitive processing meant that they retained fewer details. And because their working memories could hold less at once, they attended poorly to *context*—where they saw the movie and who went with them (Wegesin et al., 2000; Zacks & Hasher, 2006). When we try to remember, context serves as an important retrieval cue.

Because older adults take in less about a stimulus and its context, their recall is reduced in relation to that of younger people. For example, they sometimes cannot distinguish an imagined event from one they actually experienced (Rybash & Hruby-Bopp, 2000). They find it harder to remember the source of information, particularly when potential sources are similar—which member of their bridge club made a certain statement, in what magazine they read about a particular news event, and to whom and on which occasion they previously told a certain joke or story (Simons et al., 2004). Temporal memory—recall of the

order in which events occurred or how recently they happened—suffers as well (Dumas & Hartman, 2003; Hartman & Warren, 2005).

Older adults’ limited working memories increase the likelihood of another type of episodic memory difficulty: They may, for example, travel from the den to the kitchen intending to get something but then not recall what they intended to get. When the context in which they formed the memory intention (the den) differs from the retrieval context (the kitchen), they often experience memory lapses (Verhaeghen, 2012). When they return to the first context (the den), it serves as a strong cue for their memory intention because that is where they first encoded it, and they say, “Oh, now I remember why I went to the kitchen!”

A few days later, when Ruth saw a TV ad for the movie whose title she had forgotten, she recognized its name immediately. Recognition—a fairly automatic type of memory that demands little mental effort—suffers less than recall in late adulthood because a multitude of environmental supports for remembering are present. Age-related memory declines are greatest on tasks that require effortful, strategic processing (Hoyer & Verhaeghen, 2006).

Consider another automatic form of memory: **implicit memory**, or memory without conscious awareness. In a typical implicit memory task, you would be shown a list of words, then asked to fill in a word fragment (such as *t- -k*). You would probably complete the sequence with a word you had just seen (*task*) rather than another word (*took* or *teak*). Without trying to do so, you would engage in recall.

Age differences in implicit memory are much smaller than in explicit, or deliberate, memory. Memory that depends on familiarity rather than on conscious use of strategies is largely spared in old age (Fleischman et al., 2004; Hudson, 2008). This helps explain why recall of vocabulary and general information—which are mostly well-learned and highly familiar—decline far less, and do so at later ages, than recall of everyday experiences (Small et al., 2012). The episodic memory problems seniors report—for names of people, places where they put important objects, directions for getting from one place to another, and (as we will see) appointments and medication schedules—all place high demands on their more limited working memories.

Associative Memory

The memory deficits just described are part of a general, age-related decline in binding information into complex memories (Naveh-Benjamin, 2012). Researchers call this an **associative memory deficit**, or difficulty creating and retrieving links between pieces of information—for example, two items or an item and its context, such as Ruth’s attempt to remember the name of the movie with the child actor or where she had seen the movie.

To find out whether older adults have greater difficulty with associative memory than younger adults, researchers showed them pairs of unrelated words or pictures of objects (such as *table-overcoat* or *sandwich-radio*) and asked that they study the pairs for an upcoming memory test. During the test, one group

FIGURE 17.7 Young and older adults' performance on single-item and item-pair memory tests, supporting an associative memory deficit in late adulthood. After studying pairs of unrelated words or pictures, some participants were asked to identify single items they had seen. Others were asked to identify item pairs they had seen. Older adults performed almost as well as young adults on the single-item memory test. But they did far worse on the item-pair memory test. These findings support an associative memory deficit in late adulthood. (Adapted from Naveh-Benjamin, 2000.)

of participants was given a page of *single items*, some that had appeared in the study phase and some that had not, and asked to circle the ones they had studied. The other group was given a page of *item pairs*, some intact from the study phase (*table-overcoat*) and some that had been rearranged (*overcoat-radio*), and asked to circle pairs they had studied. As Figure 17.7 shows, older adults did almost as well as younger adults on the single-item memory test (Naveh-Benjamin, 2000; Naveh-Benjamin et al., 2003). But they performed far worse on the item-pair test—findings that support an associative memory deficit.

The memory tasks in the study just described relied on recognition. Older adults perform well when they are required only to recognize single pieces of information. But when researchers complicate recognition tasks by making them depend on associations between unrelated items, older people have difficulty with widely varying associations, including face–name, face–face, word–voice, and person–action pairings (Naveh-Benjamin, 2012).

Reducing task demands by providing older adults with helpful memory cues improves their associative memory (Naveh-Benjamin et al., 2003; Simons et al., 2004). For example, to associate names with faces, older people profit from mention of relevant facts about those individuals. And when older adults are directed to use the memory strategy of *elaboration* (relating word pairs by generating a sentence linking them) during both study and retrieval, the young–old difference in memory is greatly reduced (Naveh-Benjamin, Brav, & Levy, 2007). Clearly, associative deficits are greatly affected by lack of strategy use that helps bind information into integrated wholes.

Remote Memory

Although older people often say that their **remote memory**, or very long-term recall, is clearer than their memory for recent events, research does not support this conclusion. In several studies, adults ranging in age from their twenties to their seventies were asked to recall names of grade school teachers and high school classmates and Spanish vocabulary from high school—information very well learned early in life. Memory declined rapidly for the first 3 to 6 years, then changed little for the next 20 years (Bahrick, 1984; Bahrick, Bahrick, & Wittlinger, 1975). After that, additional modest forgetting occurred.

How about *autobiographical memory*, or memory for personally meaningful events, such as what you did on your first date or how you celebrated your college graduation? To test for this type of memory, researchers typically give a series of words (such as *book*, *machine*, *sorry*, *surprised*) and ask adults to report a personal memory cued by each. Or they present participants with a time line on a piece of paper, representing birth to present age, and ask them to place important life events on the line and note the age at which each occurred. People between ages 50 and 90 recall both remote and recent events more frequently than intermediate events, with recent events mentioned most often in the word-cue studies (see Figure 17.8). Among remote events recalled using either word-cue or time-line procedures, most happened between ages 10 and 30—a period of heightened autobiographical memory called the **reminiscence bump**

FIGURE 17.8 Distribution of older adults' autobiographical memories by reported age at time of the event. In the four studies of 50- to 90-year-olds represented here, later events were remembered better than early events. Among early events, most of those recalled occurred between ages 10 and 30. (From D. C. Rubin, T. A. Rahhal, & L. W. Poon, 1998, "Things Learned in Early Adulthood Are Remembered Best," *Memory and Cognition*, 26, p. 4. Copyright © 1998 by the Psychonomic Society, Inc. Adapted by permission of the Psychonomic Society.)

(Janssen, Rubin, & St. Jacques, 2011; Rubin, 2002; Schroots, van Dijkum, & Assink, 2004).

The reminiscence bump is evident in the autobiographical recall of older adults from diverse cultures—Bangladesh, China, Japan, Turkey, and the United States (Conway et al., 2005; Demiray, Gülgöz, & Bluck, 2009). Why are adolescent and early adulthood experiences retrieved more readily than those of middle adulthood? Youthful events occur during a period of rapid life change filled with novel experiences that stand out from the humdrum of daily life. Adolescence and early adulthood are also times of identity development, when many personally significant experiences occur (Glück & Bluck, 2007). Furthermore, the reminiscence bump characterizes emotionally positive, but not negative, memories. Culturally shared, important life events—school proms, graduations, marriage, birth of children—are usually positive and cluster earlier in life (Dickson, Pillemer, & Bruehl, 2011). In contrast, negative events—a serious illness, a car accident—are generally unanticipated and are not overrepresented during any life period.

Nevertheless, older people recall recent personal experiences more readily than remote ones, probably because of interference produced by years of additional experience (Verhaeghen, 2012). As we accumulate more memories, some inevitably resemble others. As a result, certain early memories become less clear than they once were. However, even when asked to recall an important event of the previous year, older adults—because of their episodic memory difficulties—provide considerably fewer details than do young adults (Levine et al., 2002).

Prospective Memory

Older people often complain that they have become more absent-minded about everyday events. Because Ruth and Walt knew they were prone to forget appointments, they asked about them repeatedly. “Sybil, what time is our dinner engagement?” Walt queried several times during the preceding two days. His questioning was not a sign of dementia. He simply wanted to be sure to remember an important date.

So far, we have considered various aspects of *retrospective memory* (remembrance of things past). **Prospective memory** refers to remembering to engage in planned actions in the future. The amount of mental effort required determines whether older adults have trouble with prospective memory. Remembering the dinner date was challenging for Walt because he typically ate dinner with his daughter on Thursday evenings at 6 P.M., but this time, dinner was set for Tuesday at 7:15 P.M.

In the laboratory, older adults do better on *event-based* than on *time-based* prospective memory tasks. In an event-based task, an event (such as a certain word appearing on a computer screen) serves as a cue for remembering to do something (pressing a key) while the participant engages in an ongoing activity (reading paragraphs). As long as the event-based task is not complex, older adults do as well as younger adults. But when researchers introduce extra attentional and working-memory

demands (for example, press the key when any one of four cues appears), older adults’ performance worsens (Kliegel, Jäger, & Phillips, 2008; McDaniel, Einstein, & Rendell, 2007). In time-based tasks, the adult must engage in an action after a certain time interval has elapsed, without any obvious external cue (for example, pressing a key every 10 minutes). Time-based prospective memory requires considerable initiative to keep the planned action in mind and monitor the passage of time while also performing an ongoing activity (Einstein, McDaniel, & Scullin, 2012). Consequently, declines in late adulthood are considerable.

But difficulties with prospective memory seen in the laboratory do not appear in real life, where adults are highly motivated to remember and good at setting up event-based reminders for themselves, such as a buzzer ringing in the kitchen to signal it’s time to take medication or a note tacked up prominently displaying the time of a same-day meeting (Henry et al., 2004). In trying to remember a future activity, younger adults rely more on strategies like rehearsal, older adults on external memory aids (Dixon, de Frias, & Bäckman, 2001). In this way, seniors compensate for their reduced-capacity working memories and the challenge of dividing attention between what they are doing now and what they must do in the future.

Nevertheless, once a prospective memory task is finished, older adults find it harder than younger adults to deactivate, or inhibit, their intention to engage in the future action, especially when cues are still present after the task has been performed. Hence, they sometimes repeat the task again (Scullin et al., 2011). Whereas forgetting whether one has washed one’s hair and doing so a second time is harmless, repeating a dose of medication can be dangerous. Older adults benefit from a system of reminders that regularly scheduled tasks have been completed, and they often arrange such systems themselves.

Language Processing

Language and memory skills are closely related. In language comprehension (understanding the meaning of spoken or written prose), we recollect what we have heard or read without conscious awareness. Like implicit memory, language comprehension changes little in late life, as long as conversational partners do not speak too quickly and older adults are given enough time to process written text accurately, enabling them to compensate for reduced working-memory capacity (Stine-Morrow & Miller, 2009). Older readers make a variety of adjustments to ensure comprehension, such as attending more closely to features of text prose, pausing more often to integrate information, and making good use of story organization to help them recall both main ideas and details. Those who have invested more time in reading and literacy activities over their lifetimes display faster and more accurate reading comprehension (Payne et al., 2012). They benefit from years of greater practice of this highly skilled activity.

In Alberta, Canada, a First Nations senior speaks out against environmental destruction caused by the oil industry. To compensate for language-production problems, older adults speak more slowly, use simplified grammatical structures, and represent information in terms of gist rather than details.

Two aspects of language production show age-related losses. The first is retrieving words from long-term memory (Connor et al., 2004). When conversing with others, Ruth and Walt sometimes had trouble finding the right words to convey their thoughts—even well-known words they had used many times in the past. Consequently, their speech contained more pronouns and other unclear references than it did at younger ages. They also spoke more slowly and paused more often, partly because they needed time to search their memories for certain words (Burke & Shafto, 2004). And compared to younger people, they more often reported a *tip-of-the-tongue state*—certainty that they knew a word accompanied by an inability to produce it.

Second, planning what to say and how to say it is harder in late adulthood. As a result, Walt and Ruth displayed slightly more hesitations, false starts, word repetitions, and sentence fragments as they aged (Bortfeld et al., 2001). Their statements were also less grammatically complex and less well-organized than before (Kemper, 2012).

What explains these changes? Whereas the meanings older people want to convey have many “mental connections” with other meanings, the sound of a word has only one mental connection to the word’s underlying concept. Consequently, as associative memory declines with age, memory difficulties in everyday conversation are especially apparent in word retrieval (Burke & Shafto, 2004). Also, diminished working-memory capacity is involved. Because less information can be held at once, older adults have difficulty coordinating the multiple tasks required to produce complex, coherent speech.

As with memory, older adults develop compensatory techniques for their language production problems. For example, they speak more slowly so they can devote more effort to retrieving words and organizing their thoughts. Sacrificing efficiency for greater clarity, they use more sentences, but shorter ones, to convey their message (Griffin & Spieler, 2006; Kemper, Thompson, & Marquis, 2001). As older people monitor their word-retrieval failures and try hard to overcome them, they show a greater frequency of tip-of-the-tongue states—but they resolve tip-of-the-tongues at a higher rate than do younger people (Schwartz & Frazier, 2005).

Furthermore, older adults often compensate by representing information they want to communicate in terms of gist rather than details (Jepson & Labouvie-Vief, 1992). For example, when Walt told his granddaughter Marci fairytales, he left out many concrete facts while substituting personal inferences and a moral lesson—elements that appear less often in the storytelling of younger adults. Here is Walt’s rendition of “Sleeping Beauty”: “An evil fairy condemns Sleeping Beauty to death. But a kind fairy changes the curse from death to sleep. Then a handsome prince awakens the girl with a kiss. So you see, Marci, both good and bad exist in the world. The bad things instill in us the need to care for others.”

Older adults often make the most of their limited working memories by extracting the essence of a message. Then, drawing on their extensive life experience, they enrich it with symbolic interpretations.

Problem Solving

Problem solving is yet another cognitive skill that illustrates how aging brings not only deterioration but also adaptive changes. Problem solving in the laboratory, where tasks have goals set by the researcher, declines in late adulthood (Finucane et al., 2005). Older adults’ memory limitations make it hard to keep all relevant facts in mind when dealing with a complex hypothetical problem.

Yet the everyday problems seniors encounter differ from hypothetical problems devised by researchers—and also from the problems they experienced at earlier ages. After retirement, older adults do not have to deal with workplace problems. Their children are typically grown and living on their own, and their marriages have endured long enough to have fewer difficulties. With age, major concerns involve dealing with extended-family relationships (for example, expectations of adult children that they babysit grandchildren) and managing IADLs, such as preparing nutritious meals, handling finances, and attending to health concerns.

How do the older people solve problems of daily living? Their strategies extend the adaptive problem solving of midlife. As long as they perceive problems as under their control and as important, they are active and effective in solving them (Berg & Strough, 2011). Older adults generate a smaller number of strategies compared to young and middle-aged adults, but this may

be due to their greater life experience. Among the strategies they do suggest, they may include only those they believe will be helpful (Strough et al., 2008). Furthermore, older adults are particularly good at adapting strategies to fit problem conditions—home, relatives, friends, and finances. And perhaps because they are especially concerned with maintaining positive relationships, they usually do what they can to avoid interpersonal conflicts (Blanchard-Fields, Chen, & Norris, 2007). As we will see in Chapter 18, this strategy also fits with their desire to conserve energy and limit stress.

The health arena illustrates the adaptiveness of everyday problem solving in late adulthood. Older adults make faster decisions about whether they are ill, seek medical care sooner, and select treatments more quickly. In contrast, young and middle-aged adults are more likely to adopt a “wait and see” approach in favor of gathering more facts, even when a health problem is serious (Meyer, Russo, & Talbot, 1995). This swift response of older people is interesting in view of their slower cognitive processing. Research reveals that they have accumulated more health-related knowledge, which enables them to move ahead with greater certainty (Meyer, Talbot, & Ranalli, 2007). Acting decisively when faced with health risks is sensible in old age.

Finally, older adults report that they often consult others—generally spouses and adult children, but also friends, neighbors, and members of their religious congregation—for advice about everyday problems (Strough et al., 2003). And compared with younger married couples, older married couples more often collaborate in problem solving, and researchers judge their jointly generated strategies as highly effective—even on demanding tasks that require complex memory and reasoning (Meegan & Berg, 2002; Peter-Wight & Martin, 2011). In jointly solving problems, older people seem to compensate for moments of cognitive difficulty, yielding enhanced performance.

Wisdom

We have seen that a wealth of life experience enhances the storytelling and problem solving of older adults. It also underlies another capacity believed to reach its height in old age: **wisdom**. When researchers ask people to describe wisdom, most mention breadth and depth of practical knowledge, ability to reflect on and apply that knowledge in ways that make life more bearable and worthwhile; emotional maturity, including the ability to listen patiently and empathetically and give sound advice; and the altruistic form of creativity discussed in Chapter 15 that involves contributing to humanity and enriching others' lives. One group of researchers summed up the multiple cognitive and personality traits that make up wisdom as “expertise in the conduct and meaning of life” (Baltes & Smith, 2008; Baltes & Staudinger, 2000, p. 124; Staudinger, Dörner, & Mickler, 2005).

During her college years, Ruth and Walt's granddaughter Marci telephoned with a pressing personal dilemma. Ruth's

advice reflected the features of wisdom just mentioned. After her boyfriend Ken moved to another city to attend medical school, Marci, unsure whether her love for Ken would endure, had begun dating another student. “I can't stand being pulled in two directions,” she exclaimed. “I'm thinking of calling Ken and telling him about Steve. Do you think I should?”

“This is not a good time, Marci,” Ruth advised. “You'll break Ken's heart before you've had a chance to size up your feelings for Steve. And you said Ken's taking some important exams in two weeks. If you tell him now and he's distraught, it could affect the rest of his life.”

Wisdom—whether applied to personal problems or to community, national, and international concerns—requires the “pinnacle of insight into the human condition” (Baltes & Staudinger, 2000; Birren, 2009). Not surprisingly, cultures around the world assume that age and wisdom go together. In village and tribal societies, the most important social positions, such as chieftain and shaman (religious leader), are reserved for the old. Similarly, in industrialized nations, older adults are chief executive officers of large corporations, high-level religious leaders, members of legislatures, and supreme court justices. What explains this widespread trend? According to an evolutionary view, the genetic program of our species grants health, fitness, and strength to the young. Culture tames this youthful advantage in physical power with the insights of the old (Csikszentmihalyi & Nakamura, 2005; Csikszentmihalyi & Rathunde, 1990). As wise older adults identify useful knowledge and reflections to transmit to younger people, they ensure balance and interdependence between generations.

In the most extensive research to date on development of wisdom, adults ranging in age from 20 to 89 responded to uncertain real-life situations—for example, what to consider and do if a good friend is about to commit suicide or if, after reflecting on your life, you discover that you have not achieved your goals (Staudinger, 2008; Staudinger, Dörner, & Mickler, 2005). Responses were rated for five ingredients of wisdom:

- Knowledge about fundamental concerns of life, including human nature, social relations, and emotions
- Effective strategies for applying that knowledge to making life decisions, handling conflict, and giving advice
- A view of people that considers the multiple demands of their life contexts
- A concern with ultimate human values, such as the common good, as well as respect for individual differences in values
- Awareness and management of the uncertainties of life—that many problems have no perfect solution

Results revealed that age is no guarantee of wisdom. A small number of adults of diverse ages ranked among the wise. But type of life experience made a difference. People in human-service careers who had extensive training and practice in grappling with human problems tended to attain high wisdom scores. Other high-scorers held leadership positions (Staudinger,

TONY KARUNBA/AFP/GETTY IMAGES

Renowned British primatologist Dr. Jane Goodall—speaking with admirers after a presentation at the National Museum in Nairobi, Kenya—exemplifies wisdom. At age 79, she continues to be a tireless leader in efforts to protect chimpanzees and their African habitats and to promote humane treatment of animals everywhere.

Smith, & Baltes, 1992; Staudinger, 1996). And when age and relevant life experiences were considered together, more older than younger people scored in the top 20 percent.

In addition to age and life experience, having faced and overcome adversity appears to be an important contributor to late-life wisdom (Brugman, 2006; Linley, 2003). In an investigation of people who were young adults during the Great Depression of the 1930s, those who experienced economic hardship and surmounted it scored especially high in wisdom nearly 40 years later, as indicated by reflections on life events that included insights into their own motives and behavior and compassionate concern for the welfare of others (Ardelt, 1998).

Compared to their age mates, older adults with the cognitive, reflective, and emotional (compassionate) qualities that make up wisdom are better educated and physically healthier, forge more positive relations with others, and score higher on the personality dimension of openness to experience (Kramer, 2003). Wisdom also predicts sense of personal growth, generativity, favorable adjustment to aging, marital happiness, and life satisfaction (Ardelt, 2011; Le, 2011). Wise older people seem to flourish, even when faced with physical and cognitive challenges. This suggests that finding ways to promote wisdom would be a powerful means of both contributing to human welfare and fostering a gratifying old age.

Factors Related to Cognitive Maintenance and Change

Heritability research suggests a modest genetic contribution to individual differences in cognitive change in late adulthood (Deary et al., 2012). At the same time, as in middle adulthood, a mentally active life is vital for preserving cognitive resources.

Above-average education, frequent contact with family members and friends, stimulating leisure pursuits, community participation, and a flexible personality predict higher mental test scores and reduced cognitive decline into advanced old age (Bielak et al., 2012; Schaie, 2011). Today's seniors in industrialized nations are better educated than any previous generation. Since 1950, the rate of high school completion among U.S. adults age 65 and older has quadrupled, reaching 80 percent. Those with at least a bachelor's degree have increased sixfold, to 23 percent (U.S. Department of Health and Human Services, 2012d). As more baby boomers enter late adulthood, these trends are expected to continue, forecasting improved preservation of cognitive functions.

As noted earlier, health status powerfully predicts older adults' cognitive functioning. In longitudinal research, cigarette smokers declined cognitively at a faster rate than their non-smoking counterparts, as did overweight and obese people, even after initial health status, SES, and mental test performance were controlled (Dahl et al., 2010; Starr et al., 2007). And a wide variety of chronic conditions, including vision and hearing impairments, cardiovascular disease, diabetes, osteoporosis, and arthritis, are strongly associated with cognitive declines (Baltes, Lindenberger, & Staudinger, 2006). But we must be cautious in interpreting this link between physical and cognitive deterioration. The relationship may be exaggerated by the fact that brighter adults are more likely to engage in health-protective behaviors, which postpone the onset of serious disease.

Retirement also affects cognitive change, both positively and negatively. When people leave routine jobs for stimulating leisure activities, outcomes are favorable. In contrast, retiring from a highly complex job without developing challenging substitutes accelerates intellectual declines (Schaie, 1996). In fact, complex, challenging work in late adulthood may have an even stronger, facilitating impact on intellectual functioning than in middle adulthood (see pages 525–526 in Chapter 15) (Hertzog et al., 2009; Schooler, Mulatu, & Oates, 1999).

As seniors grow older, their cognitive scores show larger fluctuations from one occasion to the next. This rising instability of performance—especially in speed of response—accelerates in the seventies and is associated with cognitive declines, along with neurobiological signs of shrinkage in the prefrontal cortex and deficient brain functioning (Bielak et al., 2010; MacDonald, Li, & Bäckman, 2009; Lövdén et al., 2012). It seems to signal end-of-life brain degeneration.

In the year before Walt died, those close to him noticed that he had become less active and more withdrawn, even in the company of friends. **Terminal decline** refers to acceleration in deterioration of cognitive functioning prior to death. Some longitudinal studies indicate that it is limited to a few aspects of intelligence, others that it occurs generally, across many abilities. Findings also differ greatly in its estimated length—from 1 to 3 to as long as 14 years, with an average of 4 to 5 years (Lövdén et al., 2005; MacDonald, Hultsch, & Dixon, 2011; Rabbitt, Lunn, & Wong, 2008; Wilson et al., 2003). In one investigation, a sharp drop in life satisfaction predicted mortality. The downturn appeared, on average, four years in advance of death, was

especially steep in people age 85 and older, and showed only a weak relationship to mental deterioration or chronic illnesses (Gerstorff et al., 2008).

Perhaps different kinds of terminal decline exist—one type arising from disease processes, another reflecting general biological breakdown due to normal aging. What we do know is that an extended falloff in cognitive performance or in emotional investment in life is a sign of loss of vitality and impending death.

Cognitive Interventions

For most of late adulthood, cognitive declines are gradual. Although aging of the brain contributes to them, recall from our earlier discussion that the brain can compensate by growing new neural fibers. Furthermore, some cognitive decrements may be due to disuse of particular skills rather than biological aging. If plasticity of development is possible, then interventions that train older people in cognitive strategies should at least partially reverse the age-related declines we have discussed.

Older adults' relatively well-preserved *metacognition* is a powerful asset in training efforts. Most, for example, are aware of memory declines, report troublesome anxiety when faced with demanding memory situations, and know they must take extra steps to ensure recall of important information (Castel, McGillivray, & Friedman, 2011). Their impressive metacognitive understanding is also evident in the wide-ranging techniques they devise to compensate for everyday cognitive challenges.

The Adult Development and Enrichment Project (ADEPT) is the most extensive cognitive intervention program conducted to date (Schaie, 2005). By using participants in the Seattle Longitudinal Study (see Chapter 15, page 519), researchers were able to do what no other investigation has done: assess the effects of cognitive training on long-term development.

Intervention began with adults over age 64, some of whom had maintained their scores on tests of two mental abilities (inductive reasoning and spatial orientation) over the previous 14 years and others who had shown declines. After just five one-hour training sessions in one of two types of mental test items, two-thirds of participants improved their performance on the trained skill. Gains for decliners were dramatic: Forty percent returned to the level at which they had been functioning 14 years earlier! A follow-up after 7 years revealed that although scores dropped somewhat, participants remained advantaged in their trained skill over age-mates trained in the other ability. Finally, “booster” training at this time led to further gains, although these were smaller than the earlier gains.

In another large-scale intervention study called ACTIVE (Advanced Cognitive Training for Independent and Vital Elderly), more than 2,800 65- to 84-year-olds were randomly assigned to a ten-session training program focusing on one of three abilities—speed of processing, memory, or reasoning—or to a no-intervention control group. Again, trained older adults showed an immediate advantage in the trained skill over con-

trols that was still evident—though smaller in magnitude—at one- and two-year follow-ups (Ball et al., 2002). Transfer to everyday functioning, unfortunately, was disappointing: For example, participants who improved on a laboratory processing-speed task were no faster at looking up numbers in a phone book. Nevertheless, five years after intervention, cognitive training was associated with reduced declines in general health and ability to perform IADLs—outcomes that were strongest for the speed-of-processing group (Wolinsky et al., 2006). The investigators speculated that speed-of-processing training induces a broad pattern of brain activation, affecting many regions.

Clearly, many cognitive skills can be enhanced in old age. A vital goal is to transfer intervention from the laboratory to the community, weaving it into the daily experiences of older people (Stine-Morrow & Basak, 2011). Broadening training programs by focusing not just on strategy use and practice but also on beliefs that promote sustained effort may be helpful. Seniors who are higher in self-efficacy benefit more from cognitive training, and targeting self-efficacy in training programs by emphasizing cognitive potential at any age boosts both self-efficacy and cognitive gains (West, Bagwell, & Dark-Freudeman, 2008). Furthermore, working in groups may offer unique opportunities for strengthening self-efficacy (“If they can do it, so can I”) along with social support for persisting (Hastings & West, 2009). As we will see in the next section, a promising approach is to provide older adults with well-designed, highly interesting educational experiences in which cognitive training in socially rich contexts is an integral part.

Lifelong Learning

Think about the competencies that older adults need to live in our complex, changing world. They are the same as those of younger people—communicating effectively through spoken and written systems; locating information, sorting through it, and selecting what is needed; using math strategies, such as estimation; planning and organizing activities, including making good use of time and resources; mastering new technologies; and understanding past and current events and the relevance of each to their own lives. Seniors also need to develop new, problem-centered coping strategies—ways to sustain health and operate their households efficiently and safely—and updated vocational skills, for those who continue to work.

Participation of older adults in continuing education has increased substantially over the past few decades. Successful programs include a wide variety of offerings responsive to the diversity of senior citizens and teaching methods suited to their developmental needs.

Types of Programs

One summer, Walt and Ruth attended a Road Scholar (formerly called Elderhostel) program at a nearby university. After moving into a dormitory room, they joined 30 other seniors for two weeks of morning classes on Shakespeare, afternoon visits to

Applying What We Know

Increasing the Effectiveness of Educational Experiences for Older Adults

Technique	Description
Provide a positive learning environment.	Many older adults have internalized negative stereotypes of their own abilities and come to the learning environment with low self-efficacy. A supportive group atmosphere helps convince older adults that they can learn.
Allow ample time to learn new information.	Rate of learning varies widely among older adults, and some master new material at a fairly slow rate. Presenting information over multiple sessions or allowing for self-paced instruction aids mastery.
Present information in a well-organized fashion.	Older adults do not organize information as effectively as younger adults. Material that is outlined, presented, and then summarized enhances memory and understanding. Digressions make a presentation harder to comprehend.
Relate information to older adults' experiences.	Relating new material to what older adults have already learned, by drawing on their extensive knowledge and experiences and giving many vivid examples, enhances recall.
Adapt the learning environment to fit changes in sensory systems.	Adequate lighting, availability of large-print reading materials, appropriate sound amplification, reduction in background noise, and clear, well-organized visual aids to supplement verbal teaching ease information processing.

points of interest, and evening performances of plays at a nearby Shakespeare festival.

In its most recently reported year, Road Scholar campus-based programs, and their recent extension to travel experiences around the world, attracted nearly 100,000 American and Canadian older adults. Some programs make use of community resources through classes on local ecology or folk life. Others focus on innovative topics and experiences—writing one's own life story, discussing contemporary films with screenwriters, whitewater rafting, Chinese painting and calligraphy, or acquiring French language skills. Travel programs are enriched by in-depth lectures and expert-led field trips.

Similar educational programs have sprung up in the United States and elsewhere. The Bernard Osher Foundation collaborates with more than 120 U.S. universities to establish Osher Lifelong Learning Institutes on campuses. Each offers older adults a wide array of stimulating learning experiences, from auditing regular courses, to forming learning communities that address common interests, to helping to solve community problems. Originating in France, the University of the Third Age² provides Western European, British, and Australian seniors with university- and community-sponsored courses, workshops on special topics, and excursions, with older adults often doing the teaching.

LOOK AND LISTEN

Find out if your college or university hosts Road Scholar or Osher Foundation programs. Attend a session of an on-campus program. What did you observe about older adults' capacity for complex learning? ●

Participants in the programs just mentioned tend to be active, well-educated, and financially well-off. Much less is available for older people with little education and limited income. Community senior centers with inexpensive offerings related to everyday living attract more low-SES people than programs such as Road Scholar. Regardless of course content and which seniors attend, using the techniques summarized in Applying What We Know above increases the effectiveness of educational experiences.

²The term *Third Age*, as we will see in Chapter 18, refers to the period after the "Second Age" of midlife, when older people are freed from responsibilities of earning a living and rearing children to focus on personal fulfillment.

PHOTO BY CARL STUDNAR/ROAD SCHOLAR

Active, adventurous seniors explore the sights, sounds, streets, and monuments of Dublin's authors, poets, and playwrights as part of a Road Scholar travel program to Ireland.

Benefits of Continuing Education

Older participants in continuing education report a rich array of benefits—understanding new ideas in many disciplines, learning new skills that enrich their lives, making new friends, and developing a broader perspective on the world (Preece & Findsen, 2007). Furthermore, seniors come to see themselves differently. Many abandon their own ingrained stereotypes of aging when they realize that adults in late life—including themselves—can still engage in complex learning.

Older adults' willingness to acquire new knowledge and skills is apparent in the recent, rapid rise in their use of computers and the Internet. Seniors are now the fastest growing age group to embrace online technology as they discover its many practical benefits, including assistance with shopping, banking, health-care management, and communication. Currently, just over half of adults age 65 and older access the Internet, with 86 percent using e-mail and 38 percent social networking sites such as Facebook (Brenner, 2013; Zickuhr & Madden, 2012). Still, older people have joined the computer and Internet community to a lesser extent than younger people (see page 553 in Chapter 16). Those over age 75 are especially reluctant, with many perceiving the technology as too complicated—an attitude that continuing education can overcome (Wagner, Hassanein, & Head, 2010). With patient training, support, and modified equipment and software to suit their physical and cognitive needs, older adults readily enter the online world, often becoming just as devoted as younger users.

The educational needs of seniors are likely to be given greater attention in coming decades, as their numbers grow and they assert their right to lifelong learning. Once this happens, false stereotypes—“the elderly are too old to learn” or “education is for the young”—are likely to weaken and, perhaps, disappear.

ASK YOURSELF

REVIEW Describe cognitive functions that are maintained or improve in late adulthood. What aspects of aging contribute to them?

CONNECT What processes in brain development contribute to the success of older adults' efforts to compensate for cognitive declines? (See page 568.)

APPLY Estelle complained that she had recently forgotten two of her regular biweekly hair appointments and sometimes had trouble finding the right words to convey her thoughts. What cognitive changes account for Estelle's difficulties? What can she do to compensate?

REFLECT Interview an older adult in your family, asking about ways the individual engages in selective optimization with compensation to make the most of declining cognitive resources. Describe several examples.

SUMMARY

PHYSICAL DEVELOPMENT

Life Expectancy (p. 564)

Distinguish between chronological age and functional age, and discuss changes in life expectancy over the past century.

- People age biologically at different rates, making chronological age is an imperfect indicator of **functional age**. Dramatic twentieth-century gains in **average life expectancy** confirm that biological aging can be modified by environmental factors, including improved nutrition, medical treatment, sanitation, and safety.
- Length of life and, especially, **average healthy life expectancy** can be predicted by a country's health care, housing, and social services, along with lifestyle factors. In developing nations, both are shortened by poverty, malnutrition, disease, and armed conflict.

- With advancing age, the gender gap in average life expectancy declines, as do differences between higher-SES whites and low-SES ethnic minorities.

© EVERETT KENNEDY BROWN/EPA/CORBIS

- Longevity runs in families, but environmental factors become increasingly important with age. Scientists disagree on whether **maximum lifespan** can be extended beyond 122 years—the oldest verified age.

Physical Changes (p. 567)

Describe physical declines of late adulthood, including changes in the nervous and sensory systems.

- With age, growing numbers of older adults experience physical declines, evident in difficulties carrying out **activities of daily living (ADLs)**, or basic self-care tasks, and **instrumental activities of daily living (IADLs)**, which are necessary to conduct the business of daily life.
- Neuron loss occurs throughout the cerebral cortex, with greater shrinkage in the frontal lobes and the corpus callosum. The cerebellum also loses neurons. The brain compensates by forming new synapses and, to some extent, generating new neurons. The autonomic nervous system functions less well in old age and releases more stress hormones.

- Older adults—more women than men—tend to suffer from impaired vision and may experience **cataracts** and **macular degeneration**. Hearing impairments are more common than visual impairments, especially in men, with decline in speech perception having the greatest impact on life satisfaction.

© JEFF GREENBERG/THE IMAGE WORKS

- Taste and odor sensitivity wane, making food less appealing. Touch sensitivity also deteriorates, particularly on the fingertips.

Describe cardiovascular, respiratory, and immune system changes and sleep difficulties in late adulthood.

- Reduced capacity of the cardiovascular and respiratory systems becomes more apparent in late adulthood, especially in lifelong smokers and in people who have not reduced dietary fat or who have had extensive exposure to environmental pollutants. Exercise can slow cardiovascular aging and facilitate respiratory functioning.
- The immune system functions less effectively in late life, permitting diseases to progress and making **autoimmune responses** and stress-induced infection more likely.
- Older adults find it harder to fall asleep, stay asleep, and sleep deeply. Until age 70 or 80, men have more trouble sleeping than women because of prostate enlargement (initiating frequent urination) and **sleep apnea**.

Describe changes in physical appearance and mobility in late adulthood, along with effective adaptations to these changes.

- Outward signs of aging—white hair, wrinkled and sagging skin, age spots, and decreased height and weight—become more noticeable. Mobility diminishes as muscle and bone strength and joint flexibility decline.
- “Anti-aging” dietary supplements, herbal products, and hormonal medications have shown no demonstrated benefits and may cause harm. Instead, problem-centered coping strategies yield improved physical functioning.

- A rapidly expanding **assistive technology** helps older people cope with physical declines, sustaining an effective person–environment fit that enhances psychological well-being.
- Negative stereotypes of aging have a stressful, disorganizing impact on older adults’ functioning, whereas positive stereotypes reduce stress and foster physical and mental competence.

Health, Fitness, and Disability (p. 575)

Discuss health and fitness in late life, paying special attention to nutrition, exercise, and sexuality.

- Most older adults rate their health favorably and have a high sense of self-efficacy about protecting it. Low-SES ethnic minority older people remain at greater risk for certain health problems and are less likely to believe they can control their health.
- In late life, men continue to be more prone to fatal diseases and women to disabling conditions. In industrialized nations, **compression of morbidity** has occurred, largely as a result of medical advances and improved socioeconomic conditions; further gains will depend on reducing negative lifestyle factors. In the developing world, comprehensive strategies are needed.
- Risk of dietary deficiencies increases in late life, but except for calcium and vitamin D, a daily vitamin–mineral supplement is recommended only for those suffering from malnutrition. Exercise, even when begun in late adulthood, is a powerful health intervention.
- Though sexual activity declines, especially among women, most older couples report continued, regular sexual enjoyment.

JONATHAN KIRN/GETTY IMAGES

Discuss physical disabilities common in late adulthood.

- Illness and disability increase toward the end of life. Cardiovascular disease and cancer are the leading causes of death, followed by respiratory diseases. **Primary aging** contributes to **frailty** in the elderly, but **secondary aging** (declines due to hereditary defects and negative environmental influences) plays a larger role.

- **Osteoarthritis** and **rheumatoid arthritis** are widespread among older adults, especially women. Type 2 diabetes also increases.
- The death rate from unintentional injuries reaches an all-time high from age 65 on, largely due to motor vehicle collisions and falls. Visual declines and slowed reaction time often contribute.

Discuss mental disabilities common in late adulthood.

- **Alzheimer’s disease**, the most common form of **dementia**, often starts with severe memory problems. It brings personality changes, depression, disintegration of purposeful movements, loss of ability to comprehend and produce speech, and death. Underlying these changes are abundant **neurofibrillary tangles** and **amyloid plaques** and lowered neurotransmitter levels in the brain.
- Familial Alzheimer’s, related to genes involved in generation of harmful amyloid, generally has an early onset and progresses rapidly. About half of sporadic Alzheimer’s victims have an abnormal gene that results in insulin deficiency linked to brain damage.
- Diverse environmental factors, including a high-fat diet, physical inactivity, overweight and obesity, smoking, chronic psychological stress, cardiovascular disease, stroke, diabetes, and head injuries increase the risk of Alzheimer’s. A “Mediterranean diet,” education, and an active lifestyle are associated with lower incidence.
- Heredity contributes to **cerebrovascular dementia** indirectly, through high blood pressure, cardiovascular disease, and diabetes. Many environmental influences also heighten stroke risk. Because of their greater susceptibility to cardiovascular disease, more men than women are affected.
- Treatable problems, such as depression, side effects of medication, and reactions to social isolation, can be mistaken for dementia.

Discuss health-care issues that affect senior citizens.

- Only a small percentage of U.S. seniors are institutionalized, about half the rate in other industrialized nations with more generous public financing of institutional care. Though ethnic differences exist, family members provide most long-term care in Western nations. Publicly funded in-home help and **assisted living** can reduce the high costs of institutional placement and increase older adults’ life satisfaction.

COGNITIVE DEVELOPMENT

Describe overall changes in cognitive functioning in late adulthood.

- Individual differences in cognitive functioning are greater in late adulthood than at any other time of life. Older adults can make the most of their cognitive resources through **selective optimization with compensation**. Personal goals increasingly emphasize maintaining abilities and preventing loss.

Memory (p. 591)

How does memory change in late life?

- Memory failure is more likely in older adults, especially on tasks that are complex and require deliberate processing. Recall of context, source, and temporal order of episodic events declines. Automatic forms of memory, such as recognition and **implicit memory**, suffer less. In general, an **associative memory deficit**, or difficulty creating and retrieving links between pieces of information, characterizes older adults' memory deficits.
- Contrary to what older people often report, **remote memory** is not clearer than recent memory. Autobiographical memory is best for recent experiences, followed by personally meaningful events that occurred between ages 10 and 30, a period of heightened recall called the **reminiscence bump**. In the laboratory, older adults do better on event-based than on time-based **prospective memory** tasks. In everyday life, they compensate for declines in prospective memory by using external memory aids.

Language Processing (p. 593)

Describe changes in language processing in late adulthood.

- Language comprehension changes little in late life. Age-related losses occur in two aspects of language production: retrieving words from long-term memory and planning

what to say and how to say it. Older people compensate by speaking more slowly, using shorter sentences, and communicating gist rather than details.

© ASHLEY COOPER/CORBIS

Problem Solving (p. 594)

How does problem solving change in late life?

- Hypothetical problem solving declines in late adulthood. In everyday problem solving, older adults are effective as long as they perceive problems as important and under their control. Older people make faster decisions about health than younger people and more often consult others about everyday problems.

Wisdom (p. 595)

What capacities make up wisdom, and how is it affected by age and life experience?

- Wisdom** involves extensive practical knowledge, ability to reflect on and apply that knowledge in ways that make life more bearable and worthwhile, emotional maturity, and altruistic creativity. When age and life experience in grappling with human problems are combined, more older than younger people rank among the wise.

Factors Related to Cognitive Maintenance and Change

(p. 596)

Cite factors related to cognitive maintenance and change in late adulthood.

- Mentally active people are likely to maintain their cognitive abilities into advanced old age. A wide array of chronic health conditions are associated with cognitive decline. Retirement can bring about either positive or negative changes. Stimulating leisure activities and complex, challenging work facilitate intellectual functioning.
- With age, older adults' cognitive scores become increasingly unstable. As death approaches, **terminal decline**—a marked acceleration in deterioration of cognitive functioning—often occurs.

Cognitive Interventions

(p. 597)

Can cognitive interventions help older adults sustain their mental abilities?

- Large-scale interventions like ADEPT and ACTIVE demonstrate that training in cognitive skills can offer large benefits for older people who have experienced cognitive declines. Targeting self-efficacy enhances cognitive gains.

Lifelong Learning (p. 597)

Discuss types of continuing education and benefits of such programs in late life.

- Increasing numbers of older people continue their education through university courses, community offerings, and programs such as Road Scholar and Osher Lifelong Learning Institutes. Participants acquire new knowledge and skills, new friends, a broader perspective on the world, and an image of themselves as more competent. Unfortunately, fewer continuing-education opportunities are available to low-SES seniors.

As family responsibilities and vocational pressures lessen, friendships—like the relaxed companionship of these Guatemalan seniors—take on increasing importance. Having friends is an especially strong predictor of mental health in late adulthood.

Emotional and Social Development in Late Adulthood

With Ruth at his side, Walt spoke to the guests at their sixtieth-anniversary party. “Even when things were hard,” he reflected, “the time of life I liked best always seemed to be the current one.

When I was a kid, I adored playing baseball. In my twenties, I loved learning the photography business. And of course,” Walt continued, glancing affectionately at Ruth, “our wedding was the most memorable day of all.”

He went on: “We never had much money for luxuries, but we found ways to have fun anyway—singing in the church choir and acting in community theater.

And then Sybil was born. It meant so much to me to be a father—and now a grandfather and a great-grandfather. Looking back at my parents and grandparents and forward at Sybil, Marci, and Marci’s son Jamel, I feel a sense of unity with past and future generations.” With a smile, Walt added, “We keep up with Marci and Jamel on Facebook!”

Walt and Ruth greeted old age with calm acceptance, grateful for the gift of long life and loved ones. Yet not all older adults find such peace of mind. Walt’s brother Dick was contentious, complaining about petty issues and major disappointments alike: “Goldie, why’d you serve cheesecake? No one eats cheesecake on birthdays!” “Know why we’ve got financial worries? Uncle Louie wouldn’t lend me the money to keep the bakery going, so I *had* to retire.”

A mix of gains and losses characterizes these twilight years, extending the multidirectionality of development begun early in life. On one hand, old age is a time of pleasure and tranquility, when children are grown, life’s work is nearly done, and responsibilities are lightened. On the other hand, it brings concerns about declining physical functions, unwelcome loneliness, and the growing specter of imminent death.

In this chapter, we consider how older adults reconcile these opposing forces. Although some are weary and discontented, most traverse this period with poise and calm composure. They attach deeper significance to life and reap great benefits from family and friendship bonds, leisure activities, and community involvement. We will see how personal attributes and life history combine with home, neighborhood, community, and societal conditions to mold emotional and social development in late life. ●

Optimal Aging

Erikson's Theory: Ego Integrity versus Despair

The final psychological conflict of Erikson's (1950) theory, **ego integrity versus despair**, involves coming to terms with one's life. Adults who arrive at a sense of integrity feel whole, complete, and satisfied with their achievements. They have adapted to the mix of triumphs and disappointments that are an inevitable part of love relationships, child rearing, work, friendships, and community participation. They realize that the paths they followed, abandoned, and never selected were necessary for fashioning a meaningful life course.

The capacity to view one's life in the larger context of all humanity—as the chance combination of one person and one segment in history—contributes to the serenity and contentment that accompany integrity. “These last few decades have been the happiest,” Walt murmured, clasping Ruth's hand—only weeks before the heart attack that would end his life. At peace with himself, his wife, and his children, Walt had accepted his life course as something that had to be the way it was.

In a study that followed a sample of women diverse in SES throughout adulthood, midlife generativity predicted ego integrity in late adulthood. Ego integrity, in turn, was associated with more favorable psychological well-being—a more upbeat mood, greater self-acceptance, higher marital satisfaction, closer rela-

tionships with adult children, greater community involvement, and increased ease in accepting help from others when it is needed (James & Zarrett, 2007). As Erikson's theory indicates, psychosocial maturity in late life brings increased contentment, affectionate, enjoyable bonds with others, and continued service to society.

Scanning the newspaper, Walt pondered, “I keep reading these percentages: One out of five people will get heart disease, one out of three will get cancer. But the truth is, one out of one will die. We are all mortal and must accept this fate.” The year before, Walt had given his granddaughter, Marci, his collection of prized photos, which had absorbed him for over half a century. With the realization that the integrity of one's own life is part of an extended chain of human existence, Erikson suggested, death loses its sting (Vaillant, 2002). In support of this view, older adults who report having attained intrinsic (personally gratifying) life goals typically express acceptance of their own death (Van Hiel & Vansteenkiste, 2009). Those who emphasize attainment of extrinsic goals (such as money or prestige) more often fear life's end.

The negative outcome of this stage, despair, occurs when aging adults feel they have made many wrong decisions, yet time is too short to find an alternate route to integrity. Without another chance, the despairing person finds it hard to accept that death is near and is overwhelmed with bitterness, defeat, and hopelessness. According to Erikson, these attitudes are often expressed as anger and contempt for others, which disguise contempt for oneself. Dick's argumentative, fault-finding behavior, tendency to blame others for his personal failures, and regretful view of his own life reflect this deep sense of despair.

Other Theories of Psychosocial Development in Late Adulthood

As with Erikson's stages of early and middle adulthood, other theorists have clarified and refined his vision of late adulthood, specifying the tasks and thought processes that contribute to a sense of ego integrity. All agree that optimal development involves greater integration and deepening of the personality.

Peck's Tasks of Ego Integrity and Joan Erikson's Gerotranscendence

According to Robert Peck (1968), attaining ego integrity involves three distinct tasks:

- *Ego differentiation*: For those who invested heavily in their careers, finding other ways to affirm self-worth—through family, friendship, and community life
- *Body transcendence*: Surmounting physical limitations by emphasizing the compensating rewards of cognitive, emotional, and social powers

Erik Erikson and his wife Joan exemplified the ideal of Erikson's final stage. They aged gracefully, felt satisfied with their achievements, and were often seen together, contented and deeply in love.

- *Ego transcendence*: As contemporaries die, facing the reality of death constructively through efforts to make life more secure, meaningful, and gratifying for younger generations

In Peck's theory, ego integrity requires older adults to move beyond their life's work, their bodies, and their separate identities by investing in a future that extends beyond their own lifespan. Research suggests that as seniors grow older, both *body transcendence* (focusing on psychological strengths) and *ego transcendence* (orienting toward a larger, more distant future) increase. In a study of women, those in their eighties and nineties stated with greater certainty than those in their sixties that they "accept the changes brought about by aging," "have moved beyond fear of death," "have a clearer sense of the meaning of life," and "have found new, positive spiritual gifts to explore" (Brown & Lewis, 2003).

Erikson's widow Joan Erikson suggested that these attainments actually represent development beyond ego integrity (which requires satisfaction with one's past life) to an additional psychosocial stage that she calls **gerotranscendence**—a cosmic and transcendent perspective directed forward and outward, beyond the self. Drawing on her own experience of aging, her observations of her husband's final years, and the work of others on the positive potential of the years shortly before death, Joan Erikson speculated that success in attaining gerotranscendence is apparent in heightened inner calm and contentment and additional time spent in quiet reflection (Erikson, 1998; Tornstam, 2000, 2011).

Although interviews with people in their ninth and tenth decades reveal that many (but not all) experience this peaceful, contemplative state, more research is needed to confirm the existence of a distinct, transcendent late-life stage. Besides focusing more intently on life's meaning, many of the very old continue to report investments in the real world—visiting friends, keeping up with current events, striving to be a good neighbor, and engaging in leisure and volunteer pursuits.

Labouvie-Vief's Emotional Expertise

In Chapter 13, we discussed Gisella Labouvie-Vief's research on development of adults' reasoning about emotion (see page 453). Recall that cognitive-affective complexity (awareness and coordination of positive and negative feelings into an organized self-description) increases from adolescence through middle adulthood and then declines as basic information-processing skills diminish in late adulthood.

But older people display a compensating emotional strength: They gain in **affect optimization**, the ability to maximize positive emotion and dampen negative emotion (Labouvie-Vief, 2005; Labouvie-Vief et al., 2007; Labouvie-Vief, Grünh, & Studer, 2010). Compared with younger people, older adults selectively attend to and better recall emotionally positive over negative information (Mather & Carstensen, 2005). This bias toward the emotionally positive contributes to their remarkable

© JULIA CUMES/THE IMAGE WORKS

Despite serious medical problems, this aging adult asserts, "Being an invalid does not invalidate your life." Her adopted rescue dog gives her great pleasure. The ability to maximize positive emotion and dampen negative emotion contributes to older people's remarkable resilience.

resilience. Despite physical declines, increased health problems, a restricted future, and death of loved ones, most older people sustain a sense of optimism, emotional stability, and good psychological well-being—an upbeat attitude linked to longer survival (Boyle et al., 2009; Carstensen et al., 2011). Furthermore, about 30 to 40 percent not only are high in affect optimization but also retain considerable capacity for cognitive-affective complexity—a combination related to especially effective emotional self-regulation.

Research also reveals that when asked to relate personal experiences in which they were happy, angry, fearful, or sad and to indicate how they knew they felt that emotion, aging individuals gave more vivid accounts than did younger people—evidence of being more in touch with their feelings. Consider this example:

You have sunshine in your heart. During the wedding the candles were glowing. And that's just how I felt. I was glowing too. It was kind of dull outside. But that isn't how I felt. Everybody in the church felt like they were glowing. It was that kind of feeling. (Labouvie-Vief, DeVoe, & Bulka, 1989, p. 429)

Older adults' emotional perceptiveness helps them separate interpretations from objective aspects of situations. Consequently, their coping strategies often include making sure they fully understand their own feelings before deciding on a course of action. And they readily use emotion-centered coping strategies (controlling distress internally) in negatively charged situations (Blanchard-Fields, 2007). In sum, a significant late-life psychosocial attainment is becoming expert at reflecting on one's own feelings and regulating negative affect.

Reminiscence

We often think of older adults as engaged in **reminiscence**—telling stories about people and events from their past and reporting associated thoughts and feelings. Indeed, the widespread image of a reminiscing older person ranks among negative stereotypes of aging. In this common view, older people live in the past to escape the realities of a shortened future and the nearness of death. Yet research consistently reveals no age differences exist in total quantity of reminiscing! Rather, younger and older adults often use reminiscence for different purposes (Westerhof, Bohlmeijer, & Webster, 2010). And certain types of reminiscence are positive and adaptive.

In his comments on major events in his life at the beginning of this chapter, Walt was engaging in a special form of reminiscence called *life review*—calling up past experiences with the goal of achieving greater self-understanding. According to Robert Butler (1968), most older adults engage in life review as part of attaining ego integrity—a notion that has led many therapists to encourage life-review reminiscence. Older adults who participate in counselor-led life review report increased self-esteem, greater sense of purpose in life, and reduced depression (O’Rourke, Cappeliez, & Claxton, 2011; Westerhof, Bohlmeijer, & Webster, 2010). Life-review interventions can also help bereaved adults find a place for lost loved ones in their emotional lives, reinvest energy in other relationships, and move on with life (Worden, 2009).

Although life review occurs more often among older than younger adults, many older people who are high in self-acceptance and life satisfaction spend little time evaluating their past (Wink, 2007; Wink & Schiff, 2002). Indeed, in several studies in which older people were asked what they considered to be the best time of life, 10 to 30 percent identified one of the decades of late adulthood. Early and middle adulthood received especially high marks, whereas childhood and adolescence ranked as less satisfying (Field, 1997; Mehlsoln, Platz, & Fromholt, 2003). These findings challenge the widespread belief that older adults inevitably focus on the past and wish to be young again. To the contrary, today’s seniors in industrialized nations are largely present- and future-oriented: They seek avenues for personal growth and fulfillment (see the Cultural Influences box on the following page).

Clearly, life review is not essential for adapting well to late adulthood. Indeed, reminiscence that is *self-focused*, engaged in to reduce boredom and revive bitter events, is linked to adjustment problems. Compared with younger people, older adults less often engage in this ruminative form of reminiscence, and those who do are often anxious and depressed from dwelling on painful past experiences (Bohlmeijer et al., 2007; O’Rourke, Cappeliez, & Claxton, 2011). Life review therapy aimed at helping these older adults focus on positive memories improves their psychological well-being.

In contrast, extroverted seniors favor *other-focused* reminiscence directed at social goals, such as solidifying family and friendship ties and reliving relationships with lost loved ones. And at times, older adults—especially those who score high in

openness to experience—engage in *knowledge-based* reminiscence, drawing on their past for effective problem-solving strategies and for teaching younger people. These socially engaged, mentally stimulating forms of reminiscence help make life rich and rewarding (Cappeliez, Rivard, & Guindon, 2007). Perhaps because of their strong storytelling traditions, African-American and Chinese immigrant older adults are more likely than their Caucasian counterparts to use reminiscence to teach others about the past (Merriam, 1993; Webster, 2002).

For young and old alike, reminiscence often occurs during times of life transition. Older adults who have recently retired, been widowed, or moved to a new residence may turn temporarily to the past to sustain a sense of personal continuity (Cappeliez & Robitaille, 2010). As long as they do not get stuck in mulling over unresolved difficulties, reminiscence probably helps them recapture a sense of meaning.

Stability and Change in Self-Concept and Personality

Longitudinal research reveals continuing stability of the “big five” personality traits from mid- to late life (see Chapter 16, page 542). Yet the ingredients of ego integrity—wholeness, contentment, and image of the self as part of a larger world order—are reflected in several significant late-life changes in both self-concept and personality.

Secure and Multifaceted Self-Concept

Older adults have accumulated a lifetime of self-knowledge, leading to more secure and complex conceptions of themselves than at earlier ages (Diehl et al., 2011; Labouvie-Vief & Diehl, 1999). Ruth, for example, knew with certainty that she was good at growing a flower garden, budgeting money, counseling others, giving dinner parties, and figuring out who could be trusted and who couldn’t. Furthermore, when young and older adults were asked for several life-defining memories, 65- to 85-year-olds were more likely to mention events with a consistent theme—such as the importance of relationships or personal independence—and to explain how the events were interrelated (McLean, 2008). Their autobiographical selves emphasized coherence and consistency, despite physical, cognitive, and occupational changes. As Ruth remarked humorously, “I know who I am. I’ve had plenty of time to figure it out!”

The firmness, stability, and multifaceted nature of Ruth’s self-concept enabled her to compensate for lack of skill in domains she had never tried, had not mastered, or could no longer perform as well as before. Consequently, it allowed for self-acceptance—a key feature of integrity. In a study of old (70 to 84 years) and very old (85 to 103 years) German seniors asked to respond to the question “Who am I?,” participants mentioned a broad spectrum of life domains, including hobbies, interests, social participation, family, health, and personality traits.

Cultural Influences

The New Old Age

After retiring, pediatrician Jack McConnell tried a relaxing lifestyle near a lake and golf course, but it worked poorly for the energetic 64-year-old. As his desire for a more fulfilling retirement grew, he noticed that outside his comfortable, gated neighborhood were many people serving community needs as gardeners, laborers, fast-food workers, and the like, yet who lived in or near poverty. The contrast galvanized Jack to found Volunteers in Medicine, a free clinic for working-poor adults and their families who lack health insurance (Crocker, 2007). Five years later, at age 69, Jack was overseeing a highly cost-effective operation involving 200 retired doctors, nurses, and lay volunteers, who treat 6,000 patients a year.

Jack exemplifies a revised approach to late adulthood, one infused with new cultural meanings: Increasingly, older adults are using their freedom from work and parenting responsibilities to pursue personally enriching interests and goals. In doing so, they are giving back to their communities in significant ways, serving as role models for younger generations, and strengthening their sense of ego integrity with images of themselves as living ethical, worthy lives.

Added years of longevity and health plus financial stability have granted this active, opportunistic time of life to so many contemporary seniors that some experts believe a new phase of late adulthood has evolved called the **Third Age**—a term originating over a decade ago in France that spread through Western Europe and recently has stretched to North America. According to this view, the First Age is childhood, the Second Age is the adult period of earning a living

and rearing children, and the Third Age—extending from ages 65 to 79, and sometimes longer—is a time of personal fulfillment (James & Wink, 2007). The Fourth Age brings physical decline and need for care.

The baby boomers—healthier and financially better off than any preceding aging generation—are approaching late life with the conviction that their old age will not begin until 80 (Gergen & Gergen, 2003). This self-perception has helped define the Third Age as a time of self-realization and high life satisfaction. But even people a decade ahead of the oldest baby boomers are experiencing the Third Age as a phase of new goal setting and purpose rather than as an extended vacation (Winter et al., 2007). As we will see later in this chapter, retirement is no longer a one-way, age-graded event. In one survey of 300 older Americans, very few self-identified as retired (Trafford, 2004). Instead, they were building hybrid lives—leaving career jobs to work at different jobs that utilized their skills and devoting themselves to community service that they experienced as more meaningful than the paid work they left behind (Moen & Altobelli, 2007).

Although policy makers often express concern about the huge, impending baby-boomer burden on Social Security and Medicare, this large pool of vigorous, publicly minded future seniors has the potential to make enormous economic and social contributions. Today's Third Agers donate billions to the global economy in volunteer work, continue to participate in the work force in large numbers, and give generously to their families through monetary support and other forms of help—far more than they receive (see page 626).

TRICIA WATKINSON/NEWSPIX

For child-protection advocate Freda Briggs, late adulthood is a time of personal enrichment and new goal-setting. Since retiring from her faculty position at the University of South Australia, 82-year-old Briggs continues to write and speak on behalf of abused children while also embracing new adventures, such as parasailing and hot-air ballooning.

But as midlife roles shrink and terminate, too few alternatives are available for the many aging adults eager to make a difference (Bass, 2011). Societies need to provide abundant volunteer, national service, and other public interest opportunities, thereby harnessing their rich elder resources to solve pressing problems. The U.S. Serve America Act, signed into law in 2009, offers expanded service incentives and options to American adults of all ages and, thus, is a major step in that direction.

Finally, although the majority of U.S. adults in their sixties and seventies have more energy and choice than ever before, others—more often ethnic minorities, women, and those who live alone—suffer from financial hardship and distress and, thus, have little chance for new beginnings (Holstein, 2011). When social security, health care, and housing policies ensure a comfortable Third Age to all retiring adults, benefits accrue to the entire nation.

Adults in both age groups expressed more positive than negative self-evaluations, although a slight increase in negative comments occurred in the older group (Freund & Smith, 1999). Positive, multifaceted self-definitions predicted psychological well-being.

As the future shortens, most older adults, into their eighties and nineties, continue to mention—and actively pursue—hoped-for selves in the areas of physical health, cognitive functioning, personal characteristics, relationships, social responsibility, and leisure (Frazier, 2002; Markus & Herzog, 1992).

With respect to feared selves, physical health is even more prominent than it was in midlife.

At the same time, possible selves reorganize well into old age. When the German 70- to 103-year-olds just mentioned were followed longitudinally for four years, the majority deleted some possible selves and replaced them with new ones (Smith & Freund, 2002). Although future expectations become more modest with age, older adults often characterize hoped-for selves in terms of “improving,” “achieving,” or “attaining.” Consistent with this view, they usually take concrete steps to attain their goals. Engaging in hope-related activities, in turn, is associated with gains in life satisfaction and with longer life (Hoppmann et al., 2007). Clearly, late adulthood is not a time of withdrawal from future planning!

Agreeableness, Acceptance of Change, and Openness to Experience

During late adulthood, shifts occur in personality characteristics that, once again, defy aging stereotypes. Old age is not a time in which the personality inevitably becomes rigid and morale declines. Rather, a flexible, optimistic approach to life, which fosters resilience in the face of adversity, is common.

Both open-ended interviews and personality tests reveal that older adults gain in *agreeableness*, becoming increasingly generous, acquiescent, and good-natured well into late life (Allemand, Zimprich, & Martin, 2008; Field & Millsap, 1991; Weiss et al., 2005). Agreeableness seems to characterize people who have come to terms with life despite its imperfections.

At the same time, older adults show modest age-related dips in *extroversion*, perhaps reflecting a narrowing of social contacts as people become more selective about relationships—a trend we will take up in a later section. Older people also tend to decline in *openness to experience*, likely due to their awareness of cognitive declines (Allemand, Zimprich, & Martin, 2008; Donnellan & Lucas, 2008). But engaging in cognitively challenging activities can promote openness to experience! In one study, 60- to 94-year-olds participated in a 16-week cognitive training program in reasoning, which included experience in solving challenging but enjoyable puzzles. During the program, the trained group showed steady gains in both reasoning and openness to experience not displayed by untrained controls. Sustained intellectual engagement seemed to induce seniors to view themselves as more open (Jackson et al., 2012). Openness, in turn, predicts pursuit of intellectual stimulation, thereby contributing to enhanced cognitive functioning.

Another late-life development is greater *acceptance of change*—an attribute older adults frequently mention as important to psychological well-being (Rossen, Knafl, & Flood, 2008). When asked about dissatisfactions in their lives, many seniors respond that they are not unhappy about anything! Acceptance of change is also evident in most older people’s effective coping with the loss of loved ones, including death of a spouse, which they describe as the most stressful event they ever experienced (Lund, Caserta, & Dimond, 1993). The capacity to accept life’s

twists and turns, many of which are beyond one’s control, is vital for adaptive functioning in late adulthood.

Most older adults are resilient, bouncing back in the face of adversity—especially if they did so earlier in their lives. And their heightened capacity for positive emotion contributes greatly to their resilience. Older adults’ general cheerfulness strengthens their physiological resistance to stress, enabling them to conserve physical and mental resources needed for effective coping (Ong, Mroczek, & Riffin, 2011). The minority who are high in neuroticism—emotionally negative, short-tempered, and dissatisfied—tend to cope poorly with stressful events, experience mounting negative affect, and are at risk for health problems and earlier death (Mroczek & Spiro, 2007; Mroczek, Spiro, & Turiano, 2009).

Spirituality and Religiosity

How do older adults manage to accept declines and losses yet still feel whole and complete and anticipate death with calm composure? One possibility, consistent with Peck’s and Erikson’s emphasis on a transcendent perspective among seniors, is the development of a more mature sense of spirituality. Spirituality is not the same as religion: An inspirational sense of life’s meaning can be found in art, nature, and social relationships. But for many people, religion provides beliefs, symbols, and rituals that guide this quest for meaning.

Older adults attach great value to religious beliefs and behaviors. In recent national surveys, over 70 percent of Americans age 65 and older said that religion is very important in their lives—the highest of any age group (Gallup News Service, 2006, 2012). Although health and transportation difficulties reduce organized religious participation in advanced old age, U.S. seniors generally become more religious or spiritual as they age.

The late-life increase in religiosity, however, is modest, and it is far from universal. Longitudinal research reveals that the majority of people show stability in religiosity throughout adulthood (Ai, Wink, & Ardel, 2010; Dillon & Wink, 2007). Furthermore, in a British investigation following adults for two decades, one-fourth of seniors said they had become less religious, with some citing disappointment at the support they had received from their religious institution during stressful times (such as bereavement) as the reason (Coleman, Ivani-Chalian, & Robinson, 2004).

Despite these differences, spirituality and faith may advance to a higher level in late adulthood—away from prescribed beliefs toward a more reflective approach that emphasizes links to others and is at ease with mystery and uncertainty. According to James Fowler’s theory of faith development, mature adults develop new faith capacities, including awareness of their own belief system as just one of many possible worldviews, contemplation of the deeper significance of religious symbols and rituals, openness to other religious perspectives as sources of inspiration, and (especially in late life) an enlarged vision of a common good that serves the needs of all humanity (Fowler & Dell, 2006). For example, as a complement to his Catholicism,

Biology and Environment

Religious Involvement and Quality of Life in the Final Year

Jane—deeply religious all her life—attended a Friday evening service at the synagogue on her eighty-ninth birthday, celebrating at a reception with close friends and congregants. “I love being here, but I’m tired at night so I don’t come often,” Jane said. Still, she found private ways to stay involved. An amateur poet, she composed a poetic ending to a religious school play at the request of student actors. At home, she read from her prayer book, describing certain excerpts as “incredibly thought-provoking.” Despite escalating frailty, Jane sustained a gratifying connection with her faith and her people until she died in the middle of her ninetieth year.

Religiosity is linked to an array of psychological and physical benefits for older adults. Does it predict enhanced quality of life even in the final year—a time of increasing disability for most older people?

In a longitudinal investigation of 2,800 people age 65 and older, representing the senior population of New Haven, Connecticut, researchers conducted periodic interviews addressing religious participation and quality of life over the course of a decade,

while also noting any deaths (Idler, McLaughlin, & Kasl, 2009). The study offered a unique opportunity to look closely at a subsample of nearly 500, who had died within one year of being interviewed.

For religious seniors with greater disability, public involvement (attending services) declined. In the final year of life, private religiosity more powerfully predicted of quality of life. Compared with others, the deeply religious more often saw friends and scored higher in psychological well-being: They were more upbeat in mood, displayed fewer depressive symptoms, and experienced life as more exciting and enjoyable. They also felt better physically—had less difficulty sleeping, better appetite, and better self-rated health. And among the most disabled, this link between religiosity and self-rated health was stronger!

Being deeply religious seems to fortify the mind–body connection near life’s end, with the frailest displaying the greatest resilience. These findings help us understand another outcome of the New Haven study (as well as other research): Participants were more likely to die just after than just before

PAULA BRONSTEIN/GETTY IMAGES

For this aging adult, the daily ritual of Tibetan Buddhist prayer is a powerful source of inner strength. For many people in late adulthood, religiosity is linked to physical and psychological benefits.

a major religious holiday—for Jews, Passover and Yom Kippur; for Christians, Christmas and Easter (Anson & Anson, 2001; Idler & Kasl, 1992). Religious beliefs and practices appeared to intercede in a biological pathway, extending and giving meaning to life even in its final days.

Walt became intensely interested in Buddhism, especially its focus on attaining perfect peace and happiness by mastering thoughts and feelings, never harming others, and resisting attachment to worldly objects.

Involvement in both organized and informal religious activities is especially high among low-SES ethnic minority older people, including African-American, Hispanic, and Native-American groups. In African-American communities, churches not only provide contexts for deriving meaning from life but also are centers for education, health, social welfare, and political activities aimed at improving life conditions. African-American seniors look to religion as a powerful resource for social support beyond the family and for the inner strength to withstand daily stresses and physical impairments (Armstrong & Crowther, 2002). Compared with their Caucasian agemates, more African-American older adults report collaborating with God to overcome life problems (Lee & Sharpe, 2007).

As at earlier ages, in late adulthood women are more likely than men to say that religion is very important to them, to par-

ticipate in religious activities, and to engage in a personal quest for connectedness with a higher power (Gallup News Service, 2012; Wink & Dillon, 2002). Women’s higher rates of poverty, widowhood, and participation in caregiving, including caring for chronically ill family members, expose them to higher levels of stress and anxiety. As with ethnic minorities, they turn to religion for social support and for a larger vision of community that places life’s challenges in perspective.

Religious involvement is associated with diverse benefits, including better physical and psychological well-being, more time devoted to exercising and leisure activities, greater sense of closeness to family and friends, and greater generativity (care for others) (Boswell, Kahana, & Dilworth-Anderson, 2006; Gillum et al., 2008; Krause, 2012; Wink, 2006, 2007). In longitudinal research, both organized and informal religious participation predicted longer survival, after family background, health, social, and psychological factors known to affect mortality were controlled (Helm et al., 2000; Strawbridge et al., 2001). And as the Biology and Environment box above confirms, the

benefits of religious involvement for quality of life are evident even in the final year of life.

But aspects of religion that make a difference in aging adults' lives are not always clear. In two investigations of Caucasian older adults, religious *activity*—not religious belief or membership in a congregation—was associated with favorable adjustment following loss of a spouse (Lund, Caserta, & Dimond, 1993). Increased social engagement brought about by religious participation, rather than the specifically religious nature of the activity, was the influential factor. Other evidence, however, indicates that belief in God's powers contributes substantially to self-esteem, optimism, and life satisfaction, especially among low-SES, ethnic minority seniors (Krause, 2005; Schieman, Bierman, & Ellison, 2010). Their personal relationship with God seems to help them cope with life's hardships.

Contextual Influences on Psychological Well-Being

As we have seen in this and the previous chapter, most adults adapt well to old age, yet some feel dependent, incompetent, and worthless. Personal and situational factors often combine to affect psychological well-being. Identifying these contextual influences is vital for designing interventions that foster positive adjustment.

Control versus Dependency

As Ruth's eyesight, hearing, and mobility declined in her eighties, Sybil visited daily to help with self-care and household tasks. During the hours mother and daughter were together, Sybil interacted most often with Ruth when she asked for help with activities of daily living. When Ruth handled tasks on her own, Sybil usually withdrew.

Observations of people interacting with older adults in both private homes and institutions reveal two highly predictable, complementary behavior patterns. In the first, called the **dependency-support script**, dependent behaviors are attended to immediately. In the second, the **independence-ignore script**, independent behaviors are mostly ignored. Notice how these sequences reinforce dependent behavior at the expense of independent behavior, regardless of the older person's competencies (Baltes, 1995, 1996). Even a self-reliant individual like Ruth did not always resist Sybil's unnecessary help because it brought about social contact.

Among older people who experience no difficulty with daily activities, opportunities to interact with others are related to high satisfaction with everyday life. In contrast, among older adults who have trouble performing daily activities, social contact is linked to a less positive everyday existence (Lang & Baltes, 1997). This suggests that social interaction while assisting seniors with physical care, household chores, and errands is often not meaningful and rewarding but, rather, demeaning and unpleasant. Consider these typical reactions of care recipients

to a spouse's help with daily activities: "felt dependent," "felt indebted," "felt like a weak, incapable person" (Newsom, 1999).

Longitudinal research shows that negative reactions to caregiving can result in persisting depression (Newsom & Schulz, 1998). But whether assistance from others undermines well-being depends on many factors, including the quality of help, the caregiver-older adult relationship, and the social and cultural context in which helping occurs. Why do family members and other caregivers often respond in ways that promote excessive dependency in old age? Stereotypes of older people as passive and incompetent appear to be responsible. After reading passages that activated these stereotypes (by portraying aging adults as inept), older people responded with more frequent help-seeking behavior (Coudin & Alexopoulos, 2010).

In Western societies, which highly value independence, many older adults fear relinquishing control and becoming dependent on others. This is especially so for those with a high need for self-determination (Curtiss, Hayslip, & Dolan, 2007; Frazier, 2002). As physical and cognitive limitations increase, granting older adults the freedom to choose those areas in which they desire help preserves their autonomy (Lachman, Neupert, & Agrigoroaei, 2011). Dependency can be adaptive if it permits older people to remain in control by choosing those areas in which they desire help. In this way, they can conserve their strength by investing it in self-chosen, highly valued activities, using a set of strategies considered in Chapter 17: *selective optimization with compensation*.

TAKE A MOMENT... Cite examples of the varied ways older adults optimize their functioning while compensating for

© JANE SHAUCK PHOTOGRAPHY/ALAMY

By letting her son help with grocery shopping, will this Mexican 80-year-old become too dependent? Not necessarily. When older adults assume personal control over areas of dependency, they can conserve their strength and invest it in highly valued activities.

declines. Notice how they adaptively modify their personal goals: They invest in goals that enable them to remain active and self-determining, adjust those goals to suit their changing capacities, and disengage from goals that overextend their capacities, turning toward other, attainable goals (Heckhausen, Wrosch, & Schultz, 2010). Using these strategies, older people strive to remain active agents in the direction of their own lives. When family and caregiving environments support their efforts, most older adults sustain a sense of self-efficacy, purpose, and investment in overcoming obstacles.

Assistance aimed at enabling older adults use their capacities fully in pursuit of their goals sustains an effective **person–environment fit**—a good match between their abilities and the demands of their living environments, which promotes adaptive behavior and psychological well-being. When people cannot maximize use of their capacities (have become excessively dependent), they react with boredom and passivity. When they encounter environmental demands that are too great (receive too little assistance), they experience overwhelming stress.

Physical Health

As noted in Chapter 16, physical health is a powerful predictor of psychological well-being. Physical declines and chronic disease can lead to a sense of loss of personal control—a powerful contributor to mental health problems. Physical illness resulting in disability is among the strongest risk factors for late-life depression (Morrison, 2008; Whitbourne & Meeks, 2011). Although fewer older than young and middle-aged adults are depressed (see Chapter 17), profound feelings of hopelessness rise with age as physical disability and consequent social isolation increase. But more than actual physical limitations, *perceived negative physical health* predicts depressive symptoms (Jang et al., 2007; Weinberger & Whitbourne, 2010). This helps explain the stronger physical impairment–depression relationship among higher-SES aging adults (Schieman & Plickert, 2007). Because of their lifetime of better physical health, they probably experience physical limitations as more unexpected and challenging.

The relationship between physical and mental health problems can become a vicious cycle, each intensifying the other. In survey research conducted in 15 countries, adults of all ages reported that mental health problems actually interfered more than physical disabilities with activities of daily living, including home management and social life (Ormel et al., 2008). At times, despondency and “giving up” trigger rapid physical decline in a sick aging adult. This downward spiral can be hastened by a move to a nursing home, requiring the older person to adjust to diminished control over daily life and greater distance from family and friends. In the months after admission, many residents judge their quality of life to have worsened substantially, become severely anxious and depressed, and deteriorate rapidly. The stress of illness together with institutionalization is associated with escalating physical and mental health problems and with mortality (Scocco, Rapaatoni, & Fantoni, 2006).

Depression in old age is often lethal. People age 65 and older have the highest suicide rate of all age groups (see the Social Issues: Health box on pages 612–613). What factors enable people like Ruth to surmount the physical impairment–depression relationship, remaining content? Personal characteristics discussed in this and earlier chapters—optimism, sense of self-efficacy, and effective coping—are vitally important (Morrison, 2008). But for frail aging adults to display these attributes, families and caregivers must avoid the dependency–support script and, instead, grant them autonomy.

Unfortunately, older adults generally do not get the mental health care they need—even in nursing homes, where depression and other mental health problems are widespread (Grabowski et al., 2010; Karel, Gatz, & Smyer, 2012). More than half of U.S. nursing home residents receive no regular mental health intervention.

Negative Life Changes

Ruth lost Walt to a heart attack, cared for her sister Ida as her Alzheimer’s symptoms worsened, and faced health problems of her own—all within a span of a few years. Older people are at risk for a variety of negative life changes—death of loved ones, illness and physical disabilities, declining income, and greater dependency. Negative life changes are difficult for everyone but may actually evoke less stress and depression in older than in younger adults (Charles, 2011). Many older people have learned to cope with hard times, to appraise negative changes as common and expected in late life, and to accept loss as part of human existence.

Still, when negative changes pile up, they test the coping skills of older adults. In very old age, such changes are greater for women than for men. Women over age 75 are far less likely to be married, more often have lower incomes, and suffer from more illnesses—especially ones that restrict mobility. Furthermore, older women (as at younger ages) more often say that others depend on them for caregiving and emotional support (see page 626 in Chapter 17). Thus, their social relations, even in very old age, are more often a source of stress (Antonucci, Ajrouch, & Birditt, 2008). And because of their own declining health, older women may not be able to meet others’ needs for care—circumstances associated with chronic, high distress (Charles, 2010). Not surprisingly, women of advanced age tend to report lower psychological well-being than do men (Pinquart & Sörensen, 2001).

Social Support

In late adulthood, social support continues to reduce stress, thereby promoting physical health and psychological well-being. Availability of social support increases the odds of living longer (Fry & Debats, 2006; Temkin-Greener et al., 2004). And it helps explain the relationship of religious participation to survival, discussed earlier. Usually, older adults receive informal assistance with tasks of daily living from family members—first from their spouse or, if none exists, from children and then

Social Issues: Health

Elder Suicide

When 65-year-old Abe's wife died, he withdrew from life. Living far from his two daughters, he spent his nonworking days alone, watching television and reading mystery novels. As grandchildren were born, Abe visited his daughters' homes from time to time, carrying his despondent behavior with him. "Look at my new pajamas, Grandpa!" Abe's 6-year-old grandson Tony exclaimed on one occasion. Abe didn't respond.

After arthritis made walking difficult, Abe retired. With more empty days, his depression deepened. Gradually, he developed painful digestive difficulties, but he refused to see a doctor. "Don't need to," he said abruptly when one of his daughters begged him to get medical attention. Answering her invitation to Tony's tenth birthday party, Abe wrote, "Maybe—if I'm still around next month. By the way, when I go, I want my body cremated." Two weeks later, Abe died from an intestinal blockage. His body was found in the living room chair where he habitually spent his days. Although it may seem surprising, Abe's self-destructive acts are a form of suicide.

Factors Related to Elder Suicide

Recall from Chapter 12 that suicide increases over the lifespan. Although age differences in adulthood rates are shrinking, suicide continues to climb in late adulthood. Older adults are at increased risk in most countries throughout the world (World Health Organization, 2013b).

The higher suicide rate among males persists in late life. Five times as many U.S. aging men as women take their own lives. Suicide among white men age 70 and older rises steeply with age, whereas it actually declines after age 75 in women (U.S. Census Bureau, 2012b). Compared with the white majority, most ethnic minority older adults have low suicide rates.

What explains these trends? Despite the lifelong pattern of higher rates of depression and more suicide attempts among females, older women's closer ties to family and friends, greater willingness to seek social support, and religiosity prevent many from taking their own lives. High levels of social support through extended families and church affiliations also may prevent suicide among ethnic minorities (Conwell, Van Orden, & Caine, 2011). And within certain groups, such as Alaskan Natives, deep

respect for and reliance on older adults to teach cultural traditions strengthen self-esteem and social integration (Kettl, 1998). This reduces elder suicide, making it nonexistent after age 80.

As in earlier years, the methods favored by older males (firearms, hanging) offer less chance of revival than those by older females (poisoning or drug overdose). Nevertheless, failed suicides are much rarer in old age than in adolescence. The ratio of attempts to completions for the young is as high as 300 to 1; for aging adults, it is 4 to 1 or lower (Conwell, Van Orden, & Caine, 2011). When seniors decide to die, they seem especially determined to succeed.

Underreporting of suicides probably occurs at all ages, but it is more common in old age. Medical examiners are less likely to pursue suicide as a cause of death when a person is old. And many older adults, like Abe, engage in indirect self-destructive acts rarely classified as suicide—deciding not to go to a doctor when ill or refusing to eat or take prescribed medications. Among institutionalized seniors, these efforts to hasten death are widespread (Reiss & Tishler, 2008b). Consequently, elder suicide is an even larger problem than official statistics indicate.

Two types of events prompt suicide in late life. Losses—retirement from a highly valued occupation, widowhood, or social

from siblings. If these individuals are not available, other relatives and friends may step in.

Nevertheless, many older people place such high value on independence that they do not want extensive help from others close to them unless they can reciprocate. When assistance is excessive or cannot be returned, it often results in reduced self-efficacy and psychological stress (Liang, Krause, & Bennett, 2001; Warner et al., 2011). Perhaps for this reason, adult children express a deeper sense of obligation toward their aging parents than their parents expect from them (see Chapter 16, page 549). Formal support—a paid home helper or agency-provided services—as a complement to informal assistance not only helps relieve caregiving burden but also spares aging adults from feeling overly dependent in their close relationships.

Ethnic minority older adults, however, do not readily accept formal assistance. But they are more willing to do so when home helpers are connected to a familiar neighborhood organization, especially the church. Although African-American seniors say they rely more on their families than on the church for assistance, those with support and meaningful roles in both contexts fare best in mental health (Coke, 1992; Taylor, Lincoln, & Chatters, 2005). Support from religious congregants has psychological benefits for older adults of all backgrounds, perhaps because recipients feel that it is motivated by genuine care and concern, not just obligation (Krause, 2001). Also, the warm atmosphere of religious organizations fosters a sense of social acceptance and belonging.

Overall, for social support to foster well-being, older adults must take personal control of it. This means consciously giving

isolation—place seniors who have difficulty coping with change at risk for persistent depression. Risks of another type arise when chronic and terminal illnesses severely reduce physical functioning or cause intense pain (Conwell et al., 2010). As comfort and quality of life diminish, feelings of hopelessness and helplessness deepen. Very old people, especially men, are particularly likely to take their own lives under these conditions. The chances are even greater when a sick older person is socially isolated—living alone or in a nursing home with high staff turnover, minimal caregiver support, and little opportunity for personal control over daily life (Reiss & Tishler, 2008a).

Prevention and Treatment

Warning signs of suicide in late adulthood, like those at earlier ages, include efforts to put personal affairs in order, statements about dying, despondency, and sleep and appetite changes. But family members, friends, and caregivers must also watch for indirect self-destructive acts that are unique to old age, such as refusing food or medical treatment. Too often, people in close touch with the elderly incorrectly assume that these symptoms are a “natural” consequence of aging. Older suicide victims are 2.5 times more likely to have visited their doctors within a month of

taking their lives (Vannoy et al., 2011). Yet their suicidal risk was not recognized.

When suicidal aging adults are depressed, the most effective treatment combines antidepressant medication with therapy, including help in coping with role transitions, such as retirement, widowhood, and dependency brought about by illness. Distorted ways of thinking (“I’m old—nothing can be done about my problems”) must be countered and revised. Meeting with the family to find ways to reduce loneliness and desperation is also helpful.

Although youth suicide has risen (see Chapter 12, page 422), elder suicide has diminished during the past 50 years, as a result of increased economic security among older adults, improved medical care and social services, and more favorable cultural attitudes toward retirement. Communities are beginning to recognize the importance of additional preventive steps, such as programs that help older adults cope with life transitions, telephone hot lines with trained volunteers who provide emotional support, and agencies that arrange for regular home visitors or “buddy system” phone calls (Lapierr et al., 2011). But so far, most of these efforts benefit women more than men because women are more likely to tell health professionals about high-risk symptoms, such as despondency, and to use social resources.

© RICHARD GREEN/COMMERCIAL/ALAMY

Suicide reaches its highest rate among people age 75 and older. Warning signs include despondency, sleep and appetite changes, statements about dying, and efforts to put personal affairs in order.

Finally, elder suicide raises a controversial ethical issue: Do people with incurable illnesses have the right to take their own lives? We will take up this topic in Chapter 19.

up primary control in some areas to remain in control of other, highly valued pursuits (Heckhausen, Wrosch, & Schultz, 2010). For example, although she could handle financial matters, shopping, and food preparation on her own, Ruth allowed her daughter Sybil to assist with these activities, leaving Ruth with more stamina for pleasurable reading and gardening.

When we intervene with older adults, we must ask ourselves, What kind of assistance are we providing? Help that is not wanted or needed or that exaggerates weaknesses results in poor person–environment fit, undermines mental health, and—if existing skills fall into disuse—accelerates physical disability. In contrast, help that increases autonomy—that frees up energy for endeavors that are personally satisfying and that lead to growth—enhances quality of life. These findings clarify why *perceived social support* (older adults’ sense of being able to

count on family or friends in times of need) is associated with a positive outlook in older adults with disabilities, whereas sheer *amount* of help family and friends provide has little impact (Uchino, 2009).

Finally, besides tangible assistance, older adults benefit from social support that offers affection, affirmation of their self-worth, and sense of belonging. Extroverted seniors are more likely to take advantage of opportunities to engage with others, thereby reducing loneliness and depression and fostering self-esteem and life satisfaction (Mroczek & Spiro, 2005). But as we will see in the next section, supportive social ties in old age have little to do with quantity of contact. Instead, high-quality relationships, involving expressions of kindness, encouragement, respect, and emotional closeness, have the greatest impact on mental health in late life.

ASK YOURSELF

REVIEW Many older people adapt effectively to negative life changes. List personal and situational factors that facilitate this generally positive outcome.

CONNECT Why is it important to understand older adults' perceptions of their circumstances—physical changes (see page 567 in Chapter 17), health, negative life changes, and social support? How do the perceptions of most seniors promote psychological well-being?

APPLY At age 85, Miriam took a long time to get dressed. Joan, her home helper, said, "From now on, don't get dressed until I get there. Then I can help, and it won't take so long." What impact is Joan's approach likely to have on Miriam's personality? What alternative approach would you recommend?

REFLECT Among older people you know, do any fit the description of a Third Ager? Explain.

A Changing Social World

Walt and Ruth's outgoing personalities led many family members and friends to seek them out, and they often reciprocated. In contrast, Dick's stubborn nature meant that he and Goldie, for many years, had had a far more restricted network of social ties.

As noted earlier, extroverts (like Walt and Ruth) continue to interact with a wider range of people than do introverts and people (like Dick) with poor social skills. Nevertheless, both cross-sectional and longitudinal research reveals that size of social networks and, therefore, amount of social interaction decline for virtually everyone (Antonucci, Akiyama, & Takahashi, 2004; Charles & Carstensen, 2009). This finding presents a curious paradox: If social interaction and social support are essential for mental health, how is it possible for older adults to interact less yet be generally satisfied with life and less depressed than younger adults?

Social Theories of Aging

Social theories of aging offer explanations for changes in aging adults' social activity. Two older perspectives—disengagement theory and activity theory—interpret declines in social interaction in opposite ways. More recent approaches—continuity theory and socioemotional selectivity theory—account for a wider range of findings.

Disengagement Theory. According to **disengagement theory**, mutual withdrawal between older adults and society takes place in anticipation of death (Cumming & Henry, 1961). Older people decrease their activity levels and interact less fre-

quently, becoming more preoccupied with their inner lives. At the same time, society frees the old from employment and family responsibilities. The result is viewed as beneficial for both sides. Older adults are granted a life of tranquility. And once they disengage, their deaths are less disruptive to society.

Clearly, however, most aging adults don't disengage! As we saw in Chapter 17 when we discussed wisdom, older people in many cultures move into new positions of prestige and power because of their long life experience. Even after retirement, many adults sustain aspects of their work; others develop new, rewarding roles in their communities. Disengagement, then, may represent not older peoples' personal preference but, rather, a failure of the social world to provide opportunities for engagement. The more social opportunities older adults report, the more strongly they believe they can create worthwhile social experiences for themselves (Lang, Featherman, & Nesselroade, 1997). Indeed, an obvious application of disengagement theory—encouraging older people to withdraw from vital roles—can have profound negative consequences for their sense of self-worth and, at a societal level, waste valuable social resources!

As we will see shortly, older adults' retreat from interaction is more complex than disengagement theory implies. Instead of disengaging from all social ties, they let go of unsatisfying contacts and maintain satisfying ones. And sometimes, they put up with less than satisfying relationships to remain engaged! For example, though Ruth often complained about Dick's insensitive behavior, she reluctantly agreed to travel with Dick and Goldie because she wanted to share the experience with Walt.

Activity Theory. Attempting to overcome the flaws of disengagement theory, **activity theory** states that social barriers to engagement, not the desires of aging adults, cause declining rates of interaction. When older people lose certain roles (for example, through retirement or widowhood), they try to find others in an effort to stay about as active and busy as they were in middle age (Maddox, 1963). In this view, older adults' life satisfaction depends on conditions that permit them to remain engaged in roles and relationships.

Although people do seek alternative sources of meaning in response to social losses, activity theory fails to acknowledge any psychological change in old age. Many studies show that merely offering seniors opportunities for social contact does not lead to greater social activity. In nursing homes, for example, where social partners are abundant, social interaction is very low, even among the healthiest residents—a circumstance we will examine when we discuss housing arrangements for aging adults. Especially troubling for activity theory is the repeated finding that when health status is controlled, older people who have larger social networks and engage in more activities are not necessarily happier (Charles & Carstensen, 2009; Ritchey, Ritchey, & Dietz, 2001). Recall that quality, not quantity, of relationships predicts psychological well-being in old age.

Continuity Theory. Unlike activity theory, **continuity theory** does not view older adults' efforts to remain active as simple replacement of lost social roles with new ones. Rather,

These sisters—ages 93 and 89—greet each other with enthusiasm. The one on the right traveled from Poland to New York City for this reunion. To preserve emotional equilibrium and reduce stress, older adults increasingly emphasize familiar, emotionally rewarding relationships.

according to this view, most aging adults strive to maintain a personal system—an identity and a set of personality dispositions, interests, roles, and skills—that promotes life satisfaction by ensuring consistency between their past and anticipated future. This striving for continuity does not mean that older people's lives are static. To the contrary, aging produces inevitable change, but most older adults try to minimize stress and disruptiveness by integrating those changes into a coherent, consistent life path. As much as possible, they choose to use familiar skills and engage in familiar activities with familiar people—preferences that provide a secure sense of routine and direction in life.

Research confirms a high degree of continuity in older adults' everyday pursuits and relationships. For most, friends and family members with whom they interact remain much the same, as do work, volunteer, leisure, and social activities. Even after a change (such as retirement), people usually make choices that extend the previous direction of their lives, engaging in new activities but often within familiar domains. For example, a retired manager of a children's bookstore collaborated with friends to build a children's library and donate it to an overseas orphanage. A musician who, because of arthritis, could no longer play the violin arranged regular get-togethers with musically inclined friends to listen to and talk about music. Robert Atchley (1989), originator of continuity theory, noted, "Everyday life for most older people is like long-running improvisational

theater in which . . . changes are mostly in the form of new episodes [rather] than entirely new plays" (p. 185).

Aging adults' reliance on continuity has many benefits. Participating in familiar activities with familiar people provides repeated practice that helps preserve physical and cognitive functioning, fosters self-esteem and mastery, and affirms identity (Finchum & Weber, 2000; Vacha-Haase, Hill, & Bermingham, 2012). Investing in long-standing, close relationships provides comfort, pleasure, and a network of social support. Finally, striving for continuity is essential for attaining Erikson's sense of ego integrity, which depends on preserving a sense of personal history (Atchley, 1999).

As we explore social contexts and relationships of aging, we will encounter many examples of how older adults use continuity to experience aging positively, as a "gentle slope." We will also address ways that communities can help them do so. As our discussion will reveal, people experiencing the greatest disruption to desired continuity in activities and lifestyle preferences have the most difficulty adapting to growing older.

Socioemotional Selectivity Theory. A final perspective addresses how people's social networks sustain continuity while also narrowing as they age. According to **socioemotional selectivity theory**, social interaction extends lifelong selection processes. In middle adulthood, marital relationships deepen, siblings feel closer, and number of friendships declines. In old age, contacts with family and long-term friends are sustained until the eighties, when they diminish gradually in favor of a few very close relationships. In contrast, as Figure 18.1 shows, contacts with acquaintances and willingness to form new social ties

FIGURE 18.1 Age-related change in number of social partners varying in closeness. In interviews with over 500 older adults ranging in age from 69 to 104, the number of "not close" and "less close" partners fell off steeply with age, whereas the number of "close" and "very close" partners declined minimally. (From F. R. Lang, U. M. Staudinger, & L. L. Carstensen, 1998, "Perspectives on Socioemotional Selectivity in Late Life: How Personality and Social Context Do (and Do Not) Make a Difference," *Journal of Gerontology*, 53B, p. 24. Copyright © 1998 The Gerontological Society of America. Adapted by permission of Oxford University Press and F. R. Lang.)

fall off steeply from middle through late adulthood (Carstensen, 2006; Carstensen, Fung, & Charles, 2003; Fung, Carstensen, & Lang, 2001).

What explains these changes? Socioemotional selectivity theory states that physical and psychological aspects of aging lead to changes in the functions of social interaction. **TAKE A MOMENT...** Consider the reasons you interact with members of your social network. At times, you approach them to get information. At other times, you seek affirmation of your worth as a person. You also choose social partners to regulate emotion, approaching those who evoke positive feelings and avoiding those who make you feel sad, angry, or uncomfortable. For older adults, who have gathered a lifetime of information, the information-gathering function becomes less significant. Also, they realize it is risky to approach people they do not know for self-affirmation: Stereotypes of aging increase the odds of receiving a condescending, hostile, or indifferent response.

Instead, as physical fragility makes it more important to avoid stress, older adults emphasize the emotion-regulating function of interaction. In one study, younger and older adults were asked to categorize their social partners. Younger people more often sorted them on the basis of information seeking and future contact, whereas older people emphasized anticipated feelings (Frederickson & Carstensen, 1990). They appeared highly motivated to approach pleasant relationships and avoid unpleasant ones. Interacting mostly with relatives and friends increases the chances that emotional equilibrium will be preserved.

Within these close bonds, older adults actively apply their emotional expertise to promote harmony. They are less likely than younger people to respond to tensions with destructive tactics (yelling, arguing) and more likely to use constructive strategies, such as expressing affection or disengaging to calmly let the situation blow over (Birditt & Fingerman, 2005; Luong, Charles, & Fingerman, 2011). They also reinterpret conflict in less stressful ways—often by identifying something positive in the situation (Labouvie-Vief, 2003). Consequently, despite their smaller social networks, they are happier than younger people with their number of friends and report fewer problematic relationships and less distress when they encounter interpersonal tensions (Blanchard-Fields & Coats, 2008; Fingerman & Birditt, 2003).

Extensive research confirms that people's perception of time is strongly linked to their social goals. **TAKE A MOMENT...** If you faced a shortened future, with whom would you choose to spend time? When remaining time is limited, adults of *all ages* place more emphasis on the emotional quality of their social experiences. They shift from focusing on long-term goals to emphasizing emotionally fulfilling relationships in the here and now (Charles & Carstensen, 2010). Similarly, seniors—aware that time is “running out”—don't waste it on unlikely future payoffs but, instead, turn to close friends and family members. Furthermore, we generally take special steps to facilitate positive interaction with people dear to us whose time is limited—for example, treating older friends and relatives more kindly than younger ones, easily excusing or forgiving their social transgressions (Luong, Charles, & Fingerman, 2011). In this way,

social partners contribute to older adults' gratifying relationship experiences.

Aging adults' emphasis on *relationship quality* helps explain a cultural exception to the restriction of social relationships just described. In collectivist societies, where people value an interdependent self and, thus, attach great importance to remaining embedded in their social group, older people may be motivated to sustain high-quality ties with all partners! In line with this prediction, in a Hong Kong study, aging adults scoring high in interdependence both expanded their number of emotionally close social partners and sustained the same number of peripheral social partners into advanced old age (Yeung, Fung, & Lang, 2008). In contrast, Hong Kong older people scoring low in interdependence resembled their Western counterparts: They gradually limited their social ties to a few close relationships.

In sum, socioemotional selectivity theory views older adults' preference for high-quality, emotionally fulfilling relationships as resulting from changing life conditions. But the meaning of relationship quality and, therefore, the number and variety of people to whom older people turn for pleasurable interaction and self-affirmation vary with culture.

Social Contexts of Aging: Communities, Neighborhoods, and Housing

The physical and social contexts in which aging adults live affect their social experiences and, consequently, their development and adjustment. Communities, neighborhoods, and housing arrangements vary in the extent to which they enable aging residents to satisfy their social needs.

Communities and Neighborhoods. About half of U.S. ethnic minority older adults live in cities, compared with just one-third of Caucasians. The majority of seniors reside in suburbs, where they moved earlier in their lives and usually remain after retirement. Suburban older adults have higher incomes and report better health than their inner-city counterparts do. But inner-city older people are better off in terms of public transportation. As declines in physical functioning compromise out-of-home mobility, convenient bus, tram, and rail lines become increasingly important to life satisfaction and psychological well-being (Mollenkopf, Hieber, & Wahl, 2011; Oswald et al., 2010). Furthermore, city-dwelling seniors fare better in terms of health, income, and proximity of social services and cultural activities than do the one-fifth of U.S. older people who live in small towns and rural areas (U.S. Department of Health and Human Services, 2012e). In addition, small-town and rural seniors are less likely to live near their children, who often leave these communities in early adulthood.

Yet small-town and rural aging adults compensate for distance from children and social services by establishing closer relationships with nearby extended family and by interacting more with neighbors and friends (Hooyman & Kiyak, 2011; Shaw, 2005). Smaller communities have features that foster

gratifying relationships—stability of residents, shared values and lifestyles, willingness to exchange social support, and frequent social visits as country people “drop in” on one another. And many suburban and rural communities have responded to aging residents’ needs by developing transportation programs (such as special buses and vans) to take them to health and social services, senior centers, and shopping centers.

Both urban and rural older adults report greater life satisfaction when many senior citizens reside in their neighborhood and are available as like-minded companions. Presence of family is less crucial when neighbors and nearby friends provide social support (Gabriel & Bowling, 2004). This does not mean that neighbors replace family relationships. But older adults are content as long as their children and other relatives who live far away arrange occasional visits (Hooyma & Kiyak, 2011).

Compared with older adults in urban areas, those in quiet neighborhoods in small and mid-sized communities are more satisfied with life. In addition to a friendlier atmosphere, smaller communities have lower crime rates (AARP, 2006; Krause, 2004). As we will see next, fear of crime has profound, negative consequences for seniors’ sense of security and comfort.

Victimization and Fear of Crime. Walt and Ruth’s single-family home stood in an urban neighborhood, five blocks from the business district where Walt’s photography shop had been prior to his retirement. As the neighborhood aged, some homes fell into disrepair, and the population became more transient. Although they had never been victimized, crime was on Walt and Ruth’s minds and affected their behavior: They avoided neighborhood streets after sundown.

Media attention has led to a widely held belief that crime against seniors is common. In reality, older adults are less often targets of crime, especially violent crime, than other age groups. In urban areas, however, purse snatching and pickpocketing are more often committed against seniors (especially women) than younger people (U.S. Department of Justice, 2010). A single incident can strike intense anxiety into the hearts of seniors because of its potential for physical injury and its financial consequences for those with low incomes.

Among frail aging adults living alone and in inner-city areas, fear of crime, which is sometimes greater than worries about income, health, and housing, restricts activities and undermines morale (Beaulieu, Leclerc, & Dube, 2003). In one study, older adults who had experienced a violent crime were more likely than those with physical and cognitive impairments to enter a nursing home (Lachs et al., 2006). Neighborhood Watch and other programs that encourage residents to look out for one another increase communication among neighbors, strengthen sense of neighborhood cohesion, and reduce fear (Oh & Kim, 2009).

Housing Arrangements. Seniors’ housing preferences reflect a strong desire for **aging in place**—remaining in a familiar

© ARIEL SKELLECY/CORBIS

Like many older adults, these dog lovers reap great satisfaction from residing in a neighborhood with like-minded senior residents. Presence of family is less crucial when neighbors and nearby friends provide social support.

setting where they have control over their everyday life. Overwhelmingly, older people in Western nations want to stay in the neighborhoods where they spent their adult lives; in fact, 90 percent remain in or near their old home. In the United States, fewer than 4 percent relocate to other communities (U.S. Department of Health and Human Services, 2012e). These moves are usually motivated by a desire to live closer to children or, among the more economically advantaged and healthy, a desire for a more temperate climate and a place to pursue leisure interests.

Most aging adults’ relocations occur within the same town or city and are prompted by declining health, widowhood, or disability (Sergeant, Ekerdt, & Chapin, 2008). As we look at housing arrangements for older adults, we will see that the more a setting deviates from home life, the harder it is for older people to adjust.

Ordinary Homes. For the majority of older adults, who are not physically impaired, staying in their own homes affords the greatest possible personal control—freedom to arrange space and schedule daily events as one chooses. More seniors in Western countries live on their own today than ever before—a trend due to improved health and economic well-being (U.S. Department of Health and Human Services, 2012e). But when health and mobility problems appear, independent living poses risks to an effective person–environment fit. Most homes are designed for younger people. They are seldom modified to suit the physical capacities of their older residents. And living alone with a physical disability is linked to social isolation and loneliness (Adams, Sanders, & Auth, 2004).

When Ruth reached her mid-eighties, Sybil begged her to move into her home. Like many adult children of Southern, Central, and Eastern European descent (Greek, Italian, Polish, and others), Sybil felt an especially strong obligation to care for her frail mother. Older adults of these cultural backgrounds, as well as African Americans, Asians, Hispanics, and Native

Americans, more often live in extended families (see page 549 in Chapter 16).

Yet increasing numbers of ethnic minority older adults want to live on their own, although poverty often prevents them from doing so. For example, two decades ago, most Asian-American older adults were living with their children, whereas today 65 percent live independently—a trend also evident in certain Asian nations, such as Japan (Federal Interagency Forum on Aging Related Statistics, 2012; Takagi, Silverstein, & Crimmins, 2007). With sufficient income to keep her home, Ruth refused to move in with Sybil. Continuity theory helps us understand why many older adults react this way, even after health problems accumulate. As the site of memorable life events, the home strengthens continuity with the past, sustaining a sense of identity in the face of physical declines and social losses. And it permits older adults to adapt to their surroundings in familiar, comfortable ways (Atchley, 1999). Older people also value their independence, privacy, and network of nearby friends and neighbors.

During the past half century, the number of unmarried, divorced, and widowed seniors living alone has risen dramatically. Approximately 30 percent of U.S. older adults live by themselves, a figure that rises to nearly 50 percent for those age 85 and older (U.S. Census Bureau, 2012b). This trend, though evident in all segments of the aging population, is less pronounced among men, who are far more likely than women to be living with a spouse into advanced old age.

Over 40 percent of American seniors who live alone are poverty-stricken—rates many times greater than among older couples. More than 70 percent are widowed women. Because of lower earnings in earlier years, some entered old age this way.

G.M. ANDREWS/THE PRESS-REGISTER/LANDOV

Residents of a retirement community join visiting Girl Scouts to bake dog treats for animal shelters. By sustaining an effective person–environment fit as capacities change, residential communities enable older adults to enjoy a more active lifestyle.

Others became poor for the first time, often because they outlived a spouse who suffered a lengthy, costly illness. With age, their financial status worsens as their assets shrink and their own health-care costs rise (Biegel & Liebbrant, 2006; U.S. Census Bureau, 2012b). Under these conditions, isolation, loneliness, and depression can pile up. Poverty among lone aging women is deeper in the United States than in other Western nations because of less generous government-sponsored income and health benefits. Consequently, the feminization of poverty deepens in old age.

Residential Communities. About 7 percent of U.S. adults age 65 and older live in residential communities, a proportion that rises with age as functional limitations increase. Among people age 85 and older, 22 percent live in these communities, which come in great variety (U.S. Department of Health and Human Services, 2012e). Housing developments for the aged, either single-dwelling or apartment complexes, differ from ordinary homes only in that they have been modified to suit older adults' capacities (featuring, for example, single-level living space and grab bars in bathrooms). Some are federally subsidized units for low-income residents, but most are privately developed retirement villages with adjoining recreational facilities.

For older adults who need more help with everyday tasks, *assisted-living* arrangements are available (see Chapter 17, page 589). **Congregate housing**—an increasingly popular long-term care option—provides a variety of support services, including meals in a common dining room, along with watchful oversight of residents with physical and mental disabilities. **Life-care communities** offer a range of housing alternatives, from independent or congregate housing to full nursing home care. For a large initial payment and additional monthly fees, life care guarantees that seniors' changing needs will be met within the same facility as they age.

Unlike Ruth and Walt, who remained in their own home, Dick and Goldie decided in their late sixties to move to nearby congregate housing. For Dick, the move was a positive turn of events that permitted him to relate to peers on the basis of their current life together, setting aside past failures in the outside world. Dick found gratifying leisure pursuits—leading an exercise class, organizing a charity drive with Goldie, and using his skills as a baker to make cakes for birthday and anniversary celebrations.

By sustaining an effective person–environment fit as older adults' capacities change, residential communities have positive effects on physical and mental health. A specially designed physical space and care on an as-needed basis help seniors overcome mobility limitations, enabling greater social participation and a more active lifestyle (Fonda, Clipp, & Maddox, 2002; Jenkins, Pienta, & Horgas, 2002). And in societies where old age leads to reduced status, age-segregated living is gratifying to most seniors who choose it. It may open up useful roles and leadership opportunities. The more older adults perceive the environment as socially supportive, the more they collaborate with one another in coping with stressors of aging and in

providing assistance to other residents (Lawrence & Schigelone, 2002). Congregate housing appears to be well-suited to promoting mutually supportive relationships among residents.

Nevertheless, no U.S. federal regulations govern assisted-living facilities, which vary widely in quality. Low-income ethnic minority seniors are less likely to use assisted living. When older people with limited financial resources do transition to assisted living, they usually lack control over when and where they move and enter lower-quality settings—conditions associated with high stress (Ball et al., 2009). And in some states, assisted-living facilities are prohibited from providing any nursing care and monitoring, requiring seniors to leave when their health declines (Hernandez & Newcomer, 2007). Yet physical designs and support services that enable aging in place are vital for aging adults' well-being. These include homelike surroundings, division of large environments into smaller units to facilitate meaningful activities, social roles and relationships, and the latest assistive technologies to permit adaptation to changing health needs (Cutler, 2007; Oswald & Wahl, 2013).

Shared values and goals among residents with similar backgrounds also enhance life satisfaction. Older adults who feel socially integrated into the setting are more likely to consider it their home. But those who lack like-minded companions are unlikely to characterize it as home and are at high risk for loneliness and depression (Adams, Sanders, & Auth, 2004; Cutchin, 2013).

LOOK AND LISTEN

Visit an assisted-living community, and explore its housing options, physical design, and social and leisure opportunities. Ask several residents about their satisfaction with daily life. How well does the living environment support aging in place and effective person–environment fit? ●

Nursing Homes. The 5 percent of Americans age 65 and older who live in nursing homes experience the most extreme restriction of autonomy and social integration. Although potential companions are abundant, interaction is low. To regulate emotion in social interaction (so important to aging adults), personal control over social experiences is vital. Yet nursing home residents have little opportunity to choose their social partners, and timing of contact is generally determined by staff rather than by residents' preferences. Social withdrawal is an adaptive response to these often overcrowded, hospital-like settings, which typically provide few ways for residents to use their competencies. Although interaction with people in the outside world predicts nursing home residents' life satisfaction, interaction within the institution does not (Baltes, Wahl, & Reichert, 1992). Not surprisingly, nursing home residents with physical but not mental impairments are far more depressed, anxious, and lonely than their community-dwelling counterparts (Guildner et al., 2001).

Designing more homelike nursing homes could help increase residents' sense of security and control. U.S. nursing homes, usually operated for profit, are often packed with resi-

THE GREEN HOUSE® model blurs distinctions among nursing home, assisted living, and “independent” living. In this homelike setting, residents determine their own daily schedules and help with household tasks. Green House living environments now exist in more than 20 U.S. states.

dents and institutional in their operation. In contrast, European facilities are liberally supported by public funds and resemble high-quality assisted living.

In a radically changed U.S. nursing-home concept called THE GREEN HOUSE® model, a large, outdated nursing home in Mississippi was replaced by ten small, self-contained houses (Rabig et al., 2006). Each is limited to ten or fewer residents, who live in private bedroom–bathroom suites that surround a family-style communal space. Besides providing personal care, a stable staff of nursing assistants fosters aging adults' control and independence. Residents determine their own daily schedules and are invited to join in both recreational and household activities, including planning and preparing meals, cleaning, gardening, and caring for pets. A professional support team—including licensed nurses, therapists, social workers, physicians, and pharmacists—visits regularly to serve residents' health needs. In a comparison of Green House residents with traditional nursing home residents, Green House older adults reported substantially better quality of life, and they also showed less decline over time in ability to carry out activities of daily living (Kane et al., 2007).

The Green House model—and other models like it—is blurring distinctions among nursing home, assisted living, and “independent” living. By making the home a central, organizing principle, the Green House approach includes all the aging-in-place and effective person–environment fit features that ensure late-life well-being: physical and emotional comfort, enjoyable daily pursuits enabling residents to maximize use of their capacities, and meaningful social relationships.

ASK YOURSELF

REVIEW Cite features of neighborhoods and residential communities that enhance aging adults' life satisfaction.

CONNECT According to socioemotional selectivity theory, when time is limited, adults focus on the emotional quality of their social relationships. How do older people apply their emotional expertise (discussed on page 616) to attain this goal?

APPLY Sam lives alone in the same home he has occupied for over 30 years. His adult children cannot understand why he won't move across town to a modern apartment. Using continuity theory, explain why Sam prefers to stay where he is.

REFLECT Imagine yourself as a resident in an assisted-living facility. List all the features you would want your living context to have, explaining how each helps ensure effective person-environment fit and favorable psychological well-being.

Relationships in Late Adulthood

The **social convoy** is an influential model of changes in our social networks as we move through life. **TAKE A MOMENT...** Picture yourself in the midst of a cluster of ships traveling together, granting one another safety and support. Ships in the inner circle represent people closest to you, such as a spouse, best friend, parent, or child. Those less close, but still important, travel on the outside. With age, ships exchange places in the convoy, and some drift off while others join the procession (Antonucci, Birditt, & Ajrouch, 2011; Antonucci, Birditt, & Akiyama, 2009). As long as the convoy continues to exist, you adapt positively.

In the following sections, we examine the ways older adults with diverse lifestyles sustain social networks of family members and friends. As ties are lost, older adults draw others closer and occasionally add replacements, though not at the rate they did at younger ages. Although size of the convoy decreases asagemates die, aging adults are rarely left without people in their inner circle who contribute to their well-being—a testament to their resilience in maintaining effective social networks (Fiori, Smith, & Antonucci, 2007). But for some, tragically, the social convoy breaks down. We will also explore the circumstances in which older people experience abuse and neglect at the hands of those close to them.

Marriage

Even with the high U.S. divorce rate, one in every four or five first marriages is expected to last at least 50 years. Walt's comment to Ruth that "the last few decades have been the happiest" characterizes the attitudes and behaviors of many aging couples who have spent their adult lives together. Marital satisfaction rises from middle to late adulthood, when it is at its peak (Ko

et al., 2007; Levenson, Carstensen, & Gottman, 1993). Several changes in life circumstance and couples' communication underlie this trend.

First, late-life marriages involve fewer stressful responsibilities that can negatively affect relationships, such as rearing children and balancing demands of career and family (Diamond, Fagundes, & Butterworth, 2010). Second, perceptions of fairness in the relationship increase as men participate more in household tasks after retirement. For older adults who experienced little social pressure for gender equality in their youth, division of labor in the home still reflects traditional roles. Men take on more home maintenance projects, whereas women's duties—cooking, cleaning, laundry, and shopping—continue as before. Among adults retiring today, "feminine" tasks are more equally shared than they were during work life (Kulik, 2001). In either case, men's increased involvement at home often results in a greater sense of equity in marriage than before. Third, with extra time together, the majority of couples engage in more joint leisure activities, which—especially for women—enhances sense of marital closeness (Trudel et al., 2008).

Fourth, greater emotional understanding and emphasis on regulating emotion in relationships lead to more positive interactions between spouses. Compared to younger couples, aging couples rate their relationship as higher in quality, disagree less often, and resolve their differences in more constructive ways. Even in unhappy marriages, older adults are less likely to let their disagreements escalate into expressions of anger and resentment (Hatch & Bulcroft, 2004). For example, when Dick complained about Goldie's cooking, Goldie tried to appease him: "All right, Dick, next birthday I won't make cheesecake." And when Goldie brought up Dick's bickering and criticism, Dick usually said, "I know, dear," and retreated to another room. As in other relationships, seniors protect themselves from stress by molding marital ties to make them as pleasant as possible.

As Dick and Goldie's exchanges illustrate, aging married couples do admit to times their partner gets on their nerves or

TIM GRAHAM/GETTY IMAGES

After retirement, couples have more time to devote to joint leisure activities, which contributes to the rise in marital satisfaction from middle to late adulthood.

makes too many demands—more so than they say their adult children or best friends do (Birditt, Jackey, & Antonucci, 2009). But these expressions are mild, and they likely result from frequent contact, yielding greater opportunity for minor annoyances.

Finally, compared to their single agemates, married seniors generally have larger social networks of both family members and friends, with whom they interact more frequently. As long as older adults report mostly high-quality ties, this relationship profile provides for social engagement and support from a variety of sources and is linked to higher psychological well-being (Birditt & Antonucci, 2007; Fiori, Smith, & Antonucci, 2007). Perhaps because of these benefits, simply having an intimate relationship is health-protective and is associated with increased longevity (Manzoli et al., 2007).

When marital dissatisfaction exists, however, even having close, high-quality friendships cannot reduce its profoundly negative impact on adjustment. A poor marriage often takes a greater toll on women than on men (Birditt & Antonucci, 2007; Whisman et al., 2006). Recall from Chapter 14 that women more often try to work on a troubling relationship, yet in late life, expending energy in this way is especially taxing, both physically and mentally. Men, in contrast, are more likely to protect themselves by withdrawing and avoiding discussion.

Gay and Lesbian Partnerships

Older gays and lesbians in long-term partnerships have sustained their relationships through a historical period of hostility and discrimination. Nevertheless, most report happy, highly fulfilling relationships, pointing to their partner as their most important source of social support. Compared with gay and lesbian seniors who live alone, couples rate their physical and mental health more favorably (Grossman, 2006).

A lifetime of effective coping with an oppressive social environment may have strengthened homosexuals' skill at dealing with late-life physical and social changes, thereby contributing to a satisfying partnership (Gabbay & Wahler, 2002). And changing social conditions, including the greater ease with which younger generations embrace their sexual minority identities and “come out,” may have encouraged more older adults to do the same, with benefits for their well-being (Cohler & Hostetler, 2007). Also, greater gender-role flexibility enables gay and lesbian couples to adapt easily to sharing household tasks following retirement.

Because of imagined or real strain in family relationships when they told others about their homosexuality, gays and lesbians less often assume that family members will provide support in old age. Consequently, many have forged strong friendships to replace or supplement family ties (Richard & Brown, 2006). Homosexual couples with gratifying friendship networks report high life satisfaction and less fear of aging (Slusher, Mayer, & Dunkle, 1996).

Nevertheless, because of continuing prejudice and lack of societal recognition of their partnerships, aging gays and lesbians face unique challenges. Health-care systems are often

unresponsive to their unique needs. And where gay and lesbian unions are not legally recognized (in most U.S. states), if one partner becomes frail or ill, the other may not be welcome in hospitals or nursing homes or be allowed to participate in health-care decisions—an issue we will return to in Chapter 19. These circumstances can make late-life declines and losses especially painful.

Divorce, Remarriage, and Cohabitation

When Walt's uncle Louie was 65, he divorced his wife Sandra after 32 years of marriage. Although she knew the marriage was far from perfect, Sandra had lived with Louie long enough that the divorce came as a shock. A year later, Louie married Rachella, a divorcée who shared his enthusiasm for sports and dance.

Couples who divorce in late adulthood constitute less than 5 percent of all U.S. divorces in any given year (Elliott & Simmons, 2011). But the divorce rate among people age 65 and older has increased over the past three decades as new generations of seniors—especially the baby boomers—have become accepting of marital breakup as a means of attaining self-fulfillment and as the divorce risk has risen for second and subsequent marriages.

Although one-fifth of older adults' dissolving marriages are of less than 10 years duration, about half are lengthy—30 years or more (Brown & Lin, 2012). Compared with younger adults, longtime married older people have given their adult lives to the relationship. Following divorce, they find it harder to separate their identity from that of their former spouse and, therefore, may experience a greater sense of personal failure. Relationships with family and friends shift at a time when close bonds are crucial for psychological well-being.

As in middle adulthood, aging women are more likely than men to initiate divorce. This is despite the fact that the financial consequences for women generally are severe—greater than for widowhood because many accumulated assets are lost in property settlements (McDonald & Robb, 2004; Wu & Schimmele, 2007). Still, older people of both genders seldom express regret over leaving an unhappy marriage (Bair, 2007). Usually, they experience a sense of relief.

Remarriage rates are low in late adulthood and decline with age, though remarriage is more likely after divorce than after widowhood. Aging baby boomers—accustomed to using the Internet for many purposes—are increasingly turning to contemporary ways of searching for new partners, including online dating services and personal ads, though they use dating sites far less often than younger people do. But older peoples' personal ads indicate that they are more selective with respect to the age, race, religion, and income of a potential dating partner (McIntosh et al., 2011). And as Figure 18.2 on page 622 shows, they more often refer to their own health issues and loneliness and less often to romance, sex, desire for a soulmate, and adventure than middle-aged people do (Alterovitz & Mendelsohn, 2013). In their search for the right person, seniors seem to take a candid, no-nonsense approach!

FIGURE 18.2 Themes in online personal ads of middle-aged and older adults seeking dating partners. An analysis of themes in 450 ads revealed that older adults more often mention health issues and loneliness, whereas middle-aged adults place greater emphasis on romance, sex, finding a soulmate, and adventure. Seniors appear to be practical and direct in their search for a partner. (From S. S. R. Alterovitz and G. A. Mendelsohn, 2013, "Relationship Goals of Middle-Aged, Young-Old, and Old-Old Internet Daters: An Analysis of Online Personal Ads." *Journal of Aging Studies*, 27, p. 163. Copyright © 2013, Elsevier. Reprinted by permission of Elsevier, Inc.)

Men more often succeed in finding a marriage partner than women, as their opportunities to do so are far greater. Nevertheless, increasing age makes remarriage less likely for both men and women, who frequently say they don't want to marry again (Calasanti & Kiecolt, 2007; Mahay & Lewin, 2007). Common reasons include poorer health, a shortened future (making it hard to justify radical life change), concerns about adult children's acceptance of the new partner, desire to protect their estate, and (especially for women) past negative experiences with marriage (Wu & Schimmele, 2007). Divorced men who remain single, however, no longer benefit from their former wives' kin-keeping role, are more likely to experience reduced contact and support from adult children, and more often move away from friends and neighbors (Daatland, 2007). For these reasons, they are at greater risk for adjustment difficulties.

Compared with younger people who remarry, seniors who do so enter more stable relationships, as their divorce rate is much lower. In Louie and Rachella's case, the second marriage lasted for 28 years! Perhaps late-life remarriages are more successful because they involve more maturity, patience, and a better balance of romantic with practical concerns. Remarried older couples are generally very satisfied with their new relationships, although men tend to be more content than women (Clarke, 2005; Connidis, 2010). With fewer potential mates, perhaps women who remarry in late life settle for less desirable partners.

Rather than remarrying, seniors who enter a new relationship are increasingly choosing cohabitation, a trend expected to continue as more baby boomers—the first generation to cohabit at high rates in early adulthood—reach late life. Like remarriage,

cohabitation results in more stable relationships and higher relationship quality than it did at younger ages. And cohabiting seniors are as satisfied with their partnered lives as are their married counterparts (Brown & Kawamura, 2010). This suggests that cohabitation is distinctive in late adulthood, serving as a long-term alternative to marriage.

Widowhood

Walt died shortly after Ruth turned 80. Like over 70 percent of widowed seniors, Ruth described the loss of her spouse as the most stressful event of her life. As two researchers noted, being widowed means that the survivor has "lost the role and identity of being a spouse (being married and doing things as a couple), which is potentially one of the most pervasive, intense, intimate, and personal roles that they have ever had in their life" (Lund & Caserta, 2004a, p. 29). Ruth felt lonely, anxious, and depressed for several months after the funeral.

Widows make up about one-third of older adults in industrialized nations. Because women live longer than men and are less likely to remarry, more than 40 percent of U.S. women age 65 and older are widowed, compared with just 13 percent of men (U.S. Census Bureau, 2012b).

Ethnic minorities with high rates of poverty and chronic disease are more likely to be widowed.

Earlier we mentioned that most widows and widowers live alone rather than in extended families, a trend that is stronger for whites than for ethnic minorities. Though less well-off financially than married seniors, most want to retain control over their time and living space and to avoid disagreements with

Because most men rely on their wives for social connectedness, they are less prepared than women to overcome the loneliness of widowhood. This widower, however, makes an effort to connect socially with neighbors by hosting a backyard barbecue.

their adult children. Widowed aging adults who relocate usually move closer to family but not into the same residence.

The greatest problem for recently widowed older people is profound loneliness (Connidis, 2010). But adaptation varies widely, depending on age, social support, and personality. Aging adults have fewer lasting problems than younger individuals who are widowed, probably because death in later life is viewed as less unfair (Bennett & Soulsby, 2012). And most widowed seniors—especially those with outgoing personalities and high self-esteem—are resilient in the face of loneliness (Moore & Stratton, 2002; van Baarsen, 2002). To sustain continuity with their past, they try to preserve social relationships that were important before the spouse's death and report that relatives and friends respond in kind, contacting them at least as often as before (Utz et al., 2002). Also, the stronger older adults' sense of self-efficacy in handling tasks of daily living, the more favorably they adjust (Fry, 2001).

Nevertheless, widowed individuals must reorganize their lives, reconstructing an identity that is separate from the deceased spouse. Wives whose roles depended on their husbands' typically find this harder than those who developed rewarding roles of their own. But overall, men show more physical and mental health problems and greater risk of mortality than women, for several reasons (Bennett, Smith, & Hughes, 2005; Shor et al., 2012). First, because most men relied on their wives for social connectedness, household tasks, promotion of healthy behaviors, and coping with stressors, they are less prepared than women for the challenges of widowhood. Second, because of gender-role expectations, men feel less free to express their emotions or to ask for help with meals, household tasks, and social relationships (Bennett, 2007; Lund & Caserta, 2004b). Finally, men tend to be less involved in religious activities—a vital source of social support and inner strength.

In two studies of older widowers, those in their seventies reported the most depression and showed the slowest rate of improvement over the following two years. The death of their wives occurred around the time they were adjusting to retirement, resulting in two major changes at once, with widowhood highly unexpected because most wives outlive their husbands (Lund & Caserta, 2001, 2004a). African-American widowers, however, show no elevated risk of mortality over their married agemates, and they report less depression than Caucasian widowers (Elwert & Christakis, 2006). Perhaps greater support from extended family and church is responsible.

Sex differences in the experience of widowhood contribute to men's higher remarriage rate. Women's kinkeeper role (see Chapter 16, page 545) and ability to form close friendships may lead them to feel less need to remarry. In addition, because many women share the widowed state, they probably offer one another helpful advice and sympathy. In contrast, men often lack skills for maintaining family relationships, forming emotionally satisfying ties outside marriage, and handling the chores of their deceased wives.

Still, most widowed seniors fare well within a few years, resembling their married counterparts in psychological well-

being. Older widows and widowers who participated in several months of weekly classes providing information and support in acquiring daily living skills felt better prepared to manage the challenges of widowed life (Caserta, Lund, & Obray, 2004). Those who emerge from this traumatic event with a sense of purpose in life and with confidence in their ability to meet everyday challenges often experience stress-related personal growth (Caserta et al., 2009). Many report a new-found sense of inner strength, greater appreciation of close relationships, and reevaluation of life priorities. Applying What We Know on page 624 suggests a variety of ways to foster adaptation to widowhood in late adulthood.

Never-Married, Childless Older Adults

Shortly after Ruth and Walt's marriage in their twenties, Ruth's father died. Her sister Ida continued to live with and care for their mother, who was in ill health until she died 16 years later. When, at age 25, Ida received a marriage proposal, she responded, "I can't marry anybody while my mother is still living. I'm expected to look after her." Ida's decision was not unusual for a daughter of her day. She never married or had children.

About 5 percent of older Americans have remained unmarried and childless throughout their lives. Almost all are conscious of being different from the norm, but most have developed alternative meaningful relationships. Ida, for example, formed a strong bond with a neighbor's son. In his childhood, she provided emotional support and financial assistance, which helped him overcome a stressful home life. He included Ida in family events and visited her regularly until she died. Other nonmarried seniors speak of the centrality of extended family and of younger people in their social networks—often nieces and nephews—and of influencing them in enduring ways

SUSAN WATTS/NY DAILY NEWS VIA GETTY IMAGES

For this never-married older adult, a warm relationship with his great-nephew provides a sense of family connection and an opportunity to influence a member of a younger generation.

Applying What We Know

Fostering Adaptation to Widowhood in Late Adulthood

Suggestion	Description
Self	
Mastery of new skills of daily living	Especially for men, learning how to perform household tasks such as shopping and cooking, to sustain existing family and friendship ties, and to build new relationships is vital for positive adaptation.
Family and Friends	
Social support and interaction	Social support and interaction must extend beyond the grieving period to ongoing assistance and caring relationships. Family members and friends can help most by making support available while encouraging the widowed older adult to use effective coping strategies.
Community	
Senior centers	Senior centers offer communal meals and other social activities, enabling widowed and other older adults to connect with people in similar circumstances and to gain access to other community resources, such as listings of part-time employment and available housing.
Support groups	Support groups can be found in senior centers, religious institutions, and other agencies. Besides new relationships, they offer an accepting atmosphere for coming to terms with loss, effective role models, and assistance with developing skills for daily living.
Religious activities	Involvement in a church, synagogue, or mosque can help relieve the loneliness associated with loss of a spouse and offer social support, new relationships, and meaningful roles.
Volunteer activities	One of the best ways for widowed older adults to find meaningful roles is through volunteer activities. Some are sponsored by formal service organizations, such as the Red Cross or the Retired and Senior Volunteer Program. Other volunteer programs exist in hospitals, senior centers, schools, and charitable organizations.

(Wenger, 2009; Wenger & Burholdt, 2001). In addition, same-sex friendships are key in never-married older women's lives (McDill, Hall, & Turell, 2006). These tend to be unusually close and often involve joint travel, periods of coresidence, and associations with each other's extended families.

Never-married, childless men are more likely than women to feel lonely and depressed. And without pressure from a partner to maintain a healthy lifestyle, they engage in more unhealthy behaviors. Hence, their physical and mental health is poor compared with their married counterparts (Kendig et al., 2007). Never-married older women report a level of well-being equivalent to that of married older adults and greater than that of divorcees and recently widowed seniors. Only when they cannot maintain social contacts because of declining health do they report feeling lonely (Dykstra, 2009).

Because friendships are not the same as blood ties when it comes to caregiving, being unmarried and childless in very old age reduces the likelihood of informal personal care (Chang, Wilber, & Silverstein, 2010; Wenger, 2009). And with close ties weighted toward friends, nonmarried childless seniors lose more network members with increasing age (Dykstra, 2006). Still, most say that some informal support is available.

Siblings

Nearly 80 percent of Americans age 65 and older have at least one living sibling. Most live within 100 miles of each other, communicate regularly, and visit at least several times a year. Both

men and women describe closer bonds with sisters than with brothers. Perhaps because of women's greater emotional expressiveness and nurturance, the closer the tie to a sister, the higher older people's psychological well-being (Van Volkom, 2006).

Aging siblings in industrialized nations are more likely to socialize than to provide one another with direct assistance because most older adults turn first to their spouse and children. Nevertheless, siblings seem to be an important "insurance policy" in late adulthood. After age 70, aid from siblings living near one another rises (White, 2001). Widowed and never-married seniors have more contacts with siblings, perhaps because they have fewer competing family relationships, and they also are more likely to receive sibling support when their health declines (Connidis, 2010). For example, when Ida's Alzheimer's symptoms worsened, Ruth came to her aid. Although Ida had many friends, Ruth was her only living relative.

Friendships

As family responsibilities and vocational pressures lessen, friendships take on increasing importance. Having friends is an especially strong predictor of mental health among seniors (Rawlins, 2004). Older adults report more favorable experiences with friends than with family members, in part because of the pleasurable leisure activities shared with friends (Larson, Mannell, & Zuzanek, 1986). Unique qualities of friendship interaction—openness, spontaneity, mutual caring, and common interests—are also influential.

Functions of Late-Life Friendships. The diverse functions of friendship in late adulthood clarify its profound significance:

- *Intimacy and companionship are basic to meaningful late-life friendships.* As Ida and her best friend, Rosie, took walks, went shopping, or visited each other, they disclosed their deepest sources of happiness and worry, engaged in pleasurable conversation, laughed, and had fun. Older adults' descriptions of their close friendships reveal that mutual interests, feelings of belongingness, and opportunities to confide in each other sustain these bonds over time (Field, 1999).
- *Late-life friends help shield each other from negative judgments stemming from stereotypes of aging.* "Where's your cane, Rosie?" Ida asked when the two women were about to leave for a restaurant. "Come on, don't be self-conscious. When y'get one of those 'you're finished' looks from someone, just remember: In the Greek village where my mother grew up, there was no separation between generations, so the young ones got used to wrinkled skin and weak knees. And we older women were recognized as the wise ones (Deveson, 1994). Why, we were midwives, matchmakers, experts in herbal medicine; we knew about everything!"
- *Friendships link aging adults to the larger community.* For seniors who cannot go out as often, interactions with friends can keep them abreast of events in the wider world. "Rosie," Ida reported, "did you know the Thompson girl was named high school valedictorian . . . and the city council is voting on the living-wage act tonight?" Friends can also open up new experiences, such as travel or participation in community activities.
- *Friendships help protect seniors from the psychological consequences of loss.* Older people in declining health who

remain in contact with friends through phone calls and visits show improved psychological well-being (Fiori, Smith, & Antonucci, 2007). Similarly, when close relatives die, friends offer compensating social supports.

Characteristics of Late-Life Friendships. Although older adults prefer familiar, established relationships over new ones, friendship formation continues throughout life. Ties to old and dear friends who live far away are maintained, with growing numbers of seniors staying in touch with the aid of e-mail and social networking sites, such as Facebook (see page 599 in Chapter 17). Nevertheless, with age, seniors report that the friends they interact with most often and feel closest to live in the same community.

As in earlier years, older people tend to choose friends whose age, sex, ethnicity, and values resemble their own. Compared with younger people, fewer report other-sex friendships. But some have them—usually long-standing ones dating back several decades. Seniors continue to benefit uniquely from these ties, obtaining an insider's view of the thoughts, feelings, and behavior of members of the other sex (Monsour, 2002). As age-mates die, the very old report more intergenerational friends—both same- and other-sex (Johnson & Troll, 1994). In her eighties, Ruth spent time with Margaret, a 55-year-old widow she met while serving on the board of directors of an adoption agency. Two or three times a month, Margaret came to Ruth's home for tea and lively conversation.

Sex differences in friendship, discussed in previous chapters, extend into late adulthood. Women are more likely to have intimate friends; men depend on their wives and, to a lesser extent, their sisters for warm, open communication (Waite & Das, 2013). Also, older women have more **secondary friends**—people who are not intimates but with whom they spend time occasionally, such as a group that meets for lunch, bridge, or museum tours. Through these associates, older adults meet new people, remain socially involved, and gain in psychological well-being (Blieszner & Roberto, 2012).

In late-life friendships, affection and emotional support are both given and received to maintain balance in the relationship. Although friends call on each other for help with tasks of daily living, they generally do so only in emergencies or for occasional, limited assistance. Seniors with physical limitations whose social networks consist mainly of friends and who therefore must rely frequently on them for help tend to report low psychological well-being (Fiori, Smith, & Antonucci, 2007). Feelings of excessive dependency and of being unable to reciprocate are probably responsible.

Relationships with Adult Children

About 80 percent of older adults in Western nations are parents of living children, most of whom are middle-aged. In Chapter 16, we noted that exchanges of help vary with the closeness of the parent-child bond and the needs of the parent and adult child. Recall, also, that over time, parent-to-child help declines, whereas child-to-parent assistance increases. Older adults and

AGE FOTOSTOCK/ROBERT HARDING

On a village street in Cyprus, these older adults often meet to play backgammon. Even after physical mobility declines, many seniors find ways to sustain ties with friends, who offer companionship, links to the larger community, and social support.

their adult children are often in touch, even when they live far from each other. But as with other ties, quality rather than quantity of interaction affects older adults' life satisfaction. In diverse ethnic groups and cultures, warm bonds with adult children reduce the negative impact of physical impairments and other losses (such as death of a spouse) on psychological well-being (Ajrouch, 2007; Milkie, Bierman, & Schieman, 2008). Alternatively, conflict or unhappiness with adult children contributes to poor physical and mental health.

Although aging parents and adult children in Western nations provide each other with various forms of help, level of assistance is typically modest. Older adults in their sixties and seventies—especially those who own their own home and who are married or widowed as opposed to divorced—are more likely to be providers than recipients of help, suggesting SES variations in the balance of support (Grundy, 2005). This balance shifts as older adults age, but well into late adulthood, seniors in Western nations give more than they receive, especially in financial support but also in practical assistance—a circumstance that contradicts stereotypes of older adults as “burdens” on younger generations (HSBC & Oxford Institute of Ageing, 2007).

Interviews with parents age 75 and older in five Western nations revealed that in all countries, aid received from adult children most often took the form of emotional support. Fewer than one-third said their children assisted with household chores and errands. Aging parents who provided more help of various kinds than they received scored highest in life satisfaction, those receiving more help than they gave scored lowest, while those in a balanced exchange fell in between (Lowenstein, Katz, & Gur-Yaish, 2007). To avoid dependency, older people usually do not seek children's practical assistance in the absence of a pressing need, and they express annoyance when children are overprotective or help unnecessarily (Spitze & Gallant, 2004). Moderate support, with many opportunities to reciprocate, is beneficial, fostering self-esteem and sense of family connection. Again, extensive support that cannot be returned is linked to poor well-being.

Sex differences in older parent–adult child interaction are evident. Both mothers and fathers feel ambivalent toward adult offspring with problematic lives—who are financially needy, emotionally troubled, or experiencing marital problems. But mothers are more likely to have adult children who feel similarly ambivalent toward them, perhaps because mothers more often express their mixed feelings (Fingerman et al., 2006).

Feelings of ambivalence undermine the psychological well-being of both adult children and their aging parents (Fingerman et al., 2008). But aging parents' ambivalence toward children is typically low. Consistent with socioemotional selectivity theory, older parents are more likely to describe their family ties as solely close rather than ambivalent (Fingerman, Hay, & Birditt, 2004; Willson et al., 2006). Mother–daughter ties are particularly warm, although competing demands in middle-aged daughters' busy lives may leave less time to devote to the relationship than each would like (see page 550 in Chapter 16).

As social networks shrink in size, relationships with adult children become more important sources of family involvement. People 85 years and older with children have substantially more contacts with relatives than do those without children (Hooyman & Kiyak, 2011). Why is this so? Consider Ruth, whose daughter Sybil linked her to grandchildren, great-grandchildren, and relatives by marriage. When childless adults reach their eighties, siblings, other same-age relatives, and close friends may have become frail or died and hence may no longer be available as companions.

Relationships with Adult Grandchildren and Great-Grandchildren

Seniors with adult grandchildren and great-grandchildren benefit from a wider potential network of support. Ruth and Walt saw their granddaughter, Marci, and their great-grandson, Jamel, at family gatherings. In between, they occasionally Skyped with Marci and Jamel, which enabled face-to-face communication despite physical distance. And Ruth and Walt used Facebook regularly to keep up with Marci and Jamel's activities. Staying in touch with grandchildren and other family members is the primary reason seniors say they use social networking sites (Zickuhr & Madden, 2012).

In developed nations, slightly more than half of adults over age 65 have a grandchild who is at least 18 years old (AARP, 2002). In the few studies available on grandparent–adult grandchild relationships, the overwhelming majority of grandchildren felt obligated to assist grandparents in need, more so if they had forged an affectionate bond (Even-Zohar, 2011; Fruhauf,

© ALIORA PHOTOS/ROBERT HARDING

Grandparents regard ties with adult grandchildren as a vital link between themselves and the future. And great-grandparents comment that this new role reaffirms the continuity of their families. This Japanese 102-year-old describes meeting her great-great-grandchild as “like jumping into heaven.”

Jarrott, & Allen, 2006). Grandparents expect affection (but not practical help) from grandchildren, and in most cases they receive it. They regard the adult grandchild tie as very gratifying—a vital link between themselves and the future.

Still, grandparent–adult grandchild relationships vary greatly. Degree of grandparent involvement during childhood strongly predicts the quality of the current relationship. Often, the tie with one grandchild is “special,” characterized by more frequent contact, mutual expressions of affection, and enjoyable times together—factors that enhance older adults’ psychological well-being (Fingerman, 1998). Relationships with grandmothers tend to be closer, with maternal grandmother–granddaughter bonds the closest, as was so when grandchildren were younger (Sheehan & Petrovic, 2008). However, as grandparents and grandchildren move through life, contact declines. Many grandchildren establish distant homes and become immersed in work, family, and friendship roles that compete for time with extended-family members.

LOOK AND LISTEN

Interview one or two seniors with adult grandchildren about the quality and personal meaning of those relationships. ●

But despite less contact, grandparents’ affection for their adult grandchildren strengthens with age, usually exceeding grandchildren’s expressed closeness toward their grandparents (which is still strong) (Giarrusso et al., 2001; Harwood, 2001). This difference in emotional investment reflects each generation’s distinct needs and goals—adult grandchildren in establishing independent lives, grandparents in preserving family relationships and continuity of values across generations. Grandchildren become increasingly important sources of emotional meaning for seniors in the last decade or two of life.

About 40 percent of older adults have great-grandchildren (Hooyma & Kiyak, 2011). Although most describe their new role as limited and a sign of advancing age, they welcome it with enthusiasm, commenting that it reaffirms the continuity of their families. Parents mediate contact with great-grandchildren, as they did with young grandchildren (see Chapter 16).

Elder Maltreatment

Although the majority of older adults enjoy positive relationships with family members, friends, and professional caregivers, some suffer maltreatment at the hands of these individuals. Through recent media attention, elder maltreatment has become a serious public concern.

Reports from many industrialized nations reveal widely varying rates of maltreatment, from 3 to 28 percent in general population studies. Overall, 7 to 10 percent of U.S. older adults say they were targets during the past month, amounting to 3 to 4 million victims (Acierno et al., 2010). Elder maltreatment crosses ethnic lines, although it is lower in Asian, Hispanic, and Native-American groups with strong traditions of respect for and obligation to the aged and highly disapproving attitudes

toward harming them (Sherman, Rosenblatt, & Antonucci, 2008). Yet all figures substantially underestimate the actual incidence, because most abusive acts take place in private, and victims are often unable or unwilling to complain.

Elder maltreatment usually takes the following forms:

- *Physical abuse.* Intentional infliction of pain, discomfort, or injury, through hitting, cutting, burning, physical force, restraint, sexual assault, and other acts
- *Physical neglect.* Intentional or unintentional failure to fulfill caregiving obligations, resulting in lack of food, medication, or health services or in the older person being left alone or isolated
- *Emotional abuse.* Verbal assaults (such as name calling), humiliation (being treated as a child), and intimidation (threats of isolation or placement in a nursing home)
- *Sexual abuse.* Unwanted sexual contact of any kind
- *Financial abuse.* Illegal or improper exploitation of the aging person’s property or financial resources, through theft or use without consent

Financial abuse, emotional abuse, and neglect are the most frequently reported types. Often several forms occur in combination (Anetzberger, 2005; National Academies Committee on National Statistics, 2010). The perpetrator is usually a person the older adult trusts and depends on for care and assistance.

Most abusers are family members—spouses (usually men), followed by children of both sexes and then by other relatives. Some are friends, neighbors, and in-home caregivers (National Center on Elder Abuse, 2013). Abuse in nursing homes is a major concern: From 6 to 40 percent of caregivers admit to having committed at least one act in the previous year (Schiamberg et al., 2011).

Over the past several decades, another form of neglect—referred to in the media as “granny dumping”—has risen: abandonment of older adults with severe disabilities by family caregivers, usually at hospital emergency rooms (Fulmer, 2008). Overwhelmed, their caregivers seem to have concluded that they have no other option but to take this drastic step. (See pages 549–551 in Chapter 16 and pages 586–587 in Chapter 17 for related research.)

Risk Factors. Characteristics of the victim, the abuser, their relationship, and its social context are related to the incidence and severity of elder maltreatment. The more of the following risk factors that are present, the greater the likelihood that abuse and neglect will occur.

Dependency of the Victim. Very old, frail, and mentally and physically impaired older adults are more vulnerable to maltreatment, with as many as 25 percent affected (Reay & Browne, 2008; Selwood & Cooper, 2009). This does not mean that declines in functioning cause abuse. Rather, when other conditions are ripe for maltreatment, older people with severe

© SIMON RAWLES/ALAMY

This older adult, who suffers from depression and physical disabilities, lives in a dilapidated rooming house. When conditions are ripe for elder maltreatment, those with severe impairments are least able to protect themselves.

disabilities are least able to protect themselves. Those with physical or cognitive impairments may also have personality traits that make them vulnerable—a tendency to lash out when angry or frustrated, a passive or avoidant approach to handling problems, and a low sense of self-efficacy (Salari, 2011). The worse the caregiver–recipient relationship, the greater the risk of elder abuse of all kinds, particularly when that relationship has a long negative history.

Dependency of the Perpetrator. Many abusers are dependent, emotionally or financially, on their victims. This dependency, experienced as powerlessness, can lead to aggressive, exploitative behavior. Often the perpetrator–victim relationship is one of mutual dependency (Fryling, Summers, & Hoffman, 2006). The abuser needs the older person for money or housing, and the older person needs the abuser for assistance with everyday tasks or to relieve loneliness.

Psychological Disturbance and Stress of the Perpetrator. Abusers are more likely than other caregivers to have psychological problems and to be dependent on alcohol or other drugs (Nerenberg, 2010). Often they are socially isolated, have difficulties at work, or are unemployed, with resulting financial worries. These factors increase the likelihood that they will lash out when caregiving is highly demanding or the behavior of an older adult with dementia is irritating or hard to manage.

History of Family Violence. Elder abuse is often part of a long history of family violence. Adults who were abused as children are at increased risk of harming older adults (Reay & Browne, 2008). In Chapter 8, we showed how aggressive cycles between family members can easily become self-sustaining,

leading to the development of individuals who cope with anger through hostility toward others. In many instances, elder abuse is an extension of years of partner abuse (Walsh et al., 2007).

Institutional Conditions. Elder maltreatment is more likely to occur in nursing homes that are rundown and overcrowded and that have staff shortages, minimal staff supervision, high staff turnover, and few visitors (Schiamberg et al., 2011). Highly stressful work conditions combined with minimal oversight of caregiving quality set the stage for abuse and neglect.

Preventing Elder Maltreatment. Preventing elder maltreatment by family members is especially challenging. Victims may fear retribution; wish to protect abusers who are spouses, sons, or daughters; or feel embarrassed that they cannot control the situation. And they may be intimidated into silence or not know where to turn for help (Summers & Hoffman, 2006). Once abuse is discovered, intervention involves immediate protection and provision of unmet needs for the older adult and of mental health services and social support for the spouse or caregiver.

Prevention programs offer caregivers counseling, education, and respite services, such as elder day care and in-home help. Trained volunteer “buddies” who make visits to the home can combat social isolation of aging adults and assist them with problem solving to avoid further harm. Support groups help seniors identify abusive acts, practice appropriate responses, and form new relationships. And agencies that provide informal financial services to older people who are unable to manage on their own, such as writing and cashing checks and holding valuables in a safe, reduce financial abuse.

When elder abuse is extreme, legal action offers the best protection, yet it is rare. Many victims are reluctant to initiate court procedures or, because of mental impairments, cannot do so. In these instances, social service professionals must help caregivers rethink their role, even if it means that the aging person might be institutionalized. In nursing homes, improving staff selection, training, and working conditions can greatly reduce abuse and neglect.

LOOK AND LISTEN

Contact the your state’s department of senior services. Find out about its policies and programs aimed at preventing elder abuse. ●

Combating elder maltreatment also requires efforts at the level of the larger society, including public education to encourage reporting of suspected cases and improved understanding of the needs of older people. As part of this effort, seniors benefit from information on where to go for help (National Center on Elder Abuse, 2013). Finally, countering negative stereotypes of aging reduces maltreatment because recognizing older adults’ dignity, individuality, and autonomy is incompatible with acts of physical and psychological harm.

ASK YOURSELF

REVIEW Why is adjustment to late-life divorce usually more difficult for women and adjustment to widowhood more difficult for men?

CONNECT Sex differences in friendship extend from childhood to late adulthood. What factors probably contribute to their lifelong persistence?

APPLY At age 51, Mae lost her job, couldn't afford to pay rent, and moved in with her 78-year-old widowed mother, Beryl. Although Beryl welcomed Mae's companionship, Mae grew depressed, drank heavily, and stopped looking for work. When Beryl complained about Mae's behavior, Mae pushed and slapped her. Explain why this mother–daughter relationship led to elder abuse.

REFLECT If you have living grandparents, describe your relationship with one or more of them. How have you and your grandparent contributed to each other's development?

Retirement

In Chapter 16, we noted that the period of retirement has lengthened because of increased life expectancy and a steady decline in average age of retirement—trends that have occurred in all Western industrialized nations. These changes have also led to a blurring of the distinction between work and retirement. Because mandatory retirement no longer exists for most workers in Western countries, older adults have more choices about when to retire and how they spend their time.

The late-2000s recession has had only a modest impact on raising the retirement age of the baby boomers (see page 557). Still, according to surveys of adults in many countries, the majority of baby boomers say they want to work longer, with one-third indicating that devoting some time to work is important for a happy retirement (HSBC & Oxford Institute of Ageing, 2007, 2011). Currently, nearly 40 percent of U.S. adults age 65 to 69, and nearly 20 percent of those in their seventies, are still working in some capacity.

As these figures suggest, the contemporary retirement process is highly variable: It may include a planning period, the decision itself, diverse acts of retiring, and continuous adjustment and readjustment of activities for the rest of the life course. The majority of U.S. older adults with career jobs retire gradually by cutting down their hours and responsibilities. Many take *bridge jobs* (new part-time jobs or full-time jobs of shorter duration) that serve as transitions between full-time career and retirement (Wang, 2011). Others leave their jobs but later return to paid work and even start new careers, desiring to introduce interest and challenge into their lives, to supplement limited financial resources, or both. Today, retirement is not a single

event but rather a dynamic process with multiple transitions serving different purposes.

In the following sections, we examine factors that affect the decision to retire, happiness during the retirement years, and leisure and volunteer pursuits. We will see that the process of retirement and retired life reflect an increasingly diverse retired population.

The Decision to Retire

When Walt and Ruth retired, both had worked long enough to be eligible for comfortable income-replacement benefits—Walt's through the government-sponsored Social Security program, Ruth's through a private pension plan. In addition, they had planned for retirement (see Chapter 16, pages 556–558), with a projected date for leaving the work force. They wanted to retire early enough to pursue leisure activities while both were in good health. In contrast, Walt's brother Dick was forced to retire as the operating costs of his bakery rose while his clientele declined. He looked for temporary employment in sales while his wife, Goldie, kept her part-time job as a bookkeeper to help cover living expenses.

Affordability of retirement is usually the first consideration in the decision to retire. Yet despite economic concerns, many preretirees decide to let go of a steady work life in favor of alternative, personally meaningful work, leisure, or volunteer activities. “I had been working since I was 10 years old,” said one retired auto worker. “I wanted a rest.” Exceptions to this favorable outlook are people like Dick—forced into retirement or earning very low wages—who often take bridge jobs reluctantly to make ends meet (Cahill, Giandrea, & Quinn, 2006).

Figure 18.3 on page 630 summarizes personal and workplace factors in addition to income that influence the decision to retire. People in good health, for whom vocational life is central to self-esteem, and whose work environments are pleasant and interesting are likely to keep on working. For these reasons, individuals in high-earning professional occupations usually retire later than those in blue-collar or clerical positions. And when they do retire, they more often shift to stimulating bridge jobs, with some retiring and returning to the work force multiple times (Feldman & Beehr, 2011; Wang et al., 2009). Self-employed older adults also work longer, probably because they can flexibly adapt their job's physical and cognitive demands and working hours to fit their changing capacities and needs (Feldman & Vogel, 2009). In contrast, people in declining health, who are engaged in routine, boring work, who have pleasurable leisure or family pursuits, or who otherwise perceive a decline in the fit of their work with their skills and interests often opt for retirement.

Societal factors also affect retirement decisions. When many younger, less costly workers are available to replace older workers, industries are likely to offer added incentives for people to retire, such as increments to pension plans and earlier benefits—a trend that has, until recently, contributed to many early retirements in Western nations. But when concern

FIGURE 18.3 Personal and workplace factors that influence the decision to retire.

increases about the burden on younger generations of an expanding population of retirees, eligibility for retirement benefits may be postponed to a later age.

Retirement decisions vary with gender. On average, women retire earlier than men, largely because family events—a spouse's retirement or the need to care for an ill partner or parent—play larger roles in their decisions (Moen et al., 2006). Women in or near poverty, however, are an exception (DeVaney, 2008). Lacking financial resources to retire, many continue working into old age.

In most Western nations, generous social security benefits make retirement feasible for the economically disadvantaged and sustain the standard of living of most workers after they retire. The United States is an exception: Many U.S. retirees, especially those who held low-income jobs without benefits, experience falling living standards. Denmark, France, Germany, Finland, and Sweden have gradual retirement programs in which older employees reduce their work hours, receive a partial pension to make up income loss, and continue to accrue pension benefits. Besides strengthening financial security, this approach introduces a transitional phase that fosters retirement planning and well-being (Peiró, Tordera, & Potocnik, 2012). And some countries' retirement policies are sensitive to women's more interrupted work lives. In Canada, France, and Germany, for example, time devoted to child rearing is given some credit when figuring retirement benefits (Service Canada, 2009).

In sum, individual preferences shape retirement decisions. At the same time, older adults' opportunities and limitations greatly affect their choices.

Adjustment to Retirement

Because retirement involves giving up roles that are a vital part of identity and self-esteem, it is often assumed to be a stressful process that contributes to declines in physical and mental health. Consider Dick, who reacted to the closing of his bakery with anxiety and depression. His adjustment difficulties resembled those of younger people experiencing job loss (see Chapter

16, page 556). But recall that Dick had a cranky, disagreeable personality. In this respect, his psychological well-being after retirement was similar to what it had been before!

We must be careful not to assume a cause-and-effect relationship each time retirement is paired with an unfavorable reaction. For example, a wealth of evidence confirms that physical health problems lead older adults to retire, rather than the reverse (Shultz & Wang, 2007). And for most people, mental health and perceived quality of life are fairly stable from the pre- to postretirement years, with little change prompted by retirement itself. The widely held belief that retirement inevitably leads to adjustment problems is contradicted by countless research findings indicating that most people adapt well. Contemporary seniors view retirement as a time of opportunity and personal growth and describe themselves as active and socially involved—major determinants of retirement satisfaction (Kloep & Hendry, 2007; Wang & Shultz, 2010). Still, about 10 to 30 percent mention some adjustment difficulties.

Workplace factors—especially financial worries and having to give up one's job—predict stress following retirement. Pressures at work also make a difference. Moving out of a high-stress job is associated with gains in psychological well-being following retirement, whereas leaving a pleasant, low-stress job or a highly satisfying job before one is ready is linked to greater difficulties during the retirement transition, typically followed by recovery (Wang, 2007). And especially for women, who take on greater caregiving responsibilities, retirement may not relieve the stress of family burdens (Coursolle et al., 2010). Rather, it may reduce work-based avenues of personal satisfaction, thereby triggering depressive symptoms and poorer psychological well-being.

Among psychological factors, a sense of personal control over life events, including deciding to retire for internally motivated reasons (to do other things), is strongly linked to retirement satisfaction (Kubicek et al., 2011; Quine et al., 2007). At the same time, those who find it hard to give up the predictable schedule and social contacts of the work setting or who

have few nonwork social ties experience discomfort. Overall, however, well-educated people with complex jobs adjust more favorably (Kim & Moen, 2002a). Perhaps the satisfactions derived from challenging, meaningful work readily transfer to nonwork pursuits.

As with other major life events, social support reduces stress associated with retirement. Although social-network size typically shrinks as relationships with co-workers decline, quality of relationships remains fairly stable for most people. And many seniors add to their social networks through leisure and volunteer pursuits (Kloep & Hendry, 2007). In Dick's case, entering congregate housing eased a difficult postretirement period, leading to new friends and rewarding leisure activities, some of which he shared with Goldie.

Finally, earlier in this chapter we noted that marital happiness tends to rise after retirement. When a couple's relationship is positive, it can buffer the uncertainty of retirement (van Solinge & Henkens, 2008). And retirement can enhance marital satisfaction by granting husband and wife more time for companionship. Consequently, a good marriage not only promotes adjustment to retirement but also benefits from the greater freedom of the retirement years.

In line with continuity theory, people try to sustain lifestyle patterns, self-esteem, and values following retirement and, in favorable economic and social contexts, usually succeed (Atchley, 2003). Return to Chapter 16, page 557, for ways adults can plan ahead to increase the chances of a positive transition to retirement.

Leisure and Volunteer Activities

With retirement, most older adults have more time for leisure and volunteer activities than ever before. After a “honeymoon period” of trying out new options, many discover that interests and skills do not develop suddenly. Instead, meaningful leisure and community service pursuits are usually formed earlier and sustained or expanded during retirement (HSBC & Oxford Institute of Ageing, 2007; Pinquart & Schindler, 2009). For example, Walt's fondness for writing, theater, and gardening dated back to his youth. And Ruth's strong focus on her social work career led her to become an avid community volunteer.

Involvement in leisure activities and, especially, volunteer service is related to better physical and mental health and reduced mortality (Cutler, Hendricks, & O'Neill, 2011). But simply participating does not explain this relationship. Instead, older adults select these pursuits because they permit self-expression, new achievements, the rewards of helping others, pleasurable social interaction, and a structured daily life. And those high in sense of self-efficacy are more engaged (Diehl & Berg, 2007). These factors account for gains in well-being.

As mobility limitations increase, the frequency and variety of leisure pursuits tend to decline, especially travel, outdoor recreation, and exercise, with activities increasingly becoming more sedentary and home-based (Strain et al., 2002). Older adults in residential communities participate more than those in ordinary homes because activities are conveniently available. But regard-

Time devoted to volunteering is higher in late adulthood than at any other time of life. As a Red Cross volunteer, this senior traveled to West, Texas, to provide services to those affected by the fertilizer plant explosion in April 2013.

less of living arrangements, seniors do not simply spend time in programs designed just for them. Rather, they choose activities on the basis of whether the activities are personally gratifying.

Older people contribute enormously to society through volunteer work, a trend that is strengthening. About one-third of 60- and 70-year-olds in industrialized nations report volunteering. Of those who do, over half give 200 or more hours per year (HSBC & Oxford Institute of Ageing, 2007; Kloep & Hendry, 2007). Younger, better-educated, and financially secure seniors with social interests are more likely to volunteer, women more often than men. Although most extend an earlier pattern of civic engagement, nonvolunteers are especially receptive to volunteer activities in the first few years after retiring as they look for ways to compensate for work-role losses (Mutchler, Burr, & Caro, 2003). The retirement transition is a prime time to recruit seniors into these personally rewarding, socially useful pursuits.

LOOK AND LISTEN

Interview an older adult participating in a significant community service role about the personal meaning of the experience at this time of life. ●

Volunteering grants seniors a continuing sense of making valuable contributions to society, and most sustain high commitment through their seventies. In a survey of a large, nationally representative U.S. sample, time spent volunteering did not decline until the eighties (see Figure 18.4 on page 632) (Hendricks & Cutler, 2004). Even then, it remained higher than at any other time of life! In accord with socioemotional selectivity theory, older adults eventually narrowed their volunteering to fewer roles, concentrating on one or two that meant the most to them (Windsor, Anstey, & Rodgers, 2008). They seemed to recognize that excessive volunteering reduces its emotional rewards and, thus, its benefits to life satisfaction.

FIGURE 18.4 Age-related change in number of hours spent volunteering during the past year. A nationally representative sample of nearly 29,000 U.S. adolescents and adults reported on the amount of time they devoted to each of their volunteer activities. Time devoted to volunteering increased sharply in the early twenties, dipped in the late twenties and thirties as young people focused on establishing families and careers, and then rose steadily, peaking in the seventies. Even in the eighties, when volunteering declined slightly, it remained higher than at any other time of life. (From J. Hendricks and S. J. Cutler, 2004, "Volunteerism and Socio-emotional Selectivity in Later Life," *Journal of Gerontology*, 59B, p. S255. Copyright © 2004 The Gerontological Society of America. Adapted by permission of Oxford University Press and Jon Hendricks.)

Finally, when Walt and Ruth got together with Dick and Goldie, the two couples often discussed politics. Older adults report greater awareness of and interest in public affairs and typically vote at a higher rate than any other age group. (The 2012 U.S. national election, in which 18- to 29-year-olds exceeded seniors in voter turnout, is an exception). Even in late old age, older people's political knowledge shows no sign of decline. After retiring, they have more time to keep abreast of current events. They also have a major stake in political debates over policies central to their welfare. But seniors' political concerns are far broader than those that serve their own age group, and their voting behavior is not driven merely by self-interest (Campbell & Binstock, 2011). Rather, their political involvement may stem from a deep desire for a safer, more secure world for future generations.

Optimal Aging

Walt, Ruth, Dick, Goldie, and Ida, and the research findings they illustrate, reveal great diversity in development during the final decades of life. Walt and Ruth fit contemporary experts' view of **optimal aging**, in which gains are maximized and losses minimized. Both were actively engaged with their families and communities, coped well with negative life changes, enjoyed a happy intimate partnership and other close relationships, and led daily lives filled with gratifying activities. Ida, too, experienced

optimal aging until the onset of Alzheimer's symptoms overwhelmed her ability to manage life's challenges. As a single adult, she built a rich social network that sustained her into old age, despite the hardship of having spent many years caring for her ailing mother. In contrast, Dick and Goldie reacted with despondency to physical aging and other losses (such as Dick's forced retirement). And Dick's angry outbursts restricted their social contacts, although the couple's move to congregate housing eventually led to an improved social life.

People age optimally when their growth, vitality, and striving limit and, at times, overcome physical, cognitive, and social declines. Researchers want to know more about factors that contribute to optimal aging so they can help more seniors experience it. Yet theorists disagree on the precise ingredients of a satisfying old age. Some focus on easily measurable outcomes, such as excellent cardiovascular functioning, absence of disability, superior cognitive performance, and creative achievements. But this view has been heavily criticized (Aldwin, Spiro, & Park, 2006). Not everyone can become an outstanding athlete, an innovative scientist, or a talented artist. And many older adults do not want to keep on accomplishing and producing—the main markers of success in Western nations. Each of us is limited by our genetic potential as it combines with a lifetime of environments we encounter and select for ourselves. Furthermore, outcomes valued in one culture may not be valued in others.

Recent views of a contented, fulfilling late adulthood have turned away from specific achievements toward processes people use to reach personally valued goals (Freund & Baltes, 1998; Kahana et al., 2005; Lund, 1998). Instead of identifying one set of standards as "successful," this perspective focuses on how people minimize losses while maximizing gains. In recent research on three samples of adults followed over the lifespan, George Vaillant looked at how various life-course factors contributed to late-life physical and psychological well-being. His findings revealed that factors people could control to some degree (such as health habits, coping strategies, marital stability, and years of education) far outweighed uncontrollable factors (parental SES, family warmth in childhood, early physical health, and longevity of family members) in predicting a happy, active old age (Vaillant & Mukamal, 2001).

Consider the following description of one participant, who in childhood had experienced low SES, parental discord, a depressed mother, and seven siblings crowded into a tenement apartment. Despite these early perils, he became happily married and, through the GI bill, earned an accounting degree. At 70, he was aging well:

Anthony Pirelli may have been *ill* considering his heart attack and open-heart surgery, but he did not feel *sick*. He was physically active as ever, and he continued to play tennis. Asked what he missed about his work, he exulted, "I'm so busy doing other things that I don't have time to miss work. . . . Life is not boring for me." He did not smoke or abuse alcohol; he loved his wife; he used mature [coping strategies]; he obtained 14 years of education; he watched his waistline; and he exercised regularly. (Adapted from Vaillant, 2002, pp. 12, 305.)

Vaillant concluded, “The past often predicts but never determines our old age” (p. 12). Optimal aging is an expression of remarkable resilience during this final phase of the lifespan.

In this and the previous chapter, we have considered the many ways that older adults realize their goals. **TAKE A MOMENT...** Look back and review the most important ones:

- Optimism and sense of self-efficacy in improving health and physical functioning (page 575)
- Selective optimization with compensation to make the most of limited physical energies and cognitive resources (pages 590 and 610)
- Strengthening of self-concept, which promotes self-acceptance and pursuit of hoped-for possible selves (pages 606–608)
- Enhanced emotional understanding and emotional self-regulation, which support meaningful, rewarding social ties (page 605)
- Acceptance of change, which fosters life satisfaction (page 608)
- A mature sense of spirituality and faith, permitting anticipation of death with calmness and composure (pages 608–609)
- Personal control over domains of dependency and independence (pages 610–611, 612)
- High-quality relationships, which offer social support and pleasurable companionship (page 616)

Optimal aging is facilitated by societal contexts that promote effective person–environment fit, enabling seniors to manage life changes effectively. Older adults need well-funded social security plans, good health care, safe housing, and diverse social services. (See, for example, the description of the U.S. Area Agencies on Aging in Chapter 2, page 67.) Yet because of inadequate funding and difficulties reaching rural communities, many older adults’ needs remain unmet. Isolated aging adults with little education may not know how to gain access to available assistance. Furthermore, the U.S. Medicare system of sharing health-care costs with seniors strains the financial

resources of many. And housing that adjusts to changes in older people’s capacities, permitting them to age in place without disruptive and disorienting moves, is available only to the economically well-off.

Besides improving policies that meet older adults’ basic needs, new future-oriented approaches must prepare for increased aging of the population. More emphasis on lifelong learning for workers of all ages would help people maintain and expand their skills as they grow older. Also, reforms that prepare for expected growth in the number of frail aging adults are vital, including affordable help for family caregivers, adapted housing, and sensitive nursing home care.

All these changes involve recognizing, supporting, and enhancing the contributions that seniors make to society—both the older adults of today and those of tomorrow. A nation that takes care of its aging citizens and grants them a multitude of opportunities for personal growth maximizes the chances that each of us, when our time comes to be old, will age optimally.

ASK YOURSELF

REVIEW What psychological and workplace factors predict favorable adjustment to retirement?

CONNECT Leisure and volunteer interests and skills usually form early and persist over the lifespan. Referring back to earlier parts of this book, cite examples of childhood, adolescent, and early adulthood experiences that are likely to foster meaningful pursuits after retirement.

APPLY Nate, happily married to Gladys, adjusted well to retirement, and his marriage became even happier. How can a good marriage ease the transition to retirement? How can retirement enhance marital satisfaction?

REFLECT Think of someone you know who is aging optimally. What personal qualities led you to select that person?

SUMMARY

Erikson’s Theory: Ego Integrity versus Despair

(p. 604)

According to Erikson, how does personality change in late adulthood?

- The final psychological conflict of Erikson’s theory, **ego integrity versus despair**, involves coming to terms with one’s life. Adults who arrive at a sense of integrity feel whole and satisfied with their achievements. Despair occurs when older people feel time is too short to find an alternate route to integrity.

Other Theories of Psychosocial Development in Late Adulthood

(p. 604)

Describe Peck’s, Joan Erikson’s, and Labouvie-Vief’s views of psychosocial development in late adulthood, and discuss reminiscence in older adults’ lives.

- According to Robert Peck, attaining ego integrity involves three distinct tasks: ego differentiation, body transcendence, and ego transcendence.

- Joan Erikson believes these attainments represent an additional psychosocial stage, **gerotranscendence**, evident in inner calm and quiet reflection.
- Gisella Labouvie-Vief points out that older adults improve in **affect optimization**, the ability to maximize positive emotion and dampen negative emotion. This bias toward the emotionally positive contributes an upbeat attitude that is linked to longer survival.

- **Reminiscence** about people and events from one's past can be positive and adaptive for older people. But many well-adjusted older adults spend little time seeking greater self-understanding through life review. Rather, as the term **Third Age** conveys, they are largely present- and future-oriented, seeking opportunities for personal fulfillment.

Stability and Change in Self-Concept and Personality

(p. 606)

Cite stable and changing aspects of self-concept and personality, and discuss spirituality and religiosity in late adulthood.

- The "big five" personality traits remain stable from mid- to late life. Older adults' accumulation of a lifetime of self-knowledge leads to more secure and complex self-concepts. Those who continue to actively pursue hoped-for possible selves gain in life satisfaction. In late adulthood, resilience is fostered by gains in agreeableness and acceptance of change. Engaging in cognitively challenging activities promotes openness to experience.
- While U.S. seniors generally become more religious or spiritual as they age, this increase is modest and not universal. For the majority of people, religiosity is stable throughout adulthood. Faith and spirituality may move toward a more reflective approach that accepts uncertainty and emphasizes links to others. Religious involvement is especially high among low-SES ethnic minority older people and women and is linked to better physical and psychological well-being and longer survival.

Contextual Influences on Psychological Well-Being

(p. 610)

Discuss the influence of control versus dependency, physical health, negative life changes, and social support on older adults' psychological well-being.

- In patterns of behavior called the **dependency–support script** and the **independence–ignore script**, older adults' dependency behaviors are attended to immediately while their independent behaviors are ignored. But dependency can be adaptive if older adults remain in control by selecting areas in which they desire help while conserving their strength for highly valued activities. Assistance that enables older adults to use their capacities fully in pursuit of their goals sustains an effective **person–environment fit**, which fosters psychological well-being.

- Physical health is a powerful predictor of late-life psychological well-being. The relationship between physical and mental health problems can become a vicious cycle, each intensifying the other. Older adults have the highest suicide rate of all age groups.
- Although aging adults are at risk for a variety of negative life changes, these events evoke less stress and depression in older than in younger people. But when negative changes pile up, they test older adults' coping resources.
- By easing stress, social support promotes physical health and psychological well-being. But assistance that is excessive or cannot be returned often results in reduced self-efficacy and psychological stress. Consequently, perceived social support, rather than sheer amount of help, is associated with a positive outlook.

A Changing Social World

(p. 614)

Describe social theories of aging, including disengagement theory, activity theory, continuity theory, and socioemotional selectivity theory.

- **Disengagement theory** holds that mutual withdrawal between older adults and society occurs in anticipation of death. Most aging adults, however, do not disengage but let go of unsatisfying contacts and maintain satisfying ones.
- **Activity theory** states that social barriers to engagement, not the desires of older adults, cause declining rates of interaction. Yet opportunities for social contact do not guarantee greater social activity.

© DAVID M. GROSSMAN/THE IMAGE WORKS

- **Continuity theory** proposes that most aging adults strive to maintain consistency between their past and anticipated future. By using familiar skills and engaging in familiar activities with familiar people, older people integrate late-life changes into a coherent, consistent life path.

- **Socioemotional selectivity theory** states that social networks become more selective with age. Older adults emphasize the emotion-regulating function of interaction, preferring high-quality, emotionally fulfilling relationships.

How do communities, neighborhoods, and housing arrangements affect older adults' social lives and adjustment?

- Suburban older adults have higher incomes and report better health than their inner-city counterparts, but the latter are better off in terms of public transportation. Small-town and rural aging adults, who are less likely to live near their children, compensate by interacting more with nearby relatives, neighbors, and friends. Living in neighborhoods with many like-minded seniors and in smaller communities promotes life satisfaction.

© ARIEL SKELLEY/CORBIS

- Most older people prefer **aging in place**, remaining in a familiar setting where they have control over everyday life. But for those with health and mobility problems, independent living poses risks, and many older adults who live alone are poverty-stricken.
- Residential communities for older adults who need help with everyday tasks include assisted-living arrangements such as **congregate housing** and **life-care communities**, which guarantee that residents' changing needs will be met as they age.
- The small number of U.S. older adults who live in nursing homes experience extreme restriction of autonomy. Typically, social interaction among residents is low. Homelike nursing homes that achieve an effective person–environment fit foster late-life well-being.

Relationships in Late Adulthood

(p. 620)

Describe changes in social relationships in late adulthood, including marriage, gay and lesbian partnerships, divorce, remarriage, and widowhood, and discuss never-married, childless older adults.

- The **social convoy** is an influential model of changes in individuals' social networks as they move through life. As ties are lost, aging adults seek ways to maintain gratifying relationships.

- Marital satisfaction peaks in late adulthood as stressful responsibilities decline and gains in perceptions of relationship fairness, joint leisure activities, and positive communication increase. Most gay and lesbian older adults also report happy, highly fulfilling relationships.

TIM GRAHAM/GETTY IMAGES

- Divorce in late life brings greater stress than for younger people. Although older adults' remarriage rates are low, those who do remarry enter into more stable relationships. Seniors are increasingly choosing cohabitation as a long-term alternative to marriage.
- Adaptation to widowhood varies widely, with age, social support, and personality making a difference. Aging adults fare better than younger individuals, and women better than men. Efforts to maintain social ties, an outgoing personality, high self-esteem, and a sense of self-efficacy in handling tasks of daily living promote resilience.
- Most older adults who remain unmarried and childless throughout their lives develop alternative meaningful relationships. Never-married childless women are better-adjusted than men, but—despite smaller social networks—both find social support.

How do sibling relationships and friendships change in late life?

- In late adulthood, most siblings live nearby, communicate regularly, and visit several times a year. Especially for widowed and never-married older people, siblings provide an important “insurance policy.”
- Friendships in late adulthood serve diverse functions: intimacy and companionship, a shield against negative judgments, a link to

the larger community, and protection from the psychological consequences of loss. Older adults prefer established relationships over new ones, and fewer older than younger people have other-sex friendships. Women, more than men, tend to have both intimate friends and **secondary friends**, with whom they spend time occasionally.

Describe older adults' relationships with adult children, adult grandchildren, and great-grandchildren.

- Older adults are often in touch with their adult children, who more often provide emotional support than direct assistance. Aging parents who provide more help than they receive score highest in life satisfaction.
- Seniors with adult grandchildren and great-grandchildren benefit from a wider potential network of support. Grandparents typically expect affection, but not practical help, from grandchildren. Although grandparent–grandchild contact declines over time, grandparents' emotional investment remains high and often strengthens.

Discuss elder maltreatment, including risk factors and strategies for prevention.

- Some older adults suffer maltreatment at the hands of family members, friends, or professional caregivers. Risk factors include a dependent perpetrator–victim relationship, perpetrator psychological disturbance and stress, a history of family violence, and inadequate institutional conditions. Abandonment of aging adults with severe disabilities by family caregivers has increased in recent decades.
- Elder-abuse prevention programs provide counseling, education, and respite services for caregivers. Trained volunteers and support groups can help older persons avoid future harm. Societal efforts that encourage reporting of suspected cases and increase understanding of older people's needs are also vital.

Retirement (p. 629)

Discuss the decision to retire, adjustment to retirement, and involvement in leisure and volunteer activities.

- The decision to retire depends on affordability, health status, nature of the work environment, opportunities to pursue meaningful activities, societal factors such as retirement benefits, and gender.
- On average, women retire earlier than men because family events play a larger role in their decisions. For most older adults, mental health and perceived quality of life are fairly stable before and after retirement. Factors affecting adjustment include health status, financial stability, satisfactions previously derived from work, caregiving responsibilities, a sense of personal control over life events (including the retirement decision), social support, and marital happiness.
- Meaningful leisure and volunteer pursuits are typically formed earlier and sustained or expanded during retirement. Involvement is related to better physical and mental health and to reduced mortality.

Optimal Aging (p. 632)

Discuss the meaning of optimal aging.

- Older adults who experience **optimal aging** have developed many ways to minimize losses and maximize gains. Societal contexts that permit older adults to manage life changes effectively foster optimal aging. These include well-funded social security plans, good health care, safe housing, diverse social services, and opportunities for lifelong learning.

Development in Late Adulthood

ASTRID RIECKEN/
THE WASHINGTON TIMES/LANDOV

65–80 years

PHYSICAL

- Performance of autonomic nervous system declines, impairing tolerance for extremes of heat and cold. (568)
- Declines in vision continue, with increased sensitivity to glare and impaired color discrimination, dark adaptation, depth perception, and visual acuity. (569)
- Declines in hearing continue throughout the frequency range. (569)
- Sensitivity to taste and odor may decline. (570)
- Touch sensitivity declines on the hands, especially the fingertips. (570)
- Declines in cardiovascular and respiratory functioning lead to greater physical stress during exercise. (570–571)

© FOGSTOCK/ALAMY

- Aging of the immune system increases risk for a variety of illnesses, including infectious diseases, cardiovascular disease, certain forms of cancer, and several autoimmune disorders. (571)

- Timing of sleep shifts to earlier bedtime and earlier morning waking; sleep difficulties increase. (571)
- Graying and thinning of the hair continue; the skin wrinkles and sags further and becomes more transparent as it loses its fatty layer of support; “age spots” increase. (572)
- Height and weight decline because of loss of lean body mass. (572)

© FRANCK ROBICHON/EPA/CORBIS

- Continued loss of bone mass leads to rising rates of osteoporosis. (572, 580)
- Frequency of sexual activity and intensity of sexual response decline, although most healthy married couples report regular sexual enjoyment. (578–579)

COGNITIVE

- Processing speed continues to decline, but crystallized intelligence is largely sustained. (590)

DON MASON/BLEND IMAGES/GETTY IMAGES

ELDAD CARIN/GETTY IMAGES

- More often represents to-be-communicated information in terms of gist rather than details. (594)
- Hypothetical problem solving declines, but everyday problem solving remains adaptive. (594–595)
- May hold an important position of leadership in society, such as chief executive officer, religious leader, or court justice. (595)
- May develop wisdom. (595–596)
- Can improve a wide range of cognitive skills through training. (597)

RON CHAPPLE/TAXI/GETTY IMAGES

- Ability to attend selectively and to adapt attention, switching from one task to another, continues to decline. (591)
- Amount of information that can be held in working memory, use of memory strategies, and retrieval from long-term memory diminish further; problems are greatest on tasks requiring deliberate processing and associative memory. (591–592)
- Modest forgetting of remote memories occurs. (593)
- Use of external aids for prospective memory increases. (593)
- Retrieving words from long-term memory and planning what to say and how to say it become more difficult. (594)

EMOTIONAL/SOCIAL

- Comes to terms with life, developing ego integrity. (604–605)
- Cognitive-affective complexity declines as basic information-processing skill diminish. (605)
- Affect optimization—the ability to maximize positive emotion and dampen negative emotion—increases. (605)
- May engage in reminiscence and life review, but continues to seek avenues for personal growth and fulfillment. (606)

© YADID LEVY/ALAMY

- Self-concept strengthens, becoming more secure and complex. (606)
- Agreeableness and acceptance of change increase, while extroversion and openness to experience tend to decline modestly. (608)
- Spirituality and faith may advance to a higher level, away from prescribed beliefs toward a more reflective approach. (608–609)

AFP/GETTY IMAGES

- Size of social network and amount of social interaction decline. (614)
- Selection of social partners is based on anticipated feelings, including pursuit of pleasant relationships and avoidance of unpleasant ones. (615–616)
- Marital satisfaction increases, peaking in late adulthood. (620)
- May be widowed. (622)
- Visits and support from siblings living nearby may increase. (624)
- With additional time to devote to them, friendships take on increasing importance. (624–625)
- May become a great-grandparent. (627)

ALAN HICKS/STONE/GETTY IMAGES

- May retire. (629–630)
- Likely to increase involvement in leisure and volunteer activities (631–632)
- More likely to be knowledgeable about politics and to vote. (632)

80 years and older

PHYSICAL

- Physical changes previously listed continue.
- Mobility diminishes as muscle and bone strength and joint flexibility decline. (572)

© ROBERT W. GINN/PHOTODISC

COGNITIVE

- Cognitive changes previously listed continue.
- Fluid abilities decline further; crystallized abilities drop as well, though only modestly. (590)

© HERVÉ HUGHES/HEMIS/CORBIS

EMOTIONAL/SOCIAL

- Emotional and social changes previously listed continue.
- May develop gerotranscendence, a cosmic perspective directed beyond the self. (605)

© KEVIN RL HANSON/DK STOCK/CORBIS

- Relationships with adult children become more important. (626)
- Frequency and variety of leisure and volunteer activities decline slightly. (631–632)

BRUNO MORANDI/ROBERT HARDING

Mourners on the island of Bali, Indonesia, perform a traditional Hindu ceremony marking the passage of the dead into the spirit realm. All cultures have rituals for celebrating the end of life and helping the bereaved cope with profound loss.

Death, Dying, and Bereavement

As every life is unique, so each death is unique. The final forces of the human spirit separate themselves from the body in manifold ways.

My mother Sofie's death was the culmination of a five-year battle against cancer. In her last months, the disease invaded organs throughout her body, attacking the lungs in its final fury. She withered slowly, with the mixed blessing of time to prepare against certain knowledge that death was just around the corner. My father, Philip, lived another 18 years. At age 80, he was outwardly healthy, active, and about to depart on a long-awaited vacation when a heart attack snuffed out his life suddenly, without time for last words or deathbed reconciliations.

As I set to work on this chapter, my 65-year-old neighbor Nicholas gambled for a higher quality of life. To be eligible for a kidney transplant, he elected bypass surgery to strengthen his heart. Doctors warned that his body might not withstand the operation. But Nicholas knew that without taking a chance, he would live only a few years, in debilitated condition. Shortly after the surgery, infection set in, traveling throughout his system and so weakening him that only extreme measures—a respirator to sustain breathing and powerful drugs to elevate his fading blood pressure—could keep him alive.

© CHARLES MISTRAL/LAMY

“Come on, Dad, you can do it,” encouraged Nicholas's daughter Sasha, standing by his bedside and stroking his hand. But Nicholas could not. After two months in intensive care, he experienced brain seizures and slipped into a coma. Three doctors met with his wife, Giselle, to tell her there was no hope. She asked them to disconnect the respirator, and within half an hour Nicholas drifted away.

Death is essential for the survival of our species. We die so that our own children and the children of others may live. When it comes to this fate, nature treats humankind, with all its unique capabilities, just as it treats every other living creature. As hard as it is to accept the reality that we too will die, our greatest solace lies in knowing that death is part of ongoing life.

In this chapter, we address the culmination of lifespan development. Over the past century, technology has provided so many means to keep death at bay that many people regard it as a forbidden topic. But pressing social and economic dilemmas that are an outgrowth of the dramatic increase in life expectancy are forcing us to attend to life's end—its quality, its timing, and ways to help people adjust to their

own and others' final leave taking. The interdisciplinary field of **thanatology**, devoted to the study of death and dying, has expanded tremendously over the past 25 years.

Our discussion addresses the physical changes of dying; understanding of and attitudes toward death in childhood, adolescence, and adulthood; the thoughts and feelings of people as they stand face to face with death; where people die; hopelessly ill patients' right to die; and coping with the death of a loved one. The experiences of Sofie, Philip, Nicholas, their families, and others illustrate how each person's life history joins with social and cultural contexts to shape death and dying, lending great diversity to this universal experience. ●

How We Die

In industrialized countries, opportunities to witness the physical aspects of death are less available today than in previous generations. Most people in the developed world die in hospitals, where doctors and nurses, not loved ones, typically attend their last moments. Nevertheless, many want to know how we die, either to anticipate their own end or grasp what is happening to a dying loved one. As we look briefly at the physical dying, we must keep in mind that the dying person is more than a physical being requiring care of and attention to bodily functions. The dying are also mind and spirit—for whom the end of life is still life. They benefit profoundly in their last days and hours from social support responsive to their needs for emotional and spiritual closure.

Physical Changes

My father's fatal heart attack came suddenly during the night. When I heard the news, I longed for reassurance that his death had been swift and without suffering.

When asked how they would like to die, most people say they want "death with dignity"—either a quick, agony-free end during sleep or a clear-minded final few moments in which they can say farewell and review their lives. In reality, death is the culmination of a straightforward biological process. For about 20 percent of people, it is gentle—especially when narcotic drugs ease pain and mask the destructive events taking place (Nuland, 1993). But most of the time it is not.

Recall that unintentional injuries are the leading cause of death in childhood and adolescence, cardiovascular disease and cancer in adulthood. Of the one-quarter of deaths in industrialized nations that are sudden, 80 to 90 percent are due to heart attacks (American Heart Association, 2012; Winslow, Mehta, & Fuster, 2005). My yearning for a painless death for my father was probably not fulfilled. Undoubtedly he felt the sharp, crushing sensation of a heart deprived of oxygen. As his heart twitched uncontrollably (called *fibrillation*) or stopped entirely, blood circulation slowed and ceased, and he was thrust

into unconsciousness. A brain starved of oxygen for more than two to four minutes is irreversibly damaged—an outcome indicated by the pupils of the eyes becoming unresponsive to light and widening into large, black circles. Other oxygen-deprived organs stop functioning as well.

Death is long and drawn out for three-fourths of people—many more than in times past, as a result of life-saving medical technology. They succumb in different ways. Of those with heart disease, most have congestive heart failure, the cause of Nicholas's death (Gruenewald & White, 2006). His scarred heart could no longer contract with the force needed to deliver enough oxygen to his tissues. As it tried harder, its muscle weakened further. Without sufficient blood pressure, fluid backed up in Nicholas's lungs. This hampered his breathing and created ideal conditions for inhaled bacteria to multiply, enter the bloodstream, and run rampant in his system, leading many organs to fail.

Cancer also chooses diverse paths to inflict its damage. When it metastasizes, bits of tumor travel through the bloodstream and implant and grow in vital organs, disrupting their functioning. Medication made my mother's final days as comfortable as possible, granting a relatively easy death. But the preceding weeks involved physical suffering, including impaired breathing and digestion and turning and twisting to find a comfortable position in bed.

In the days or hours before death, activity declines; the person moves and communicates less and shows little interest in food, water, and surroundings. At the same time, body temperature, blood pressure, and circulation to the limbs fall, so the hands and feet feel cool and skin color changes to a duller, grayish hue (Hospice Foundation of America, 2005). When the transition from life to death is imminent, the person often moves through three phases:

1. **The agonal phase.** The Greek word *agon* means "struggle." Here agonal refers to gasps and muscle spasms during the first moments in which the regular heartbeat disintegrates (Manole & Hickey, 2006).
2. **Clinical death.** A short interval follows in which heartbeat, circulation, breathing, and brain functioning stop, but resuscitation is still possible.
3. **Mortality.** The individual passes into permanent death. Within a few hours, the newly lifeless being appears shrunken, not at all like the person he or she was when alive.

Defining Death

TAKE A MOMENT... Consider what we have said so far, and note the dilemma of identifying just when death occurs. Death is not an event that happens at a single point in time but, rather, a process in which organs stop functioning in a sequence that varies from person to person. Because the dividing line between life and death is fuzzy, societies need a definition of death to help doctors decide when life-saving measures should be terminated, to signal survivors that they must begin to grieve their loss and

© MICHAELS, YAMASHITA/CORBIS

A monk prays with mourners during a Shinto funeral in Japan. Shinto beliefs, emphasizing ancestor worship and time for the spirit to leave the corpse, may partly explain the Japanese discomfort with the brain death standard and organ donation.

reorganize their lives, and to establish when donated organs can be removed.

Several decades ago, loss of heartbeat and respiration signified death. But these criteria are no longer adequate because resuscitation techniques frequently permit vital signs to be restored. Today, **brain death**, irreversible cessation of all activity in the brain and the brain stem (which controls reflexes), is used in most industrialized nations.

But not all countries accept this standard. In Japan, for example, doctors rely on traditional criteria—absence of heartbeat and respiration. This approach has hindered the development of a national organ transplant program because few organs can be salvaged from bodies without artificially maintaining vital signs. Buddhist, Confucian, and Shinto beliefs about death, which stress ancestor worship and time for the spirit to leave the corpse, may be partly responsible for the Japanese discomfort with brain death and organ donation. Today, Japanese law allows organ donation using the standard of brain death, even if the wishes of the deceased are not clear, as long as the family does not object (Ida, 2010). Otherwise, people are considered to be alive until the heart stops beating.

Often the brain death standard does not solve the problem of when to halt treatment. Consider Nicholas, who, though not brain dead, had entered a **persistent vegetative state**, in which the cerebral cortex no longer registered electrical activity but the brain stem remained active. Doctors were certain they could not restore consciousness or body movement. Because thousands of people in the United States and other nations are in a persistent vegetative state, with health-care costs totaling many millions of dollars annually, some experts believe that absence of activity in the cerebral cortex should be sufficient to declare a person dead. But others point to a few cases in which patients who had been vegetative for months regained cortical responsiveness and consciousness, though usually with very limited functioning (Laureys & Boly, 2007). In still other instances of illness, a fully conscious but suffering person refuses life-saving

measures—an issue we will consider later when we take up the right to die.

Death with Dignity

We have seen that nature rarely delivers the idealized, easy end most people want, nor can medical science guarantee it. Therefore, the greatest dignity in death is in the integrity of the life that precedes it—an integrity we can foster by the way we communicate with and care for the dying person.

First, we can assure the majority of dying people, who succumb gradually, that we will support them through their physical and psychological distress. We can treat them with respect by taking interest in those aspects of their lives that they most value and by addressing their greatest concerns (Keegan & Drick, 2011). And we can do everything possible to ensure the utmost compassionate care through their last months, weeks, and even final hours—restful physical surroundings, soothing emotional and social support, closeness of loved ones, and pastoral care that helps relieve worries about the worth of one's life, important relationships, and mortality.

Second, we can be candid about death's certainty. Unless people are aware that they are dying and understand (as far as possible) the likely circumstances of their death, they cannot plan for end-of-life care and decision making and share the sentiments that bring closure to relationships they hold most dear. Because Sofie knew how and when her death would probably take place, she chose a time when she and Philip could express what their lives had meant to each other. Among those precious bedside exchanges was Sofie's last wish that Philip remarry after her death so he would not live out his final years alone. Openness about impending death granted Sofie a final generative act, helped her let go of the person closest to her, and offered comfort as she faced death.

AP IMAGES/COEUR DALENE PRESS, JEROME A. POLLOS

Dying patient Dick Warner's wife, Nancy, wears a nurse's hat she crafted from paper to symbolize her dual roles as medical and emotional caregiver. The evening of this photo, Nancy heard Dick's breaths shortening. She kissed him and whispered, "It's time to let go." Dick died as he wished, with his loving wife at his bedside.

Finally, doctors and nurses can help dying people learn enough about their condition to make reasoned choices about whether to fight on or say no to further treatment. An understanding of how the normal body works simplifies comprehension of how disease affects it—education that can begin as early as the childhood years.

In sum, when the conditions of illness do not permit an easy death, we can still ensure the most dignified exit possible by offering the dying person care, affection, companionship, and esteem; the truth about diagnosis; and the maximum personal control over this final phase of life (American Hospice Foundation, 2013). These are essential ingredients of a “good death,” and we will revisit them throughout this chapter.

Understanding of and Attitudes Toward Death

A century ago, when most deaths occurred at home, people of all ages, including children, helped with care of the dying family member and were present at the moment of death. They saw their loved one buried on family property or in the local cemetery, where the grave could be visited regularly. Because infant and childhood mortality rates were high, all people were likely to know someone their own age, or even younger, who had died. And it was common for children to experience the death of a parent.

Compared with earlier generations, today more young people reach adulthood without having experienced the death of someone they know well (Morgan, Laungani, & Palmer, 2009). When a death does occur, professionals in hospitals and funeral homes take care of most tasks that involve confronting it directly.

This distance from death undoubtedly contributes to a sense of uneasiness about it. Despite frequent images of death in television shows, movies, and news reports of accidents, murders, wars, and natural disasters, we live in a death-denying culture. Adults are often reluctant to talk about death with children and adolescents. And substitute expressions, such as “passing away,” “going out,” or “departing,” permit us to avoid acknowledging it candidly. In the following sections, we examine the development of conceptions of and attitudes toward death, along with ways to foster increased understanding and acceptance.

Childhood

Five-year-old Miriam arrived at our university laboratory preschool the day after her dog Pepper died. Instead of joining the other children, she stayed close to her teacher, Leslie, who noticed Miriam’s discomfort. “What’s wrong?” Leslie asked.

“Daddy said Pepper was so sick the vet had to put him to sleep.” For a moment, Miriam looked hopeful. “When I get home, Pepper might wake up.”

Leslie answered directly, “No, Pepper won’t get up again. He’s not asleep. He’s dead, and that means he can’t sleep, eat, run, or play anymore.”

Miriam wandered off but later returned to Leslie and, sobbing, confessed, “I chased Pepper too hard.”

Leslie put her arm around Miriam. “Pepper didn’t die because you chased him,” she explained. “He was very old and sick.”

Over the next few days, Miriam asked many questions: “When I go to sleep, will I die?” “Can a tummy ache make you die?” “Does Pepper feel better now?” “Will Mommy and Daddy die?”

Development of the Death Concept. An understanding of death is based on five ideas:

1. *Permanence.* Once a living thing dies, it cannot be brought back to life.
2. *Inevitability.* All living things eventually die.
3. *Cessation.* All living functions, including thought, feeling, movement, and bodily processes, cease at death.
4. *Applicability.* Death applies only to living things.
5. *Causation.* Death is caused by a breakdown of bodily functioning.

To understand death, children must acquire some basic notions of biology—that animals and plants contain body parts (brain, heart, stomach; leaf, stem, roots) essential for maintaining life. They must also break down their global category of *not alive* into *dead*, *inanimate*, *unreal*, and *nonexistent*. Until children grasp these ideas, they interpret death in terms of familiar experiences—as a change in behavior (Slaughter, Jaakkola, & Carey, 1999; Slaughter & Lyons, 2003). Consequently, they may believe that they caused a relative’s or pet’s death; that having a stomachache can cause someone to die; that dead people eat, go to the bathroom, see, and think; and that death is like sleep.

Permanence is the first understood component of the death concept. Preschoolers accept this fact quickly, perhaps because they have seen it in other situations—for example, in the dead butterflies and beetles they pick up and inspect while playing outside. Appreciation of *inevitability* soon follows. At first, children think that certain people do not die—themselves, people like themselves (other children), and people with whom they have close emotional ties. *Cessation*, *applicability*, and *causation* are more challenging ideas (Kenyon, 2001). Preschoolers and kindergartners say that the dead lose the capacity for most bodily processes. But the majority of 10- to 12-year-olds continue to say that the dead are able to perceive, think, and feel (Bering & Bjorklund, 2004).

Many adults, too, believe in the persistence of mental activity and consciousness after death. And they probably encourage these ideas in children when, in conversations with them about a dead relative or pet, they invite the child to think of the deceased’s positive qualities and to sustain an emotional connection (Harris, 2011). It is not surprising, then, that most older children conclude that even if biological functions largely cease after death, thoughts and feelings continue in some form.

© GIANNI GIANSANTI/SYGMA/CORBIS

Because of exposure to the realities of death, these children in El Salvador—carrying the coffin of an infant during a funeral—likely exceed many agetates in their grasp of what death means.

Individual and Cultural Variations. Although children typically attain an adultlike understanding of death in middle childhood, wide individual differences exist (Speece & Brent, 1996). Terminally ill children under age 6 often have a well-developed concept of death (Linebarger, Sahler, & Egan, 2009; Nielson, 2012). If parents and health professionals have not been forthright, they discover that they are deathly ill in other ways—through nonverbal communication, eavesdropping, talking with other child patients, and perceiving physiological changes in their bodies. Children growing up on Israeli kibbutzim (agricultural settlements) who have witnessed terrorist attacks, family members' departure on army tours, and parental anxiety about safety express an adultlike grasp of death by age 5 (Mahon, Goldberg, & Washington, 1999).

Ethnic variations suggest that religious teachings affect children's understanding. In a comparison of four ethnic groups in Israel, Druze and Moslem children's death concepts differed from those of Christian and Jewish children (Florian & Kravetz, 1985). The Druze emphasis on reincarnation and the greater religiosity of both Druze and Moslem groups may have led more of their children to deny that death is permanent and that the body stops functioning. Similarly, children of U.S. Southern Baptist families, who believe in an afterlife, were less likely to endorse permanence than were children of Unitarian families, who do not dwell on an afterlife (Candy-Gibbs, Sharp, & Petrun, 1985).

Enhancing Children's Understanding. Parents often worry that discussing death candidly with children will fuel their fears. But children with a good grasp of the facts of death express less anxiety about it (Slaughter & Griffiths, 2007). Direct explanations, like Leslie's, that fit the child's capacity to

understand, work best. When adults use clichés or make misleading statements about the permanence of death, children may take these literally and react with confusion. For example, when a parent told her 5-year-old daughter, "Grandpa went on a long trip," the child wondered, "Why didn't he take me?" "When is he coming back?" Sometimes children ask difficult questions, such as "Will I die?" "Will you die?" Parents can be truthful as well as comforting by taking advantage of the child's sense of time. "Not for many, many years," they can say. "First I'm going to enjoy you as a grownup and be a grandparent."

Another way to foster an accurate appreciation of death is to teach young children about human biology. Three- to 5-year-olds given lessons in the role of the heart, brain, lungs, stomach, and other organs in sustaining life have more advanced death concepts than children not given such lessons (Slaughter & Lyons, 2003).

Adult-child discussions should also be culturally sensitive. Rather than presenting scientific evidence as negating religious beliefs, parents and teachers can help children blend the two sources of knowledge. Older children often combine their appreciation of the death concept with religious and philosophical views, which offer solace in times of bereavement (Talwar, 2011). As we will see later, open, honest discussions not only contribute to a realistic understanding of death but also facilitate grieving after a child has experienced a loss.

Adolescence

Recall that teenagers have difficulty integrating logical insights with the realities of everyday life. In this sense, their understanding of death is not yet fully mature, as both their reasoning and behavior reveal.

The Gap Between Logic and Reality. Teenagers can explain the permanence and cessation aspects of death, but they are attracted to alternatives. For example, adolescents often describe death as an enduring abstract state—"darkness," "eternal light," "transition," or "nothingness" (Brent et al., 1996). They also formulate personal theories about life after death. Besides images of heaven and hell influenced by their religious background, they speculate about reincarnation, transmigration of souls, and spiritual survival on earth or at another level (Noppe & Noppe, 1997; Yang & Chen, 2002).

Although mortality in adolescence is low compared with that in infancy and adulthood, teenage deaths are typically sudden and human-induced; unintentional injuries, homicide, and suicide are leading causes. Adolescents are clearly aware that death happens to everyone and can occur at any time. But as their high-risk activities suggest, they do not take death personally.

What explains teenagers' difficulty integrating logic with reality in the domain of death? First, adolescence is a period of rapid growth and onset of reproductive capacity—attainments that are the opposite of death! Second, recall the adolescent personal fable: Wrapped up in their own uniqueness, teenagers

Applying What We Know

Discussing Concerns About Death with Children and Adolescents

Suggestion	Description
Take the lead.	Be alert to the child's or adolescent's nonverbal behaviors, bringing up the subject sympathetically, especially after a death-related situation has occurred.
Listen perceptively.	Give full attention to the child or adolescent and the feelings underlying his or her words. When adults pretend to listen while thinking about other things, young people quickly pick up this sign of indifference and withdraw their confidence.
Acknowledge feelings.	Accept the child's or adolescent's emotions as real and important; avoid being judgmental. For example, paraphrase sentiments you detect, such as "I see you're very puzzled about that. Let's talk more about it."
Provide factual information in a candid, culturally sensitive fashion.	For children who do not yet have a realistic understanding of death, provide simple, direct, and accurate explanations. Avoid misleading statements, such as "went for a rest" or "sleeping." Do not contradict the young person's religious beliefs. Rather, assist him or her in blending biological with religious knowledge.
Engage in joint problem solving.	When questions do not have easy answers, such as "Where does your soul go when you die?," convey your belief in the young person's worth by indicating that you do not want to impose a point of view but rather to help him or her come to personally satisfying conclusions. To questions you cannot answer, say, "I don't know." Such honesty shows a willingness to generate and evaluate solutions jointly.

may conclude they are beyond reach of death. Finally, as teenagers construct a personal identity and experience their first freely chosen love relationships, they may be strongly attracted to romantic notions of death, which challenge logic (Noppe & Noppe, 1996). Not until early adulthood are young people

© DENNIS McDONALD/PHOTOEDIT

This teenager knows that death happens to everyone and can occur at any time, but his risk taking suggests otherwise. Wrapped up in their own uniqueness, adolescents may conclude they are beyond reach of death.

capable of the relativistic thinking needed to reconcile these conflicting ideas (see Chapter 13, page 451).

Enhancing Adolescents' Understanding. By encouraging adolescents to discuss concerns about death, adults can help them build a bridge between death as a logical concept and their personal experiences. In Chapter 12, we noted that teenagers with authoritative parents are more likely to turn to adults for guidance on important issues. But the majority of parents feel uncomfortable about addressing the topic of death and inadequately prepared to do so (Talwar, 2011).

Taking up adolescents' thoughts and feelings about death can be part of everyday conversation, sparked by a news report or the death of an acquaintance. Parents can capitalize on these moments to express their own views, listen closely, accept teenagers' feelings, and correct misconceptions. Such mutual sharing deepens bonds of love and provides the basis for further exploration when the need arises. Applying What We Know above suggests ways to discuss concerns about death with children and adolescents.

Adulthood

In early adulthood, many people brush aside thoughts of death (Corr & Corr, 2013). This avoidance may be prompted by death anxiety, which we will consider in the next section. Alternatively, it may be due to relative lack of interest in death-related issues, given that young adults typically do not know very many people who have died and (like adolescents) think of their own death as a long way off.

In Chapters 15 and 16, we described midlife as a time of stock taking in which people begin to view the lifespan in terms

of time left to live and focus on tasks to be completed. Middle-aged people no longer have a vague conception of their own death. They know that in the not-too-distant future, it will be their turn to grow old and die.

In late adulthood, adults think and talk more about death because it is much closer. Increasing evidence of mortality comes from physical changes, higher rates of illness and disability, and loss of relatives and friends (see Chapter 17). Compared with middle-aged people, older adults spend more time pondering the process and circumstances of dying than the state of death (Kastenbaum, 2012). Nearness to death seems to lead to a practical concern with how and when it might happen.

Finally, although we have traced overall age-related changes, large individual differences exist. Some adults focus on life and death issues early on; others are less reflective, moving into old age without giving these matters much attention.

Death Anxiety

TAKE A MOMENT... As you read the following statements, do you find yourself agreeing, disagreeing, or reacting neutrally?

“Never feeling anything again after I die upsets me.”

“I hate the idea that I will be helpless after I die.”

“The total isolation of death is frightening to me.”

“The feeling that I will be missing out on so much after I die disturbs me.” (Thorson & Powell, 1994, pp. 38–39)

Items like these appear on questionnaires used to measure **death anxiety**—fear and apprehension of death. Even people who clearly accept the reality of death may fear it.

What predicts whether thoughts of our own demise trigger intense distress, relative calm, or something in between? To answer this question, researchers measure both general death anxiety and specific factors—fear of no longer existing, loss of control, a painful death, decay of the body, separation from loved ones, and the unknown (Neimeyer, 1994). Findings reveal large individual and cultural variations in aspects of death that arouse fear. For example, in a study of devout Islamic Saudi Arabians, certain factors that appear repeatedly in the responses of Westerners, such as fear of the body decaying and of the unknown, were entirely absent (Long, 1985).

Among Westerners, spirituality—a sense of life’s meaning—seems to be more important than religious commitment in limiting death anxiety (Ardelt, 2003; Routledge & Juhl, 2010). People with a well-developed personal philosophy of death are also less fearful. And in two studies, Christian older adults whose religious beliefs and behavior were contradictory—who believed in a rewarding afterlife but rarely prayed or attended services, or who regularly prayed and attended services but doubted the existence of an afterlife—reported higher death anxiety (Wink, 2006; Wink & Scott, 2005). Together, these findings indicate that both firmness of beliefs and consistency between beliefs and practices, rather than religiousness itself, reduce fear of death. Death anxiety is especially low among

adults with deep faith in some form of higher force or being—faith that may or may not be influenced by religion (Cicirelli, 2002; Neimeyer et al., 2011).

TAKE A MOMENT... From what you have learned about adult psychosocial development, how do you think death anxiety might change with age? If you predicted it would decline, reaching its lowest level in late adulthood, you are correct (see Figure 19.1) (Russac et al., 2007; Tomer, Eliason, & Smith, 2000). This age-related drop has been found in many cultures and ethnic groups. Recall from Chapter 18 that older adults are especially effective at regulating negative emotion. As a result, most cope with anxieties, including fear of death, effectively. Furthermore, attainment of ego integrity reduces death anxiety. Older people have had more time to develop symbolic immortality—the belief that one will continue to live on through one’s children or through one’s work or personal influence (see Chapter 16, page 533).

As long as it is not overly intense, death anxiety can motivate people to strive to live up to internalized cultural values—for example, to be kind to others and to work hard to reach one’s goals. These efforts increase adults’ sense of self-esteem, self-efficacy, and purpose in life—powerful antidotes against the terrifying thought that, in the overall scheme of things, they “are no more important or enduring than any individual potato, pineapple, or porcupine” (Fry, 2003; Pyszczynski et al., 2004, p. 436). In a study of Israeli adults, symbolic immortality predicted reduced fear of death, especially among those with secure attachments (Florian & Mikulincer, 1998). Gratifying, close interpersonal ties seem to help people feel worthwhile and forge a sense of symbolic immortality. And people who view death as an opportunity to pass a legacy to future generations are less likely to fear it (Cicirelli, 2001; Mikulincer, Florian, & Hirschberger, 2003).

FIGURE 19.1 Relationship of age and gender to death anxiety. In this study comparing young and older adults, death anxiety declined with age. Women expressed greater fear of death than men. Many other studies show similar findings. (Adapted from Tomer, Eliason, & Smith, 2000.)

Regardless of age, in both Eastern and Western cultures, women appear more anxious about death than men do (refer again to Figure 19.1) (Madnawat & Kachhawa, 2007; Tomer, Eliason, & Smith, 2000). Women may be more likely to admit and men more likely to avoid troubled feelings about mortality—an explanation consistent with females' greater emotional expressiveness throughout the lifespan. Furthermore, in one study, women showed a temporary rise in death anxiety in their early fifties not seen in men (Russac et al., 2007). Perhaps menopause, in marking the end of reproductive capacity, provides women with a stark reminder of their mortality.

Experiencing some anxiety about death is normal and adaptive. But like other fears, very intense death anxiety can undermine effective adjustment. Although physical health in adulthood is not related to death anxiety, mental health clearly is. In cultures as different as China and the United States, people who are depressed or generally anxious are likely to have more severe death concerns (Neimeyer & Van Brunt, 1995; Wu, Tang, & Kwok, 2002). In contrast, people who are good at inhibition (keeping their minds from straying to irrelevant thoughts) and at emotional self-regulation report less death anxiety (Gailliot, Schmeichel, & Baumeister, 2006). They are better able to manage their concerns about death.

Death anxiety is largely limited to adolescence and adulthood. Children rarely display it unless they live in high-crime neighborhoods or war-torn areas where they are in constant danger (see the Cultural Influences box on the impact of ethnic and political violence on children on page 533 in Chapter 10). Terminally ill children are also at risk for high death anxiety. Compared with other same-age patients, children with cancer express more destructive thoughts and negative feelings about death (Malone, 1982). For those whose parents make the mistake of not telling them they are going to die, loneliness and death anxiety can be extreme (O'Halloran & Altmaier, 1996).

Death anxiety declines in old age, and this 81-year-old from the Netherlands seems to have very little! She had this coffin made to serve as a bookshelf because, she said, "It's a waste to use a coffin just for burial." The pillow on the top will support her head after she dies.

ASK YOURSELF

REVIEW Explain why older adults think and talk more about death than do younger people but feel less anxious about it.

CONNECT How do advances in cognition contribute to adolescents' concepts of death? (Refer to Chapter 11, pages 382–383 and 386–387.)

APPLY When 4-year-old Chloe's aunt died, Chloe asked, "Where's Aunt Susie?" Her mother explained, "Aunt Susie is taking a long, peaceful sleep." For the next two weeks, Chloe refused to go to bed, and, when finally coaxed into her room, lay awake for hours. What is the likely reason for Chloe's behavior? What might be a better way of answering her question?

REFLECT Ask members of earlier generations in your family about their childhood experiences with death. Compare these to your own experiences. What differences did you find, and how would you explain them?

Thinking and Emotions of Dying People

In the year before her death, Sofie did everything possible to surmount her illness. In between treatments to control the cancer, she tested her strength. She continued to teach high school, traveled to visit her children, cultivated a garden, and took weekend excursions with Philip. Hope pervaded Sofie's approach to her deadly condition, and she spoke often about the disease—so much so that her friends wondered how she could confront it so directly.

As Sofie deteriorated physically, she moved in and out of various mental and emotional states. She was frustrated, and at times angry and depressed, about her inability to keep on fighting. I recall her lamenting anxiously on a day when she was in pain, "I'm sick, so very sick! I'm trying so hard, but I can't keep on." Once she asked when my husband and I, who were newly married, would have children. "If only I could live long enough to hold them in my arms!" she cried. In the last week, she appeared tired but free of struggle. Occasionally, she spoke of her love for us and commented on the beauty of the hills outside her window. But mostly, she looked and listened, rather than actively participating in conversation. One afternoon, she fell permanently unconscious.

Do Stages of Dying Exist?

As dying people move closer to death, are their reactions predictable? Do they go through a series of changes that are the same for everyone, or are their thoughts and feelings unique?

Kübler-Ross's Theory. Although her theory has been heavily criticized, Elisabeth Kübler-Ross (1969) is credited with awakening society's sensitivity to the psychological needs of dying patients. From interviews with over 200 terminally ill people, she devised a theory of five typical responses—initially proposed as stages—to the prospect of death and the ordeal of dying:

- **Denial.** On learning of the terminal illness, the person denies its seriousness—refusing to accept the diagnosis, avoiding discussions with doctors and family members—to escape from the prospect of death. While the patient still feels reasonably well, denial is self-protective, allowing the individual to deal with the illness at his or her own pace. Most people move in and out of denial, making great plans one day and, the next, acknowledging that death is near (Rousseau, 2000). Although denial can reduce emotional distress, enabling patients to absorb the news while addressing unfinished life tasks, Kübler-Ross recommends that family members and health professionals not prolong denial by distorting the truth about the person's condition. In doing so, they prevent the dying person from adjusting to impending death and hinder necessary arrangements—for social support, for bringing closure to relationships, and for making decisions about medical interventions.
- **Anger.** Recognition that time is short promotes anger at having to die without having had a chance to do all one wants to do. Family members and health professionals may be targets of the patient's rage, resentment, and envy. Even so, they must tolerate rather than lash out at the patient's behavior, recognizing that the underlying cause is the unfairness of death.
- **Bargaining.** Realizing the inevitability of death, the terminally ill person attempts to bargain for extra time—a deal he or she may try to strike with family members, friends, doctors, nurses, or God. The best response to these efforts to sustain hope is to listen sympathetically, as one doctor did to the pleas of a young AIDS-stricken father, whose wish was to live long enough to dance with his daughter—then 8 years old—at her wedding (Selwyn, 1996). Sometimes, bargains are altruistic acts. Tony, a 15-year-old leukemia patient, expressed to his mother:

I don't want to die yet. Gerry [youngest brother] is only 3 and not old enough to understand. If I could live just one more year, I could explain it to him myself and he will understand. Three is just too young. (Komp, 1996, pp. 69–70)

Although many dying patients' bargains are unrealistic and impossible to fulfill, Tony lived for exactly one year—a gift to those who survived him.

- **Depression.** When denial, anger, and bargaining fail to postpone the illness, the person becomes depressed about the loss of his or her life—a response that intensifies suffering. Unfortunately, many experiences associated with dying, including physical and mental deterioration, pain,

lack of control, certain medications, and being hooked to machines, contribute to despondency. Compassionate medical and psychological treatment, aimed at clarifying and alleviating the patients concerns, can limit hopelessness and despair.

- **Acceptance.** Most people who reach acceptance, a state of peace and quiet about upcoming death, do so only in the last weeks or days. The weakened patient yields to death, disengaging from all but a few family members, friends, and caregivers. Some dying people, in an attempt to pull away from all they have loved, withdraw into themselves for long periods of time. “I'm getting my mental and emotional house in order,” one patient explained (Samarel, 1995, p. 101).

Evaluation of Kübler-Ross's Theory. Kübler-Ross cautioned that her five stages should not be viewed as a fixed sequence and that not all people display each response. But her use of the term *stages* has made it easy for her theory to be interpreted simplistically, as the series of steps a “normal” dying person follows. Some health professionals, unaware of diversity in dying experiences, have insensitively tried to push patients through Kübler-Ross's sequence. And caregivers, through callousness or ignorance, can too easily dismiss a dying patient's legitimate complaints about treatment as “just what you would expect in Stage 2” (Corr & Corr, 2013; Kastenbaum, 2012).

Research confirms that, in line with Kübler-Ross's observations, dying people are more likely to display denial after learning of their condition and acceptance shortly before death (Kalish, 1985). But rather than stages, the five reactions Kübler-Ross observed are best viewed as coping strategies that anyone may call on in the face of threat. Furthermore, dying people react in many additional ways—for example, through efforts to conquer the disease, as Sofie displayed; through an overwhelming need to control what happens to their bodies during the dying process; through acts of generosity and caring, as seen in Tony's concern for his 3-year-old brother, Gerry; and through shifting their focus to living in a fulfilling way—“seizing the day” because so little time is left (Silverman, 2004; Wright, 2003).

As these examples suggest, the most serious drawback to Kübler-Ross's theory is that it looks at dying patients' thoughts and feelings outside the contexts that give them meaning. As we will see next, people's adaptations to impending death can be understood only in relation to the multidimensional influences that have contributed to their life course and that also shape this final phase.

Contextual Influences on Adaptations to Dying

From the moment of her diagnosis, Sofie spent little time denying the deadliness of her disease. Instead, she met it head on, just as she had dealt with other challenges of life. Her impassioned plea to hold her grandchildren in her arms was

© PITTSBURGH POST-GAZETTE, 2009. ALL RIGHTS RESERVED. REPRINTED WITH PERMISSION.

On September 18, 2007, Carnegie Mellon University computer science professor Randy Pausch, diagnosed with pancreatic cancer, gave his final lecture to a packed house. His message, which focused on achieving one's childhood dreams and enabling the dreams of others, can be viewed at www.cmu.edu/homepage/multimedia/andy-pausch-lecture.shtml. He died nine months later, at age 47, having approached his death in a way that suited his pattern of living and deepest values.

less a bargain with fate than an expression of profound defeat that on the threshold of late adulthood, she would not live to enjoy its rewards. At the end, her quiet, withdrawn demeanor was probably resignation, not acceptance. All her life, she had been a person with a fighting spirit, unwilling to give in to challenge.

According to recent theorists, a single strategy, such as acceptance, is not best for every dying patient. Rather, an **appropriate death** is one that makes sense in terms of the individual's pattern of living and values and, at the same time, preserves or restores significant relationships and is as free of suffering as possible (Worden, 2000). When asked about a "good death," most patients are clear about what, ideally, they would like to happen. They mention the following goals:

- Maintaining a sense of identity, or inner continuity with one's past
- Clarifying the meaning of one's life and death
- Maintaining and enhancing relationships
- Achieving a sense of control over the time that remains
- Confronting and preparing for death (Goldstein et al., 2006; Kleespies, 2004; Proulx & Jacelon, 2004)

Research reveals that biological, psychological, and social and cultural forces affect people's coping with dying and, therefore, the extent to which they attain these goals. Let's look at some important influences on how people fare.

Nature of the Disease. The course of the illness and its symptoms affect the dying person's reactions. For example, the extended nature of Sofie's illness and her doctor's initial optimism about achieving a remission undoubtedly contributed to her attempts to try to conquer the disease. During the final

month, when cancer had spread to Sofie's lungs and she could not catch her breath, she was agitated and fearful until oxygen and medication relieved her uncertainty about being able to breathe. In contrast, Nicholas's weakened heart and failing kidneys so depleted his strength that he responded only with passivity.

Because of the toll of the disease, about one-third of cancer patients experience severe depression—reactions distinct from the sadness, grief, and worry that typically accompany the dying process. Profound depression amplifies pain, impairs the immune response, interferes with the patient's capacity for pleasure, meaning, and connection, and is associated with poorer survival (Satin, Linden, & Phillips, 2009; Williams & Dale, 2006). It therefore requires immediate treatment. Among the most successful approaches are meaning-focused life review (see page 606 in Chapter 18), medical control of pain, and advance care planning with the patient that ensures that his or her end-of-life wishes are known and respected (Rosenstein, 2011).

Personality and Coping Style. Understanding the way individuals view stressful life events and have coped with them in the past helps us appreciate the way they manage the dying process. In a study in which terminally ill patients discussed their images of dying, responses varied greatly. For example,

- Beth regarded *dying as imprisonment*: "I felt like the clock started ticking . . . like the future has suddenly been taken. . . . In a way, I feel like I'm already dead."
- To Faith, dying was *a mandate to live ever more fully*: "I have a saying: . . . 'You're not ready to live until you're ready to die.' . . . It never meant much to me until I . . . looked death in the eye, and now I'm living. . . . This life is a lot better than the one before."
- Dawn viewed dying as *part of life's journey*: "I learned all about my disease. . . . I would read, read, read. . . . I wanted to know as much as I can about it, and I don't think hiding . . . behind the door . . . could help me at all. And, I realized for the first time in my life—*really, really, really realized* that I could handle anything."
- Patty approached dying as *an experience to be transformed* so as to make it more bearable: "I am an avid, rabid fan of *Star Trek*, a trekkie like there never has been. . . . I watch it to the point that I've memorized it. . . . [In my mind, I play the various characters so] I'm not [always] thinking about cancer or dying. . . . I think that's how I get through it." (Wright, 2003, pp. 442–444, 447)

Each patient's view of dying helps explain her responses to worsening illness. Poorly adjusted individuals—those with conflict-ridden relationships and many disappointments in life—are usually more distressed (Kastenbaum, 2012).

Family Members' and Health Professionals' Behavior. Earlier we noted that a candid approach, in which everyone close to and caring for the dying person acknowledges

© ED KASHI/CORBIS

A doctor listens patiently to the concerns of a terminally ill 94-year-old. Through sensitive, open communication, health professionals help dying people prepare for death by bringing relationships to closure, reflecting on life, and dealing with fears and regrets.

the terminal illness, is best. Yet this also introduces the burden of participating in the work of dying with the patient—bringing relationships to closure, reflecting on life, and dealing with fears and regrets.

People who find it hard to engage in these tasks may pretend that the disease is not as bad as it is. In patients inclined toward denial, a “game” can be set in motion in which participants are aware that the patient is dying but act as though it were not so. Though this game softens psychological pain for the moment, it makes dying much more difficult. Besides impeding communication, it frequently leads to futile medical interventions, in which the patient has little understanding of what is happening and is subjected to great physical and emotional suffering. One attending physician provided this account of a cancer patient’s death:

The problem was that she had a young husband and parents who were pretty much in complete denial. We were trying to be aggressive up to the end. To the point that we actually hung a new form of chemotherapy about four hours before she died, even though everybody knew except her immediate family that she was going to die within the next four to eight hours. (Jackson et al., 2005, p. 653)

At other times, the patient suspects what he or she has not been told. In one instance, a terminally ill child flew into a rage because his doctor and a nurse spoke to him in ways that denied the fact that he would not grow up. Trying to get the child to cooperate with a medical procedure, the doctor said,

“I thought you would understand, Sandy. You told me once you wanted to be a doctor.”

He screamed back, “I’m not going to be anything!” and threw an empty syringe at her.

The nurse standing nearby asked, “What are you going to be?”

“A ghost,” said Sandy, and turned away from them. (Bluebond-Langner, 1977, p. 59)

The behavior of health professionals impeded Sandy’s efforts to form a realistic time perspective and intensified his anger at the injustice of his premature death.

When doctors do want to inform patients of their prognosis, they may encounter resistance, especially within certain ethnic groups. Withholding information is common in Southern and Eastern Europe, Central and South America, much of Asia, and the Middle East. Japanese terminally ill cancer patients are seldom told the truth about their condition, partly because dying disrupts important interdependent relationships (Yamamoto, 2004). Many Mexican Americans and Korean Americans believe that informing patients is wrong and will hasten death (Blackhall et al., 1995, 2001). In these instances, providing information is complex. When a family insists that a patient not be told, the doctor can first offer information to the patient and then, if the patient refuses, ask who should receive information and make health-care decisions (Zane & Yeh, 2002). The patient’s preference can be honored and reassessed at regular intervals.

Care of the terminally ill is demanding and stressful. Nurses who respond effectively to the psychological needs of dying patients and their families benefit from inservice training aimed at strengthening interpersonal skills, day-to-day mutual support among staff, and development of a personal philosophy of living and dying (Efstathiou & Clifford, 2011; Hebert, Moore, & Rooney, 2011; Morris, 2011). Extensive experience working with dying patients in a sensitive, supportive environment is associated with low death anxiety, perhaps because such caregivers observe their patients’ distress decline and, thus, gradually learn that their own previous fears are less founded (Bluck et al., 2008; Peters et al., 2013).

Social support from family members also affects adaptation to dying. Dying patients who feel they have much unfinished business to attend to are more anxious about impending death. But family contact reduces their sense of urgency to prolong life (Mutran et al., 1997; Zimmerman, 2012). Perhaps it permits patients to work through at least some incomplete tasks.

Effective communication with the dying person is honest, fostering a trusting relationship, yet also oriented toward maintaining hope. Many dying patients move through a hope trajectory—at first, hope for a cure; later, hope for prolonging life; and finally, hope for a peaceful death with as few burdens as possible (Fanslow, 1981). Once patients near death stop expressing hope, those close to them must accept this. Family members who find letting go very difficult may benefit from expert guidance. Applying What We Know on page 650 offers suggestions for communicating with the dying.

Spirituality, Religion, and Culture. Earlier we noted that a sense of spirituality reduces fear of death. Research indicates that this is as true for the dying as for people in general.

Applying What We Know

Communicating with Dying People

Suggestion	Description
Be truthful about the diagnosis and course of the disease.	Be honest about what the future is likely to hold, thereby permitting the dying person to bring closure to his or her life by expressing sentiments and wishes and participating in decisions about treatment.
Listen perceptively and acknowledge feelings.	Be truly present, focusing full attention on what the dying person has to say and accepting the patient's feelings. Patients who sense another's presence and concern are more likely to relax physically and emotionally and express themselves.
Maintain realistic hope.	Assist the dying person in maintaining hope by encouraging him or her to focus on a realistic goal that might yet be achieved—for example, resolution of a troubled relationship or special moments with a loved one. Knowing the dying person's hope, family members and health professionals can often help fulfill it.
Assist in the final transition.	Assure the dying person that he or she is not alone, offering a sympathetic touch, a caring thought, or just a calm presence. Some patients who struggle may benefit from being given permission to die—the message that giving up and letting go is all right.

Source: Lugton, 2002.

Terminally ill patients who score higher in spiritual well-being (belief in life's meaning) experience less end-of-life despair (desire for a hastened death and suicidal thoughts) (McClain, Rosenfeld, & Breitbart, 2003; McClain-Jacobson et al., 2004). As one experienced nurse commented,

At the end, those [patients] with a faith—it doesn't really matter in what, but a faith in something—find it easier. Not always, but as a rule. I've seen people with faith panic and I've seen those without faith accept it [death]. But, as a rule, it's much easier for those with faith. (Samarel, 1991, pp. 64–65)

Vastly different cultural beliefs, guided by religious ideas, also shape people's dying experiences:

- Buddhism, widely practiced in China, India, and Southeast Asia, fosters acceptance of death. By reading sutras (teachings of Buddha) to the dying person to calm the mind and emphasizing that dying leads to rebirth in a heaven of peace and relaxation, Buddhists believe that it is possible to reach Nirvana, a state beyond the world of suffering (Kubotera, 2004; Yeung, 1996).
- In many Native-American groups, death is met with stoic self-control, an approach taught at an early age through stories that emphasize a circular, rather than linear, relationship between life and death and the importance of making way for others (Cox, 2002).
- For African Americans, a dying loved one signals a crisis that unites family members in caregiving (Crawley et al., 2000; Jenkins et al., 2005). The terminally ill person remains an active and vital force within the family until he or she can no longer carry out this role—an attitude of respect that undoubtedly eases the dying process.
- Among the Maori of New Zealand, relatives and friends gather around the dying person to give spiritual strength

and comfort. Older adults, clergy, and other experts in tribal customs conduct a *karakia* ceremony, in which they recite prayers asking for peace, mercy, and guidance from the creator. After the ceremony, the patient is encouraged to discuss important matters with those closest to her—giving away of personal belongings, directions for interment, and completion of other unfinished tasks (Ngata, 2004).

In sum, dying prompts a multitude of thoughts, emotions, and coping strategies. Which ones are emphasized depends on a wide array of contextual influences. A vital assumption of the lifespan perspective—that development is multidimensional and multidirectional—is just as relevant to this final phase as to each earlier period.

A Place to Die

Whereas in the past most deaths occurred at home, in the United States today about 40 percent take place in hospitals and another 20 percent in long-term care facilities, mostly nursing homes (Centers for Disease Control and Prevention, 2013). In the large, impersonal hospital environment, meeting the human needs of dying patients and their families is secondary, not because professionals lack concern, but because the work to be done focuses on saving lives. A dying patient represents a failure.

In the 1960s, a death awareness movement arose as a reaction to hospitals' death-avoiding practices—attachment of complicated machinery to patients with no chance of survival and avoidance of communication with dying patients. This movement soon led to medical care better suited to the needs of dying people and also to hospice programs, which have spread to many countries in the industrialized world. Let's visit each of these settings for dying.

Home

Had Sofie and Nicholas been asked where they wanted to die, undoubtedly each would have responded, “At home”—the preference of 80 to 90 percent of Americans (NHPCO, 2005; O’Connor, 2003). The reason is clear: The home offers an atmosphere of intimacy and loving care in which the terminally ill person is unlikely to feel abandoned or humiliated by physical decline or dependence on others.

However, only about one-fourth of Americans experience home death (Centers for Disease Control and Prevention, 2013). And it is important not to romanticize dying at home. Because of dramatic improvements in medicine, dying people tend to be sicker or much older than in the past. Consequently, their bodies may be extremely frail, making ordinary activities—eating, sleeping, taking a pill, toileting, and bathing—major ordeals for informal caregivers (Singer et al., 2005). Health problems of aging spouses, work and other responsibilities of family members, and the physical, psychological, and financial strain of providing home care can make it difficult to honor a terminally ill person’s wish to die at home.

For many people, the chance to be with the dying person until the very end is a rewarding tradeoff for the high demands of caregiving. But to make dying at home feasible, adequate support for the caregiver is essential (Karlsson & Berggren, 2011; Newbury, 2011). A specially trained home health aide is usually necessary—a service (as we will see shortly) that hospice programs have made more accessible. Still, when family relationships are conflict-ridden, a dying patient introduces additional family strains and is subjected to increased distress, negating the benefits of home death. Furthermore, even with professional help, most homes are poorly equipped to handle the medical and comfort-care needs of the dying. Hospital-based equipment and technical support often must be transported to the home.

For all these reasons, older adults—although they view home as their ideal place to die—express concerns about quality of care, about burdening family and friends, and about the need for adult children to engage in unduly intimate caregiving tasks (Gott et al., 2004). And 10 months after a home death, family members continue to report more psychological stress than do family members whose loved one died elsewhere (Addington-Hall, 2000).

Hospital

Hospital dying takes many forms. Each is affected by the physical state of the dying person, the hospital unit in which it takes place, and the goal and quality of care.

Sudden deaths, due to injury or critical illness, typically occur in emergency rooms. Doctors and nurses must evaluate the problem and take action quickly. Little time is available for contact with family members. When staff break the news of death in a sympathetic manner and provide explanations, family members are grateful. Otherwise, feelings of anger, frustra-

Dying in intensive care is a depersonalizing experience unique to technologically sophisticated societies. In such settings, medical responses supersede privacy and communication with patient and family.

tion, and confusion can add to their grief (Walsh & McGoldrick, 2004). Crisis intervention services are needed to help survivors cope with sudden death.

Nicholas died on an intensive care ward focused on preventing death in patients whose condition can worsen quickly. Privacy and communication with the family were secondary to monitoring his condition. To prevent disruption of nurses’ activities, Giselle and Sasha could be at Nicholas’s side only at scheduled times. Dying in intensive care—an experience unique to technologically sophisticated societies—is especially depersonalizing for patients like Nicholas, who linger between life and death while hooked to machines often for months.

Cancer patients, who account for most cases of prolonged dying, typically die in general or specialized cancer care hospital units. When hospitalized for a long time, they reach out for help with physical and emotional needs, too often with mixed success. In these hospital settings, as in intensive care, a conflict of values is apparent (Costello, 2006). The tasks associated with dying must be performed efficiently so that all patients can be served and health professionals are not drained emotionally by repeated attachments and separations.

Although hospital comprehensive treatment programs aimed at easing physical, emotional, and spiritual suffering at the end of life have increased steadily over the past decade, one-third of hospitals still do not have them (Center to Advance Palliative Care, 2012). And because just 16 percent of U.S. and Canadian medical schools offer even a single pain-focused course (usually an elective), few doctors and nurses are specially trained in managing pain in chronically ill and dying people (Mezei & Murinson, 2011). At present, many people die in painful, frightening, and depersonalizing hospital conditions, without their wishes being met.

Nursing Home

Though deaths in U.S. nursing homes—mostly elderly patients—are common, care emphasizes rehabilitation rather than high-quality terminal care. Too often, residents' end-of-life preferences are not gathered and recorded in medical records. The few studies that have addressed what it is like to die in nursing homes concur that many patients suffer from inattention to their emotional and spiritual needs and from high levels of untreated pain (Massachusetts Expert Panel on End of Life Care, 2010).

In one investigation, researchers conducted in-depth interviews with a nationally representative sample of nearly 600 family members whose loved one had spent at least 48 hours of the final month of life in a nursing home. Respondents frequently mentioned unsatisfactory physical care of the dying patient, difficulty obtaining basic information from staff members on the patient's condition, staff members' lack of compassion and attentiveness to the patient's medical deterioration, and physicians who were "missing in action"—rarely seen in the nursing home (Wetle et al., 2005; Shield et al., 2010). Relatives often felt the need to advocate for their dying relative, though their efforts met with limited success—circumstances that greatly increased both patient and family distress.

The hospice approach—which we consider next—aims to reduce profound caregiving failures in hospitals and nursing homes. When combined with hospice, nursing home care of the dying improves greatly in pain management, emotional and spiritual support, and family satisfaction. But referrals of dying nursing-home residents to hospice, though increasing, are often not made—or made too late to be useful (Zheng et al., 2012).

The Hospice Approach

In medieval times, a *hospice* was a place where travelers could find rest and shelter. In the nineteenth and twentieth centuries, the word referred to homes for dying patients. Today, **hospice** is not a place but a comprehensive program of support services for terminally ill people and their families. It aims to provide a caring community sensitive to the dying person's needs so patients and family members can prepare for death in ways that are satisfying to them. Quality of life is central to the hospice approach, which includes these main features:

- The patient and family as a unit of care
- Emphasis on meeting the patient's physical, emotional, social, and spiritual needs, including controlling pain, retaining dignity and self-worth, and feeling cared for and loved
- Care provided by an interdisciplinary team: a doctor, a nurse or home health aide, a chaplain, a counselor or social worker, and a trained volunteer
- The patient kept at home or in an inpatient setting with a homelike atmosphere where coordination of care is possible
- Focus on protecting the quality of remaining life with **palliative**, or **comfort**, care that relieves pain and other

symptoms (nausea, breathing difficulties, insomnia, and depression) rather than prolonging life

- In addition to regularly scheduled home care visits, on-call services available 24 hours a day, 7 days a week
- Follow-up bereavement services offered to families in the year after a death

Because hospice care is a philosophy, not a facility, it can be applied in diverse ways. In Great Britain, care in a special hospice inpatient unit, sometimes associated with a hospital, is typical. In the United States, home care has been emphasized: About 42 percent of hospice patients die in their own home, 26 percent in a hospice inpatient unit, 18 percent in a nursing home, 7 percent in another type of residential setting, and 7 percent in a typical hospital room (NHPCO, 2012).

But hospice programs everywhere have expanded to include a continuum of care, from home to inpatient options, including hospitals and nursing homes. Central to the hospice approach is that the dying person and his or her family be offered choices that guarantee an appropriate death. Some programs offer hospice day care, which enables caregivers to continue working or be relieved of the stresses of long-term care (Kernohan et al., 2006). Contact with others facing terminal illness is a supportive byproduct of many hospice arrangements. And to find out about a comforting musical intervention for patients near death, consult the Biology and Environment box on the following page.

Music as Palliative Care for Dying Patients

When Peter visits 82-year-old Stuart to play the harp, Stuart reports being transported to an idyllic place with water, children, and trees—far from the lung tumors that will soon take his life. “When Peter plays for me, . . . I am no longer frightened,” Stuart says.

Peter is a specialist in *music thanatology*, an emerging specialty in music therapy that focuses on providing palliative care to the dying through music. He uses his harp, and sometimes his voice, to induce calm and give solace to the dying, their families, and their caregivers. Peter applies music systematically—matching it to each patient’s breathing patterns and other responses, delivering different sounds to uplift or comfort, depending on his assessment of the patient’s moment-by-moment needs.

Chaplains and counselors informally report that after music vigils, patients’ conversations indicate that they more easily

come to terms with their own death (Fyfe, 2006). And in a study of 65 dying patients in which pre- and post-intervention physiological measures were compared, music vigils averaging an hour in length resulted in decreased agitation and wakefulness and slower, deeper, less effortful breathing (Freeman et al., 2006). These physiological benefits extended to patients who, on the basis of their behavior, were clearly in pain.

Why is music effective in easing the distress of those who are dying? In patients close to death, hearing typically functions longer than other senses. Thus, responsiveness to music may persist until the individual’s final moments. Besides

reducing anxiety, music can, in some instances, enhance the effects of medication administered to control pain (Starr, 1999). For these reasons, music vigils may be an especially effective end-of-life therapy.

Currently, the United States has over 5,300 hospice programs serving approximately 1.6 million terminally ill patients annually. About 38 percent of hospice patients have cancer. The top noncancer diagnoses are extreme frailty in the elderly (14 percent), dementia (13 percent), heart disease (11 percent), and lung disease (9 percent) (NHPCO, 2012). Because hospice care is a cost-effective alternative to expensive life-saving treatments, U.S. government health-care benefits (Medicare and Medicaid) cover it, as do most private insurance plans. In addition, community and foundation contributions allow many hospices to provide free services to uninsured patients who cannot pay (Hospice Foundation of America, 2013). Consequently hospice is affordable for most dying patients and their families. Hospices also serve dying children—a tragedy so devastating that social support and bereavement intervention are vital.

Besides reducing patient physical suffering, hospice contributes to improved family functioning. The majority of patients and families report high satisfaction with quality of care and pain management, enhanced sense of social support, and (in the case of home hospice) increased ability to sustain patient care at home (Candy et al., 2011). In one study, family members

experiencing hospice scored higher than nonhospice family members in psychological well-being one to two years after their loved one’s death (Ragow-O’Brien, Hayslip, & Guarnaccia, 2000).

As a long-range goal, hospice organizations are striving for broader acceptance of their patient- and family-centered approach. Culturally sensitive approaches are needed to reach more ethnic minority patients, who are far less likely than white patients to participate in hospice (NHPCO, 2012). Canada has a Web-based hospice outreach service, the Canadian Virtual Hospice (www.virtualhospice.ca), to support patients, families, and care providers—whether or not they are part of a hospice program—with information, resources, and connections to others with similar concerns.

In developing countries, where millions die of cancer and other devastating illnesses each year, community-based teams working under a nurse’s supervision sometimes deliver palliative care. But they face many obstacles, including lack of funding, pain-relieving drugs, and professional and public education about hospice. As a result, they are small “islands of excellence,” accessible to only a few families (Ddungu, 2011).

ASK YOURSELF

REVIEW Why is the stage notion an inaccurate account of dying patients' mental and emotional reactions?

CONNECT Reread the description of Sofie's mental and emotional reactions to dying on pages 646–647. Then review the story of Sofie's life on pages 3–4 in Chapter 1. How were Sofie's responses consistent with her personality and lifelong style of coping with adversity?

APPLY When 5-year-old Timmy's kidney failure was diagnosed as terminal, his parents could not accept the tragic news. Their hospital visits became shorter, and they evaded his anxious questions. Eventually, Timmy blamed himself. He died with little physical pain, but alone, and his parents suffered prolonged guilt. How could hospice care have helped Timmy and his family?

REFLECT If you were terminally ill, where would you want to die? Explain.

The Right to Die

In 1976, the parents of Karen Ann Quinlan, a young woman who had fallen into an irreversible coma after taking drugs at a party, sued to have her respirator turned off. The New Jersey Supreme Court, invoking Karen's right to privacy and her parents' power as guardians, complied with this request. Although Karen was expected to die quickly, she breathed independently, continued to be fed intravenously, and lived another 10 years in a persistent vegetative state.

In 1990, 26-year-old Terri Schiavo's heart stopped briefly, temporarily cutting off oxygen to her brain. Like Karen, Terri lay in a persistent vegetative state. Her husband and guardian, Michael, claimed that she had earlier told him she would not want to be kept alive artificially, but Terri's parents disagreed. In 1998, the Florida Circuit Court granted Michael's petition to have Terri's feeding tube removed. In 2001, after her parents had exhausted their appeals, the tube was taken out. But on the basis of contradictory medical testimony, Terri's parents convinced a circuit court judge to order the feeding tube reinserted, and the legal wrangling continued. In 2002, Michael won a second judgment to remove the tube.

By that time, publicity over the case and its central question—who should make end-of-life decisions when the patient's wishes are unclear—had made Terri a political issue. In 2003, the Florida legislature passed a law allowing the governor to stay the circuit court's order to keep Terri alive, but on appeal, the law was declared unconstitutional. In 2005, the U.S. Congress entered the fray, passing a bill that transferred Terri's fate to the U.S. District Court. When the judge refused to intervene, the feeding tube was removed for a third time. In 2005—15 years

after losing consciousness—Terri Schiavo died. The autopsy confirmed the original persistent vegetative state diagnosis: Her brain was half normal size.

Before the 1950s, the right to die was of little concern because medical science could do little to extend the lives of terminally ill patients. Today, medical advances mean that the same procedures that preserve life can prolong inevitable death, diminishing both quality of life and personal dignity.

The Quinlan and Schiavo cases—and others like them—have brought right-to-die issues to the forefront of public attention. Today, all U.S. states have laws that honor patients' wishes concerning withdrawal of treatment in cases of terminal illness and, sometimes, in cases of a persistent vegetative state. But no uniform right-to-die policy exists, and heated controversy persists over how to handle the diverse circumstances in which patients and family members make requests.

Euthanasia is the practice of ending the life of a person suffering from an incurable condition. Its various forms are summarized in Table 19.1. As we will see, public acceptance of euthanasia is high, except when it involves ending the life of an anguished, terminally ill patient without his or her expressed permission.

Passive Euthanasia

In **passive euthanasia**, life-sustaining treatment is withheld or withdrawn, permitting a patient to die naturally. **TAKE A MOMENT...** Do you think Terri Schiavo should have been allowed to die sooner? Was it right for Nicholas's doctors to turn off his respirator at Giselle's request? When an Alzheimer's victim has lost all awareness and bodily functions, should life support be withheld?

TABLE 19.1 Forms of Euthanasia

FORM	DESCRIPTION
Passive euthanasia	At the patient's request, the doctor withholds or withdraws treatment, thereby permitting the patient to die naturally. For example, the doctor does not perform surgery or administer medication that could prolong life, or the doctor turns off the respirator of a patient who cannot breathe independently.
Voluntary active euthanasia	The doctor ends a suffering patient's life at the patient's request. For example, the doctor administers a lethal dose of drugs.
Assisted suicide	The doctor helps a suffering patient take his or her own life. For example, the doctor enables the patient to swallow or inject a lethal dose of drugs.
Involuntary active euthanasia	The doctor ends a suffering patient's life without the patient's permission. For example, without obtaining the patient's consent, the doctor administers a lethal dose of drugs.

FIGURE 19.2 Example of a living will. This document is legal in the State of Illinois. Each person completing a living will should use a form specific to the U.S. state or Canadian province in which he or she resides because laws vary widely. (Courtesy of Office of the Attorney General, State of Illinois.)

In recent polls, more 70 percent of U.S. adults and 95 percent of physicians supported the right of patients or family members to end treatment when there is no hope of recovery (Curlin et al., 2008; Pew Research Center, 2006). In 1986, the American Medical Association endorsed withdrawing all forms of treatment from the terminally ill when death is imminent and from those in a permanent vegetative state. Consequently, passive euthanasia is widely practiced as part of ordinary medical procedure, in which doctors exercise professional judgment.

Still, a minority of citizens oppose passive euthanasia. Religious denomination has surprisingly little effect on people's opinions. For example, most Catholics hold favorable views, despite slow official church acceptance because of fears that passive euthanasia might be a first step toward government-approved mercy killing. However, ethnicity makes a difference: Nearly twice as many African Americans as Caucasian Americans desire all medical means possible, regardless of the patient's condition, and African Americans more often receive life-sustaining intervention, such as feeding tubes (Haley, 2013; Johnson et al., 2008). Their reluctance to forgo treatment reflects strong cultural and religious beliefs in overcoming adversity and in the power of God to promote healing (Johnson, Elbert-Avila, & Tulsky, 2005).

Because of controversial court cases like Terri Schiavo's, some doctors and health-care institutions are unwilling to end treatment without legal protection. In the absence of national consensus on passive euthanasia, people can best ensure that their wishes will be followed by preparing an **advance medical directive**—a written statement of desired medical treatment should they become incurably ill. U.S. states recognize two types of advance directives: a *living will* and a *durable power of attorney for health care* (U.S. Living Will Registry, 2005). Sometimes these are combined into one document.

In a **living will**, people specify the treatments they do or do not want in case of a terminal illness, coma, or other near-death situation (see Figure 19.2). For example, a person might state that without reasonable expectation of recovery, he or she should not be kept alive through medical intervention of any kind. In addition, a living will sometimes specifies that pain-relieving medication be given, even though it might shorten life. In Sofie's case, her doctor administered a powerful narcotic to relieve labored breathing and quiet her fear of suffocation. The narcotic suppressed respiration, causing death to occur hours or days earlier than if the medication had not been prescribed, but without distress. Such palliative care is accepted as appropriate and ethical medical practice.

LIVING WILL

THIS DECLARATION is made this _____ day of _____, 20____.

I, _____, being of sound mind, willfully and voluntarily make known my desires that my moment of death shall not be artificially postponed. If at any time I should have an incurable and irreversible injury, disease, or illness judged to be a terminal condition by my attending physician who has personally examined me and has determined that my death is imminent except for death delaying procedures, I direct that such procedures which would only prolong the dying process be withheld or withdrawn, and that I be permitted to die naturally with only the administration of medication, sustenance, or the performance of any medical procedure deemed necessary by my attending physician to provide me with comfort care.

In the absence of my ability to give directions regarding the use of such death delaying procedures, it is my intention that this declaration shall be honored by my family and physician as the final expression of my legal right to refuse medical or surgical treatment and accept the consequences from such refusal.

Signed: _____

City, County and State of Residence: _____

The declarant is personally known to me and I believe him or her to be of sound mind. I saw the declarant sign the declaration in my presence (or the declarant acknowledged in my presence that he or she had signed the declaration) and I signed the declaration as a witness in the presence of the declarant. At the date of this instrument, I am not entitled to any portion of the estate of the declarant according to the laws of intestate succession or, to the best of my knowledge and belief, under any will of declarant or other instrument taking effect at declarant's death, or directly financially responsible for declarant's medical care.

Witness: _____

Witness: _____

Although living wills help ensure personal control, they do not guarantee it. Recognition of living wills is usually limited to patients who are terminally ill or are otherwise expected to die shortly. Only a few U.S. states cover people in a persistent vegetative state or aging adults who linger with many chronic problems, including Alzheimer's disease, because these conditions are not classified as terminal. Even when terminally ill patients have living wills, doctors sometimes do not follow them for a variety of reasons (van Asselt, 2006). These include fear of lawsuits, their own moral beliefs, failure to inquire about patients' directives, and inaccessibility of those directives—for example, located in the family safe or family members unaware of them.

Because living wills cannot anticipate all future medical conditions and can easily be ignored, a second form of advance directive has become common. The **durable power of attorney for health care** authorizes appointment of another person (usually, though not always, a family member) to make health-care decisions on one's behalf. It generally requires only a short signed and witnessed statement like this:

I hereby appoint [name] as my attorney-in-fact (my "agent") to act for me and in my name (in any way I could act in person) to make any and all decisions for me concerning my personal care,

BRUCE AYRES/GETTY IMAGES

This couple discusses a durable power of attorney with a hospital chaplain. This advance directive authorizes a trusted spokesperson to make health-care decisions and helps ensure that one's desires will be granted.

medical treatment, hospitalization, and health care and to require, withhold, or withdraw any type of medical treatment or procedure, even though my death may ensue. (Courtesy of Office of the Attorney General, State of Illinois)

The durable power of attorney for health care is more flexible than the living will because it permits a trusted spokesperson to confer with the doctor as medical circumstances arise. Because authority to speak for the patient is not limited to terminal illnesses, more latitude exists for dealing with unexpected situations. And in gay and lesbian and other close relationships not sanctioned by law, the durable power of attorney can ensure the partner's role in decision making and in advocating for the patient's health-care needs.

Whether or not a person supports passive euthanasia, it is important to have a living will, durable power of attorney, or both, because most deaths occur in hospitals. Yet only about 30 percent of Americans have executed such documents, perhaps because of widespread uneasiness about bringing up the topic of death, especially with relatives (Harris Interactive, 2011; Pew Research Center, 2006). The percentage with advance directives does increase with age; almost two-thirds of adults over age 65 have them. To encourage people to make decisions about potential treatment while they are able, U.S. federal law now requires that all medical facilities receiving federal funds provide information at admission about state laws and institutional policies on patients' rights and advance directives.

As happened with Karen Quinlan and Terri Schiavo, health-care professionals—unclear about a patient's intent and fearing liability—will probably decide to continue treatment regardless of cost and a person's prior oral statements. Perhaps for this reason, some U.S. states permit appointment of a health-care proxy, or substitute decision maker, if a patient failed to provide an advance medical directive while competent. Proxies are an important means of covering children and adolescents, who cannot legally execute advance medical directives.

Voluntary Active Euthanasia

In recent years, the right-to-die debate has shifted from withdrawal of treatment for the hopelessly ill to more active alternatives. In **voluntary active euthanasia**, doctors or others act directly, at a patient's request, to end suffering before a natural end to life. The practice, a form of mercy killing, is a criminal offense in most countries, including almost all U.S. states. But support for voluntary active euthanasia has grown. As Figure 19.3 shows, about 70 to 90 percent of people in Western nations approve of it (World Federation of Right to Die Societies, 2006). In these countries, religiosity has little impact on acceptance. But in Eastern European nations where most of the population is religious, such as Croatia, Poland, Romania, and Turkey, approval rates tend to be lower (Cohen et al., 2006). In the United States and other Western nations, when doctors engage in voluntary active euthanasia, judges are usually lenient, granting suspended sentences or probation—a trend reflecting rising public interest in self-determination in death as in life.

Nevertheless, attempts to legalize voluntary active euthanasia have prompted heated controversy. Supporters believe it represents the most compassionate option for terminally ill people in severe pain. Opponents stress the moral difference between “letting die” and “killing” and point out that at times, even very sick patients recover. They also argue that involving doctors in taking the lives of suffering patients may impair people's trust in health professionals. Finally, a fear exists that legalizing this practice—even when strictly monitored to make sure it does not arise out of depression, loneliness, coercion, or a desire

FIGURE 19.3 Public opinion favoring voluntary active euthanasia in five nations. A struggle exists between public opinion, which has increasingly favored voluntary active euthanasia over the past 30 years, and legal statutes, which prohibit it. The majority of people in Western nations believe that a hopelessly ill, suffering patient who asks for a lethal injection should be granted that request. Public support for voluntary active euthanasia is highest in the Netherlands—the only nation in the world where the practice is legal under certain conditions. (From Harris Interactive, 2011; Pew Research Center, 2006.)

Social Issues: Health

Voluntary Active Euthanasia: Lessons from Australia and the Netherlands

In 1996, Australia's Northern Territory passed legislation allowing a terminally ill patient of sound mind and suffering from pain or other distress to ask a doctor to end his or her life. Two other doctors had to agree that the patient could not be cured, and a psychiatrist had to confirm the absence of treatable depression.

In the months that followed, four deaths occurred under the Northern Territory euthanasia statute, and it was heavily criticized. The Aborigines, valuing harmony and balance with nature, regarded it as culturally inappropriate. Their leaders claimed the law would discourage Aboriginal aging adults, many of whom had experienced a lifetime of persecution at the hands of European settlers, from seeking medical care (Fleming, 2000). Others considered the law to be a national issue because patients traveled from other states to make use of it. In 1997, the Northern Territory legislation was overturned by the Australian Parliament, which claimed that assemblies do not have the right to legislate intentional killing.

The episode placed Australia at the center of the debate over euthanasia—an issue that continues to spark high passions across the country. Opponents worry about error and abuse of the practice (Fickling, 2004). Supporters emphasize compassion and the right of individuals to control the course of their own lives. June Burns, an Australian woman with bladder cancer who participated in TV ads documenting the course of her illness, responded, “If I were a dog, they would have put me down by now. I feel life is very precious and . . . I wish I could go on, but I can't and I'd like to die with dignity.” Eventually, she took her own life with a

lethal dose of a barbiturate, which she had kept for the purpose for nearly a decade (Voluntary Euthanasia Society of New South Wales, 2008).

For the past several decades, doctors in the Netherlands have engaged in voluntary active euthanasia without criminal prosecution. In 2002, the practice became legal under the following conditions: when physical or mental suffering is severe, with no prospect of relief; when no doubt exists about the patient's desire to die; when the patient's decision is voluntary, well-informed, and stable over time; when all other options for care have been exhausted or refused; and when another doctor has been consulted.

Over 50 percent of Dutch doctors say they perform euthanasia, most often with cancer patients. Despite safeguards, both voluntary and involuntary (without patient permission) active euthanasia have occurred. A small minority of doctors admit granting the euthanasia requests of physically healthy patients—usually older people who felt “weary of life” (Rurup et al., 2005; van Tol, Rietjens, & van der Heide, 2010). And some say they actively caused a death when a patient did not ask for it, defending their action by referring to the impossibility of treating pain, a low quality of life, or drawn-out dying in a patient near death.

Voluntary active euthanasia in the Netherlands has risen steadily over the past decade. Doctors report about 2,000 cases annually to medical examiners—nearly 2 percent of all deaths. But anonymous surveys reveal additional cases—as many as 20 percent of all such deaths—that probably

Australian Aboriginal peoples regard voluntary active euthanasia as contrary to the values of their culture. The natural images that permeate their artwork reflect the priority they place on harmony and balance with nature.

were voluntary active euthanasia but were not reported. In most of these, attending doctors said that they had not perceived their act (sedation to relieve pain) as ending a life. But for some, they expressed doubts about whether they had properly followed legal standards of practice, such as ascertaining patient consent or consulting a second doctor (Onwuteaka-Philipsen et al., 2005; van der Heide et al., 2007).

The Northern Territory and Dutch examples reveal that legalizing voluntary active euthanasia can spark both the fear and the reality of death without consent. And the Dutch experience highlights the challenges of monitoring euthanasia practices. Nevertheless, terminally ill individuals in severe pain continue to plead for such laws. Probably all would agree that when doctors feel compelled to relieve suffering and honor self-determination by assisting a patient in dying, they should be subject to the most stringent professional and legal oversight possible.

to diminish the burden of illness on others—could lead to a broadening of euthanasia. Initially limited to the terminally ill, it might be applied involuntarily to the frail, demented, or disabled—outcomes that most people find unacceptable and immoral.

Will legalizing voluntary active euthanasia lead us down a “slippery slope” to the killing of vulnerable people who did not ask to die? The Social Issues: Health box above presents lessons from the Australian state of the Northern Territory, where a law allowing voluntary active euthanasia was passed in 1996,

and from the Netherlands, where doctors had practiced it for years before its 2002 legalization.

Assisted Suicide

After checking Diane's blood count, Dr. Timothy Quill gently broke the news: leukemia. If she were to have any hope of survival, a strenuous course of treatment with only a 25 percent success rate would have to begin immediately. Convinced that she would suffer unspeakably from side effects and lack of control over her body, Diane chose not to undergo chemotherapy and a bone marrow transplant.

Dr. Quill made sure that Diane understood her options. As he adjusted to her decision, Diane raised another issue: She wanted no part of a lingering death. She calmly insisted that when the time came, she desired to take her own life in the least painful way possible—a choice she had discussed with her husband and son, who respected it. Realizing that Diane could get the most out of the time she had left only if her fears of prolonged pain were allayed, Dr. Quill granted her request for sleeping pills, making sure she knew the amounts needed for both sleep and suicide.

Diane's next few months were busy and fulfilling. Her son took leave from college to be with her, and her husband worked at home as much as possible. Gradually, bone pain, fatigue, and fever set in. Saying goodbye to her family and friends, Diane asked to be alone for an hour, took a lethal dose of medication, and died at home (Quill, 1991).

Assisting a suicide is illegal in Canada and in most, but not all, U.S. states. In Western Europe, doctor-assisted suicide is legal in Belgium, the Netherlands, Luxembourg, and Switzerland and is tacitly accepted in many other countries. In the United States, Oregon's 1997 Death with Dignity Act explicitly allows physicians to prescribe drugs so terminally ill patients can end their lives. To get a prescription, patients must have two doctors

agree that they have less than six months to live and must request the drugs at least twice, with an interval of at least 15 days. In January 2006, the U.S. Supreme Court rejected a challenge to the Oregon law, but the Court has also upheld the right of other states to ban assisted suicide. In 2008, the state of Washington passed legislation—similar to Oregon's—permitting assisted suicide. In 2013, the Montana and Vermont legislatures also legalized the practice.

Nearly 60 percent of Americans approve of assisted suicide for terminally ill patients in great pain (Harris Interactive, 2011). In a review of studies carried out in the United States, Canada, and Western Europe, level of support among terminally ill patients was about the same as for the general public, with about one-third of patients saying they would consider it for themselves in particular circumstances (Hendry et al., 2012). People who support the practice tend to be higher in SES and less religious.

The number of Oregon residents dying by assisted suicide has increased since passage of the law, from 16 in 1998 to 77 in 2012. Most (68 percent) were age 65 or older, and the overwhelming majority (97 percent) were enrolled in hospice and died at home. Their most common diagnosis (75 percent) was cancer. Still, assisted suicide accounts for only one-fifth of 1 percent of Oregon deaths (Oregon Public Health Division, 2013). Doctors report that the most common reasons for assisted-suicide requests are loss of autonomy, decreasing ability to participate in activities that make life enjoyable, and loss of control of bodily functions (Oregon Department of Human Services, 2009). Ten times as many terminally ill people initiate the qualification process for assisted suicide as engage in it. But thousands of Oregonians say they find comfort in knowing the option is available should they suffer while dying (Hedberg et al., 2009).

Public interest in assisted suicide was sparked in the 1990s by Dr. Jack Kevorkian, a vigorous proponent of euthanasia who devised "suicide machines" that permitted more than 100 terminally ill patients, after brief counseling, to self-administer lethal drugs and carbon monoxide. Less publicity surrounded Dr. Quill's decision to assist Diane—a patient he knew well after serving for years as her personal doctor. After he told her story in a prestigious medical journal, reactions were mixed, as they are toward assisted suicide in general. Some view doctors who help suffering people who want to die as compassionate and respectful of patients' personal choices. Others oppose assisted suicide on religious and moral grounds or believe that the role of doctors should be limited to saving, not taking, lives.

Like euthanasia, assisted suicide poses grave dilemmas. Analyzing the practice, the American Academy of Hospice and Palliative Medicine (2007) advises great caution on the part of doctors practicing in regions where assisted suicide is legal, including making sure before engaging in it that the following conditions are met:

- The patient has access to the best possible palliative care and will continue to receive such care throughout the dying process.

© BOB MAHONEY/THE IMAGE WORKS

In a prestigious medical journal, Dr. Timothy Quill explained how and why he aided a terminally ill patient in taking her own life. Doctor-assisted suicide is legal in the states of Oregon, Washington, Montana, and Vermont and in several Western European countries.

- The patient has full decision-making capacity and requests assisted suicide voluntarily; health-care financial pressures and coercive influences from family members play no role.
- All reasonable alternatives to assisted suicide have been considered and implemented, if acceptable to the patient.
- The practice is consistent with the doctor's fundamental values, and he or she is willing to participate. (If not, the doctor should recommend transfer of care.)

Juries have seldom returned guilty verdicts in cases involving doctor-assisted suicide. Yet in April 1999, Kevorkian—after giving a terminally ill man a lethal injection, videotaping the death, and permitting the event to be broadcast on the CBS television program *60 Minutes*—was convicted of second-degree murder and served 8 years of a 10- to 25-year sentence. The murder indictment prevented Kevorkian from introducing evidence indicating that the man wanted to kill himself—evidence that would have been permissible had the charge been assisted suicide or voluntary active euthanasia.

Public opinion consistently favors voluntary active euthanasia over assisted suicide. Yet in assisted suicide, the final act is solely the patient's, reducing the possibility of coercion. For this reason, some experts believe that legalizing assisted suicide is preferable to legalizing voluntary active euthanasia. However, in an atmosphere of high family caregiving burdens and intense pressure to contain health-care costs (see Chapter 17), legalizing either practice poses risks. The American Medical Association opposes both voluntary active euthanasia and assisted suicide. In a survey of 1,140 U.S. doctors, only 18 percent objected to sedating a dying patient to unconsciousness if pain can be controlled in no other way, whereas nearly 70 percent opposed assisted suicide—attitudes resembling those of physicians in other Western nations (Curlin et al., 2008; Seale, 2009). Helping incurable, suffering patients who yearn for death poses profound moral and legal problems.

ASK YOURSELF

REVIEW What benefits and risks does legalizing voluntary active euthanasia pose?

APPLY Thinking ahead to the day she dies, Noreen imagines a peaceful scene in which she says goodbye to loved ones. What social and medical practices are likely to increase Noreen's chances of dying in the manner she desires?

APPLY Ramón is certain that, if he ever became terminally ill, he would want doctors to halt life-saving treatment. To best ensure that his wish will be granted, what should Ramón do?

REFLECT Do you approve of passive euthanasia, voluntary active euthanasia, or assisted suicide? If you were terminally ill, would you consider any of these practices? Explain.

Bereavement: Coping with the Death of a Loved One

Loss is an inevitable part of existence throughout the lifespan. Even when change is for the better, we must let go of some aspects of experience so we can embrace others. In this way, our development prepares us for profound loss.

Bereavement is the experience of losing a loved one by death. The root of this word means “to be robbed,” suggesting unjust and injurious theft of something valuable. Consistent with this image, we respond to loss with **grief**—intense physical and psychological distress. When we say someone is grief-stricken, we imply that his or her total way of being is affected.

Because grief can be overwhelming, cultures have devised ways of helping their members move beyond it to deal with the life changes demanded by death of a loved one. **Mourning** is the culturally specified expression of the bereaved person's thoughts and feelings. Customs—such as gathering with family and friends, dressing in black, attending the funeral, and observing a prescribed mourning period with special rituals—vary greatly among societies and ethnic groups. But all have in common the goal of helping people work through their grief and learn to live in a world that does not include the deceased.

Clearly, grief and mourning are closely linked—in everyday language, we often use the two words interchangeably. Let's look closely at how people respond to the death of a loved one.

Grief Process

Theorists formerly believed that bereaved individuals—both children and adults—moved through three phases of grieving, each characterized by a different set of responses (Bowlby, 1980; Rando, 1995). In reality, however, people vary greatly in behavior and timing and often move back and forth between these reactions. A more accurate account compares grief to a roller-coaster ride, with many ups and downs and, over time, gradual resolution (Lund, 1996). Rather than phases, the grieving process can be conceived as a set of *tasks*—actions the person must take to recover and return to a fulfilling life: (1) to accept the reality of the loss; (2) to work through the pain of grief; (3) to adjust to a world without the loved one; and (4) to develop an inner bond with the deceased and move on with life (Worden, 2009). According to this view, people can take active steps to overcome grief—a powerful remedy for the overwhelming feelings of vulnerability that the bereaved often experience.

Avoidance. On hearing the news, the survivor experiences shock followed by disbelief, which may last from hours to weeks. A numbed feeling serves as “emotional anesthesia” while the person begins the first task of grieving: becoming painfully aware of the loss.

Confrontation. As the mourner confronts the reality of the death, grief is most intense. The person often experiences a cascade of emotional reactions, including anxiety, sadness, protest, anger, helplessness, frustration, abandonment, and yearning for the loved one. Common responses include obsessively reviewing the circumstances of death, asking how it might have been prevented, and searching for meaning in it (Neimeyer, 2001). In addition, the grief-stricken person may be absent-minded, unable to concentrate, and preoccupied with thoughts of the deceased, and may experience loss of sleep and appetite. Self-destructive behaviors, such as taking drugs or driving too fast, may occur. Most of these responses are symptoms of depression—an invariable component of grieving.

Although confrontation is difficult, it enables the mourner to grapple with the second task: working through the pain of grief. Each surge of anguish that results from an unmet wish to be reunited with the deceased brings the mourner closer to acceptance that the loved one is gone. After hundreds, perhaps thousands, of these painful moments, the grieving person comprehends that a cherished relationship must be transformed from a physical presence to an inner representation. As a result, the mourner makes progress on the third task: adjusting to a world in which the deceased is missing.

Restoration. Adjusting to the loss is more than an internal, emotional task. The bereaved must also deal with stressors that are secondary outcomes of the death—overcoming loneliness by reaching out to others; mastering skills (such as finances or cooking) that the deceased had performed; reorganizing daily life without the loved one; and revising one's identity from “spouse” to “widow” or from “parent” to “parent of a deceased child.”

According to a recent perspective, called the **dual-process model of coping with loss**, effective coping requires people to oscillate between dealing with the emotional consequences of loss and attending to life changes, which—when handled successfully—have restorative, or healing, effects (Hansson & Stroebe, 2007; Stroebe & Schut, 1999, 2010). Moving back and forth offers temporary distraction and relief from painful grieving. Much research indicates that confronting grief without relief has severe negative consequences for physical and mental health (Corr & Corr, 2007). Consistent with the dual-process model, in a study that assessed widowed older adults at 6, 18, and 48 months after the death of their spouses, both loss-oriented and restoration-oriented activities occurred throughout bereavement. As predicted, restoration-oriented activities—such as visiting friends, attending religious services, and volunteering—reduced the stress of grieving (Richardson, 2007). Using the dual-process approach, one 14-session intervention for older adults grieving the loss of a spouse addresses both emotional and life-change issues, alternating between them (Lund et al., 2004, 2010).

As grief subsides, emotional energies increasingly shift toward the fourth task—forging a symbolic bond with the deceased and moving on with life by meeting everyday respon-

sibilities, investing in new activities and goals, strengthening old ties, and building new relationships. On certain days, such as family celebrations or the anniversary of death, grief reactions may resurface and require attention, but they do not interfere with a healthy, positive approach to life.

In fact, throughout the grieving process, individuals report experiencing positive as well as negative emotions, with expressions of happiness and humor aiding in coping with grief (Ong, Bergeman, & Bisconti, 2004). In an investigation of several hundred people age 50 and older whose spouse or partner had died within the previous six months, 90 percent agreed that “feeling happy” and “having humor” in daily life is important, and more than 75 percent said they had experienced humor, laughter, or happiness during the past week. The greater participants’ valuing and experience of positive emotion, the better their bereavement adjustment, as indicated by reduced levels of grief and depression (Lund et al., 2008–2009). Expressions of happiness can be viewed as a restoration-oriented activity, offering distraction from grieving and strengthening bonds with others.

How long does grieving last? There is no single answer. Sometimes confrontation continues for a few months, at other times for several years. An occasional upsurge of grief may persist for a lifetime and is a common response to losing a much-loved spouse, partner, child, or friend.

Personal and Situational Variations

Like dying, grieving is affected by many factors, including personality, coping style, and religious and cultural background. Sex differences are also evident. Compared with women, men typically express distress and depression less directly and seek social support less readily—factors that may contribute to the much higher mortality rate among bereaved men than women (Doka & Martin, 2010; Lund & Caserta, 2004b; McGoldrick, 2004).

Furthermore, the quality of the mourner’s relationship with the deceased is important. An end to a loving, fulfilling bond leads to more anguished grieving, but it is less likely to leave a long-term residue of anger, guilt, and regret than the dissolution of a conflict-ridden, ambivalent tie (Abakoumkin, Stroebe, & Stroebe, 2010; Mikulincer & Shaver, 2008). And end-of-life care makes a difference: Widowed older adults whose spouses experienced a painful death reported more anxiety, intrusive thoughts, and yearning for the loved one six months later (Carr, 2003).

Circumstances surrounding the death—whether it is sudden and unanticipated or follows a prolonged illness—also shape mourners’ responses. The nature of the lost relationship and the timing of the death within the life course make a difference as well.

Sudden, Unanticipated Deaths versus Prolonged, Expected Deaths. In instances of sudden, unexpected deaths—usually the result of murder, suicide, war, accident, or natural disaster—avoidance may be especially pronounced and

confrontation highly traumatic because shock and disbelief are extreme. In a survey of a representative sample of 18- to 45-year-old adults in a large U.S. city, the trauma most often reported as prompting an intense, debilitating stress reaction was the sudden, unanticipated death of a loved one (Breslau et al., 1998). In contrast, during prolonged dying, the bereaved person has had time to engage in **anticipatory grieving**—acknowledging that the loss is inevitable and preparing emotionally for it. Survivors may feel less overwhelmed immediately following the death (Johansson & Grimby, 2013). But they may display more persistent anxiety due to long-term stressors, such as highly demanding caregiving and having watched a loved one suffer from a debilitating illness (Carr et al., 2001).

Adjusting to a sudden death is easier when the survivor understands the reasons for it. This barrier to confronting loss is tragically apparent in cases of sudden infant death syndrome (SIDS), in which doctors cannot tell parents exactly why their apparently healthy baby died (see Chapter 3, page 110). That death seems “senseless” also complicates grieving after suicides, terrorist attacks, school and drive-by shootings, and natural disasters. In Western societies, people tend to believe that momentous events should be comprehensible and non-random (Lukas & Seiden, 2007). A death that is sudden and unexpected can threaten basic assumptions about a just, benevolent, and controllable world.

Suicide, particularly that of a young person, is especially hard to bear. Compared with survivors of other sudden deaths, people grieving a suicidal loss are more likely to conclude that they contributed to or could have prevented it—self-blame that can trigger profound guilt and shame. These reactions are likely to be especially intense and persisting when a mourner’s culture or religion condemns suicide as immoral (Dunne & Dunne-Maxim, 2004). Individuals who have survived a suicide typically score higher than those who have experienced other types of losses in feelings of guilt and shame, sense of rejection by the deceased, and desire to conceal the cause of death (Sveen & Walby, 2008). Typically, recovery from grief after a suicide is prolonged.

Parents Grieving the Loss of a Child. The death of a child, whether unexpected or foreseen, is the most difficult loss an adult can face (Dent & Stewart, 2004). Children are extensions of parents’ feelings about themselves—the focus of hopes and dreams, including parents’ sense of immortality. Also, because children depend on, admire, and appreciate their parents in a deeply gratifying way, they are an unmatched source of love. Finally, the death of a child is unnatural: Children are not supposed to die before their parents.

Parents who have lost a child often report considerable distress many years later, along with frequent thoughts of the deceased. The guilt triggered by outliving their child frequently becomes a tremendous burden, even when parents “know” better (Murphy, 2008). For example, a mother whose daughter died of cancer said despairingly, “I gave her her genes, and her genes killed her. I had a hand in this.”

AP IMAGES/MANU BRABO

A father weeps while holding the body of his son, killed during the Syrian armed conflict in 2012. The death of a child, whether unexpected or foreseen, is the most difficult loss an adult can face.

Although a child’s death sometimes leads to marital breakup, this is likely to happen only when the relationship was already unsatisfactory (Wheeler, 2001). If parents can reorganize the family system and reestablish a sense of life’s meaning through valuing the lost child’s impact on their lives and investing in other children and activities, then the result can be firmer family commitments and personal growth. The process, which often takes years, is associated with improved physical and mental health and gains in marital satisfaction (Murphy, 2008; Price et al., 2011). Five years after her son’s death, one parent reflected on her progress:

I was afraid to let go [of my pain, which was] a way of loving him. . . . Finally I had to admit that his life meant more than pain, it also meant joy and happiness and fun—and living. . . . When we release pain we make room for happiness in our lives. My memories of S. became lighter and more spontaneous. Instead of hurtful, my memories brought comfort, even a chuckle. . . . realized S. was still teaching me things. (Klass, 2004, p. 87)

Children and Adolescents Grieving the Loss of a Parent or Sibling. The loss of an attachment figure has long-term consequences for children. When a parent dies, children’s basic sense of security and being cared for is threatened. And the death of a sibling not only deprives children of a close emotional tie but also informs them, often for the first time, of their own vulnerability.

Children grieving a family loss describe frequent crying, trouble concentrating in school, sleep difficulties, headaches, and other physical symptoms several months to years after a death. And clinical studies reveal that persistent depression, anxiety, angry outbursts, social withdrawal, loneliness, and worries about dying themselves are common (Luecken, 2008;

Marshall & Davies, 2011). At the same time, many children say they have actively maintained mental contact with their dead parent or sibling, dreaming about and speaking to them regularly. In a follow-up seven to nine years after sibling loss, thinking about the deceased brother or sister at least once a day was common (Martinson, Davies, & McClowry, 1987; Silverman & Nickman, 1996). These images, reported by bereaved adults as well, seem to facilitate coping with loss.

Cognitive development contributes to the ability to grieve. For example, children with an immature understanding of death may believe the dead parent left voluntarily, perhaps in anger, and that the other parent may also disappear. For these reasons, young children need careful, repeated explanations assuring them that the parent did not want to die and was not angry at them (Christ, Siegel, & Christ, 2002). Keeping the truth from children isolates them and often leads to profound regrets. One 8-year-old who learned only a half-hour in advance that his sick brother was dying reflected, “If only I’d known, I could have said goodbye.”

Regardless of children’s level of understanding, honesty, affection, and reassurance help them tolerate painful feelings of loss. Grief-stricken school-age children are usually more willing than adolescents to confide in parents. To appear normal, teenagers tend to keep their grieving from both adults and peers. Consequently, they are more likely than children to become depressed or to escape from grief through acting-out behavior (Granot, 2005). Overall, effective parenting—warmth combined with rational discipline—fosters adaptive coping and positive long-term adjustment in both children and adolescents (Luecken, 2008).

Adults Grieving the Loss of an Intimate Partner. Recall from Chapter 18 that after the death of a spouse, adaptation to widowhood varies greatly, with age, social support, and personality making a difference. After a period of intense grieving, most widowed older adults in Western nations fare well, while younger individuals display more negative outcomes (see page 623 to review). Older widows and widowers have many more contemporaries in similar circumstances. And most have already attained important life goals or adjusted to the fact that some goals will not be attained.

In contrast, loss of a spouse or partner in early or middle adulthood is a nonnormative event that profoundly disrupts life plans. Interviews with a large, U.S. nationally representative sample of adults who had been widowed from less than 1 to 64 years previously (typically in middle adulthood) revealed that thoughts about and conversations with the lost spouse occurred often in the first few years, then declined gradually (Carnelley et al., 2006). But they did not reach their lowest level for several decades, when the typical respondent still thought about the deceased partner once every week or two and conversed with him or her about once a month.

In addition to dealing with feelings of loss, young and middle-aged widows and widowers often must assume a greater role in comforting others, especially children. They also face the

stresses of single parenthood and rapid shrinking of the social network established during their life as a couple. The death of an intimate partner in a gay or lesbian relationship presents unique challenges. When relatives limit or bar the partner from participating in funeral services, the survivor experiences *disenfranchised grief*—a sense of loss without the opportunity to mourn publicly and benefit from others’ support—which can profoundly disrupt the grieving process (Doka, 2008). Fortunately, gay and lesbian communities provide helpful alternative support in the form of memorial services and other rituals.

Bereavement Overload. When a person experiences several deaths at once or in close succession, bereavement overload can occur. Multiple losses deplete the coping resources of even well-adjusted people, leaving them emotionally overwhelmed and unable to resolve their grief (Lattanzi-Licht & Doka, 2003).

Because old age often brings the death of spouse, siblings, and friends in close succession, aging adults are at risk for bereavement overload (Kastenbaum, 2008). But recall from Chapter 18 that compared with young people, older adults are often better equipped to handle these losses. They know that decline and death are expected in late adulthood, and they have had a lifetime of experience through which to develop effective coping strategies.

Public tragedies—terrorist attacks, natural disasters, random murders in schools, or widely publicized kidnappings—can spark bereavement overload (Rynearson & Salloum, 2011). Many survivors who lost loved ones, co-workers, or friends in the September 11, 2001, terrorist attacks (including an estimated 3,000 children who lost a parent) experienced repeated images of horror and destruction, which impeded coming to terms with loss. Children and adolescents suffered profoundly—from intense shock, prolonged grief, frequent mental replays of

Villagers in Sichuan Province, China, grieve for relatives who died in a massive earthquake in 2013 that left nearly 200 dead. Public tragedies can spark bereavement overload, leaving mourners at risk for prolonged, overwhelming grief.

Applying What We Know

Suggestions for Resolving Grief After a Loved One Dies

Suggestion	Description
Give yourself permission to feel the loss.	Permit yourself to confront all thoughts and emotions associated with the death. Make a conscious decision to overcome your grief, recognizing that this will take time.
Accept social support.	In the early part of grieving, let others reach out to you by making meals, running errands, and keeping you company. Be assertive; ask for what you need so people who would like to help will know what to do.
Be realistic about the course of grieving.	Expect to have some negative and intense reactions, such as feeling anguished, sad, and angry, that last from weeks to months and may occasionally resurface years after the death. There is no one way to grieve, so find the best way for you.
Remember the deceased.	Review your relationship to and experiences with the deceased, permitting yourself to see that you can no longer be with him or her as before. Form a new bond based on memories, keeping it alive through photographs, commemorative donations, prayers, and other symbols and actions.
When ready, invest in new activities and relationships, and master new tasks of daily living.	Identify which roles you must give up and which ones you must assume as a consequence of the death, and take deliberate steps to modify daily life accordingly. Set small goals at first, such as a night at the movies, a dinner date with a friend, a cooking or household repair class, or a week's vacation.

the vicious attack and gruesome outcomes, and fear of the settings in which those events occurred (Nader, 2002; Webb, 2002). The greater the bereaved individual's exposure to the catastrophic death scene, the more severe these reactions.

Funerals and other bereavement rituals, illustrated in the Cultural Influences box on page 664, assist mourners of all ages in resolving grief with the help of family and friends. Bereaved individuals who remain preoccupied with loss and who have difficulty resuming interest in everyday activities benefit from special interventions designed to help them adjust.

Bereavement Interventions

Sympathy and understanding are sufficient to enable most people to undertake the tasks necessary to recover from grief (see Applying What We Know above). Yet effective support is often difficult to provide, and relatives and friends can benefit from training in how to respond. Sometimes they give advice aimed at hastening recovery or ask questions aimed at managing their own anxiety ("Were you expecting him to die?" "Was she in a lot of pain?")—approaches that most bereaved people dislike (Kastenbaum, 2012). Listening patiently and assuring the bereaved of "being there" for them—"I'm here if you need to talk," "Let me know what I can do"—are among the best ways to help.

Bereavement interventions typically encourage people to draw on their existing social network, while providing additional social support through group or individual counseling. Controversy exists over whether grief counseling benefits most bereaved people, or whether it helps only those experiencing

profound difficulties (CFAH, 2003; Jordan & Neimeyer, 2003). One analysis of research expressed optimism about broadly favorable effects (Larson & Hoyt, 2007). Furthermore, evidence is mounting that bereaved adults who struggle with and surmount challenges and losses often experience stress-related personal growth, including greater awareness of their own strengths, enhanced appreciation of close relationships, and new spiritual insights (Calhoun et al., 2010).

Support groups that bring together mourners who have experienced the same type of loss seem highly effective in promoting recovery. In a program for recently widowed older adults based on the dual-process model of coping with loss, in which group members helped one another resolve grief and master tasks of daily living, participants readily bonded with one another and gained in sense of self-efficacy at managing their own lives (Caserta, Lund, & Rice, 1999). A widow expressed the many lasting benefits:

We shared our anger at being left behind, . . . our fright of that aloneness. We shared our favorite pictures, so each of us could know the others' families and the fun we used to have. We shared our feelings of guilt if we had fun . . . and found out that it was okay to keep on living! . . . We cheered when one of us accomplished a new task. We also tried to lend a helping hand and heart when we would have one of our bad days! . . . This group will always be there for me and I will always be there for them. I love you all! (Lund, 2005)

Follow-up research suggests that group sessions are best suited for fostering loss-oriented coping (confronting and resolving grief), whereas an individually tailored approach works best for restoration-oriented coping (reorganizing daily life) (Lund

Cultural Influences

Cultural Variations in Mourning Behavior

The ceremonies that commemorated Sofie's and Nicholas's deaths—the first Jewish, the second Quaker—were strikingly different. Yet they served common goals: announcing that a death had occurred, ensuring social support, commemorating the deceased, and conveying a philosophy of life after death.

At the funeral home, Sofie's body was washed and shrouded, a Jewish ritual signifying return to a state of purity. Then it was placed in a plain wooden (not metal) coffin, so as not to impede the natural process of decomposition. To underscore the finality of death, Jewish tradition does not permit viewing of the body; it remains in a closed coffin. Traditionally, the coffin is not left alone until burial; in honor of the deceased, the community maintains a day-and-night vigil.

To return the body quickly to the life-giving earth from which it sprang, Sofie's funeral was scheduled as soon as relatives could gather—just three days after death. Sofie's husband and children symbolized their anguish by cutting a black ribbon and pinning it to their clothing. The rabbi recited psalms of comfort, followed by a eulogy. The service continued at the graveside. Once the coffin had been lowered into the ground, relatives and friends took turns shoveling earth onto it, each participating in the irrevocable act of burial. The service concluded with the *Kaddish* prayer, which affirms life while accepting death.

At home, the family lit a memorial candle, which burned throughout *shiva*, the seven-day mourning period. A meal of consolation prepared by others followed, creating a warm feeling of community. Jewish custom prescribes that after 30 days, life should gradually return to normal. When a parent dies, the mourning period is extended to 12 months.

In the Quaker tradition of simplicity, Nicholas was cremated promptly. During the next week, relatives and close friends

gathered with Giselle and Sasha at their home. Together, they planned a memorial service to celebrate Nicholas's life.

When people arrived on the appointed day, a clerk of the Friends (Quaker) Meeting welcomed them and explained to newcomers the Quaker custom of worshipping silently, with those who feel moved to speak rising at any time to share thoughts and feelings. Many mourners offered personal statements about Nicholas or read poems and selections from Scripture. After concluding comments from Giselle and Sasha, everyone joined hands to close the service. A reception for the family followed.

Variations in mourning behavior are vast, both within and across societies. At African-American funerals, for example, grief is expressed freely: Eulogies and music are usually designed to trigger release of deep emotion (McGoldrick et al., 2004). In contrast, the Balinese of Indonesia believe they must remain calm in the face of death so that the gods can hear their prayers. While acknowledging their underlying grief, Balinese mourners work hard to maintain their composure (Rosenblatt, 2008).

Religions also render accounts of the aftermath of death that console both dying and bereaved individuals. Beliefs of tribal and village cultures typically include an elaborate world of ancestor spirits and customs designed to ease the journey of the deceased to this afterlife (Rosenblatt, 2008). Jewish tradition emphasizes personal survival through giving life and care to others. Unlike other Christian groups, Quakers give little attention to hope of heaven or fear of hell, focusing mainly on “salvation by

Mourners light candles at a memorial service for six Sikhs who died in a shooting rampage in Wisconsin in 2012. Sikh funeral customs include singing hymns, saying prayers, and offering remembrances of the deceased, followed by cremation and scattering of the ashes.

character”—working for peace, justice, and a loving community.

In recent years, a new ritual has arisen: “virtual cemeteries” on the Internet, which allow postings whenever bereaved individuals feel ready to convey their thoughts and feelings, creation of tributes at little or no cost, and continuous, easy access to the memorial. Most creators of Web tributes choose to tell personal stories, highlighting a laugh, a favorite joke, or a touching moment. Some survivors use Web memorials to grieve openly, others to converse with the lost loved one. Cemetery guestbooks offer a place for visitors to connect with other mourners. Web cemeteries also provide a means for people excluded from traditional death rituals to engage in public mourning (Roberts, 2006; Stroebe, van der Houwen, & Schut, 2008). The following “gravesite” message captures the unique qualities of this highly flexible medium for mourning:

I wish I could maintain contact with you, to keep alive the vivid memories of your impact on my life. . . . Because I cannot visit your grave today, I use this means to tell you how much you are loved.

et al., 2010). Bereaved adults differ widely in the new roles, relationships, and life skills they need most, and in the formats and schedules best suited to acquiring them.

LOOK AND LISTEN

Arrange to sit in on a bereavement support group session sponsored by a local hospice program or hospital, noting both emotional and daily living challenges expressed by group members. Ask participants to explain how the group has helped them. ●

Interventions for children and adolescents following violent deaths must protect them from unnecessary reexposure and assist parents and teachers with their own distress so they can effectively offer comfort (Dowd, 2013). In the aftermath of horrific tragedies—such as the December 14, 2012, mass shooting at Sandy Hook Elementary School in Newtown, Connecticut, or the April 15, 2013, Boston Marathon bombings—nurturing and caring relationships with adults are the most powerful way to help children recover from trauma.

A sudden, violent, and unexplainable death; the loss of a child; a death that the mourner feels he or she could have prevented; or an ambivalent or dependent relationship with the deceased makes it harder for bereaved people to overcome their loss. In these instances, grief therapy, or individual counseling with a specially trained professional, can be helpful. Assisting bereaved adults in finding some value in the grieving experience—for example, gaining insight into the meaning of relationships, discovering their own capacity to cope with adversity, or crystallizing a sense of purpose in their lives—is particularly effective (Neimeyer et al., 2010).

Nevertheless, most bereaved individuals do not participate in bereavement interventions. In several studies, only 30 to 50 percent of family caregivers of dying patients made use of bereavement services—such as phone support, support groups, and referrals for counseling—even though these were readily available through hospice, hospitals, or other community organizations (Bergman, Haley, & Small, 2010, 2011; Cherlin et al., 2007). Many who refused bereavement services were severely distressed yet did not realize that intervention could be helpful.

Death Education

Preparatory steps can help people of all ages cope with death more effectively. The death awareness movement that sparked increased sensitivity to the needs of dying patients has also led to the rise of college and university courses in death, dying, and bereavement. Instruction has been integrated into the training of doctors, nurses, psychologists, and social workers, although most professional offerings are limited to only a few lectures (Wass, 2004). Death education is also found in adult education programs in many communities and even in a few elementary and secondary schools.

Death education at all levels has the following goals:

- Increasing students' understanding of the physical and psychological changes that accompany dying
- Helping students learn how to cope with the death of a loved one
- Preparing students to be informed consumers of medical and funeral services
- Promoting understanding of social and ethical issues involving death

Educational format varies widely. Some programs simply convey information. Others are experiential and include activities such as role playing, discussions with the terminally ill, visits to mortuaries and cemeteries, and personal awareness exercises. Research reveals that although using a lecture style leads to gains in knowledge, it often leaves students more uncomfortable about death than when they entered. In contrast, experiential programs that help people confront their own mortality are less likely to heighten death anxiety and may sometimes reduce it (Hurtig & Stewin, 2006; Maglio & Robinson, 1994).

Whether acquired in the classroom or in our daily lives, our thoughts and feelings about death are forged through interactions with others. Becoming more aware of how we die and of our own mortality, we encounter our greatest loss, but we also gain. Dying people have at times confided in those close to them that awareness of the limits of their lifespan permitted them to dispense with superficial distractions and wasted energies and focus on what is truly important in their lives. As one terminally ill patient summed up, “[It’s] kind of like life, just speeded up”—an accelerated process in which, over a period of weeks to months, one grapples with issues that normally would have taken years or decades to resolve (Selwyn, 1996, p. 36). Applying this lesson to ourselves, we learn that by being in touch with death and dying, we can live ever more fully.

ASK YOURSELF

REVIEW What circumstances are likely to induce bereavement overload? Cite examples.

CONNECT Compare grieving individuals' reactions with terminally ill patients' thoughts and feelings as they move closer to death, described on page 647. Can a dying person's reactions be viewed as a form of grieving? Explain.

APPLY List features of self-help groups that contribute to their effectiveness in helping people cope with loss.

REFLECT Visit a Web cemetery, such as Virtual Memorials (virtualmemorials.com). Select examples of Web tributes, guestbook entries, and testimonials that illustrate the unique ways in which virtual cemeteries help people cope with death.

SUMMARY

How We Die (p. 640)

Describe the physical changes of dying, along with their implications for defining death and the meaning of death with dignity.

- Death is long and drawn-out for three-fourths of people, many more than in times past, as a result of life-saving medical technology. Of those who die suddenly, 80 to 90 percent are victims of heart attacks.
- In general, dying takes place in three phases: the **agonal phase**, in which regular heartbeat disintegrates; **clinical death**, a short interval in which resuscitation is still possible; and **mortality**, or permanent death.
- In most industrialized nations, **brain death** is accepted as the definition of death. But for incurable patients who remain in a **persistent vegetative state**, the brain death standard does not solve the problem of when to halt treatment.

- We can best ensure death with dignity by supporting dying patients through their physical and psychological distress, being candid about death's certainty, and helping them learn enough about their condition to make reasoned choices about treatment.

Understanding of and Attitudes Toward Death

(p. 642)

Discuss age-related changes in conceptions of and attitudes toward death, and cite factors that influence death anxiety.

- Compared with earlier generations, more young people reach adulthood having had little contact with death, contributing to a sense of unease about it.

- To understand death, children must have some basic notions of biology and must be able to distinguish between *dead*, *inanimate*, *unreal*, and *nonexistent*. Most children attain an adultlike concept of death in middle childhood, gradually mastering concepts of permanence, inevitability, cessation, applicability, and causation. Experiences with death and religious teachings affect children's understanding, as do open, honest discussions.
- Adolescents are aware that death happens to everyone and can occur at any time, but their high-risk activities suggest that they do not take death personally. Candid discussions can help teenagers build a bridge between death as a logical concept and their personal experiences.
- In early adulthood, many people avoid thinking about death, but in midlife, they become more conscious that their own lives are finite. In late adulthood, as death nears, people are more apt to ponder the process of dying than the state of death.
- Wide individual and cultural variations exist in **death anxiety**. People with a sense of spirituality or a well-developed personal philosophy of death are less fearful, as are those with deep faith in a higher force or being. Older adults' greater ability to regulate negative emotion and their sense of symbolic immortality reduce death anxiety. Across cultures, women exhibit more death anxiety than men.

Thinking and Emotions of Dying People (p. 646)

Describe and evaluate Kübler-Ross's theory of typical responses to dying, citing factors that influence dying patients' responses.

- Elisabeth Kübler-Ross proposed that dying people typically express five responses, initially proposed as stages: denial, anger, bargaining, depression, and acceptance. These reactions do not occur in fixed sequence, and dying people often display other coping strategies.

- An **appropriate death** is one that makes sense in terms of the individual's pattern of living and values, preserves or restores significant relationships, and is as free of suffering as possible. The extent to which people attain these goals depends on many contextual variables—nature of the disease, personality and coping style, family members' and health professionals' behavior, and spirituality, religion, and cultural background.

A Place to Die (p. 650)

Evaluate the extent to which homes, hospitals, nursing homes, and the hospice approach meet the needs of dying people and their families.

- Although most people say they want to die at home, only about one-fourth of Americans do. Even with professional help and hospital-supplied equipment, caring for a dying patient is highly demanding.

- Sudden deaths typically occur in hospital emergency rooms, where sympathetic explanations from staff can reduce family members' anger, frustration, and confusion. Intensive care is especially depersonalizing for patients, lingering between life and death while hooked to machines. Many U.S. hospitals still lack comprehensive treatment programs aimed at easing end-of-life suffering.
- Though deaths in U.S. nursing homes are common, high-quality terminal care is lacking. Too many patients die in pain without having their needs met.
- The **hospice** approach is a comprehensive program of support services designed to meet the dying person's physical, emotional, social, and spiritual needs by providing **palliative**, or **comfort, care**, rather than prolonging life. Hospice care also contributes to improved family functioning and better psychological well-being among family survivors.

The Right to Die (p. 654)

Discuss controversies surrounding euthanasia and assisted suicide.

- Modern medical procedures that preserve life can also prolong inevitable death, diminishing quality of life and personal dignity. **Euthanasia**—ending the life of a person suffering from an incurable condition—takes various forms.
- **Passive euthanasia**, withholding or withdrawing life-sustaining treatment from a hopelessly ill patient, is widely accepted and practiced. People can best ensure that their wishes will be followed by preparing a written **advance medical directive**. A **living will** contains instructions for treatment, whereas the **durable power of attorney for health care** names another person to make health care decisions on one's behalf.

© PENNY TWEEDIE/ALAMY

- Public support for **voluntary active euthanasia**, in which doctors or others act directly, at a patient's request, to end suffering before a natural end to life, is high. Nevertheless, the practice remains a criminal offense in most countries and has sparked heated controversy, fueled by fears that it will be applied involuntarily to vulnerable people.
- Less public support exists for assisted suicide. But because the final act is solely the patient's, some experts believe that legalizing assisted suicide is preferable to legalizing voluntary active euthanasia.

Bereavement: Coping with the Death of a Loved One

(p. 659)

Describe the phases of grieving, factors that underlie individual variations, and bereavement interventions.

- **Bereavement** refers to the experience of losing a loved one by death, **grief** to the intense physical and psychological distress that accompanies loss. **Mourning** is the culturally prescribed expression of the bereaved person's thoughts and feelings.
- Although theorists previously believed that grieving occurred in orderly phases—avoidance, confrontation, and finally restoration—a more accurate image is a roller-coaster ride, with the mourner completing a set of tasks to overcome grief. According to the **dual-process model of coping with loss**, effective coping involves oscillating between dealing with the emotional consequences of loss and attending to life changes, which can have restorative effects. Bereaved individuals who experience positive as well as negative emotions cope more effectively.
- Like dying, grieving is affected by many personal and situational factors. Bereaved men express grief less directly than bereaved women. After a sudden, unanticipated death, avoidance may be especially pronounced and confrontation highly traumatic. In contrast, a prolonged, expected death grants the bereaved person time to engage in **anticipatory grieving**.
- When a parent loses a child or a child loses a parent or sibling, grieving is generally intense and prolonged. Because early loss of a life partner is a nonnormative event with a major impact on life plans, younger widowed individuals usually fare less well than widowed older people. Disenfranchised grief can profoundly disrupt the process of grieving.

- People who experience several deaths at once or in close succession may suffer from bereavement overload. Those at risk include aging adults, individuals who have lost loved ones to public tragedies, and people who have witnessed unexpected, violent deaths.

AP IMAGES/ZHANG HAO/COLOR CHINA PHOTO

- Sympathy and understanding are sufficient for most people to recover from grief. Support groups are highly effective in aiding recovery, whereas individually tailored approaches help mourners reorganize their daily lives. Interventions for children and adolescents following violent deaths must protect them from unnecessary reexposure and assist parents and teachers in offering comfort.

Death Education (p. 665)

Explain how death education can help people cope with death more effectively.

- Today, instruction in death, dying, and bereavement is integrated into training programs for doctors, nurses, psychologists, and social workers. It is also found in adult education programs and in a few elementary and secondary schools. Courses with an experiential component may reduce death anxiety.

Important Terms and Concepts

Glossary

- A**
- academic programs** Preschool and kindergarten programs in which teachers structure children's learning, teaching academic skills through formal lessons that often involve repetition and drill. Distinguished from *child-centered programs*. (p. 244)
- accommodation** In Piaget's theory, that part of adaptation in which new schemes are created and old ones adjusted to produce a better fit with the environment. Distinguished from *assimilation*. (p. 152)
- acculturative stress** Psychological distress resulting from conflict between an individual's minority culture and the host culture. (p. 406)
- activities of daily living (ADLs)** Basic self-care tasks required to live on one's own, such as bathing, dressing, getting in and out of bed or a chair, and eating. (p. 567)
- activity theory** A social theory of aging that states that declining rates of interaction in late adulthood reflect social barriers to engagement, not the desires of aging adults. Older people try to preserve life satisfaction by finding roles that allow them to remain about as active and busy as they were in middle age. Distinguished from *disengagement theory*, *continuity theory*, and *socioemotional selectivity theory*. (p. 614)
- adaptation** In Piaget's theory, the process of building schemes through direct interaction with the environment. Consists of two complementary activities: *assimilation* and *accommodation*. (p. 152)
- adolescence** The transition between childhood and adulthood that begins with puberty. It involves accepting one's full-grown body, acquiring adult ways of thinking, attaining greater independence from one's family, developing more mature ways of relating to peers of both sexes, and beginning to construct an identity. (p. 361)
- advance medical directive** A written statement of desired medical treatment should a person become incurably ill. (p. 655)
- affect optimization** The ability to maximize positive emotion and dampen negative emotion. An emotional strength of late adulthood. (p. 605)
- age-graded influences** Influences on lifespan development that are strongly related to age and therefore fairly predictable in when they occur and how long they last. (p. 10)
- age of viability** The age at which the fetus can first survive if born early. Occurs sometime between 22 and 26 weeks. (p. 84)
- aging in place** In late adulthood, remaining in a familiar setting where one has control over one's everyday life. (p. 617)
- agonal phase** The phase of dying in which gasps and muscle spasms occur during the first moments in which the regular heart beat disintegrates. Distinguished from *clinical death* and *mortality*. (p. 640)
- alcohol-related neurodevelopmental disorder (ARND)** The least severe form of fetal alcohol spectrum disorder, involving brain injury but with typical physical growth and absence of facial abnormalities. Distinguished from *fetal alcohol syndrome (FAS)* and *partial fetal alcohol syndrome (p-FAS)*. (p. 89)
- allele** Each of two or more forms of a gene located at the same place on corresponding pairs of chromosomes. (p. 48)
- Alzheimer's disease** The most common form of dementia, in which structural and chemical brain deterioration is associated with gradual loss of many aspects of thought and behavior, including memory, skilled and purposeful movements, and comprehension and production of speech. (p. 582)
- amnion** The inner membrane that that encloses the prenatal organism in amniotic fluid, which helps keep temperature constant and provides a cushion against jolts caused by the mother's movements. (p. 81)
- amyloid plaques** A structural change in the cerebral cortex associated with Alzheimer's disease, in which dense deposits of a deteriorated protein called *amyloid* develop, surrounded by clumps of dead nerve and glial cells. (p. 583)
- androgyny** The gender identity held by individuals who score high on both traditionally masculine and traditionally feminine personality characteristics. (p. 276)
- anorexia nervosa** An eating disorder in which young people, mainly females, starve themselves because of a compulsive fear of getting fat and an extremely distorted body image. (p. 372)
- anoxia** Inadequate oxygen supply. (p. 100)
- anticipatory grieving** Before a prolonged, expected death, acknowledging the inevitability of the loss and preparing emotionally for it. (p. 661)
- Apgar Scale** A rating system used to assess a newborn baby's physical condition immediately after birth on the basis of five characteristics: heart rate, respiratory effort, reflex irritability, muscle tone, and color. (p. 98)
- appropriate death** A death that makes sense in terms of the individual's pattern of living and values, preserves or restores significant relationships, and is as free of suffering as possible. (p. 648)
- assimilation** In Piaget's theory, that part of adaptation in which the external world is interpreted in terms of current schemes. Distinguished from *accommodation*. (p. 152)
- assisted living** A homelike housing arrangement for older adults who require more care than can be provided at home but less than is usually provided in nursing homes. (p. 589)
- assistive technology** An array of devices that permits people with disabilities, including older adults, to improve their functioning. (p. 573)
- associative memory deficit** Age-related difficulty creating and retrieving links between pieces of information—for example, two items or an item and its context. (p. 591)
- associative play** A form of social interaction in which children engage in separate activities but interact by exchanging toys and commenting on one another's behavior. Distinguished from *nonsocial activity*, *parallel play*, and *cooperative play*. (p. 261)
- attachment** The strong affectionate tie that humans have with special people in their lives, which leads them to feel pleasure when interacting with those people and to be comforted by their nearness in times of stress. (p. 195)
- Attachment Q-Sort** A method for assessing the quality of attachment in children between 1 and 4 years of age through home observations of a variety of attachment-related behaviors. (p. 198)
- attention-deficit hyperactivity disorder (ADHD)** A childhood disorder involving inattention, impulsivity, and excessive motor activity, resulting in academic and social problems. (p. 304)
- authoritarian child-rearing style** A child-rearing style that is low in acceptance and involvement, high in coercive control, and low in autonomy granting. Distinguished from *authoritative*, *permissive*, and *uninvolved child-rearing styles*. (p. 279)
- authoritative child-rearing style** A child-rearing style that is high in acceptance and involvement, emphasizes adaptive control techniques, and includes gradual, appropriate autonomy granting. Distinguished from *authoritarian*, *permissive*, and *uninvolved child-rearing styles*. (p. 278)
- autobiographical memory** Long-lasting recollections of personally meaningful one-time events from both the recent and the distant past. (p. 164)
- autoimmune response** A malfunction of the immune system in which it turns against normal body tissues. (p. 571)
- automatic processes** Cognitive activities that are so well-learned that they require no space in working memory and, therefore, permit an individual to focus on other information while performing them. (p. 162)
- autonomy** At adolescence, a sense of oneself as a separate, self-governing individual. Involves relying more on oneself and less on parents for support and guidance and engaging in careful, well-reasoned decision making. (p. 415)
- autonomy versus shame and doubt** In Erikson's theory, the psychological conflict of toddlerhood, which is resolved favorably when parents provide young children with suitable guidance and reasonable choices. (p. 184)
- autosomes** The 22 matching chromosome pairs in each human cell. (p. 47)
- average healthy life expectancy** The number of years that an individual born in a particular year can expect to live in full health, without disease or injury. Distinguished from *maximum lifespan* and *average life expectancy*. (p. 564)
- average life expectancy** The number of years that an individual born in a particular year can expect to live, starting at any given age. Distinguished from *maximum lifespan* and *average healthy life expectancy*. (p. 564)

avoidant attachment The attachment pattern characterizing infants who seem unresponsive to the parent when she is present, are usually not distressed by parental separation, react to the stranger in much the same way as to the parent, and avoid or are slow to greet the parent when she returns. Distinguished from *secure*, *resistant*, and *disorganized/disoriented attachment*. (p. 197)

B

babbling Repetition of consonant–vowel combinations in long strings, beginning around 6 months of age. (p. 176)

basal metabolic rate (BMR) The amount of energy the body uses at complete rest. (p. 439)

basic emotions Emotions such as happiness, interest, surprise, fear, anger, sadness, and disgust that are universal in humans and other primates and have a long evolutionary history of promoting survival. (p. 185)

basic trust versus mistrust In Erikson's theory, the psychological conflict of infancy, which is resolved positively when the balance of care is sympathetic and loving. (p. 184)

behavioral genetics A field devoted to uncovering the contributions of nature and nurture to the diversity of human traits and abilities. (p. 69)

behaviorism An approach that regards directly observable events—stimuli and responses—as the appropriate focus of study and views the development of behavior as taking place through classical and operant conditioning. (p. 17)

behavior modification Procedures that combine conditioning and modeling to eliminate undesirable behaviors and increase desirable responses. (p. 18)

bereavement The experience of losing a loved one by death. (p. 659)

bicultural identity The identity constructed by individuals who explore and adopt values from both their family's subculture and the dominant culture. (p. 406)

“big five” personality traits Five basic factors into which hundreds of personality traits have been organized: neuroticism, extroversion, openness to experience, agreeableness, and conscientiousness. (p. 542)

biological aging, or senescence Genetically influenced, age-related declines in the functioning of organs and systems that are universal in all members of our species. Sometimes called *primary aging*. (p. 432)

blended, or reconstituted, family A family structure resulting from remarriage or cohabitation that includes parent, child, and steprelatives. (p. 349)

body image Conception of and attitude toward one's physical appearance. (p. 371)

brain death Irreversible cessation of all activity in the brain and the brain stem. The definition of death accepted in most industrialized nations. (p. 641)

brain plasticity The capacity of various parts of the cerebral cortex to take over functions of damaged regions. Declines as hemispheres of the cerebral cortex lateralize. (p. 124)

breech position A position of the baby in the uterus that would cause the buttocks or feet to be delivered first. (p. 100)

bulimia nervosa An eating disorder in which individuals, mainly females, engage in strict dieting and excessive exercise accompanied by binge eating, often followed by deliberate vomiting and purging with laxatives. (p. 373)

burnout A condition in which long-term job stress leads to mental exhaustion, a sense of loss of personal control, and feelings of reduced accomplishment. (p. 554)

C

canalization The tendency of heredity to restrict the development of some characteristics to just one or a few outcomes. (p. 72)

cardinality The mathematical principle specifying that the last number in a counting sequence indicates the quantity of items in the set. (p. 243)

carrier A heterozygous individual who can pass a recessive trait to his or her offspring. (p. 48)

cataracts Cloudy areas in the lens of the eye that increase from middle to old age, resulting in foggy vision and (without surgery) eventual blindness. (p. 569)

categorical self Classification of the self according to prominent ways in which people differ, such as age, sex, physical characteristics, and goodness and badness. Develops between 18 and 30 months. (p. 208)

central executive In information processing, the conscious, reflective part of our mental system that directs the flow of information, coordinating incoming information with information already in the system and selecting, applying, and monitoring strategies that facilitate memory storage, comprehension, reasoning, and problem solving. (p. 162)

centration In Piaget's theory, the tendency of preoperational children to focus on one aspect of a situation while neglecting other important features. (p. 229)

cephalocaudal trend An organized pattern of physical growth that proceeds from the upper to the lower part of the body (“head to tail”). Distinguished from *proximodistal trend*. (p. 121)

cerebellum A structure at the rear and base of the brain that aids in balance and control of body movements. (p. 218)

cerebral cortex The largest, most complex structure of the human brain, containing the greatest number of neurons and synapses and accounting for the highly developed intelligence of the human species. (p. 124)

cerebrovascular dementia A form of dementia that develops when a series of strokes leaves areas of dead brain cells, producing step-by-step degeneration of mental ability, with each step occurring abruptly after a stroke. (p. 585)

cesarean delivery A surgical delivery in which the doctor makes an incision in the mother's abdomen and lifts the baby out of the uterus. (p. 101)

child-centered programs Preschool and kindergarten programs in which teachers provide a variety of activities from which children select, and much learning takes place through play. Distinguished from *academic programs*. (p. 244)

child-rearing styles Combinations of parenting behaviors that occur over a wide range of situations, creating an enduring child-rearing climate. (p. 278)

chorion The outer membrane that forms a protective covering around the prenatal organism. It sends out tiny hairlike villi, from which the placenta begins to develop. (p. 82)

chromosomes Rodlike structures in the cell nucleus that store and transmit genetic information. (p. 46)

chronosystem In ecological systems theory, temporal changes in environments, either externally imposed or arising from within the person, that produce new conditions affecting development. Distinguished from *microsystem*, *mesosystem*, *exosystem*, and *macrosystem*. (p. 25)

circular reaction In Piaget's theory, a means of building schemes in which infants try to repeat a chance event caused by their own motor activity. (p. 153)

classical conditioning A form of learning that involves associating a neutral stimulus with a stimulus that leads to a reflexive response. Once the nervous system makes the connection between the two stimuli, the neutral stimulus alone produces the behavior. (p. 133)

climacteric The midlife transition in which fertility declines, bringing an end to reproductive capacity in women and diminished fertility in men. (p. 504)

clinical death The phase of dying in which heartbeat, circulation, breathing, and brain functioning stop, but resuscitation is still possible. Distinguished from *agonal phase* and *mortality*. (p. 640)

clinical interview An interview method in which the researcher uses a flexible, conversational style to probe for the participant's point of view. Distinguished from *structured interview*. (p. 30)

clinical, or case study, method A research method in which the aim is to obtain as complete a picture as possible of one individual's psychological functioning by bringing together interview data, observations, and sometimes test scores. (p. 30)

clique A group of about five to seven members who are good friends and, therefore, usually resemble one another in family background, attitudes, and values. (p. 419)

cognitive-affective complexity A form of thinking that increases from adolescence through middle adulthood, involving awareness of conflicting positive and negative feelings and coordination of them into a

- complex, organized structure that recognizes the uniqueness of individual experiences. (p. 452)
- cognitive-developmental theory** An approach introduced by Piaget that views children as actively constructing knowledge as they manipulate and explore their world and that regards cognitive development as taking place in stages. (p. 18)
- cognitive maps** Mental representations of familiar large-scale spaces, such as neighborhood or school. (p. 300)
- cognitive self-regulation** The process of continuously monitoring progress toward a goal, checking outcomes, and redirecting unsuccessful efforts. (p. 307)
- cohabitation** The lifestyle of unmarried couples who have a sexually intimate relationship and who share a residence. (p. 487)
- cohort effects** The effects of cultural–historical change on the accuracy of longitudinal and cross-sectional research findings. Results based on one cohort—individuals developing in the same time period, who are influenced by particular historical and cultural conditions—may not apply to other cohorts. (p. 37)
- collectivist societies** Societies in which people define themselves as part of a group and stress group goals over individual goals. Distinguished from *individualistic societies*. (p. 65)
- commitment within relativistic thinking** In Perry’s theory, the mature individual’s formulation of a perspective that synthesizes contradictions between opposing views, rather than choosing between them. (p. 451)
- companionate love** Love based on warm, trusting affection and caregiving. Distinguished from *passionate love*. (p. 473)
- compliance** Voluntary obedience to requests and commands. (p. 208)
- compression of morbidity** The public health goal of reducing the average period of diminished vigor before death as life expectancy extends. Medical advances, improved socioeconomic conditions, and good health habits all promote this goal. (p. 576)
- concrete operational stage** Piaget’s third stage of cognitive development, extending from about 7 to 11 years of age, during which thought becomes logical, flexible, and organized in its application to concrete information, but the capacity for abstract thinking is not yet present. (p. 299)
- conditioned response (CR)** In classical conditioning, a new response produced by a conditioned stimulus (CS) that is similar to the unconditioned, or reflexive, response (UCR). (p. 134)
- conditioned stimulus (CS)** In classical conditioning, a neutral stimulus that, through pairing with an unconditioned stimulus (UCS), leads to a new, conditioned response. (CR). (p. 134)
- congregate housing** Housing for older adults that provides a variety of support services, including meals in a common dining room, along with watchful oversight of residents with physical and mental disabilities. (p. 618)
- conservation** The understanding that certain physical characteristics of objects remain the same, even when their outward appearance changes. (p. 229)
- constructivist classroom** A classroom grounded in Piaget’s view of children as active agents who construct their own knowledge. Features include richly equipped learning centers, small groups and individuals solving self-chosen problems, a teacher who guides and supports in response to children’s needs, and evaluation based on individual students’ progress in relation to their own prior development. Distinguished from *traditional* and *social-constructivist classrooms*. (p. 319)
- contexts** Unique combinations of personal and environmental circumstances that can result in different paths of development. (p. 7)
- continuity theory** A social theory of aging that states that most aging adults, in their choice of everyday activities and social relationships, strive to maintain a personal system—an identity and a set of personality dispositions, interests, roles, and skills—that promotes life satisfaction by ensuring consistency between their past and anticipated future. Distinguished from *disengagement theory*, *activity theory*, and *socioemotional selectivity theory*. (p. 614)
- continuous development** The view that development is a process of gradually augmenting the same types of skills that were there to begin with. Distinguished from *discontinuous development*. (p. 6)
- contrast sensitivity** A general principle accounting for early pattern preferences, which states that if babies can detect a difference in contrast between two patterns, they will prefer the pattern with more contrast. (p. 144)
- controversial children** Children who receive many votes, both positive and negative, on self-report measures of peer acceptance, indicating that they are both liked and disliked. Distinguished from *popular*, *neglected*, and *rejected children*. (p. 341)
- conventional level** Kohlberg’s second level of moral development, in which moral understanding is based on conforming to social rules to ensure positive human relationships and maintain societal order. (p. 408)
- convergent thinking** The type of cognition emphasized on intelligence tests, which involves arriving at a single correct answer to a problem. Distinguished from *divergent thinking*. (p. 322)
- cooing** Pleasant vowel-like noises made by infants beginning around 2 months of age. (p. 176)
- cooperative learning** Collaboration on a task by a small group of classmates who work toward common goals by resolving differences of opinion, sharing responsibilities, and providing one another with sufficient explanation to correct misunderstandings. (p. 320)
- cooperative play** A form of social interaction in which children orient toward a common goal, such as acting out a make-believe theme. Distinguished from *nonsocial activity*, *parallel play*, and *associative play*. (p. 261)
- coparenting** Parents’ mutual support of each other’s parenting behaviors. (p. 60)
- coregulation** A form of supervision in which parents exercise general oversight while letting children take charge of moment-by-moment decision making. (p. 345)
- core knowledge perspective** A perspective that states that infants are born with a set of innate knowledge systems, or core domains of thought, each of which permits a ready grasp of new, related information and therefore supports early, rapid development of certain aspects of cognition. (p. 159)
- corpus callosum** The large bundle of fibers connecting the two hemispheres of the cerebral cortex. (p. 218)
- correlational design** A research design in which the investigator gathers information on individuals without altering their experiences and then examines relationships between participants’ characteristics and their behavior or development. Does not permit inferences about cause and effect. (p. 34)
- correlation coefficient** A number, ranging from +1.00 to –1.00, that describes the strength and direction of the relationship between two variables. (p. 34)
- creativity** The ability to produce work that is original yet appropriate—something others have not thought of that is useful in some way. (p. 322)
- cross-linkage theory of aging** A theory of biological aging asserting that the formation of bonds, or links, between normally separate protein fibers causes the body’s connective tissue to become less elastic over time, leading to many negative physical outcomes. (p. 434)
- cross-sectional design** A research design in which groups of participants of different ages are studied at the same point in time. Distinguished from *longitudinal design*. (p. 37)
- crowd** A large, loosely organized social group consisting of several cliques with similar values. Membership is based on reputation and stereotype. (p. 419)
- crystallized intelligence** Intellectual skills that depend on accumulated knowledge and experience, good judgment, and mastery of social conventions—abilities acquired because they are valued by the individual’s culture. Distinguished from *fluid intelligence*. (p. 518)
- D**
- death anxiety** Fear and apprehension of death. (p. 645)
- deferred imitation** The ability to remember and copy the behavior of models who are not present. (p. 154)
- delay of gratification** The ability to wait for an appropriate time and place to engage in a tempting act. (p. 209)

- dementia** A set of disorders occurring almost entirely in old age in which many aspects of thought and behavior are so impaired that everyday activities are disrupted. (p. 582)
- deoxyribonucleic acid (DNA)** Long, double-stranded molecules that make up chromosomes. (p. 46)
- dependency-support script** A typical pattern of interaction in which caregivers attend to older adults' dependent behaviors immediately, thereby reinforcing those behaviors. Distinguished from *independence-ignore script*. (p. 610)
- dependent variable** The variable the researcher expects to be influenced by the independent variable in an experiment. Distinguished from *independent variable*. (p. 35)
- developmental cognitive neuroscience** An area of investigation that brings together researchers from psychology, biology, neuroscience, and medicine to study the relationship between changes in the brain and the developing person's cognitive processing and behavior patterns. (p. 21)
- developmentally appropriate practice** A set of standards devised by the U.S. National Association for the Education of Young Children, specifying program characteristics that meet the developmental and individual needs of young children of varying ages, based on current research and consensus among experts. (p. 172)
- developmental quotient (DQ)** A score on an infant intelligence test, computed in the same manner as an IQ but labeled more conservatively because it does not tap the same dimensions of intelligence assessed in older children. (p. 170)
- developmental science** An interdisciplinary field devoted to understanding constancy and change throughout the lifespan. (p. 5)
- differentiation theory** The view that perceptual development involves the detection of increasingly fine-grained, invariant features in the environment. (p. 146)
- difficult child** A child whose temperament is characterized by irregular daily routines, slow acceptance of new experiences, and a tendency to react negatively and intensely. Distinguished from *easy child* and *slow-to-warm-up child*. (p. 190)
- discontinuous development** The view that development is a process in which new ways of understanding and responding to the world emerge at specific times. Distinguished from *continuous development*. (p. 6)
- disengagement theory** A social theory of aging that states that declines in social interaction in late adulthood are due to mutual withdrawal between older adults and society in anticipation of death. Distinguished from *activity theory*, *continuity theory*, and *socioemotional selectivity theory*. (p. 614)
- disorganized/disoriented attachment** The attachment pattern reflecting the greatest insecurity, characterizing infants who show confused, contradictory responses when reunited with the parent after a separation. Distinguished from *secure*, *avoidant*, and *resistant attachment*. (p. 198)
- displaced reference** The realization that words can be used to cue mental images of things that are not physically present. (p. 157)
- divergent thinking** The type of thinking associated with creativity, which involves generating multiple and unusual possibilities when faced with a task or problem. Distinguished from *convergent thinking*. (p. 322)
- dominance hierarchy** A stable ordering of group members that predicts who will win when conflict arises. (p. 297)
- dominant cerebral hemisphere** The hemisphere of the cerebral cortex responsible for skilled motor action and other important abilities. In right-handed individuals, the left hemisphere is dominant; in left-handed individuals, motor and language skills are often shared between the hemispheres. (p. 217)
- dominant-recessive inheritance** A pattern of inheritance in which, under heterozygous conditions, the influence of only one allele is apparent. (p. 48)
- dualistic thinking** In Perry's theory, the cognitive approach typical of younger college students, who divide information, values, and authority into right and wrong, good and bad, we and they. Distinguished from *relativistic thinking*. (p. 451)
- dual-process model of coping with loss** A perspective that assumes that people cope most effectively with loss when they oscillate between dealing with the emotional consequences of loss and attending to life changes, which—when handled successfully—have restorative, or healing, effects. (p. 660)
- dual representation** The ability to view a symbolic object as both an object in its own right and a symbol. (p. 227)
- durable power of attorney for health care** A written statement authorizing appointment of another person (usually, though not always, a family member) to make health care decisions on one's behalf. (p. 655)
- dynamic assessment** An approach to testing consistent with Vygotsky's zone of proximal development, in which purposeful teaching is introduced into the testing situation to find out what the child can attain with social support. (p. 315)
- dynamic systems theory of motor development** A theory that views new motor skills as reorganizations of previously mastered skills, which lead to more effective ways of exploring and controlling the environment. Each new skill is a joint product of central nervous system development, the body's movement capacities, the child's goals, and environmental supports for the skill. (p. 137)
- ## E
- easy child** A child whose temperament is characterized by quick establishment of regular routines in infancy, general cheerfulness, and easy adaptation to new experiences. Distinguished from *difficult child* and *slow-to-warm-up child*. (p. 190)
- ecological systems theory** Bronfenbrenner's approach, which views the person as developing within a complex system of relationships affected by multiple levels of the surrounding environment, from immediate settings of family and school to broad cultural values and programs. (p. 24)
- educational self-fulfilling prophecies** Teachers' positive or negative views of individual children, who tend to adopt and start to live up to those views. (p. 320)
- effortful control** The self-regulatory dimension of temperament, involving the capacity to voluntarily suppress a dominant response in order to plan and execute a more adaptive response. (p. 191)
- egalitarian marriage** A form of marriage in which partners relate as equals, sharing power and authority. Both try to balance the time and energy they devote to their occupations, their children, and their relationship. Distinguished from *traditional marriage*. (p. 480)
- egocentrism** Failure to distinguish others' symbolic viewpoints from one's own. (p. 228)
- ego integrity versus despair** In Erikson's theory, the psychological conflict of late adulthood, which is resolved positively when older adults come to terms with their lives and feel whole, complete, and satisfied with their achievements, recognizing that the paths they followed, abandoned, or never selected were necessary for fashioning a meaningful life course. (p. 604)
- elaboration** A memory strategy that involves creating a relationship, or shared meaning, between two or more pieces of information that do not belong to the same category in order to improve recall. (p. 305)
- embryo** The prenatal organism from 2 to 8 weeks after conception—the period when the groundwork for all body structures and internal organs is laid down. (p. 82)
- emergent literacy** Children's active efforts to construct literacy knowledge through informal experiences. (p. 240)
- emerging adulthood** A new transitional period of development, extending from the late teens to the mid- to late twenties, during which young people have left adolescence but have not yet assumed adult responsibilities. Rather, they continue to explore alternatives in education, work, personal beliefs and values, and love. (p. 464)
- emotional intelligence** A set of emotional abilities that enable individuals to process and adapt to emotional information. Measured by tapping the emotional skills people use to manage their own emotions and interact competently with others. (p. 313)
- emotional self-regulation** Strategies for adjusting our emotional state to a comfortable level of intensity so we can accomplish our goals. (p. 189)
- emotion-centered coping** A strategy for managing emotion that is internal, private, and aimed at controlling distress when little can be done to change an outcome. Distinguished from *problem-centered coping*. (p. 336)

- empathy** The ability to understand another's emotional state and to *feel with* that person, or respond emotionally in a similar way. (p. 208)
- epigenesis** Development resulting from ongoing, bidirectional exchanges between heredity and all levels of the environment. (p. 73)
- episodic memory** Memory for everyday experiences. (p. 238)
- epistemic cognition** Reflections on how one arrived at facts, beliefs, and ideas. (p. 451)
- ethnic identity** A sense of ethnic group membership and attitudes and feelings associated with that membership, as an enduring aspect of the self. (p. 406)
- ethnography** A method in which the researcher attempts to understand a culture or a distinct social group through participant observation—living with its members and taking field notes for an extended time. (p. 32)
- ethological theory of attachment** Bowlby's theory, the most widely accepted view of attachment, which regards the infant's emotional tie to the caregiver as an evolved response that promotes survival. (p. 196)
- ethology** An approach concerned with the adaptive, or survival, value of behavior and its evolutionary history. (p. 22)
- euthanasia** The practice of ending the life of a person suffering from an incurable condition. (p. 654)
- evolutionary developmental psychology** An area of research that seeks to understand the adaptive value of specieswide cognitive, emotional, and social competencies as those competencies change with age. (p. 22)
- executive function** In information processing, the diverse cognitive operations and strategies that enable us to achieve our goals in cognitively challenging situations. Includes controlling attention, suppressing impulses, coordinating information in working memory, and flexibly directing and monitoring thought and behavior. (p. 162)
- exosystem** In ecological systems theory, social settings that do not contain the developing person but nevertheless affect experiences in immediate settings. Distinguished from *microsystem*, *mesosystem*, *macrosystem*, and *chronosystem*. (p. 25)
- expansions** Adult responses that elaborate on children's speech, increasing its complexity. (p. 251)
- experience-dependent brain growth** Growth and refinement of established brain structures as a result of specific learning experiences that vary widely across individuals and cultures. Distinguished from *experience-expectant brain growth*. (p. 128)
- experience-expectant brain growth** The young brain's rapidly developing organization, which depends on ordinary experiences—opportunities to explore the environment, interact with people, and hear language and other sounds. Distinguished from *experience-dependent brain growth*. (p. 127)
- experimental design** A research design in which the investigator randomly assigns participants to two or more treatment conditions and studies the effect that manipulating an independent variable has on a dependent variable. Permits inferences about cause and effect. (p. 35)
- expertise** Acquisition of extensive knowledge in a field or endeavor. (p. 453)
- expressive style of language learning** A style of early language learning in which toddlers use language mainly to talk about their own and others' feelings and needs, with an initial vocabulary emphasizing social formulas and pronouns. Distinguished from *referential style of language learning*. (p. 178)
- extended-family household** A household in which three or more generations live together. (p. 65)
- F**
- family life cycle** A series of phases characterizing the development of most families around the world. In early adulthood, people typically live on their own, marry, and bear and rear children. In middle age, parenting responsibilities diminish. Late adulthood brings retirement, growing old, and (more often for women) death of one's spouse. (p. 478)
- fantasy period** Period of vocational development in which children gain insight into career options by fantasizing about them. Distinguished from *tentative period* and *realistic period*. (p. 455)
- fast-mapping** Children's ability to connect new words with their underlying concepts after only a brief encounter. (p. 248)
- feminization of poverty** A trend in which women who support themselves or their families have become the majority of the adult population living in poverty, regardless of age and ethnic group. (p. 544)
- fetal alcohol spectrum disorder (FASD)** A range of physical, mental, and behavioral outcomes caused by prenatal alcohol exposure, including *fetal alcohol syndrome (FAS)*, *partial fetal alcohol syndrome (p-FAS)*, and *alcohol-related neurodevelopmental disorder (ARND)*. (p. 88)
- fetal alcohol syndrome (FAS)** The most severe form of fetal alcohol spectrum disorder, distinguished by slow physical growth, facial abnormalities, and brain injury. Usually affects children whose mothers drank heavily throughout pregnancy. Distinguished from *partial fetal alcohol syndrome (p-FAS)* and *alcohol-related neurodevelopmental disorder (ARND)*. (p. 88)
- fetal monitors** Electronic instruments that track the baby's heart rate during labor. (p. 100)
- fetus** The prenatal organism from the ninth week to the end of pregnancy—the period during which body structures are completed and dramatic growth in size occurs. (p. 83)
- fluid intelligence** Intellectual skills that largely depend on basic information-processing skills—ability to detect relationships among visual stimuli, speed of analyzing information, and capacity of working memory. Influenced less by culture than by conditions in the brain and by learning unique to the individual. Distinguished from *crystallized intelligence*. (p. 518)
- formal operational stage** Piaget's highest stage, beginning around 11 years of age, in which adolescents develop the capacity for abstract, systematic, scientific thinking. (p. 382)
- frailty** Weakened functioning of diverse organs and body systems, which profoundly interferes with everyday competence and leaves older adults highly vulnerable in the face of infection, extremely hot or cold weather, or injury. (p. 580)
- fraternal, or dizygotic, twins** Twins resulting from the release and fertilization of two ova. They are genetically no more alike than ordinary siblings. Distinguished from *identical, or monozygotic, twins*. (p. 47)
- free radicals** Naturally occurring, highly reactive chemicals that form in the presence of oxygen and destroy nearby cellular material, including DNA, proteins, and fats essential for cell functioning. Believed to be involved in many disorders of aging. (p. 433)
- functional age** Actual competence and performance of an older adult, as distinguished from chronological age. (p. 564)
- G**
- gametes** Sex cells, or sperm and ova, which contain half as many chromosomes as regular body cells. (p. 46)
- gender constancy** A full understanding of the biologically based permanence of one's gender, including the realization that sex remains the same even if clothing, hairstyle, and play activities change. (p. 276)
- gender identity** An image of oneself as relatively masculine or feminine in characteristics. (p. 276)
- gender intensification** Increased gender stereotyping of attitudes and behavior and movement toward a more traditional gender identity, typical of early adolescence. (p. 414)
- gender schema theory** An information-processing approach to gender typing that explains how environmental pressures and children's cognitions work together to shape gender-role development. (p. 277)
- gender typing** Any association of objects, roles, or traits with one sex or the other in ways that conform to cultural stereotypes. (p. 273)
- gene** A segment of a DNA molecule that contains instructions for production of various proteins that contribute to growth and functioning of the body. (p. 46)
- gene-environment correlation** The idea that heredity influences the environments to which individuals are exposed. (p. 72)
- gene-environment interaction** The view that people have unique, genetically influenced reactions to particular experiences and qualities of the environment. (p. 71)
- generativity versus stagnation** In Erikson's theory, the psychological conflict of midlife, which is resolved positively if the adult can integrate

personal goals with the welfare of the larger social world. The resulting strength is the capacity to give to and guide the next generation. (p. 532)

genetic counseling A communication process designed to help couples assess their chances of giving birth to a baby with a hereditary disorder and choose the best course of action in view of risks and family goals. (p. 53)

genomic imprinting A pattern of inheritance in which alleles are imprinted, or chemically marked, in such a way that one pair member is activated, regardless of its makeup. (p. 51)

genotype An individual's genetic makeup. Distinguished from *phenotype*. (p. 45)

gerotranscendence According to Joan Erikson, a psychosocial stage characterizing the very old and representing development beyond ego integrity. Involves a cosmic, transcendent perspective directed forward and outward, beyond the self. Apparent in heightened inner calm and contentment and in additional time spent in quiet reflection. (p. 605)

gifted Displaying exceptional intellectual strengths, such as high IQ, high potential for creativity, and specialized talent. (p. 322)

glass ceiling Invisible barrier to advancement up the corporate ladder, faced by women and ethnic minorities. (p. 555)

glaucoma A disease in which poor fluid drainage leads to a buildup of pressure within the eye, damaging the optic nerve. A leading cause of blindness among older adults. (p. 503)

glial cells Cells that are responsible for myelination of neural fibers, improving the efficiency of message transfer. (p. 122)

goodness-of-fit model A model that describes how favorable adjustment depends on an effective match, or good fit, between a child's temperament and the child-rearing environment. (p. 194)

grief Intense physical and psychological distress following the death of a loved one. (p. 659)

growth hormone (GH) A pituitary hormone that affects the development of all body tissues except the central nervous system and the genitals. (p. 219)

growth spurt Rapid gain in height and weight that is the first outward sign of puberty. (p. 363)

guided participation Shared endeavors between more expert and less expert participants, without specifying the precise features of communication in order to allow for variations across situations and cultures. A broader concept than *scaffolding*. (p. 235)

H

habituation A gradual reduction in the strength of a response due to repetitive stimulation. (p. 134)

hardiness A set of three personal qualities—control, commitment, and challenge—that, together, help people cope adaptively with stress brought on by inevitable life changes. (p. 516)

heritability estimate A statistic that measures the extent to which individual differences in complex traits, such as intelligence or personality, in a specific population are due to genetic factors. (p. 70)

heterozygous Having two different alleles at the same place on a pair of chromosomes. Distinguished from *homozygous*. (p. 48)

hierarchical classification The organization of objects into classes and subclasses on the basis of similarities and differences. (p. 229)

hippocampus An inner-brain structure that plays a vital role in memory and in images of space that help us find our way. (p. 218)

history-graded influences Influences on lifespan development that are unique to a particular historical era and explain why people born around the same time (called a *cohort*) tend to be alike in ways that set them apart from people born at other times. (p. 11)

Home Observation for Measurement of the Environment (HOME) A checklist for gathering information about the quality of children's home lives through observation and parental interview. (p. 170)

homozygous Having two identical alleles at the same place on a pair of chromosomes. Distinguished from *heterozygous*. (p. 48)

hormone therapy Low daily doses of estrogen, either alone or in combination with progesterone, aimed at reducing the physical discomforts of menopause. (p. 506)

hospice A comprehensive program of support services for terminally ill people and their families, which regards the patient and family as a

unit of care and emphasizes meeting the patient's physical, emotional, social, and spiritual needs while also providing follow-up bereavement services to the family. (p. 652)

hypothetico-deductive reasoning A formal operational problem-solving strategy in which adolescents begin with a *hypothesis*, or prediction, about variables that might affect an outcome. From the hypothesis, they *deduce* logical, testable inferences. Then they systematically isolate and combine variables to see which of those inferences are confirmed in the real world. (p. 382)

I

identical, or monozygotic, twins Twins that result when a zygote, during early cell duplication, separates into two clusters of cells with the same genetic makeup, which develop into two individuals. Distinguished from *fraternal, or dizygotic, twins*. (p. 48)

identity A well-organized conception of the self, consisting of values, beliefs, and goals, to which the individual is solidly committed. (p. 402)

identity achievement The identity status of individuals who, after a period of exploration, have committed themselves to a clearly formulated set of self-chosen values and goals. Distinguished from *identity moratorium, identity foreclosure, and identity diffusion*. (p. 403)

identity diffusion The identity status of individuals who do not engage in exploration and are not committed to values and goals. Distinguished from *identity achievement, identity moratorium, and identity foreclosure*. (p. 403)

identity foreclosure The identity status of individuals who do not engage in exploration but, instead, are committed to ready-made values and goals chosen for them by authority figures. Distinguished from *identity achievement, identity moratorium, and identity diffusion*. (p. 403)

identity moratorium The identity status of individuals who are exploring but not yet committed to self-chosen values and goals. Distinguished from *identity achievement, identity foreclosure, and identity diffusion*. (p. 403)

identity versus role confusion In Erikson's theory, the psychological conflict of adolescence, which is resolved positively when adolescents achieve an identity through a process of exploration and inner soul-searching. (p. 402)

imaginary audience Adolescents' belief that they are the focus of everyone else's attention and concern. (p. 386)

imitation Learning by copying the behavior of another person. Also known as *modeling* or *observational learning*. (p. 135)

implantation Attachment of the blastocyst to the uterine lining, which occurs 7 to 9 days after fertilization. (p. 81)

implicit memory Memory without conscious awareness. (p. 591)

inclusive classrooms Classrooms in which students with learning difficulties learn alongside typical students in a regular educational setting for all or part of the school day—a practice designed to prepare them for participation in society and to combat prejudices against individuals with disabilities. (p. 322)

incomplete dominance A pattern of inheritance in which both alleles are expressed in the phenotype, resulting in a combined trait, or one that is intermediate between the two. (p. 50)

independence-ignore script A typical pattern of interaction in which older adults' independent behaviors are mostly ignored and, as a result, occur less often. Distinguished from *dependency-support script*. (p. 610)

independent variable In an experiment, the variable the investigator expects to cause changes in another variable and that the researcher manipulates by randomly assigning participants to treatment conditions. Distinguished from *dependent variable*. (p. 35)

individualistic societies Societies in which people think of themselves as separate entities and are largely concerned with their own personal needs. Distinguished from *collectivist societies*. (p. 65)

induction A type of discipline in which an adult helps the child notice feelings by pointing out the effects of the child's misbehavior on others. (p. 264)

industry versus inferiority In Erikson's theory, the psychological conflict of middle childhood, which is resolved positively when experiences

lead children to develop a sense of competence at useful skills and tasks. (p. 330)

infant-directed speech (IDS) A form of communication used by adults to speak to infants and toddlers, consisting of short sentences with high-pitched, exaggerated expression, clear pronunciation, distinct pauses between speech segments, and repetition of new words in a variety of contexts. (p. 178)

infantile amnesia The inability of most older children and adults to retrieve events that happened before age 3. (p. 164)

infant mortality The number of deaths in the first year of life per 1,000 live births. (p. 104)

information-loss view A view that attributes age-related slowing of cognitive processing to greater loss of information as it moves through the system. As a result, the whole system must slow down to inspect and interpret the information. Distinguished from *neural network view*. (p. 520)

information processing A perspective that views the human mind as a symbol-manipulating system through which information flows and that regards cognitive development as a continuous process. (p. 20)

inhibited, or shy, child A child whose temperament is such that he or she reacts negatively to and withdraws from novel stimuli. Distinguished from *uninhibited, or sociable, child*. (p. 191)

initiative versus guilt In Erikson's theory, the psychological conflict of early childhood, which is resolved positively through play experiences that foster a healthy sense of initiative and through development of a superego, or conscience, that is not overly strict and guilt-ridden. (p. 256)

instrumental activities of daily living (IADLs) Tasks necessary to conduct the business of daily life and also requiring some cognitive competence, such as telephoning, shopping, food preparation, housekeeping, and paying bills. (p. 567)

intelligence quotient (IQ) A score that permits an individual's performance on an intelligence test to be compared to the performances of other individuals of the same age. (p. 169)

intentional, or goal-directed, behavior A sequence of actions in which schemes are deliberately coordinated to solve a problem. (p. 154)

interactional synchrony A form of communication in which the caregiver responds to infant signals in a well-timed, rhythmic, appropriate fashion and both partners match emotional states, especially the positive ones. (p. 200)

intermodal perception The process of making sense of simultaneous input from more than one modality, or sensory system, perceiving them as an integrated whole. (p. 145)

internal working model A set of expectations about the availability of attachment figures and the likelihood that they will provide support in times of stress. It becomes a vital part of personality, serving as a guide for all future close relationships. (p. 197)

intimacy versus isolation In Erikson's theory, the psychological conflict of early adulthood, reflected in the young person's thoughts and feelings about making a permanent commitment to an intimate partner. (p. 469)

irreversibility The inability to mentally go through a series of steps in a problem and then reverse direction, returning to the starting point. Distinguished from *reversibility*. (p. 229)

J

joint attention A state in which the child attends to the same object or event as the caregiver, who often labels it. Supports language development. (p. 176)

K

kinkeeper Role assumed by members of the middle generation, especially mothers, who take responsibility for gathering the family for celebrations and making sure everyone stays in touch. (p. 545)

kinship studies Studies that compare the characteristics of family members to determine the importance of heredity in complex human characteristics. (p. 70)

kwashiorkor A disease caused by an unbalanced diet very low in protein that usually appears after weaning, between 1 and 3 years of age.

Symptoms include an enlarged belly, swollen feet, hair loss, skin rash, and irritable, listless behavior. (p. 132)

L

language acquisition device (LAD) In Chomsky's theory, an innate system containing a universal grammar, or set of rules common to all languages, that enables children, no matter which language they hear, to understand and speak in a rule-oriented fashion as soon as they pick up enough words. (p. 174)

lanugo White, downy hair that covers the entire body of the fetus, helping the vernix stick to the skin. (p. 83)

lateralization Specialization of functions in the two hemispheres of the cerebral cortex. (p. 124)

learned helplessness Attribution of success to external factors, such as luck, and failure to low ability, which is fixed and cannot be improved through effort. Distinguished from *mastery-oriented attributions*. (p. 333)

learning disabilities Great difficulty with one or more aspects of learning, usually reading, resulting in achievement considerably behind what would be expected on the basis of a child's IQ. (p. 322)

life-care communities Housing for older adults that offers a range of alternatives, from independent or congregate housing to full nursing home care, guaranteeing that residents' changing needs will be met within the same facility as they age. (p. 618)

lifespan perspective A dynamic systems approach to development that assumes development is lifelong, multidimensional and multidirectional, highly plastic, and affected by multiple interacting forces. (p. 8)

living will A written statement specifying the treatments a person does or does not want in case of a terminal illness, coma, or other near-death situation. (p. 655)

loneliness Unhappiness resulting from a gap between actual and desired social relationships. (p. 477)

longitudinal design A research design in which participants are studied repeatedly, and changes are noted as they get older. Distinguished from *cross-sectional design*. (p. 35)

long-term memory In information processing, the largest storage area in memory, containing our permanent knowledge base. (p. 162)

M

macrosystem In ecological systems theory, cultural values, laws, customs, and resources that influence experiences and interactions at inner levels of the environment. Distinguished from *microsystem*, *mesosystem*, *exosystem*, and *chronosystem*. (p. 25)

macular degeneration Blurring and eventual loss of central vision due to a breakdown of light-sensitive cells in the macula, or central region of the retina. (p. 569)

make-believe play A type of play in which children act out everyday and imaginary activities. (p. 154)

marasmus A wasted condition of the body caused by a diet low in all essential nutrients, which usually appears in the first year of life. (p. 132)

mastery-oriented attributions Attributions that credit success to ability, which can be improved through effort, and failure to insufficient effort. Distinguished from *learned helplessness*. (p. 333)

matters of personal choice Concerns that do not involve rights or others' welfare and, therefore, are up to the individual, such as choice of friends, hairstyle, and leisure activities. Distinguished from *moral imperatives* and *social conventions*. (p. 269)

maximum lifespan The species-specific biological limit to length of life (in years), corresponding to the age at which the oldest known individual died. Distinguished from *average life expectancy* and *average healthy life expectancy*. (p. 566)

meiosis The process of cell division through which gametes are formed and in which the number of chromosomes in each cell is halved. (p. 46)

memory strategies Deliberate mental activities that improve the likelihood of remembering. (p. 237)

menarche First menstruation. (p. 365)

menopause The end of menstruation and, therefore, of a woman's reproductive capacity. (p. 504)

mental representation An internal depiction of information that the mind can manipulate, including images and concepts. (p. 154)

mesosystem In ecological systems theory, connections between a person's microsystems, or immediate settings. Distinguished from *microsystem*, *exosystem*, *macrosystem*, and *chronosystem*. (p. 25)

metacognition Thinking about thought; a theory of mind, or coherent set of ideas about mental activities. (p. 239)

microsystem In ecological systems theory, the innermost level of the environment, consisting of activities and interaction patterns in the person's immediate surroundings. Distinguished from *mesosystem*, *exosystem*, *macrosystem*, and *chronosystem*. (p. 24)

midlife crisis Self-doubt and stress that prompt major restructuring of the personality during the transition to middle adulthood. Characterizes the experience of only a minority of adults. (p. 536)

mirror neurons Specialized cells in motor areas of the cerebral cortex in primates that underlie the ability to imitate by firing identically when a primate hears or sees an action and when it carries out the action on its own. (p. 136)

mitosis The process of cell duplication, in which each new cell receives an exact copy of the original chromosomes. (p. 46)

moral identity The degree to which morality is central to an individual's self-concept. (p. 411)

moral imperatives Rules and expectations that protect people's rights and welfare. Distinguished from *social conventions* and *matters of personal choice*. (p. 269)

mortality The phase of dying in which the individual passes into permanent death. Distinguished from *agonal phase* and *clinical death*. (p. 640)

mourning The culturally specified expression of the bereaved person's thoughts and feelings through funerals and other rituals. (p. 659)

mutation A sudden but permanent change in a segment of DNA. (p. 51)

myelination The coating of neural fibers with an insulating fatty sheath, called *myelin*, that improves the efficiency of message transfer. (p. 122)

N

naturalistic observation A research method in which the researcher goes into the field, or natural environment, and records the behavior of interest. Distinguished from *structured observation*. (p. 28)

natural, or prepared, childbirth A group of techniques designed to reduce pain and medical intervention and to make childbirth as rewarding an experience as possible. (p. 99)

nature–nurture controversy Disagreement among theorists about whether genetic or environmental factors are more important influences on development. (p. 7)

neglected children Children who are seldom mentioned, either positively or negatively, on self-report measures of peer acceptance. Distinguished from *popular*, *rejected*, and *controversial children*. (p. 341)

Neonatal Behavioral Assessment Scale (NBAS) A test used to evaluate a newborn infant's reflexes, muscle tone, state changes, responsiveness to physical and social stimuli, and other reactions. (p. 114)

neural network view A view that attributes age-related slowing of cognitive processing to breaks in neural networks as neurons die. The brain adapts by forming bypasses—new synaptic connections that go around the breaks but are less efficient. Distinguished from *information-loss view*. (p. 520)

neural tube During the period of the embryo, the primitive spinal cord that develops from the ectoderm, the top of which swells to form the brain. (p. 82)

neurofibrillary tangles A structural change in the cerebral cortex associated with Alzheimer's disease, in which bundles of twisted threads appear that are the product of collapsed neural structures. (p. 583)

neurons Nerve cells that store and transmit information. (p. 121)

neurotransmitters Chemicals released by neurons that cross the synapse to send messages to other neurons. (p. 121)

niche-picking A type of gene–environment correlation in which individuals actively choose environments that complement their heredity. (p. 72)

nonnormative influences Influences on lifespan development that are irregular, in that they happen to just one or a few individuals and do not follow a predictable timetable. (p. 12)

non-rapid-eye-movement (NREM) sleep A “regular” sleep state during which the body is almost motionless and heart rate, breathing, and

brain-wave activity are slow and even. Distinguished from *rapid-eye-movement (REM) sleep*. (p. 108)

nonsocial activity Unoccupied, onlooker behavior and solitary play. Distinguished from *parallel*, *associative*, and *cooperative play*. (p. 261)

normal distribution The bell-shaped distribution that results when individual differences are measured in large samples. Most scores cluster around the mean, or average, with progressively fewer falling toward the extremes. (p. 169)

normative approach An approach in which measures of behavior are taken on large numbers of individuals, and age-related averages are computed to represent typical development. (p. 15)

O

obesity A greater-than-20-percent increase over healthy body weight, based on body mass index, a ratio of weight to height associated with body fat. (p. 291)

object permanence The understanding that objects continue to exist when out of sight. (p. 154)

operant conditioning A form of learning in which a spontaneous behavior is followed by a stimulus that changes the probability that the behavior will occur again. (p. 134)

optimal aging Aging in which gains are maximized and losses minimized. (p. 632)

ordinality The mathematical principle specifying order relationships (more than and less than) between quantities. (p. 242)

organization In Piaget's theory, the internal rearrangement and linking together of schemes to create a strongly interconnected cognitive system. In information processing, a memory strategy that involves grouping related items together to improve recall. (p. 152, p. 304)

osteoarthritis A form of arthritis that involves deteriorating cartilage on the ends of bones of frequently used joints, which leads to swelling, stiffness, and loss of flexibility. Also known as “wear-and-tear” arthritis or “degenerative joint disease.” Distinguished from *rheumatoid arthritis*. (p. 580)

osteoporosis Severe age-related bone loss, which greatly magnifies the risk of bone fractures. (p. 512)

overextension An early vocabulary error in which young children apply a word too broadly, to a wider collection of objects and events than is appropriate. Distinguished from *underextension*. (p. 177)

overregularization Overextension of regular grammatical rules to words that are exceptions. (p. 249)

P

palliative, or comfort, care Care for terminally ill, suffering patients that relieves pain and other symptoms (such as nausea, breathing difficulties, insomnia, and depression), with the goal of protecting the patient's quality of remaining life rather than prolonging life. (p. 652)

parallel play A form of limited social participation in which a child plays near other children with similar materials but does not try to influence their behavior. Distinguished from *nonsocial*, *associative*, and *cooperative play*. (p. 261)

parental imperative theory A theory that claims that identification with traditional gender roles is maintained during the active parenting years to help ensure the survival of children but that after children reach adulthood, parents are free to express the “other-gender” side of their personalities. (p. 540)

partial fetal alcohol syndrome (p-FAS) A form of fetal alcohol spectrum disorder characterized by facial abnormalities and brain injury, but less severe than fetal alcohol syndrome. Usually affects children whose mothers drank alcohol in smaller quantities during pregnancy. Distinguished from *fetal alcohol syndrome (FAS)* and *alcohol-related neurodevelopmental disorder (ARND)*. (p. 89)

passionate love Love based on intense sexual attraction. Distinguished from *companionate love*. (p. 473)

passive euthanasia The practice of withholding or withdrawing life-sustaining treatment, permitting a patient to die naturally. Distinguished from *voluntary active euthanasia*. (p. 654)

peer acceptance Likability, or the extent to which a child is viewed by a group of agemates as a worthy social partner. (p. 341)

- peer group** A collective of peers who generate unique values and standards for behavior and a social structure of leaders and followers. (p. 339)
- peer victimization** A destructive form of peer interaction in which certain children become frequent targets of verbal and physical attacks or other forms of abuse. (p. 342)
- perceptual narrowing effect** Perceptual sensitivity that becomes increasingly attuned with age to information most often encountered. (p. 141)
- permissive child-rearing style** A child-rearing style that is warm and accepting but uninvolved, low in control (either overindulgent or inattentive), and lenient rather than appropriate in autonomy granting. Distinguished from *authoritative*, *authoritarian*, and *uninvolved child-rearing styles*. (p. 279)
- persistent vegetative state** A state in which the cerebral cortex no longer registers electrical activity but the brain stem remains active. The person is unconscious and displays no voluntary movements. (p. 641)
- personal fable** Adolescents' inflated opinion of their own importance—a feeling that they are special and unique. (p. 386)
- person–environment fit** A good match between older adults' abilities and the demands of their living environments. Promotes adaptive behavior and psychological well-being. (p. 611)
- phenotype** An individual's directly observable physical and behavioral characteristics, which are determined by both genetic and environmental factors. Distinguished from *genotype*. (p. 45)
- phobia** An intense, unmanageable fear that leads to persistent avoidance of the feared situation. (p. 352)
- phonics approach** An approach to beginning reading instruction that emphasizes coaching children on phonics—the basic rules for translating written symbols into sounds—before exposing them to complex reading material. Distinguished from the *whole-language approach*. (p. 308)
- phonological awareness** The ability to reflect on and manipulate the sound structure of spoken language, as indicated by sensitivity to changes in sounds within words, to rhyming, and to incorrect pronunciation. A strong predictor of emergent literacy knowledge. (p. 242)
- physical aggression** A form of aggression that harms others through physical injury to themselves or their property. Distinguished from *verbal aggression* and *relational aggression*. (p. 269)
- pituitary gland** A gland located at the base of the brain that releases hormones that induce physical growth. (p. 219)
- placenta** The organ that permits exchange of nutrients and waste products between the bloodstreams of the mother and the embryo, while also preventing the mother's and embryo's blood from mixing directly. (p. 82)
- plasticity** Openness of development to change in response to influential experiences. (p. 7)
- polygenic inheritance** A pattern of inheritance in which many genes influence a characteristic. (p. 52)
- popular-antisocial children** A subgroup of popular children who are admired for their socially adept yet belligerent behavior. Includes “tough” boys who are athletically skilled, aggressive, and poor students, as well as relationally aggressive boys and girls. Distinguished from *popular-prosocial children*. (p. 341)
- popular children** Children who receive many positive votes on self-report measures of peer acceptance, indicating they are well-liked. Distinguished from *rejected*, *controversial*, and *neglected children*. (p. 341)
- popular-prosocial children** A subgroup of popular children who combine academic and social competence. Distinguished from *popular-antisocial children*. (p. 341)
- possible selves** Future-oriented representations of what one hopes to become and what one is afraid of becoming. The temporal dimension of self-concept. (p. 538)
- postconventional level** Kohlberg's highest level of moral development, in which individuals define morality in terms of abstract principles and values that apply to all situations and societies. (p. 408)
- postformal thought** Cognitive development beyond Piaget's formal operational stage. (p. 450)
- practical problem solving** Problem solving that requires people to size up real-world situations and analyze how best to achieve goals that have a high degree of uncertainty. (p. 524)
- pragmatics** The practical, social side of language, concerned with how to engage in effective and appropriate communication. (p. 250)
- pragmatic thought** In Labouvie-Vief's theory, a structural advance in thinking in adulthood, in which logic becomes a tool for solving real-world problems and contradictions are accepted as part of existence. (p. 452)
- preconventional level** Kohlberg's first level of moral development, in which children accept the rules of authority figures and judge actions by their consequences, viewing behaviors that result in punishment as bad and those that lead to rewards as good. (p. 407)
- prefrontal cortex** The region of the cerebral cortex, lying in front of areas controlling body movement, that is responsible for thought—in particular, for consciousness, inhibition of impulses, integration of information, and use of memory, reasoning, planning, and problem-solving strategies. (p. 124)
- prenatal diagnostic methods** Medical procedures that permit detection of developmental problems before birth. (p. 56)
- preoperational stage** Piaget's second stage of cognitive development, extending from about 2 to 7 years of age, in which children undergo an extraordinary increase in representational, or symbolic, activity, although thought is not yet logical. (p. 226)
- presbycusis** Age-related hearing impairment, beginning around age 50 with a noticeable decline in sensitivity to high-frequency sounds, which gradually extends to all frequencies. (p. 503)
- presbyopia** A condition of aging in which, around age 60, the lens of the eye loses its capacity to adjust to objects at varying distances. (p. 502)
- preterm infants** Infants born several weeks or more before their due date. (p. 102)
- primary aging** Genetically influenced age-related declines in the functioning of organs and systems that affect all members of our species and occur even in the context of overall good health. Also called *biological aging*. Distinguished from *secondary aging*. (p. 580)
- primary sexual characteristics** Physical features that involve the reproductive organs (ovaries, uterus, and vagina in females; penis, scrotum, and testes in males). Distinguished from *secondary sexual characteristics*. (p. 365)
- private speech** Self-directed speech that children use to plan and guide their own behavior. (p. 234)
- proactive aggression** A type of aggression in which children act to fulfill a need or desire—obtain an object, privilege, space, or social reward, such as adult or peer attention—and unemotionally attack a person to achieve their goal. Also called *instrumental aggression*. Distinguished from *reactive aggression*. (p. 269)
- problem-centered coping** A strategy for managing emotion that involves appraising the situation as changeable, identifying the difficulty, and deciding what to do about it. Distinguished from *emotion-centered coping*. (p. 336)
- programmed cell death** An aspect of brain growth whereby, as synapses form, many surrounding neurons die, making space for these connective structures. (p. 122)
- Project Head Start** A U.S. federal early intervention program that provides children from low-income families with a year or two of preschool, along with nutritional and health services, and that encourages parent involvement in children's learning and development. (p. 245)
- propositional thought** A type of formal operational reasoning involving the ability to evaluate the logic of propositions, or verbal statements, without referring to real-world circumstances. (p. 383)
- prosocial, or altruistic, behavior** Actions that benefit another person without any expected reward for the self. (p. 260)
- prospective memory** Recall that involves remembering to engage in planned actions in the future. (p. 593)
- proximodistal trend** An organized pattern of physical growth that proceeds from the center of the body outward. Distinguished from *cephalocaudal trend*. (p. 121)
- psychoanalytic perspective** An approach to personality development introduced by Freud that assumes people move through a series of stages in which they confront conflicts between biological drives and social expectations. How these conflicts are resolved determines the person's ability to learn, to get along with others, and to cope with anxiety. (p. 15)

psychological control Parental behaviors that intrude on and manipulate children's verbal expressions, individuality, and attachments to parents. (p. 279)

psychosexual theory Freud's theory, which emphasizes that how parents manage children's sexual and aggressive drives in the first few years is crucial for healthy personality development. (p. 15)

psychosocial theory Erikson's theory, which emphasizes that in each Freudian stage, individuals not only develop a unique personality but also acquire attitudes and skills that make them active, contributing members of their society. Recognizes the lifespan nature of development and the impact of culture. (p. 16)

puberty Biological changes at adolescence that lead to an adult-sized body and sexual maturity. (p. 361)

public policies Laws and government programs designed to improve current conditions. (p. 65)

punishment In operant conditioning, removal of a desirable stimulus or presentation of an unpleasant one to decrease the occurrence of a response. (p. 134)

R

random assignment An unbiased procedure for assigning participants to treatment conditions in an experiment, such as drawing numbers out of a hat or flipping a coin. Increases the chances that participants' characteristics will be equally distributed across treatment groups. (p. 35)

rapid-eye-movement (REM) sleep An "irregular" sleep state in which brain-wave activity is similar to that of the waking state. Distinguished from *non-rapid-eye-movement (NREM) sleep*. (p. 108)

reactive aggression An angry, defensive response to provocation or a blocked goal that is meant to hurt another person. Also called *hostile aggression*. Distinguished from *proactive aggression*. (p. 269)

realistic period Period of vocational development in which older adolescents and young adults narrow their vocational options, engaging in further exploration before focusing on a general vocational category and, slightly later, settling on a single occupation. Distinguished from *fantasy period* and *tentative period*. (p. 456)

recall A type of memory that involves remembering something that is not present. Distinguished from *recognition*. (p. 164)

recasts Adult responses that restructure children's grammatically inaccurate speech into correct form. (p. 251)

recognition A type of memory that involves noticing whether a stimulus is identical or similar to one previously experienced. Distinguished from *recall*. (p. 164)

recovery Following habituation, an increase in responsiveness to a new stimulus. (p. 134)

referential style of language learning A style of early language learning in which toddlers use language mainly to name things, producing many words that refer to objects. Distinguished from *expressive style of language learning*. (p. 178)

reflex An inborn, automatic response to a particular form of stimulation. (p. 106)

rehearsal A memory strategy that involves repeating information to oneself to improve recall. (p. 304)

reinforcer In operant conditioning, a stimulus that increases the occurrence of a response. (p. 134)

rejected-aggressive children A subgroup of rejected children who show high rates of conflict, physical and relational aggression, and hyperactive, inattentive, and impulsive behavior. Distinguished from *rejected-withdrawn children*. (p. 341)

rejected children Children who receive many negative votes on self-report measures of peer acceptance, indicating they are actively disliked. Distinguished from *popular, controversial, and neglected children*. (p. 341)

rejected-withdrawn children A subgroup of rejected children who are passive and socially awkward. Distinguished from *rejected-aggressive children*. (p. 341)

relational aggression A form of aggression that damages another's peer relationships through social exclusion, malicious gossip, or friendship manipulation. Distinguished from *physical aggression* and *verbal aggression*. (p. 269)

relativistic thinking In Perry's theory, the cognitive approach typical of older college students, who view all knowledge as embedded in a

framework of thought and, therefore, give up the possibility of absolute truth in favor of multiple truths, each relative to its context. Distinguished from *dualistic thinking*. (p. 451)

remembrance The process of telling stories about people and events from the past and reporting associated thoughts and feelings. (p. 606)

remembrance bump Older adults' heightened autobiographical memory for events that occurred between ages 10 and 30. (p. 592)

remote memory Very long-term recall. (p. 592)

resilience The ability to adapt effectively in the face of threats to development. (p. 10)

resistant attachment The attachment pattern characterizing infants who remain close to the parent and fail to explore before separation, are usually distressed when the parent leaves, and combine clinginess with angry, resistive behavior when the parent returns. Distinguished from *secure, avoidant, and disorganized/disoriented attachment*. (p. 198)

reticular formation A structure in the brain stem that maintains alertness and consciousness. (p. 218)

reversibility The ability to think through a series of steps in a problem and then mentally reverse direction, returning to the starting point. Distinguished from *irreversibility*. (p. 299)

rheumatoid arthritis A form of arthritis in which an autoimmune response leads to inflammation of connective tissue, particularly the membranes that line the joints, resulting in overall stiffness, inflammation, and aching. Leads to deformed joints and often serious loss of mobility. Distinguished from *osteoarthritis*. (p. 580)

Rh factor incompatibility A condition that arises when the Rh protein is present in the fetus's blood but not in the mother's, causing the mother to build up antibodies. If these enter the fetus's system, they destroy red blood cells, reducing the oxygen supply to organs and tissues. Mental retardation, miscarriage, heart damage, and infant death can occur. (p. 93)

rough-and-tumble play A form of peer interaction involving friendly chasing and play-fighting that emerges in the preschool years and peaks in middle childhood. In our evolutionary past, it may have been important for developing fighting skill. (p. 297)

S

sandwich generation A term used to describe middle-aged adults who must care for multiple generations above and below them at the same time. (p. 549)

scaffolding Adjusting the support offered during a teaching session to fit the learner's current level of performance. Direct instruction is offered when a task is new; less help is provided as competence increases, thereby keeping the task within the zone of proximal development. (p. 234)

scale errors Toddlers' attempts to do things that their body size makes impossible, possibly indicating lack of an accurate understanding of their own body dimensions. (p. 207)

scheme In Piaget's theory, a specific psychological structure, or organized way of making sense of experience, that changes with age. (p. 152)

scripts General descriptions of what occurs and when it occurs in a particular situation, used to organize and interpret everyday experiences. (p. 238)

secondary aging Age-related declines due to hereditary defects and environmental influences, such as poor diet, lack of exercise, disease, substance abuse, environmental pollution, and psychological stress. Distinguished from *primary aging*. (p. 580)

secondary friends People who are not intimates but with whom an individual spends time occasionally, such as a group that meets for lunch, bridge, or museum tours. (p. 625)

secondary sexual characteristics Physical features visible on the outside of the body that serve as signs of sexual maturity but do not involve the reproductive organs (for example, breast development in females, appearance of underarm and pubic hair in both sexes). Distinguished from *primary sexual characteristics*. (p. 365)

secular trend A change from one generation to the next in an aspect of development, such as body size or pubertal timing. (p. 367)

secure attachment The attachment pattern characterizing infants who use the parent as a secure base from which to explore, may be distressed by parental separation, but actively seek contact and are easily comforted by the parent when she returns. Distinguished from *avoidant, resistant, and disorganized/disoriented attachment*. (p. 197)

- secure base** The familiar caregiver as a point from which the baby explores, venturing into the environment and then returning for emotional support. (p. 187)
- selective optimization with compensation** A set of strategies used by older adults who sustain high levels of functioning. Narrowing their goals, they *select* personally valued activities to *optimize* returns from their diminishing energy and also find new ways to *compensate* for losses. (p. 590)
- self-care children** Children who are without adult supervision for some period of time after school. (p. 351)
- self-concept** The set of attributes, abilities, attitudes, and values that an individual believes defines who he or she is. (p. 256)
- self-conscious emotions** Emotions involving injury to or enhancement of the sense of self, including guilt, shame, embarrassment, envy, and pride. (p. 188)
- self-esteem** An aspect of self-concept that involves judgments about one's own worth and the feelings associated with those judgments. (p. 257)
- self-recognition** Identification of the self as a physically unique being. (p. 207)
- sensitive caregiving** Caregiving that involves responding promptly, consistently, and appropriately to infants and holding them tenderly and carefully. (p. 199)
- sensitive period** A time that is optimal for certain capacities to emerge and in which the individual is especially responsive to environmental influences. (p. 22)
- sensorimotor stage** Piaget's first stage, spanning the first two years of life, during which infants and toddlers "think" with their eyes, ears, hands, and other sensorimotor equipment. (p. 152)
- sensory register** The part of the information-processing system in which sights and sounds are represented directly and stored briefly. (p. 161)
- separation anxiety** An infant's distressed reaction to the departure of the familiar caregiver. (p. 196)
- seriation** The ability to order items along a quantitative dimension, such as length or weight. (p. 300)
- sequential designs** Developmental designs in which investigators conduct several similar cross-sectional or longitudinal studies (called *sequences*) at varying times, sometimes combining longitudinal and cross-sectional strategies. (p. 38)
- sex chromosomes** The twenty-third pair of chromosomes, which determines the sex of the individual. In females, it is called XX; in males, XY. (p. 47)
- short-term memory store** The part of the mind in which attended-to information is retained briefly so that we can actively "work" on it to achieve our goals. (p. 161)
- skipped-generation family** A family structure in which children live with grandparents but apart from parents. (p. 548)
- sleep apnea** A condition in which breathing ceases for 10 seconds or longer during sleep, resulting in many brief awakenings. (p. 571)
- slow-to-warm-up child** A child whose temperament is characterized by inactivity; mild, low-key reactions to environmental stimuli; negative mood; and slow adjustment to new experiences. Distinguished from *easy child* and *difficult child*. (p. 190)
- small-for-date infants** Infants whose birth weight is below their expected weight considering length of the pregnancy. Some are full-term; others are preterm infants who are especially underweight. (p. 102)
- social clock** Age-graded expectations for major life events, such as beginning a first job, getting married, birth of the first child, buying a home, and retiring. (p. 471)
- social comparisons** Judgments of one's own appearance, abilities, and behavior in relation to those of others. (p. 330)
- social-constructivist classroom** A classroom grounded in Vygotsky's sociocultural theory, in which children participate in a wide range of challenging activities with teachers and peers, with whom they jointly construct understandings. Distinguished from *traditional* and *constructivist classrooms*. (p. 319)
- social conventions** Customs determined solely by consensus within a society, such as table manners and politeness rituals. Distinguished from *moral imperatives* and *matters of personal choice*. (p. 269)
- social convoy** A model of age-related changes in social networks, which views the individual as moving through life within a cluster of relationships, with close ties in the inner circle and less close ties on the outside. With age, people change places in the convoy, new ties are added, and some are lost entirely. (p. 620)
- social learning theory** An approach that emphasizes the role of modeling, otherwise known as imitation or observational learning, in the development of behavior. (p. 18)
- social referencing** Actively seeking emotional information from a trusted person in an uncertain situation. (p. 188)
- social smile** The infant's broad grin, evoked by the parent's communication, that first appears between 6 and 10 weeks of age. (p. 185)
- sociocultural theory** Vygotsky's theory, in which children acquire the ways of thinking and behaving that make up their community's culture through social interaction—in particular, cooperative dialogues with more knowledgeable members of society. (p. 23)
- sociodramatic play** The make-believe with others that is under way by the end of the second year and increases rapidly in complexity during early childhood. (p. 227)
- socioeconomic status (SES)** A measure of an individual's or a family's social position and economic well-being that combines three related, but not completely overlapping, variables: years of education, the prestige of one's job and the skill it requires, and income. (p. 61)
- socioemotional selectivity theory** A social theory of aging that states that social interaction in late adulthood extends lifelong selection processes. Physical and psychological aspects of aging lead to an increased emphasis on the emotion-regulating function of social interaction, leading older adults to prefer familiar social partners with whom they have developed pleasurable relationships. Distinguished from *disengagement theory*, *activity theory*, and *continuity theory*. (p. 615)
- spermarche** First ejaculation of seminal fluid. (p. 366)
- stage** A qualitative change in thinking, feeling, and behaving that characterizes a specific period of development. (p. 6)
- standardization** The practice of giving a newly constructed test to a large, representative sample and using the results as the standard for interpreting individual scores. (p. 169)
- states of arousal** Different degrees of sleep and wakefulness. (p. 108)
- statistical learning capacity** The capacity to analyze the speech stream for regularly occurring sound sequences, through which infants acquire a stock of speech structures for which they will later learn meanings. (p. 142)
- stereotype threat** The fear of being judged on the basis of a negative stereotype, which can trigger anxiety that interferes with performance. (p. 314)
- stranger anxiety** The infant's expression of fear in response to unfamiliar adults, which appears in many babies in the second half of the first year. (p. 186)
- Strange Situation** A laboratory procedure used to assess the quality of attachment between 1 and 2 years of age by observing the baby's response to eight short episodes involving brief separations from and reunions with the caregiver in an unfamiliar playroom. (p. 197)
- structured interview** An interview method in which each participant is asked the same questions in the same way. Distinguished from *clinical interview*. (p. 30)
- structured observation** A research method in which the investigator sets up a laboratory situation that evokes the behavior of interest so that every participant has an equal opportunity to display the response. Distinguished from *naturalistic observation*. (p. 29)
- subculture** A group of people with beliefs and customs that differ from those of the larger culture. (p. 65)
- sudden infant death syndrome (SIDS)** The unexpected death, usually during the night, of an infant under 1 year of age that remains unexplained after thorough investigation. (p. 110)
- sympathy** Feelings of concern or sorrow for another's plight. (p. 260)
- synapses** The gaps between neurons, across which chemical messages are sent. (p. 121)
- synaptic pruning** Loss of synapses by seldom-stimulated neurons, a process that returns them to an uncommitted state so they can support future development. (p. 122)
- T**
- talent** Outstanding performance in a specific field. (p. 323)
- telegraphic speech** Toddlers' two-word utterances that, like a telegram, focus on high-content words while omitting smaller, less important words. (p. 177)

telomeres A special type of DNA located at the ends of chromosomes—serving as a “cap” to protect the ends from destruction—that shortens with each cell duplication. Eventually, so little remains that the cells no longer duplicate at all. (p. 432)

temperament Early-appearing, stable individual differences in reactivity (quickness and intensity of emotional arousal, attention, and motor activity) and self-regulation (strategies that modify that reactivity). (p. 190)

tentative period Period of vocational development in which adolescents begin to evaluate vocational options in terms of their interests, abilities, and values. Distinguished from *fantasy period* and *realistic period*. (p. 456)

teratogen Any environmental agent that causes damage during the prenatal period. (p. 85)

terminal decline Acceleration in deterioration of cognitive functioning prior to death. (p. 596)

thanatology An interdisciplinary field devoted to the study of death and dying. (p. 640)

theory An orderly, integrated set of statements that describes, explains, and predicts behavior. (p. 5)

theory of multiple intelligences Gardner’s theory, which identifies eight independent intelligences, defined in terms of distinct sets of processing operations that permit individuals to engage in a wide range of culturally valued activities: linguistic, logico-mathematical, musical, spatial, bodily-kinesthetic, naturalist, interpersonal, and intrapersonal. (p. 311)

Third Age A new phase of late adulthood extending from ages 65 to 79 or longer, resulting from added years of longevity plus good health and financial stability, in which older adults pursue personally enriching interests and goals. (p. 607)

thyroid-stimulating hormone (TSH) A pituitary hormone that stimulates the thyroid gland to release thyroxine, which is necessary for brain development and for growth hormone to have its full impact on body size. (p. 219)

time out A form of mild punishment that involves removing children from the immediate setting until they are ready to act appropriately. (p. 266)

traditional classroom A classroom in which the teacher is the sole authority for knowledge, rules, and decision making and students are relatively passive learners whose progress is evaluated in relation to how well they keep pace with a uniform set of standards for their grade. Distinguished from *constructivist* and *social-constructivist classrooms*. (p. 319)

traditional marriage A form of marriage involving clear division of husband’s and wife’s roles, in which the man is the head of household and economic provider, and the woman devotes herself to caring for her husband and children and creating a nurturant, comfortable home. Distinguished from *egalitarian marriage*. (p. 480)

transitive inference The ability to seriate, or order items along a quantitative dimension, mentally. (p. 300)

triarchic theory of successful intelligence Sternberg’s theory, in which intelligent behavior involves balancing three broad, interacting intelligences—analytical intelligence, creative intelligence, and practical intelligence—to achieve success in life according to one’s personal goals and the requirements of one’s cultural community. (p. 310)

triangular theory of love Sternberg’s view of love as including three components—intimacy, passion, and commitment—that shift in emphasis as romantic relationships develop. (p. 473)

trimesters Three equal time periods, each lasting three months, into which prenatal development is sometimes divided. (p. 83)

Type A behavior pattern A behavior pattern characterized by extreme competitiveness, ambition, impatience, hostility, angry outbursts, and a sense of time pressure. (p. 513)

U

umbilical cord The long cord connecting the prenatal organism to the placenta that delivers nutrients and removes waste products. (p. 82)

unconditioned response (UCR) In classical conditioning, a reflexive response that is produced by an unconditioned stimulus (UCS). Distinguished from *conditioned response*. (p. 133)

unconditioned stimulus (UCS) In classical conditioning, a stimulus that leads to a reflexive response. Distinguished from *conditioned stimulus*. (p. 133)

underextension An early vocabulary error in which young children apply a word too narrowly, to a smaller number of objects and events than is appropriate. Distinguished from *overextension*. (p. 177)

uninhibited, or sociable, child A child whose temperament is such that he or she displays positive emotion to and approaches novel stimuli. Distinguished from *inhibited, or shy, child*. (p. 191)

uninvolved child-rearing style A child-rearing style that combines low acceptance and involvement with little control and general indifference to issues of autonomy. Distinguished from *authoritative, authoritarian, and permissive child-rearing styles*. (p. 280)

V

verbal aggression A type of aggression that harms others through threats of physical aggression, name-calling, or hostile teasing. Distinguished from *physical aggression* and *relational aggression*. (p. 269)

vernix A white, cheese-like substance that covers the fetus, preventing the skin from chapping due to constant exposure to amniotic fluid. (p. 83)

video deficit effect In toddlers, poorer performance on tasks after watching a video than after seeing a live demonstration. (p. 159)

violation-of-expectation method A method in which researchers show babies an expected event (one that follows physical laws) and an unexpected event (a variation of the first event that violates physical laws). Heightened attention to the unexpected event suggests that the infant is “surprised” by a deviation from physical reality and, therefore, is aware of that aspect of the physical world. (p. 155)

visual acuity Fineness of visual discrimination. (p. 113)

voluntary active euthanasia The practice of acting directly, at a patient’s request, to end suffering before a natural end to life. Distinguished from *passive euthanasia*. (p. 656)

W

whole-language approach An approach to beginning reading instruction that exposes children to text in its complete form, using reading materials that are whole and meaningful, to promote appreciation of the communicative function of written language. Distinguished from *phonics approach*. (p. 308)

wisdom A capacity made up of multiple cognitive and personality traits, combining breadth and depth of practical knowledge; ability to reflect on and apply that knowledge in ways that make life more bearable and worthwhile; emotional maturity, including the ability to listen, evaluate, and give advice; and altruistic creativity, which involves contributing to humanity and enriching others’ lives. (p. 595)

working memory The number of items that can be briefly held in mind while also engaging in some effort to monitor or manipulate those items—a “mental workspace” that we use to accomplish many activities in daily life. A contemporary view of the short-term memory store. (p. 161)

X

X-linked inheritance A pattern of inheritance in which a recessive gene is carried on the X chromosome, so that males are more likely than females to be affected. (p. 50)

Z

zone of proximal development In Vygotsky’s theory, a range of tasks too difficult for a child to do alone but possible with the help of more-skilled partners. (p. 167)

zygote The newly fertilized cell formed by the union of sperm and ovum at conception. (p. 46)

Subject Index

Figures and tables are indicated by f and t following page numbers.

- A**
A-not-B search error in sensorimotor stage, 154, 156
AARP, 69
Aboriginals, Australian, 657
Abortion
 in adolescent pregnancy, 378, 379
 spontaneous. *See* Miscarriage
Abstinence from sexual activity, 374, 379
Abstract thinking
 consequences of changes in, 386
 and expertise, 453, 524
 in formal operational stage, 19, 382–384
 and mathematical abilities, 389
 and moral development, 408
 and self-concept, 402
 and work experiences, 525
Abuse
 of child. *See* Child maltreatment
 in dating relationship, 420–421
 of elderly, 627–628
 of substances. *See* Substance abuse
Academic achievement
 in adolescence, 392–396
 child-rearing style affecting, 392
 class size affecting, 318
 cultural influences on, 393
 divorce of parents affecting, 348
 early intervention programs affecting, 245f, 245–246
 family beliefs on, 33
 gender stereotypes on, 276, 334, 343
 of immigrant youths, 32–33
 intelligence quotient as predictor of, 243, 309
 international comparison of, 324, 324t
 mathematical abilities affecting, 243
 parent–school partnership affecting, 393–394
 part-time work affecting, 395–396
 reading skills affecting, 242
 recess time affecting, 298
 of rejected children, 343
 school characteristics affecting, 394–395
 school transitions affecting, 391
 and self-esteem, 331
 and social skills, 263
 in teenage pregnancy, 378
Academic learning, 318–325, 391–397. *See also* Education
Academic programs in preschool and kindergarten, 244
Acceptance
 of change in late adulthood, 608
 in child rearing, 278, 279, 279t, 280
 in coping with dying, 604, 605, 647, 648
 in peer relations. *See* Peer acceptance
 of self. *See* Self-acceptance
Accidental injuries. *See* Injuries, unintentional
Accommodation in cognitive development, 152, 228
Accommodation of eyes, 502
Acculturative stress, 406, 416
Accutane (isotretinoin), 87
Acetylcholine
 in Alzheimer's disease, 584, 585
 drug therapy affecting, 588
Achievement
 ability and effort in, 333, 334
 academic. *See* Academic achievement
 attributions related to, 333–334
 gender stereotypes on, 276, 334, 343
 and identity, 403, 403t, 404
 and learned helplessness, 333
 and self-esteem, 333–334
Acquired immune deficiency syndrome. *See* AIDS
ACTIVE (Advanced Cognitive Training for Independent and Vital Elderly) study, 597
Active correlation, 72
Activities of daily living in late adulthood, 567–568
 cognitive interventions affecting, 597
 control versus dependency in, 610–611, 613
 problem solving in, 594–595
Activity level and temperament, 191, 191t, 193
Activity theory of aging, 614
Actors, memory strategies of, 523
Adaptation
 of baby to labor and delivery, 97
 coping strategies in. *See* Coping strategies
 Darwin on, 14
 to dying, contextual influences on, 647–650
 in early adulthood, 470–471
 ethology of, 22
 evolutionary developmental psychology on, 22–23
 to family changes, 60–61, 115
 and habituation, 85
 of immigrant youths, 32–33
 in late adulthood, 572–575, 595, 623, 624
 in middle adulthood, 514–517, 536, 537
 Piaget on, 18–19, 152
 and practical intelligence, 311
 and resilience, 10–11
 Vaillant on, 470–471, 536
 in widowhood, 623, 624
Adaptation to Life (Vaillant), 470
Addiction
 to alcohol, 444–445
 of infants, 87
 to nicotine, 444
Adjustment
 in adolescence, 362, 391–392, 419
 affluence affecting, 62–63, 63f
 child-care facilities affecting, 202–203
 child maltreatment affecting, 283
 child-rearing styles affecting, 279, 280
 divorce of parents affecting, 347, 348, 349
 early intervention programs affecting, 246
 family mealtimes affecting, 63, 63f
 and friendships, 419
 of immigrant youths, 32–33
 and infant sleeping arrangements, 129
 to parenthood, 115
 peer acceptance affecting, 341, 343
 to retirement, 630–631
 and shyness, 195, 195f
Adolescence (11 to 18 years old), 8t, 361–427
 academic achievement in, 392–396
 in adoption, 58
 aggression in, 298
 arousal states in, 368
 autonomy in, 372–373, 415–416, 485–486
 bereavement interventions in, 665
 biological perspective of, 362
 in blended families, 350
 body composition in, 363–364
 body proportions in, 363
 body size in, 363, 364f
 brain development in, 367–368, 381, 387
 causes of death in, 643
 cognitive-affective complexity in, 452, 452f
 cognitive development in, 367, 382–397
 conflicts in, 369–370, 415, 418
 cultural influences on, 362, 369, 370, 373–374, 415–416
 dating in, 420–421
 death concept in, 643–644, 646
 death of parent or sibling during, 661–662
 decision making in, 387–388
 delinquency in, 423–426
 depression in, 421–423
 divorce of parents during, 348
 dropping out of school during, 396–397
 early phase of, 362
 eating disorders in, 372–373
 emotional and social development in, 401–427
 employment in, 459
 family in, 414–416, 485–486
 fetal alcohol exposure affecting, 89
 formal operational stage in, 382–384
 free time in, 417
 friendships in, 417–419
 gender typing in, 414
 health issues in, 371–381
 hormone changes in, 363, 369, 373
 hypothetico-deductive reasoning in, 382–383
 idealism and criticism in, 387
 identity development in, 402, 403–405
 identity versus role confusion in, 16t, 402
 of immigrant youths, 32, 33
 impulsivity and sensation seeking in, 367–368, 368f
 information processing in, 384–386
 initiation ceremonies in, 369
 language development in, 383
 late phase of, 362
 learning in school during, 391–397
 mathematical abilities in, 388–391
 media multitasking in, 394
 memory of events in late adulthood, 593
 middle phase of, 362
 milestones of development, 428–429
 moodiness in, 369
 moral development in, 405–414
 motor development in, 364–365
 nutrition in, 366–367, 371–373
 obesity in, 291, 292
 parent relationship in, 369–370, 415. *See also* Parent–adolescent relationship
 peer relations in, 370, 371, 417–421
 physical attractiveness in, 370–371
 physical development in, 362–381
 play in, 298
 pregnancy in, 93, 378–380. *See also* Teenage pregnancy and parenthood
 propositional thought in, 383
 psychosexual and psychosocial development in, 16t, 362
 puberty in, 363–371. *See also* Puberty
 school transitions in, 391–392
 scientific reasoning in, 385–386
 self-consciousness and self-focusing in, 386–387
 self-understanding in, 402–405
 sex differences in, 363, 364, 365–366, 366f, 368–369, 388–391, 417–418
 sexual abuse in, 353
 sexuality in, 373–380
 sexually transmitted diseases in, 376–377
 sexual maturation in, 365–366
 shyness in, 192
 sibling relationship in, 416
 sleep schedule in, 368
 social perspective of, 362
 spatial abilities in, 390
 substance use and abuse in, 364, 370, 376, 380–381, 419, 420
 suicide in, 422–423
 time spent with family in, 416, 417
 verbal abilities in, 388
 vocational choice in, 456
Adoption, 57–59, 416t
 attachment security in, 199
 deprivation prior to, 125–127, 127f
 and environmental influences on gene expression, 73
 by gay and lesbian couples, 492
 heritability research in, 70
 intelligence and IQ research in, 70, 313–314
 schizophrenia research in, 70, 73
 in surrogate motherhood, 54–55
Adrenal androgens, 363
